Final Release			

IV-1 PURPOSE.

To evaluate the Nimbus "B" Pulse Code Modulator (PCM) mechanical model when subjected to vibration environments required by the Nimbus qualification test specification.

IV-2 RESULTS.

The results of the vibration evaluation tests are illustrated by the attached x-y curves produced by accelerometers in and on the package housing.

IV-3 PROCEDURE.

IV-3.1 FIXTURING.

The vibration fixture used for these evaluation tests was an open ended box made of two inch magnesium plate. The end opposite the package had a cover made of one inch aluminum plate which was fastened to the box fixture with bolts. This cover was used in all axes except the thrust or vertical axis. The total weight of the fixture and the adapter plate is 130 pounds.

IV-3.2 FIXTURE MOUNTING.

The fixture is mounted to a standard three inch thick magnesium adapter plate that is attached to the shaker armature head. This plate serves as an armature stiffening member. See figure IV-1 for a sketch of the setup.

IV-3.3 PACKAGE DESCRIPTION.

The PCM consists of an exterior housing measuring 6.0" x 8.0" x 6.5" (figure IV-2), a group of plates and columns used as stack loading structure, and an electronic stack consisting of both modular and planar circuit boards. The loading structure is designed to exert a compressive load on the card stack independent of the exterior housing. The loading structure and stack are completely contained without the housing but effectively isolated from it through the use of silicone rubber.

IV-3.4 VIBRATION TESTS.

The vibration evaluation was as follows:

a. Sine vibration sweeps at various vibration levels up to a maximum of 7.1 Grms from 30 cps to 2 KCS were made. VMS recordings and X-Y records were made of the output voltages of the module and the external accelerometers.

b. Random vibration was applied to the package in the form of a flat spectrum with a bandwidth of 20 cps to 2 KCS at a Power Spectral Density of 0.2G^2/cps (approximately 20 Grms). The random response of the module accelerometer aligned with the axis of input vibration was analyzed and plotted on an X-Y recorder.

IV-1 PURPOSE.

To evaluate the Nimbus "B" telemetry electronics mechanical model when subjected to vibration environments required by the Nimbus qualification test specification.

IV-2 RESULTS.

The results of the vibration evaluation tests are illustrated by the attached x-y curves produced by accelerometers in and on the package housing.

IV-3 PROCEDURE.

IV-3.1 FIXTURING.

The vibration fixture used for these evaluation tests was T-6134. This fixture is a hollow cube, made of two inch aluminum plate. The open end of this cube has a cover made of one inch magnesium that is fastened to the cube with bolts. The total weight of the fixture and the adapter plate is 105 pounds.

IV-3.2 FIXTURE MOUNTING.

The fixture is mounted to a standard three inch thick magnesium adapter plate that is attached to the shaker armature head. This plate serves as an armature stiffening member. See figure IV-21 for a sketch of the setup.

IV-3.3 PACKAGE DESCRIPTION.

The packaging is a modular system with the modules mounted on printed circuit cards. These module-cards are then packaged in a housing that is designed to contain this module stack under mechanical pressure. The housing size is 6" x 4" x 6.5" (see figure IV-22).

a. Sine vibration sweeps at various vibration levels up to a maximum of 7.1 Grms from 30 cps to 2 KCS were made. VMS recordings and X-Y records were made of the output voltages of the module and the external accelerometers.

b. Random vibration was applied to the package in the form of a flat spectrum with a bandwidth of 20 cps to 2 KCS at a Power Spectral Density of 0.2 G^2/cps (approximately 20 Grms). The random response of the module accelerometer aligned with the axis of input vibration was analyzed and plotted on an X-Y recorder.

The originals of the X-Y curves and VMS oscillograms are on file in the Environmental Laboratory.

The evaluation was started in the longitudinal axis and proceeded as follows:

Vertical Axis Random

Figure IV-29.

Longitudinal Axis Random

Figure IV-30.

The tests were discontinued at this point due to a "rattle" which developed in the package. The package was disassembled for inspection. This inspection revealed that the cards had worn in the areas of the loading feet. The cards were resized and epoxy shims were bonded to the loading feet to compensate for the undersize condition of the cards. When the package was reassembled, 1/4" strips of rubber were added between the card-stack and the housing top and bottom covers. The testing was resumed starting in the lateral axis.

Lateral Axis

Figures IV-31 and IV-32.

Longitudinal Axis

Figures IV-33 through IV-35.

Vertical Axis

Figure IV-36.

The tests were discontinued at this point due to a "rattle" which again developed in the package. The package was opened for an inspection and it was found that the corners of the cards had pounded into the tooling holes of the cards creating large tolerances allowing the cards to "rattle." This condition was repaired by adding fiber blocks on the cards to replace the worn corners of the cards and the tests were continued.

APPENDIX V

ENCODING ACCURACY

APPENDIX V

ENCODING ACCURACY

TABLE OF CONTENTS

Paragraph	Title	Page
V-1	General	V-1
V-2	Coder Quantizing Error	V-1
V-3	Linearity	V-1
V-4	Input Transducer Source Impedance Versus PCM Unit Input Impedance	V-1
V-5	Feedback Current	V-3
V-6	Aperture Time	V-3
V-7	Capacity Charge Transfer	V-4
V-8	Input Noise	V-4

V-1 GENERAL.

The encoding accuracy of the Nimbus B PCM unit (figure V-1) is primarily dependent on the coder quantizing error, coder linearity, coder input impedance versus transducer source impedance, and feedback leakage current from the multiplexer overvoltage clamp circuit. Other factors that contribute to error but are deemed negligible for the PCM unit are aperture time error and capacity charge transfer error. Noise error could become a large percentage of the total error, but proper signal conditioning and wiring can reduce the total noise to a negligible amount.

V-2 CODER QUANTIZING ERROR.

Coder quantizing error is ± one-half of the least significant bit weight used. For a seven bit coder with 128 total possible binary coded levels, each level represents 0.78 percent of full scale. Thus, the total quantizing error for a 7-bit binary coder is ±0.39 percent.

V-3 LINEARITY.

The encoding process occurs with a design limit of less than ±0.5 percent nonlinearity, with probable nonlinearity being less than ±0.1 percent because of the ramp coder technique used. The low end switching point can be measured at approximately -50 millivolts, the high end switching point can be measured at approximately -6.375 volts, and a straight line can be drawn between these two voltages. All other points should occur within ±0.5 percent, or ±32 millivolts, of this line. In all probability, the points will occur within ±0.1 percent of this line or ±6.4 millivolts. This type of measurement should be made with 0-ohm source impedance to reduce noise to a minimum in order to stabilize the output binary code switching points. Linearity must be measured using the encoder switching points because they are approximately 2 millivolts wide, while the bit weight of a 7-bit coder is 50 millivolts. Thus, the switching points can be in error ±1 millivolt, while the normal output code can be in error ±25 millivolts with no switching taking place.

In summary, total encoding accuracy should be within ±0.78 percent of full scale (±50 millivolts) for the 7-bit code with a maximum source impedance of 3.3K ohms. An increase in source impedance degrades the accuracy due to increased noise and offset voltages. The 10-bit coder resolution of 1024 levels gives an overall resolution of approximately ±0.1 percent of full scale. This is actually 6.256 millivolts per bit or ±3.128 millivolts of overall resolution. Since the noise is a minimum of approximately 3 millivolts, the overall maximum accuracy using the 10-bit coder is ±0.1 percent. If greater noise is present, 8-bit or 9-bit accuracy should be used.

V-4 INPUT TRANSDUCER SOURCE IMPEDANCE VERSUS PCM UNIT INPUT IMPEDANCE.

The input source impedance should be 3.3K ohms (maximum) for an error of ±0.78 percent. Higher input impedances up to 10K ohms can reduce this accuracy to ±1 percent. Actual accuracy is determined by the voltage divider effect of source impedance and input impedance. This input impedance is 1 megohm (minimum) and is greater than 10 megohms in most cases.

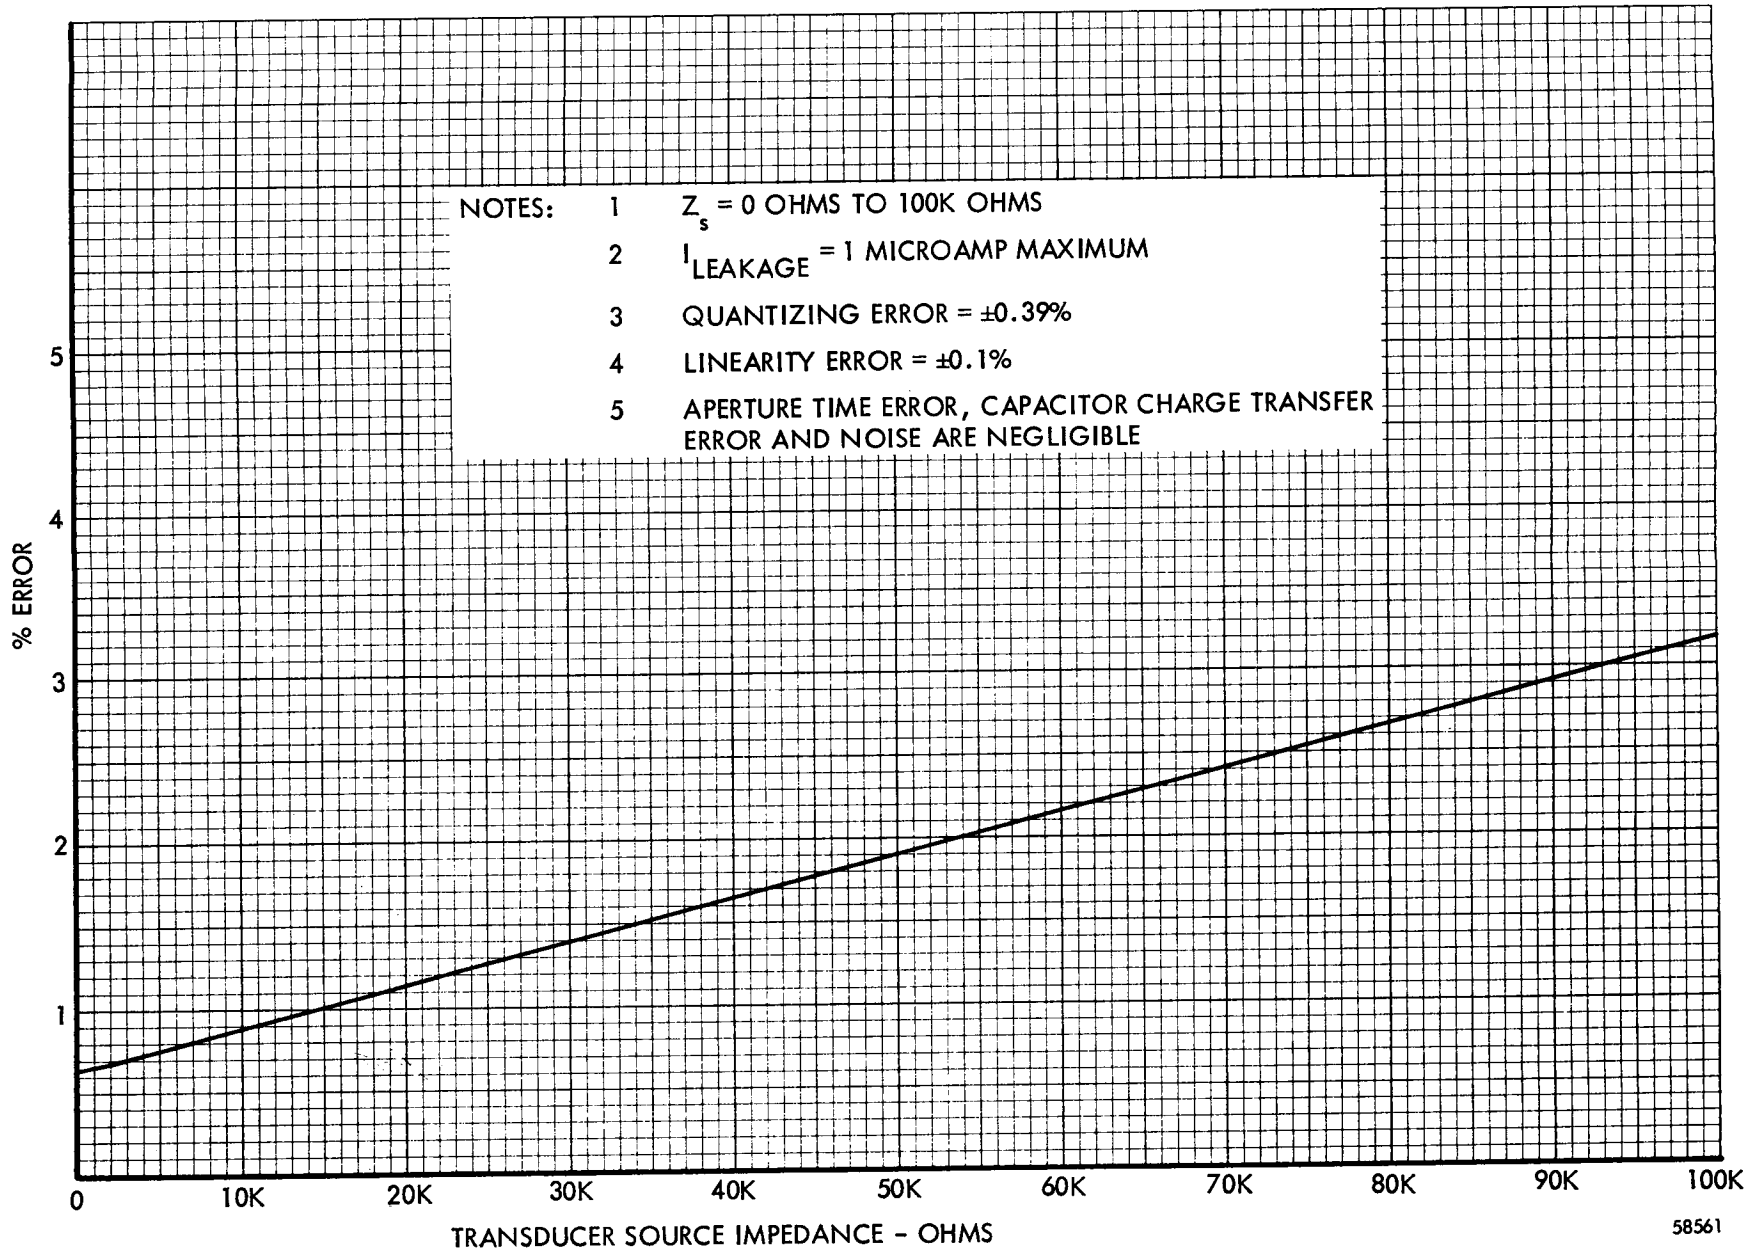

Figure V-1. Nimbus B PCM Unit Encoding Accuracy

However, in the case of 1 megohm (minimum), the 3.3K ohm source impedance becomes a possible error of 0.33 percent, but this error drops to 0.33 percent if the higher value of 10 megohms is realized in every system. The possible error of 0.33 percent of full scale represents a voltage error offset of 21.12 millivolts, which is solely due to the source impedance-input impedance voltage divider action. This offset drops to approximately 2.1 millivolts if the input impedance can be maintained at 10 megohms (minimum).

If the input source impedance goes up to 10K ohms and the input impedance is as low as 1 megohm, a possible error offset of 1 percent results.

V-5 FEEDBACK CURRENT.

The feedback current from the PCM unit to the transducer is a leakage current and can cause a constant signal offset depending on the source impedance. For example, the specified maximum feedback current during sample time is 1 microampere, which drops 3.3 millivolts across the 3.3K ohm input source impedance. If the source impedance is increased to 10K ohms, voltage offset increases to 10 millivolts.

In the Nimbus B PCM, the majority of leakage current is fed back through channel gates from the input channel gate overvoltage protection clamping circuit diodes. These diodes are biased at approximately -20 volts and prevent any fault voltages in excess of -20.5 volts from being applied to the multiplexer output sequencer gates. These diodes protect against multiple gate failures or total failure if a channel gate faults up to -24 volts. (These circuits can protect the input channel gate sequencers up to approximately -35 volts fault at the input.) The diodes are necessary because: if an input channel gate shorts out due to an overvoltage, it will apply the overvoltage to the output sequencer; if the output sequencer gate fails by shorting out, the entire multiplexer is useless. Thus, diode clamps provide fail-safe redundancy during the presence of input fault overvoltages.

The diodes leak a maximum of 100 nanoamperes with 0 volt input (maximum voltage across the clamping diode) at +55°C. Thus, the offset maximum caused by these protection diodes is 0.33 millivolts as seen at the input terminal using 3.3K ohms source impedance. However, because the MOSFET on resistance is approximately 2.2K ohms plus the fixed resistor of 1K ohm, the total offset presented to the coder is approximately (3.3K + 2.2K + 1K) x 0.1 microampere, or 0.65 millivolts.

V-6 APERTURE TIME.

The aperture time of the coder while storing the input analog sample is 170 ±30 microseconds. The aperture time error occurs when the transducer voltage changes during the time the coder is storing the sample. This dv/dt becomes a maximum at the highest input frequency which is 0.2 cps (one fifth of the maximum sampling rate of 1 sps for prime channels). This aperture time error in the Nimbus B PCM is negligible because the resulting maximum dv/dt of a 0.2-cps sine wave during the 170-microsecond sampling time is less than 1 millivolt.

NOTE

If a noise spike occurs on the input sample just before the 170 microsecond aperture time is completed, the sample stored on the ramp capacitor will be in error by the amount of added noise.

V-7 CAPACITY CHARGE TRANSFER.

When any analog channel gate is turned on, the stray capacity (approximately 30 picofarads) inside the Nimbus B PCM multiplexer must be charged and stabilized before the coder completes its 170-microsecond sample time, otherwise an error will result. The correct value of the analog sample is reached only after the multiplexer capacity has been completely charged from both the external capacity and input transducer. Before the sample occurs, the transducer has already completely charged the PCM external stray capacity through the transducer source impedance. When the sample occurs, the external stray capacity discharges into the multiplexer stray capacity and then both the external and internal capacities must be stabilized through the transducer source impedance before the sample time is completed. Because the PCM multiplexer contains only 30 picofarads of stray capacity, this charge transfer time is approximately 30 microseconds for 10 R-C time constants with a source impedance of 100K ohms. Since 30 microseconds is small compared to the 170-microsecond aperture time, the charge transfer error is negligible.

V-8 INPUT NOISE.

Input noise can cause errors depending on the magnitude of the peak noise in the input data sample. However, these errors can be averaged over a period of time if the noise remains fairly constant. If this noise is purely random and occurs with large maximum-to-minimum ratios, some data points will have to be discarded as no correlation will exist between the sample and the noise. This noise will increase directly with an increase in transducer source impedance, so that noise-free measurements require a 0-ohm source impedance. Inversely, large amounts of stray wiring capacity on a transducer will help filter out the noise peaks. With special care and attention given to the transducer cabling problem, the noise can be reduced to a negligible amount.

APPENDIX VI

USE OF 10-BIT CODING CAPABILITY

VI-1 GENERAL.

The accuracy of selected analog measurands can be increased to 8, 9, or 10 bits by externally connecting the desired three least significant bits of the coded value to an immediately following digital channel.

The seven most significant bits from the 10-bit coder are automatically connected into the output register to provide the standard Nimbus B 8-bit data word consisting of a word sync ZERO bit plus seven data bits. The three least significant bits (2^0, 2^1, and 2^2) are applied to failsafe isolation buffer amplifiers in each programmer, thus connecting the three bits from each PCM to the same three outputs. In this way the three bits are always supplied from the selected PCM (PCM 1 or PCM 2). These three wires are applied to pins 1, 2, and 3 of both connector J1 and connector J13. For 8-bit analog words (±0.4 percent resolution), only the 2^2 bit is used; for 9-bit analog words (±0.2 percent resolution) both the 2^2 and the 2^1 bits are used; and for 10-bit analog words (±0.1 percent resolution) the 2^2, 2^1, and 2^0 bits are used. It does not matter which digital channels in the following digital word are used for the three bits, as read-in is performed in parallel for all seven digital bits. However, the BTE equipment is designed such that the first three data bit positions must be used if the analog 10-bit word is to be displayed. The digital channels in the digital word that are not used for the increased resolution bits remain available for use as digital channels.

There are four possible combinations for increased analog word resolution:

a. Prime analog channel followed by a prime digital word.

b. Prime analog channel followed by a subcommutated digital word.

c. Subcommutated analog channel followed by a prime digital word.

d. Subcommutated analog channel followed by a subcommutated digital word.

These four combinations are described in the following paragraphs. The combination in c, above, achieves the maximum number of increased resolution analog channels with the minimum number of external jumper wires.

VI-2 PRIME ANALOG CHANNELS FOLLOWED BY PRIME DIGITAL CHANNELS.

There are five prime analog channels followed by prime digital channels as shown in figure VI-1. (Figure VI-1 is derived from the PCM output format tables.) These channels are 1A1, 1A8, 1A9, 1A20, and 1A21. Ten bits of resolution on any one of these channels requires that three external jumper wires be connected from the drivers for bits 2^2, 2^1, and 2^0 to the digital channel immediately following. Thus, if all five prime analog channels are connected for 10 bits of resolution, 15 external jumper wires are required. All five of these prime analog 10-bit samples will occur at a 1-sps rate.

NOTES:
1. THIS TABLE SHOWS ALL ANALOG CHANNELS THAT ARE FOLLOWED BY DIGITAL CHANNELS IN THE PCM FORMAT, ALONG WITH THEIR WORD POSITIONS WITHIN THE MAJOR FRAME.
2. THERE ARE 5 PRIME ANALOG CHANNELS FOLLOWED BY PRIME DIGITAL CHANNELS.
3. THERE ARE 10 PRIME ANALOG CHANNELS FOLLOWED BY SUBCOMMUTATED DIGITAL CHANNELS.
4. THERE ARE 58 SUBCOMMUTATED ANALOG CHANNELS FOLLOWED BY PRIME DIGITAL CHANNELS.
5. THERE ARE 8 SUBCOMMUTATED ANALOG CHANNELS FOLLOWED BY SUBCOMMUTATED DIGITAL CHANNELS.
6. THERE IS A MAXIMUM OF 81 ANALOG CHANNELS FOLLOWED BY DIGITAL CHANNELS THAT CAN BE USED FOR 8, 9 OR 10 BITS OF RESOLUTION.

Figure VI-1, Ten-Bit Analog Word Availability

VI-3 PRIME ANALOG CHANNELS FOLLOWED BY SUBCOMMUTATED DIGITAL CHANNELS.

There are ten prime analog channels followed by subcommutated digital channels as shown in figure VI-1. Five of these channels (1A5, 1A7, 1A11, 1A14, and 1A15) are each followed by one subcommutated digital channel in each major frame. Each channel requires three external wires for 10-bit capability, but only one analog sample out of 16 has 10 bits of resolution. The other 15 analog samples have the normal seven bits of resolution. The remaining five analog channels (1A2, 1A3, 1A13, 1A17, and 1A19) are each followed by two subcommutated digital channels in each major frame. When connected with three external jumper wires for each digital channel, two increased resolution samples and fourteen 7-bit samples are obtained in every major frame. To connect all 10 channels for maximum capability would require 45 external jumper wires.

VI-4 SUBCOMMUTATED ANALOG CHANNELS FOLLOWED BY PRIME DIGITAL CHANNELS.

There are 58 subcommutated analog channels followed by prime digital channels as shown in figure VI-1, word positions 8, 12, 40, and 44. The 58 subcommutated analog channels can obtain increased resolution through use of only four digital words (1D2, 1D3, 1D6, and 1D7). This arrangement requires only 12 external jumper wires (3 per digital word) for 10 bits of resolution. Thus, the addition of three external jumper wires will provide for 15 high resolution subcommutated analog channels if digital words 1D2 or 1D7 are used, or 14 high resolution subcommutated analog channels if digital words 1D3 or 1D6 are used. For example, if three additional bits from pins 1, 2, and 3 of connector J1 were jumpered into 1D2 and the same 3 bits from pins 1, 2, and 3 of connector J13 were jumpered into 1D7, these six added wires provide a total of 30 subcommutated 10-bit analog words. This is the maximum 10-bit channels-to-external cabling ratio that can be obtained.

VI-5 SUBCOMMUTATED ANALOG CHANNELS FOLLOWED BY SUBCOMMUTATED DIGITAL CHANNELS.

There are eight subcommutated analog channels followed by eight subcommutated digital channels as shown in figure VI-1. The subcommutated analog channels are 1/16 A31, 1/16 A32, 1/16 A63, 1/16 A64, 1/16 A244, 1/16 A369, 1/16 A400, and 1/16 A401. For ten bits of resolution on each one of these channels, three external jumper wires per channel are required. Therefore, 24 external wires are required if all eight channels are to contain ten bits of resolution. All eight channels will have a sampling rate of one sample every 16 seconds (1/16 sps).

VI-6 SUMMARY.

If it is desired that the sampling rates for 8-, 9-, or 10-bit channels be 1 sps, only two of the five available prime analog channels are readily usable. These would be connected with 3 wires from pins 1, 2, and 3 of connector J1 to one digital word, and 3 wires from pins 1, 2, and 3 of connector J13 to a second digital word. More 10-bit channels could be added, but the complexity of the external cabling harness would be increased, and an additional special junction box would probably be required in the satellite.

If only one channel must have a rate of 1 sps, then the three wires from J1 (or J13) will provide this capability. The remaining three wires from the other connector can be used to obtain one of the channels at 1/16 sps or up to 15 channels at 1/16 sps, depending upon the digital words selected.

If the required sampling rate can be the subcommutated rate of 1/16 sps for all 10-bit analog channels, a maximum of thirty 10-bit channels can be used with the addition of 3 jumper wires from J1 and another 3 jumper wires from J13 (paragraph VI-4).

To obtain maximum capability utilizing all 81 available 10-bit channels, 96 external jumper wires are required.

APPENDIX VII

MOSFET HANDLING

VII-1. GENERAL.

This appendix contains a brief history of the MOSFET handling problem and includes handling procedures used by Fairchild and Radiation to prevent MOSFET damage.

VII-2. HANDLING PROBLEMS.

During a visit early in 1964, Fairchild advised Radiation that the biggest problem to be expected in the use of MOSFET's would be the handling of the MOSFET, both at Fairchild and at Radiation. At that time, Fairchild did not have a flatpack carrier designed to protect the MOSFET and a design modification was initiated. Controlled humidity ($< 70\%$) and the wearing of nylon smocks tend to build up an electrostatic charge; thus, the conventional "white room" aggravates the problem. Therefore, operators were instructed to wear grounding bracelets and all test chassis were tied to a common ground.

The three most usual failure modes in a conventional MOSFET are: (1) increased leakage current, gate to body, (2) increased leakage current, drain to body and/or source to body, and (3) change in threshold voltage. These generally occur in the order listed if the device has an "unprotected" gate.

The first evidence of a serious handling problem came with the delay in shipment of the first production run. An excessive number of units failed due to blown gates (excessive potential applied) and a team was dispatched to Fairchild to investigate the situation. Apparently, either a flatpack carrier problem still existed or the devices were destroyed during burn-in.

The first devices received were shipped in plastic boxes lined with a foam filler. This packaging was found to be undesirable from an electrostatic standpoint since all the material was susceptible to charge build-up. Fairchild subsequently prepared (in July 1966) an internal MOSFET handling procedure, adopted a new shipping container, and printed a warning sticker, similar to Radiation form R-599, to be placed on MOSFET shipping containers. A major excerpt from the Fairchild Mos Handling Procedure is shown on subsequent pages of this Appendix.

VII-3. RADIATION HANDLING PROCEDURES.

The MOSFET handling procedures employed at Radiation (Radiation drawing 110174) were developed from experience over the period from early 1964 to mid 1966. Many of these procedures are based on similar procedures developed by Fairchild's R&D facility.

The requirements outlined in Radiation specification 110174 consists of three basic provisions:

(1) Special handling requirements during MOSFET testing, e.g., grounding of the test chassis and operator.

(2) Special packaging provisions that require the MOSFET leads to be shorted together at all times.

(3) Special marking requirements (tag) to be placed on shipping containers. Radiation form R-599, shown below, was developed for this purpose.

III. OPERATOR PROCEDURE

Because MOS devices are extremely sensitive to electrical charges, operators must be careful to observe the following precautions, both in routine handling of the devices and in actual electrical testing.

A. Handling MOS Devices

1. Ground bracelets will be worn by operators during all processing of the MOS devices.

2. Operators will not handle MOS devices with plastic tweezers or with finger cots. Metal tweezers may be used if the operator wears a ground bracelet.

B. Transporting MOS Devices

1. Cans

   MOS cans may be transported only in metal carrier racks. The plug holes in such racks must be small enough to ensure that all leads are shorted to the circumference of the holes when the devices are inserted.

2. Flat Packs

   MOS flat packs may be transported only when the leads have been shorted to a strip of tin foil. The procedure is as follows (see Fig. 1):

   a. Lay a strip of tin foil of suitable length and width on a magnetic holder.

   b. Place the MOS flat packs in the center line of the tin foil strip with the leads perpendicular to the length of the tin foil.

   c. Fold the edges of the tin foil over the flat packs so that all leads are shorted to the foil.

   CAUTION: Steps b and c may be performed only while wearing ground bracelets.

3. MOS jobs may be transported from one location to the next only when accompanied by a Handling Precautions Card (Exhibit I). This card will be attached to the controlling documents by the Control Cage immediately after the documents have been issued by the scheduling group.

C. Testing MOS Devices

1. Ground bracelets must be worn by operators throughout the entire test procedure; when removing and replacing devices from and to the metal carrier racks, and when inserting and pulling devices from test sockets.

2. Operators must be careful not to insert MOS devices into a socket that has power applied to it.

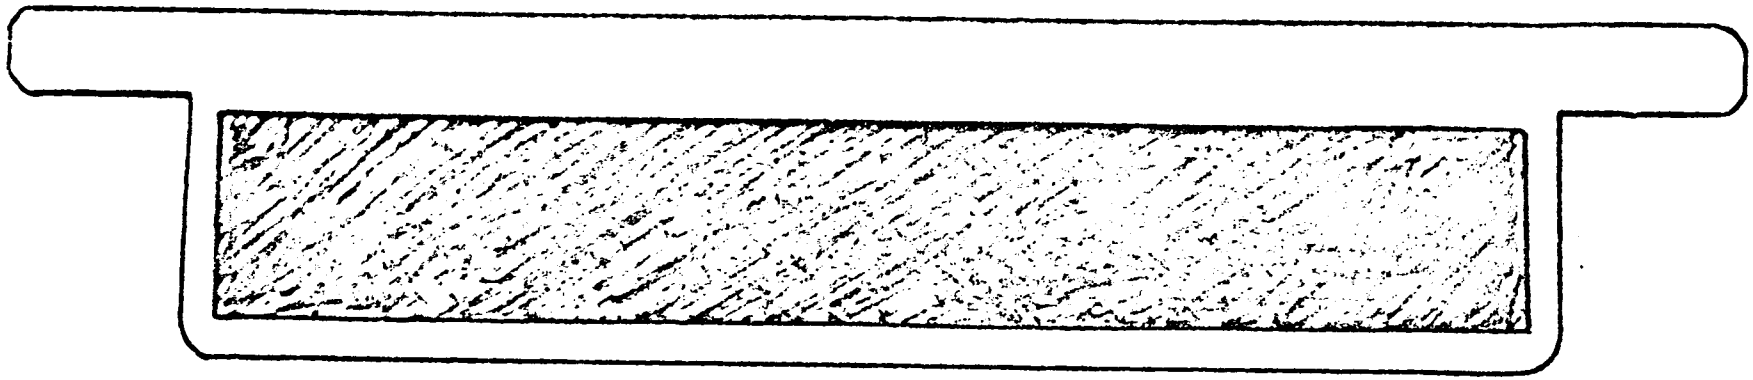
3. Devices shall be inserted carefully into sockets to ensure the best possible contact.

4. Operators shall not test devices on a Curve Tracer without the direct supervision of a foreman.

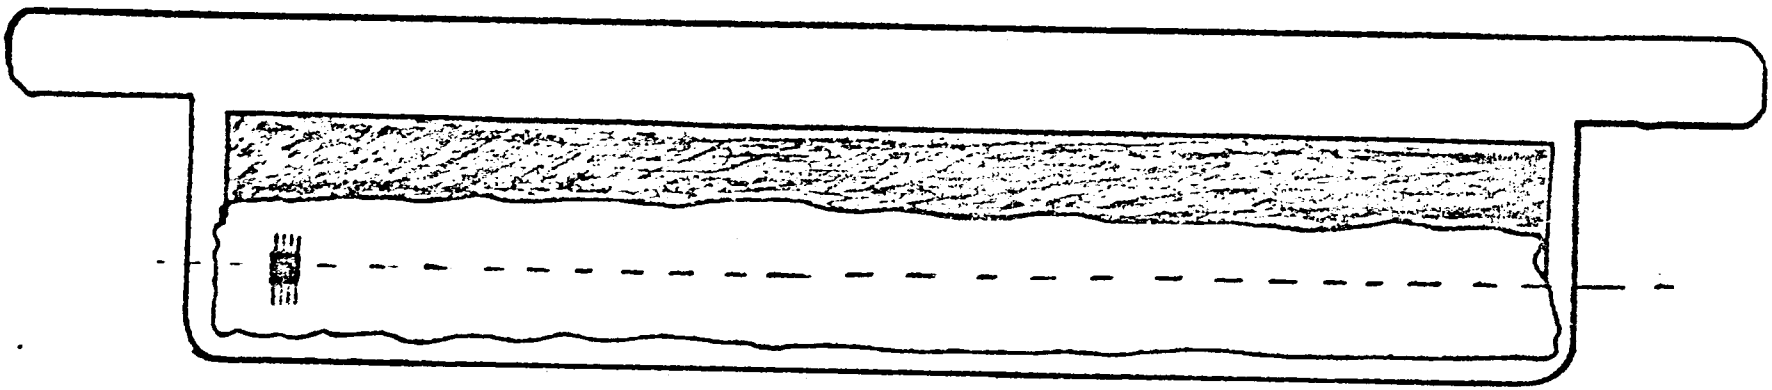
D. Storage of MOS Devices

When MOS devices are awaiting further processing, they shall be stored in the transportation carriers described in paragraph B and the carriers grounded to metal shelves.

FIGURE 1



Place strip of tin foil of suitable length and width on magnetic strip.



Place units on the center line of the tin foil with the leads perpendicular to the length of the foil strip.

Fold the edges of the tin foil over the flat packs so that all leads are shorted to the foil.

TITLE

HANDLING AND SHIPPING
FLATPACK AND MOS-FET DEVICES

CODE IDENT NO.	SIZE		REV
91417	A	110174	
SCALE	VII-6	1064	SHEET 1 of 3

RAD FORM 459 REV 7-61

1. SCOPE

This drawing specifies special handling and shipping procedures for flatpacks and MOS-FET (metal oxide silicon-field effect transistor) devices.

1.1 Implementation. The Quality Control Division shall be responsible for enforcing the procedures established in this document.

2. REFERENCED DOCUMENTS

N/A

3. REQUIREMENTS

3.1 General. More than normal care should be exercised in the handling of flatpacks and MOS-FET's because of the fragile nature of the devices.

3.2 Packaging.

3.2.1 Flatpack Packaging. Flatpacks shall be received at Radiation Incorporated in individual packages. In the event they are not:

1. Stop processing of shipment
2. Notify Quality Control and Reliability
3. Determine damage, if any
4. Determine disposition by Engineering Quality Control and Reliability
   (a) Return to manufacturer
   (b) Obtain proper packaging

The units shall remain in their individual packages until removed from the stock room for assembly purposes. The packages shall be of such quality to prevent damage to the device leads.

3.2.2 MOS-FET Packaging. The devices shall be individually packaged with all device leads shorted together. The units shall not be removed from this package except by the approved handling procedures called out herein for purposes of testing. After any required testing is complete, the device shall be repackaged and stored until required by assembly.

3.2.3 Manufacturer Packaging. Each device shall be packaged in such a manner to facilitate easy removal of individual devices. This is best accomplished by placing each device in individual packages which may be packed together in a larger container.

3.3 Handling.

3.3.1 Flatpack Handling. Where at all possible flatpacks shall be handled without removal from the individual packages. When removal is necessary the device shall be removed only by persons wearing finger cots, or equivalent. In no case shall a flatpack be placed in a bare hand. Care should be exercised to avoid bending of the device leads; the best method being to handle flatpacks with tweezers only.

3.3.2 MOS-FET Handling. Where at all possible the devices shall be handled without removal from the individual packages. When removal from the packages is necessary the procedures specified in Paragraph 3.3.2.1 shall be followed.

3.3.2.1 Removal from the Individual Packages. Before the MOS-FET is removed from its individual container the following steps shall be taken.

1. The unit shall be removed from its container only on a conducting bench top: In the event testing is to be performed, a common scheme shall be established.
2. All workers must have ground straps from the bench top attached to their wrists.
3. All workers must wear finger cots, or equivalent.
4. Surfaces of hands and probing tools must be discharged to the bench top prior to touching the devices.

3.3.3 Manufacturer Handling. The manufacturer shall exercise all handling procedures called out in this document or approved equivalent as minimum handling requirements.

3.4 Lead Straightening. In the event the leads inadvertantly become bent they may be straightened by use of tweezers or fingers (properly cotted) provided the bend is a gentle bend having no crimping. In the event the lead is sharply bent or crimped or bent in two or more opposing directions, the device shall be forwarded to the Reliability Section for evaluation.

3.5 Purchasing. The responsible Radiation Incorporated buyer shall attach Radiation Form Number R-599 to all copies of the Purchase Order, and provide the manufacturer with an adequate number to be attached to the outside of the device shipping containers.

3.6 Improper Shipping Notice. In the event that an MOS shipment is received without the required marking (reference Para 3.9) and/or packaging, Receiving shall notify Purchasing, the appropriate project, Quality Control, and the Reliability Components Engineer.

3.7 MOS Storing. The devices shall be stored (in the individual packages with all leads shorted together), by normal stockroom procedures. However, precautions shall be taken to assure the devices are stored in an area absent of any strong magnetic or electric fields, such as those found around electric motors and immediately surrounding fluorescent lights.

3.8 MOS-FET Leads. Each MOS-FET shall have all leads shorted together.

3.9 MOS-FET Shipping Instructions. Each shipment of MOS-FET's shall be marked plainly and visibly on at least two opposing sides of the shipping container "MOS-FET - SPECIAL HANDLING REQUIRED". Special Radiation Form Number R-599 for this purpose may be obtained from the Purchasing Department, Radiation Incorporated.

APPENDIX VIII

GLOSSARY OF TERMS

TERM	DEFINITION
A	Analog measurand
A/D Converter	Converts analog measurements to equivalent digital words.
Accuracy	Accuracy of final encoded data compared to original analog transducer input is ±0.7%.
Analog Gate	A transistor switch through which an analog measurand is applied to the A/D converter.
Aperture Time	The time a given measurand is applied to the A/D converter (170 ±30 μs).
BTE	Bench Test Equipment
Beacon	Transmitted 10-kc time code or transmitted 10-kc time code plus PCM real-time data.
Binary Code	A combination of bits, each of which can assume one of two possible states.
Bit	One binary digit
Bit Rate	500 cps in real-time; 15 kc in playback
Block Redundant	Identical assemblies/circuits within the PCM.
CC	Column command
Clock (Nimbus C Clock)	Master timing device in the Nimbus B satellite.
Clock Command	Command to the PCM subsystem; originated by the clock from ground command.
Coder	A/D converter
CY1A	1 cps from clock
CY10	10 cps from clock
CY500	500 cps from clock
D	Digital measurand

TERM	DEFINITION
DC-to-DC Converter	Converts -24.5 vdc to all voltages required for PCM operation.
DG	Subcommutated digital channel
DGP	Prime digital channel
Data	The final encoded output of all measurands.
Data ZERO	Digital bit between +0.5 vdc and -1 vdc at input.
Data ONE	Digital bit between -5 vdc and -10 vdc at input.
Digital Gate	A transistor switch through which a digital measurand is applied.
Energy Gap	Voltage magnitude required to break down a semiconductor in the forward bias direction.
Fail-Safe	Built-in safeguard that reasonably ensures the recovery of data through redundant techniques and ensures that chain reaction as a result of any one failure is limited.
Flat-Pack	A device containing several integrated circuits.
Format	The composition of the telemetered data.
GPA	General purpose amplifier
Ground Command	Command from the ground station causing the PCM subsystem to execute a given function.
Integrated Circuit	Diffused electronic circuit including transistors, diodes, resistors and capacitors.
LSB	Least significant bit
Line Capacity	Stray internal or external wiring capacitance to ground.
Linearity	All PCM encoded levels must be within ±0.5% of a straight line from zero scale to full scale (-6.4 vdc).
MD	Matrix driver

TERM	DEFINITION
MM10A	10-kc time code from clock; pulse width modulated.
MO	Time code from clock
Major Frame	One complete sample of all data plus time code; 1000 words (16 subframes).
MOSFET	Metal oxide silicon field effect transistor.
NRZ	Non-return-to-zero; a form of coding telemetry data.
NRZ to Split-Phase Converter	Converts non-return-to-zero type binary code to split phase Mark 0 type of code.
Nimbus A	The first Nimbus weather satellite, launched 8-28-64.
Nimbus B	The third Nimbus weather satellite; a redesigned version of Nimbus A .
Nimbus C	The second Nimbus weather satellite. Designed as back-up for Nimbus A but since modified to include additional experiments. Successfully launched 5-15-66.
Noise Immunity	The ability of a device to resist the effects of electrical noise.
PAM	Pulse amplitude modulation
PCM	Pulse code modulation. PCM telemetry unit.
PSC	Power supply common
Prime	Data channels sampled once per second.
RC	Row command
Real Time	Time in which reporting on events or recording of events is simultaneous with the events.
Resolution	Binary weight of least significant bit of the encoded word.
SPS	Samples per second
Sample Time	The time during which an analog gate or digital gate is enabled and capable of accepting a data input.

TERM	DEFINITION
SAT	Select at test.
Sequencer	A device used to make a series of events follow in a given sequence. Used as a commutator and subcommutator.
Split Phase	A form of coding telemetry data.
Strobe	A digital pulse used to enable a gate or trigger a flip-flop.
Subcommutated	Data sampled every 16 seconds.
Subframe	One complete sample of all prime data (62.5 words).
Supercommutation	Data sampled more than once per second.
Sync Word	Fixed binary code used as recognition for start of every major frame, subframe and word.
TME	Telemetry electronics unit
Time Code	Code generated by the clock and included with the data; used as a time reference.
Transducer	A device that responds to a physical stimulus and produces an electrical signal equivalent.
Word	Eight binary digits
YA1	100 cps from clock
YB1	100 cps from clock
