FOREWORD

This report was prepared by Air Products and Chemicals, Inc. under NASA Contract NASr-107.

This report covers work conducted from April 1962 to September 1963 in the R&D Laboratory in Emmaus, Pennsylvania.

The report is issued in accordance to Article V, Paragraph (d) of the contract dated April 1, 1962 and Revision 1 dated January 6, 1965.

The work performed under this contract was the basis of a Doctoral Dissertation presented to the Graduate Faculty of Lehigh University by A. Lapin in September 1963.

The authors wish to thank the following individuals whose help and advice made the successful completion of the contract possible: Dr. J. M. Geist; Dr. C. McKinley; Prof. L. Wenzel, Chairman Chemical Engineering Department, Lehigh University; Messrs. L. Binder, G. Freeby, A. Palencar, J. Simpson; Mrs. J. Meagher and Mrs. K. David; and Mr. F. Kocon.

I. ABSTRACT

The purpose of this investigation was to determine the boiling characteristics of liquid nitrogen and neon in narrow annuli.

The basic concept for the experimental study consisted of three major parts.

1. Design and construction of test equipment consisting of the main test section and auxiliary equipment. The design of the test section incorporated the capability of visual observation of the boiling mechanism during operation.
2. Experimental evaluation of the test heaters under pool boiling conditions in order to establish a basis for the evaluation of the annular gap boiling.
3. Investigation of boiling characteristics in narrow annuli.

The test section consisted of precision machined heaters having different diameters, which were centered in a precision Pyrex pipe. The gap between the Pyrex sleeve and the heater ranged in size between 0.006-inches and 0.080-inches at liquid nitrogen and neon temperatures.

The nitrogen pool boiling data were correlated by $Q/A_w = 87.2 (\Delta T_b)^{1.20}$ with an average percent deviation of $\pm 16\%$, except for the cadmium plated heater. $Q/A_w = 30.0 (\Delta T_b)^{1.20}$ correlated the data obtained with the cadmium plated heater.

Observation of the annular gap boiling suggested a convective type heat transfer. A generalized equation was thus derived on the basis of this observation.

The data obtained with nitrogen and neon in the six annuli, with varying submergences, were correlated with an average percent deviation of $\pm 23\%$ by the following equation:

$$\frac{h_b D_e}{k_L} = 150 \left(\frac{D_e G}{\mu_L} \right)^{0.18} \left(\frac{L}{D_e} \right)^{-0.82} \left(\frac{C_{pL} \mu_L}{k_L} \right)^{0.95}$$

The ability of this equation to correlate data obtained under a wide range of operating conditions covering: gap size range of 0.006 inch to 0.080 inch; length to equivalent diameter ratio of about 310 to 10; copper, nickel plated and cadmium plated surfaces; and two fluids substantiates the assumptions made in deriving the equation.

Visual observation of both pool boiling and annular gap boiling with neon and nitrogen, showed several types of behavior which were observed by other investigators. These consisted of patch-by-patch boiling, nuclei sites remaining active even with decreasing heat flux, superheating of the surface resulting in sudden explosive boiling with generation of active sites covering the whole surface.

Maximum heat fluxes resulting from gap size limitation were obtained in only four cases: with nitrogen in a 6 mil gap heater, and with neon in 6, 20, and 21 mil gap heaters.

II. INTRODUCTION

Magnets with field strength of the order of 10^5 oersteds or higher are required for research in such areas as controlled nuclear fusion and high energy nuclear physics. The field strength of an electromagnet depends upon its configuration and the current flowing in the coil, which in turn depends upon the voltage applied to the coil, the geometry of the coil, and the resistivity of the coil material. Compactness and lowest possible resistivity are necessary to obtain very high field strengths.

Many pure materials have very low resistivities at low temperatures. It is possible to incorporate this property in the design of compact high field magnets. Several cryogenically cooled magnets have been designed to optimize energy consumption and instantaneous power demand.

The optimum operating temperature for cryogenically cooled magnets depends upon conductor material, field strength, refrigeration efficiency, and magnet design. For example, optimum operating temperatures are about 30°K for copper and about 10°K for sodium.

Magnets may be maintained at their desired temperatures by removing the required energy input as sensible heat in a fluid or as latent heat. Air, water, or kerosene are used for magnets operating at ambient temperatures. Removal of the heat generated in cryogenic magnets by means of a boiling liquid offers two major advantages over the use of a fluid utilizing sensible heat transfer: (1) a lower temperature difference

can be maintained between the boiling liquid and the magnet surface, and (2) a much smaller volume of coolant is required.

At 30°K the only fluid refrigerants are helium, hydrogen and neon. Hydrogen and neon are more suitable from the heat transfer point of view, but safety considerations preclude the use of liquid hydrogen until more operating experience with cryomagnets is obtained. Other refrigerants are available for operation at higher cryogenic temperatures. Some cryogenically cooled magnets have been operated at 78°K by using liquid nitrogen as a coolant.

In general, information on boiling heat transfer in narrow annuli is scarce and is almost completely lacking in the case of cryogenic fluids. Since the mechanical design of magnets includes narrow annuli and confined spaces between conductors, it is necessary to develop the necessary design information concerning the cooling characteristics under such conditions.

This research study was undertaken to investigate the various factors affecting the boiling performance of neon and nitrogen in narrow annuli.

III. LITERATURE

The technical literature contains many studies and analyses of heat transfer to boiling liquids.

General Description of Boiling

General descriptions of the various types of boiling are given in textbooks such as McAdams - Heat Transmission (47), and in papers by Asch (4), Kutateladze (38) and (39) and many others.

Boiling involves change of phase from liquid to vapor and usually depends on some form of natural circulation to replenish the vaporized liquid in the vicinity of the heating surface. As early as 1756 Leidenfrost (44) and in 1888 Lang (40) recognized the existence of minimum and maximum heat flux in a boiling liquid. It was Nukiyama (53), however, as late as 1934, who discussed and identified several regimes of boiling, which depend upon different heat transfer mechanisms.

Although there are serious inconsistencies in boiling data which are difficult to explain, the general features and characteristics of the different types of boiling are well known. If boiling data are represented by the logarithm of the heat flux as a function of the logarithm of the temperature difference between the heating surface and the bulk of the liquid, a general type of curve is obtained. The general shape of this curve (Figure 1) is characteristic of boiling for all liquids, although the numerical values of the heat flux or temperature difference

FIGURE 1 , VARIATION OF HEAT FLUX WITH TEMPERATURE DIFFERENCE

differs from system to system. It is possible to identify several boiling regions in Figure 1. For instance, the first part of the curve AB represents the natural convection heat transfer for the liquid. In this zone the liquid is superheated and evaporation occurs only at the free surface. In the region BC bubbles are generated on the heated surface and rise to the surface. This bubble movement through the pool of liquid sets up natural circulation currents. In this range, called nucleate boiling, the heat flux, q/A varies as the temperature driving force, ΔT to the n^{th} power where n varies from system to system. Bubbles are generated as the result of irregularities in the surface where small quantities of trapped liquid act as nuclei for the bubbles. The heat flux reaches a maximum or peak heat flux at the point C on the curve of Figure 1 and the temperature driving force corresponding to this maximum is called the critical ΔT .

As the temperature driving force increases beyond the critical ΔT , the liquid vaporizes rapidly and in many places. A vapor blanket covers the surface which leads to the reduction of heat flux, to point D on the curve. This boiling region is very unstable and is referred to as the transition regime. This region is limited by a maximum, the maximum heat flux C, and a minimum, D, called the Leidenfrost point. These two critical points represent the conditions at which nucleate boiling ceases and at which destruction of the vapor film takes place. For example, if the temperature driving force rises beyond that of the maximum heat flux, the heat flux is lowered and the vapor film tends to

decrease for a while. It is possible to have both nucleate and film boiling alternately on the same surface. The continuous shifting from nucleate to film boiling is the main reason for instability.

At high temperature differences, EF, film boiling is obtained in which heat is transferred through the vapor film by conduction and radiation. At point F the driving force ΔT is such that the temperature at the surface of the metal corresponds to the metal melting point and any tendency of further increase in driving force results in the metal "burning out."

Literature Surveys

Comprehensive surveys of heat transfer to boiling cryogenic liquids have been presented by several authors such as Class, et.al. (11), Richards, et.al (61), and Drayer and Timmerhaus (18). Class briefly examined the work of Haselden and Peters (29), Weil and Lacaze (67 and 68) as well as of many other authors. Most of the review relates to cryogenic fluids.

The conclusions reached by Class are that:

"The results of the several investigators do not agree, there being as much as twenty-fold variations in the value of heat flux for a given value of temperature difference. The theoretical curves are bracketed by the experimental data in the nucleate boiling range. In the film boiling range, the theoretical curve for one atmosphere was made to agree with the experimental curve by selection of the proper value for the constant. In neither case is the theory sufficiently well developed to justify its use in the absence of adequate supporting experimental data."

Richards, et.al. reviewed 156 references on heat transfer from solid surfaces to fluids, and related phenomena. They present the heat transfer data obtained from experimental work on cryogenic fluids in graphical form and compare the theoretical equations to the experimental data. The formulations are also presented graphically to permit comparison with the results of the experimental work. In this case, again, the literature survey is limited to the cryogenic fluids. Richards conclusions are quite similar to the ones reached by Class. These are as follows:

- a. "The existing experimental data on heat transfer between solid surfaces and cryogenic liquids (helium, hydrogen, nitrogen, and oxygen) vary appreciably between experimenters, even when heater geometries and orientations, pressures, etc. are comparable. The variations are both in the magnitude of the heat flux and in the shape of the heat-flux-versus-temperature-difference curves, and are possibly due to uncontrolled parameters such as surface roughness and contamination.
- b. Existing theoretical and empirical formulations are in qualitative agreement with some of the experimental data. More carefully controlled experiments are needed, and formulations which account for parameters such as surface condition should be developed."

Nucleate Boiling

Forster, Kurt, and Greif (20), Forster and Zuber (21), Zuber (70), Zuber and Fried (71, 72), Rohsenow (62, 63, Reeber (59), and Drayer and Timmerhaus (18) studied the nucleate boiling region. Zuber and Rohsenow presented several general equations to cover nucleate boiling while Drayer and Timmerhaus, and Reeber offered experimental data for hydrogen boiling and helium boiling respectively.

Zuber and Fried (72) conclude that

"The proposed correlations for nucleate pool boiling do not take into account the conditions of the heating surface. Consequently, these equations are not general and cannot predict the heat transfer rates for any solid-liquid combination.

For a 'smooth' surface and for a given solid-liquid combination, the equation proposed by Rohsenow can be used for predicting the heat transfer rates to liquid hydrogen at various pressures when the value of a constant is determined from one set of experimental conditions. An equally satisfactory agreement was obtained using the equation proposed by Labountzov."

Drayer and Timmerhaus established that the Forster and Zuber equation

$$\frac{Q/A}{(T_w - T_l)k} \left[\left(\frac{\Delta T_c \rho_L (\pi \sigma)^{1/2}}{L \rho_V} \right) \left(\frac{2\sigma}{\Delta P} \right)^{1/2} \left(\frac{\rho_L}{\Delta P} \right)^{1/4} \right] =$$

$$\left[\frac{\rho_L}{\mu} \left(\frac{\Delta T_c \rho_L (\pi \sigma)^{1/2}}{L \rho_V} \right)^2 \right]^m \left[\frac{c_p}{k} \right] \quad (1)$$

agrees within 12% with their data on hydrogen boiling with a temperature driving force of 1.17°F. The agreement is poorer at lower values of ΔT_b .

Reeber measured the coefficient of heat transfer between a smooth vertical silver surface and boiling liquid helium to be about 388 Btu/hr-ft²-°F for a temperature difference of 0.040°K at the 4.0°K level. He determined that the heat transfer rate for pool boiling decreases with decreasing

temperature between 4.0° and 2.5° K in proportion to the latent heat of vaporization and inversely as the molar volume of the vapor at the pressure and temperature of the experiment. He also states that the heat transfer curves in the boiling range have a definite hysteric nature. This suggests a nucleation mechanism which is dependent on the thermal history of the surface. It can be explained by associating an activation energy with initiation of a nucleation site. Once a site is activated, it remains active even if the heat flow is decreased below the one required to initiate it.

Film Boiling

Film boiling has received much less attention than pool boiling in theoretical treatment and experimental work. Bromley (7) was the first to present a formal equation on film boiling in 1950. His theory is based on the following assumptions:

- "(1) The liquid is separated from the hot tube by a continuous vapor blanket.
- (2) Heat travels through vapor film by conduction and radiation.
- (3) Vapor rises under the action of buoyant forces.
- (4) Vapor-liquid interface is smooth in that section of tube where most of the heat is transferred.
- (5) Rise of the vapor is retarded by the viscous drag on the tube and more or less on the liquid.
- (6) Latent heat of vaporization is the major item in the heat supplied to the vapor film.
- (7) The kinetic energy of vapor in film is negligible.
- (8) Vapor-liquid interface is smooth and continuous and is not affected by a variation in the vapor-liquid interfacial tension.
- (9) It is permissible to use an average value for the temperature difference between the hot tube and the boiling liquid and treat it as a constant value around the tube in the integrations. This approach to the problem is essentially that used by Nusselt for condenser problems....

- (10) The boiling liquid is at its boiling point at the vapor-liquid interface.
- (11) For engineering calculations it will be satisfactory to evaluate all physical properties of the vapor at the arithmetic average temperature of the hot surface and the boiling liquid.
- (12) The combined effect of most of the errors in the foregoing assumptions may be corrected by evaluating a suitable 'constant' factor to be determined from the experimental data."

The derived equation is:

$$h_{co} = (\text{constant}) \left[\frac{k^2 \rho (\rho_L - \rho) g \lambda' C_p}{D \Delta t Pr} \right]^{1/4} \tag{2}$$

where the constant should theoretically have the value 0.512 if the liquid surrounding the tube is assumed stagnant and 0.724 if the liquid moves completely freely with the vapor.

Corrections, for the kinetic energy of the vapor in the film, and for radiation, should be made if either effect is appreciable.

Hanson and Richards (28) investigated heat transfer coefficients for large Δt 's measured for a stainless steel surface in a liquid nitrogen bath. They correlated their experimental data in the Δt range of 36° to 540°F, to within 5% by the following equation:

$$h = 5120 \Delta t^{-0.583} \text{ Btu/hr-ft}^2\text{-}^\circ\text{F}. \tag{3}$$

They found that measurements were difficult to make for Δt smaller than 110°F, as the tube would tend to wet and return to nucleate boiling.

Hendricks, et.al. (32) established that heat transfer in the convective film boiling regime for liquid hydrogen, can be predicted by correlating the ratio of experimental to predicted Nusselt numbers with the Martinelli two-phase parameter:

$$\left(\frac{\text{Nu}_{\text{calc.}}}{\text{Nu}_{\text{exp.}}}_f \right) = 0.611 + 1.93 \chi_{\text{tt},f} \quad (4)$$

Specialized Studies

Many of the investigators restricted their work to some specific aspect of nucleate boiling behavior. The following is a brief summary of their conclusions.

Effect of Pressure

Weil and Lacaze (67 and 68) observed in their nucleate boiling experiments with nitrogen at 120 and 755 mm. Hg that the heat flux at the higher pressure was about 2 times greater than the one at the lower pressure. Similarly, Cichelli and Bonilla (8) found that the coefficient of heat transfer in nucleate boiling continues to rise as the pressure is increased. The boiling surface usually becomes vapor bound near the critical pressure, and nucleate boiling ceases to be stable. They reached their conclusion from studies with water, ethanol, benzene, propane, normal pentane, normal hexane, 50 mol% water-ethanol, and 33-67% propane-pentane mixtures, at pressures ranging from atmospheric pressure to the vicinity of the critical pressure of the system.

Effect of Forced Circulation

Schweppe and Foust (65) measured boiling-film heat-transfer coefficients for streams of boiling water at incipient boiling conditions in about a 10-inch section of three different diameters. Their results indicate an influence of agitation even with increasing velocity up to the highest velocity measured in the test which was approximately 40 ft/sec. Their conclusion is that the boiling-film heat-transfer coefficient increases with an increase in ΔT even at high velocities.

Boiling Burnout

It was stated earlier that burnout occurs whenever the ΔT is large enough so that the melting point of the surface is reached. This point is represented by point F on Figure 1. A change of regime from nucleate to film boiling in any boiler, will result in a sudden sharp increase in ΔT . The abrupt rise in temperature may be sufficient to melt the boiler material. The understanding of boiling burnout is therefore of great industrial interest. Gambill (23) made a thorough survey of this phenomenon. He considers eight possible conditions for regimes of burnout; subcooled and saturated liquid conditions for each one of the following: unconfined natural convection, confined natural convection, forced convection in axial flow, and forced convection with swirl flow. He reviews the various factors affecting burnout and suggests several correlations for burnout prediction. He states however, "it is apparent that a considerable amount of work remains to be done in this area before good predictions for the general case can be made."

Boiling Studies for Oxygen and Nitrogen

Many studies of the boiling behavior of liquid oxygen and nitrogen have been made in the past twenty to thirty years, probably many more than for any one of the other cryogenic fluids. This is probably because of the importance of these two liquids in air separation processes, and because of their extensive use industrially and in military applications. In general these studies were made under conditions similar to the ones found in air separation plants and related applications. Guter (27), Haselden and Peters (29), Haselden and Prosad (30), Monroe, Bristow and Newell (51) have studied heat transfer to boiling liquid oxygen and nitrogen. In general, they have considered the effect of such factors as non-condensable, tube diameter, length to diameter ratio, and pressure effect on boiling coefficients. The experimental technique generally consisted of a boiling-condensing system. Overall and individual heat transfer coefficients were measured and usually reported in graph form.

Ruzicka (64) obtained data for heat transfer to boiling nitrogen by means of electric resistance heating. He derived the following equations for nucleate boiling on the surface of a copper tube, and platinum and copper wires:

$$Nu = 0.1292 Pr^{-0.45} \left[\frac{(\gamma' - \gamma'') \delta^2 p'}{\gamma' \epsilon'} \right]^{0.63} \left[\frac{\gamma' c_p \sigma'}{(\gamma' - \gamma) \gamma'' r_p' \delta} \right]^{1/3} \quad (5)$$

$$\text{or } \alpha = 0.00701 \left[\frac{\lambda^{0.82} \gamma^{1/3} (\gamma' - \gamma'')^{0.0365} q^{0.63}}{c_p^{0.117} \eta^{0.45} b^{1/3} (r \gamma'')^{0.036} T_s^{0.297}} \right] \text{ k-cal/m}^2\text{-hr-}^\circ\text{C} \quad (6)$$

Effect of Material and Surface Roughness on Nucleate Boiling

Since it was postulated that surface irregularities where small quantities of trapped liquid act as nuclei for the build-up of bubbles, it is reasonable to postulate that the surface material and roughness have a pronounced effect on boiling behavior. Berenson (5) studied the characteristics of pool boiling for n-pentane at atmospheric pressure as a function of surface roughness, material, and cleanliness. He has shown that changes in surface roughness can result in variations of 500 to 600% in nucleate boiling heat transfer coefficient but that surface roughness has no effect on film boiling coefficient. This is reasonable since a vapor blanket completely covers the wall in film boiling and therefore the hot surface has no direct contact with the liquid. He has also concluded that the maximum nucleate boiling burn-out heat flux is essentially independent of surface material, roughness and cleanliness. Berenson listed the effects of the surface material on the nucleate boiling coefficients and has shown that the temperature difference required to produce a given heat flux for the same surface-finishing technique depends on the surface material. This may be explained by the fact that differences in surface hardness may result in surface irregularities and cavity sizes which would differ even though the surface received the same finishing treatment. It is also possible that the thermal conductivity of the material has a direct effect on nucleate boiling performance. Corty and Foust (13) studied

the effect of micro-roughness of a surface on the ΔT necessary to sustain nucleate boiling at a given heat flux. Figure 2 represents their results which indicates the effect of micro-roughness in the range of 0 to 24 micro inch RMS on ΔT . It can be seen from this curve that the lower the roughness, the higher the ΔT required to maintain the same heat flux. They also showed that the position of boiling curves (h versus ΔT) and their slopes vary with roughness.

Cryder and Finalborgo (14) studied the effect of metal surfaces on boiling liquids such as water, methanol, CCl_4 , n-butanol, kerosene and other systems. They found that the boiling coefficients decreased when the tubes were allowed to remain in the boiling liquid even though the character of the metal surface did not appear to have changed.

Danilova and Belsky (16) obtained experimental heat transfer coefficients for boiling refrigerant 22 using nickel and brass tubes. They determined that the coefficients of heat transfer were different for the nickel and brass tubes especially at the low heat loads. This difference was caused by the greater roughness of the brass tube surface. Their experimental data fit the equations of Kutateladze and Kruzhilina well, except for the coefficients which differ from those recommended by the authors of the two equations. Equations 7 and 8 are the Kutateladze equation with a modified coefficient to fit the experimental data.

$$Nu = 0.25 \times 10^{-2} (Re)^{0.75} (Pr)^{0.35} K_p^{0.65} \text{ for nickel tubes} \quad (7)$$

$$\text{and } Nu = 0.46 \times 10^{-2} (Re)^{0.70} (Pr)^{0.35} K_p^{0.65} \text{ for brass tubes} \quad (8)$$

FIGURE 2, EFFECT OF ROUGHNESS ON
TEMPERATURE DRIVING FORCE TO
SUPPORT A COEFFICIENT OF 1000

Equation 9 is the Kruzhilina equation similarly modified to fit the data.

$$\text{Nu} = 0.194 (\text{Re})^{0.70} (\text{Pr})^{0.25} K_t^{0.367} \text{ for the nickel tube} \quad (9)$$

Since it is extremely difficult to duplicate surface finish, it is believed that the effect of surface on boiling is the main factor causing the very large variations in the experimentally obtained boiling heat transfer coefficients. Even though experimental conditions were described as "identical", undetected differences in surface finish may have been sufficiently large to have an appreciable effect on the boiling behavior.

Effect of Active Sites on Nucleate Boiling

The distribution of active sites on the surface is an important factor in determining the thermodynamic and hydrodynamic characteristics of nucleate boiling. Gaertner (22) treats statistically the subject of distribution of active sites. He determined that the local density of nucleation sites for boiling water containing dissolved metal salts at heat fluxes of 200,000; 294,000; and 317,000 Btu/hr-ft² fit a Poisson distribution quite well. The fraction of the surface having a local active site population N in the local area a is given by the equation:

$$P_u(N_a) = \frac{e^{-\bar{N}_a} (\bar{N}_a)^{N_a}}{(N_a) !} \quad (10)$$

He has also established from cursory examination of published data for

five liquids boiling from three different surfaces, that the nucleation of active sites depends on surface temperature in accordance with the equation:

$$\bar{N} = N_o \exp \left\{ - \left[\frac{16\pi\sigma^3 M^2 N^*}{3 \rho_L^2 R^3 \ln \frac{P_\infty}{P_v}} \right] \phi \left(\frac{1}{T_w} \right) \right\} = N_o e^{-K/T_w^3} \quad (11)$$

The author also offers an explanation for the patch-by-patch boiling which has been observed by many experimenters. The patch-by-patch boiling is the apparent tendency of nucleation sites to cluster on the heat transfer surface. An increase in the surface temperature results in a larger number and size of active site patches. This phenomenon was also observed in the present nitrogen and neon boiling study. Corty and Foust (13) advanced two theories to explain how patch-by-patch boiling can occur. The first one postulates that oscillations and pressure surges created by bubbles growing at an active site may increase the supersaturation at neighboring potential active site cavities on the surface thereby creating new centers for nucleation. The second theory suggests that bubbles from one original site expand and fill many adjacent cavities which were previously wetted with vapor. These cavities will then create new centers for nucleation causing a patch of bubbles to form in the vicinity of the parent active site.

Heat Transfer to Boiling Liquids Flowing in Narrow Channels

The study of heat transfer to boiling liquids flowing in narrow channels is limited. Neusen, Kangas and Sher (52) studied heat transfer and

pressure drop for superheated steam flowing in thin annular passages at 600 psia. The test section consisted of annuli formed by an 0.878-inch OD tube inside of an 0.997-inch ID tube, giving a gap of 59.5 mils. The authors determined that the Heineman's correlation of Nusselt number for L/De greater than 60 correlated their data for superheated steam in the thin annulus with both walls heated. Heineman derived the following correlation:

$$Nu_f = 0.0133 (Re_f)^{0.84} (Pr_f)^{1/3} \text{ for } L/De \geq 60 \quad (12)$$

when he investigated short round tubes and rectangular channels having an equivalent diameter of 0.332 inch and 0.091 inch respectively at high pressures and temperatures.

Polomik, Levy and Sawochka (56) investigated the heat transfer coefficients at elevated pressures for annular flow with water boiling to 100% quality. The study was made in a 0.625-inch OD tube with two annuli 0.060 inch and 0.120 inch. The surface finish of their stainless steel surface was 50 micro-inches or better. The experimental data were correlated within $\pm 20\%$ by using a Colburn type equation modified by steam quality and steam void groupings. The correlation applied only to the film boiling data. The authors however, discussed the three boiling regimes:

- a. Nucleate boiling
- b. Transition region
- c. Film boiling region

The data obtained in the nucleate boiling region and transition zone

were not correlated but are tabulated in their paper.

Kapinos and Nikitenko (37) correlated the data obtained in their study of heat transfer in channels by means of an equation of the type $Nu = f(Re)$. They modified the characteristic length of both the Nusselt and Reynolds number by the introduction of a size factor correction.

Only two references related to the investigation of cryogenic fluids boiling in narrow passages were found. The first one by Sydoriak and Roberts (66) determined experimentally the critical heat input to liquid hydrogen and nitrogen boiling in an annular gap. They derived the following equation:

$$Q = AL (\rho_{v2} \rho_L Z_e g f_2)^{1/2} \quad (13)$$

on the assumption of a homogeneous and frictionless two-phase flow. This work was duplicated by Richards, Robbins, Jacobs and Holten (60). The heat transfer test section which was identical to the one used by Sydoriak and Roberts simulated the design of an electromagnet operable at a low temperature of 20°K. It consisted of a 7-inch long stainless steel plug which was accurately centered in a 5-inch long stainless steel tube. Various sizes of plugs were used in order to obtain different size annular spaces in the test section. Gap sizes between 7 and 20 mils were tested. The authors concluded that a prediction of the maximum operating power of an electromagnet by theoretical analysis is not

reliable at this time. The ratio of Q observed to Q calculated by the Sydoriak-Roberts correlation varied from 1 to 1.8 for the hydrogen runs and from 1.3 to 2.4 for the nitrogen runs.

IV. THEORY OF BOILING

Heat transfer in nucleate boiling is a combination of liquid free convection and agitation caused by the bubble movement in the liquid.

The mechanism of nucleate boiling is therefore dependent on the generation of small bubbles on the heated surface. At a given temperature the vapor pressure from a very small concave liquid surface is less than the vapor pressure from a flat liquid surface. Hence, for a given pressure, a liquid must be hotter to evaporate into a small bubble of vapor than into the vapor space above the liquid. The relationship between the two pressures, that is, the vapor pressure inside the bubble and the vapor pressure of the free liquid is as follows:

$$P_c = P_s - \frac{2\sigma}{R} \quad (14)$$

where P_c is the pressure inside the bubble, P_s is the saturation pressure of the liquid, σ is the surface tension of the liquid and R is the radius of the bubble (11).

The six steps sketched in Figure 3 can explain the mechanism of bubble formation which is a major factor in nucleate boiling.

Step 1. Heat is transferred from the hot surface to the surrounding liquid through a thin film and superheats it.

Step 2. As a result of the superheat, several small bubbles form in the hot surface defects such as crevices.

FIGURE 3, THE SIX STEPS OF BOILING

- Step 3. Heat transferred to the attached bubbles through the liquid causes the superheated liquid to flash at the vapor-liquid interface which results in a gradual growth of the bubbles.
- Step 4. Upon reaching a certain size, the bubbles break away from the surface and disturb the surrounding film of superheated liquid.
- Step 5. The freed bubbles continue to grow as they rise through the bulk of the liquid.
- Step 6. Fresh liquid rushes into the newly vacated nucleation sites on the heating surface. These sites, having been blanketed by the vapor of the previous bubbles, are slightly overheated. New bubbles are generated and the cycle repeated.

The bubbles break away from the heated surface, when they reach a characteristic diameter D_b . The escape of the bubbles is governed by the dynamics of the surrounding liquid as well as by the buoyant and adhesion forces of the bubble.

Since nucleate boiling is a combination of free convection, bubble formation, and behavior in liquid, the various theoretical and empirical approaches to the study of boiling covered several methods such as empirical correlations, dimensional analysis, study of bubbles, study of surfaces, statistical analysis, etc.

In most of the nucleate boiling studies, it was assumed that heat flows from the hot surface into the liquid and from the liquid to the vapor bubbles, the controlling resistance to heat transfer being a stagnant film around the vapor bubbles.

Rohsenow's Theory

Rohsenow (62) assumed that the movement of the bubbles at the instant of break-off from the hot surface is the major factor in providing good agitation to the liquid and therefore improving the convection currents and decreasing the resistance of the stagnant film through which the heat must flow. The form of his equation was influenced by the traditional equation for non-boiling liquids.

This equation

$$\text{Nu} = \alpha (\text{Re})^a (\text{Pr})^b \quad (15)$$

is obtained from dimensional analysis and has its coefficient and exponents established by correlating experimental data. Rohsenow modified this equation for boiling. The Reynolds number was taken to be the Reynolds number of a bubble just after breaking away from the hot solid surface. Previous workers found experimentally that the velocity of a released bubble is constant for a short time. Furthermore the following relation between the frequency of emission of bubbles and diameter has also been established:

$$f D_b = C_1 \quad (16)$$

A correlation for the average diameter of a bubble at the instant of break-off derived by others, is also used by Rohsenow for his correlation.

$$D_b = C_2 \beta \left[\frac{2 g_o \sigma}{g (\rho_L - \rho_V)} \right]^{1/2} \quad (17)$$

And now assuming that the bubbles are spheres leaving the solid from n points per unit area the estimated bubble velocity becomes

$$V = f n \pi D_b^3 / 6 \quad (18)$$

and the bubble Reynold number is then

$$Re = \frac{D_b V \rho_L}{\mu_L} = \frac{C_3 \beta f n \rho_L D_b^3}{\mu_L} \left[\frac{2 g_o \sigma}{g (\rho_L - \rho_V)} \right]^{1/2} \quad (19)$$

Using the relationship that the product of the mass of vapor formed per unit time and the latent heat of vaporization must equal the heat transfer rate

$$q = w \lambda \quad (20)$$

the bubble diameter can be eliminated from the Reynolds number which becomes

$$Re = \frac{C_4 \beta q/A}{\mu_L \lambda} \left[\frac{g_o \sigma}{g (\rho_L - \rho_V)} \right]^{1/2} \quad (21)$$

The Nusselt number is treated in a similar manner, that is, the characteristic length D is replaced by the bubble diameter D_b and

$$\text{Nu} = \frac{h D_b}{k_L} \quad (22)$$

In substituting the experimental expression for the bubble diameter, the modified Nusselt number becomes

$$\text{Nu} = \frac{h\beta}{k_L} \left[\frac{g_o \sigma}{g (\rho_L - \rho_V)} \right]^{1/2} \quad (23)$$

Since it was assumed that the heat is transferred from the surface of the bubble through a stagnant film of liquid, the Prandtl number is based on liquid properties.

$$\text{Pr}_L = \frac{C_L \mu_L}{k_L} \quad (24)$$

Rohsenow's final correlation becomes

$$\text{Nu} = \text{const.} (\text{Re})^{2/3} (\text{Pr}_L)^{-0.7} \quad (25)$$

$$\text{or } \frac{h\beta}{k_L} \left[\frac{g_o \sigma}{g (\rho_L - \rho_V)} \right]^{1/2} = \text{const.} \left[\left(\frac{\beta q/A}{\mu_L \lambda} \right) \left(\frac{g_o \sigma}{g (\rho_L - \rho_V)} \right)^{1/2} \right]^{2/3} \times \left[\frac{C_L \mu_L}{k_L} \right]^{-0.7} \quad (26)$$

The coefficient and the two exponents of the equation were obtained experimentally from data of five systems. The exponents were quite constant for all the experimental data tested however the coefficient varied from 0.006 to 0.015 from system to system. Arithmetic modifi-

cation of the Nusselt form equation results in the new equation relating the heat transfer coefficient of boiling to the temperature driving force and the physical properties of the liquid as follows:

$$h = \text{const.} \frac{(\Delta T)^2 k_L^{5.1} g^{1/2} (\rho_L - \rho_V)^{1/2}}{\beta \sigma^{1/2} c_L^{2.1} \lambda^2 \mu_L^{4.1}} \quad (27)$$

Forster and Zuber's Theory

Forster and Zuber (21) also approached the problem of nucleate boiling theoretically. They assumed that the movement of well developed bubbles is of little importance in nucleate boiling. The important movement is imagined to be that of the vapor-liquid interface of a growing bubble while the bubble is still attached to the surface. Westwater (69) compares the two approaches of Rohsenow and Forster and Zuber and points out that the linear velocity of the Forster-Zuber interface is much greater than the velocity described by Rohsenow. For example, values of 10 ft/sec were obtained for the Forster-Zuber model as compared with 0.3 ft/sec for Rohsenow small bubbles.

The starting point for the Forster-Zuber theory is the Rayleigh equation for a bubble growing in a liquid medium.

$$R \frac{d^2 R}{d \theta^2} + \frac{3}{2} \left(\frac{d R}{d \theta} \right)^2 + \frac{2 \sigma}{\rho_L R} = \frac{p_V - p_\infty}{\rho_L} \quad (28)$$

In this case it is assumed that the bubble is spherical, the liquid is incompressible, the viscosity effects are negligible and that the Joule-

Thomson equation is applicable during the growth period (time from the appearance of a nucleus of size R_0 , $R_0 = 2\sigma/(p_v - p_\infty)$ to some later time). It is possible to obtain a theoretical expression for a vapor growing in a superheated liquid, by combining Equation (28) with the Clausius-Clapeyron equation which relates vapor pressure to temperature. The basic Clausius-Clapeyron equation

$$\frac{d P_V}{d T} = \frac{L}{T \Delta V} \quad (29)$$

can be approximated as follows:

$$\frac{d P_V}{d T} = \frac{L P_V}{R T^2} \quad (30)$$

The derived equation which is a second order differential equation, is so complex that it has a very limited usefulness. It becomes enormously simpler if the inertia of the liquid can be ignored during bubble growth. Forster and Zuber discuss this point and define the physical requirements for neglecting inertia of a liquid. These are that either the bubble must be very small or the temperature of the bubble must be nearly equal to the saturation temperature. Both requirements are met in boiling at different times, the first one when the bubble is first growing from the nucleus and the second one when the bubble becomes large. For intermediate conditions it is assumed that both requirements are met in part and that the liquid inertia is negligible for these cases also. The growing bubble equation becomes

$$r + \ln \left(\frac{r - 1}{r_1 - 1} \right) = \frac{\Delta T C_L \rho_L \sqrt{\pi \alpha_L} \theta}{\lambda \rho_V R_0} \quad (31)$$

In this equation θ is the time for the bubble to grow from radius R_1 to R_2 . The symbol r is the generalized dimensionless radius = R/R_0 . The temperature of a bubble growing in a superheated liquid is a function of the bubble size and assuming liquid inertia to be negligible the Forster-Zuber derivation gives the following expression.

$$\frac{T_0 - T_V}{T_0 - T_{\infty}} = 1 - \frac{R_0}{R} \quad (32)$$

This equation states that as a bubble grows from a nucleus to double the radius of a nucleus it will lose 1/2 its temperature of superheat. After the bubble has grown by several orders of magnitude it will have practically no superheat and will be at the saturation temperature.

Differentiation of Equation(31) results in an equation giving the velocity of the wall of a growing bubble. The logarithmic term of the equation 31 can be neglected since a growing bubble is considerably larger than a nucleus during most of its life and the following wall radial velocity is obtained.

$$\frac{dR}{d\theta} = \frac{\Delta T C_L \rho_L}{2 \lambda \rho_V} \left(\frac{\pi \alpha_L}{\theta} \right)^{1/2} \quad (33)$$

It is seen that the radial velocity is directly proportional to the temperature driving force and inversely proportional to the square root

of the elapsed time of growth. It is also noted that the bubble radius is proportional to the temperature driving force and to the direct square root of the time. This results in an independence of time for the product of the bubble radius and its radial velocity

$$R \frac{dR}{d\theta} = \left[\frac{C_L \rho_L \Delta T \sqrt{\pi \alpha_L}}{\lambda \rho_V} \right]^2 \quad (34)$$

The meaning of this equation is that small bubbles grow rapidly and large ones grow slowly but that the agitation in the surrounding liquid caused by the growth of either bubbles remains uniform.

The correlation derived by Forster and Zuber is also in the form of the Nusselt equation

$$Nu = \text{const.} (Re)^a (Pr)^b \quad (35)$$

where the Reynolds number is based on the bubble radius and is defined as follows:

$$Re = \frac{R (dR/d\theta) \rho_L}{\mu_L} = \frac{\rho_L}{\mu_L} \left[\frac{C_L \rho_L \Delta T \sqrt{\pi \alpha_L}}{\lambda \rho_V} \right]^2 \quad (36)$$

and the Nusselt number as follows:

$$Nu = \frac{R q/A}{k \Delta T} \quad (37)$$

Since the bubble radius is usually not known it is convenient to eliminate it by solving for its value in the equation describing

bubble dynamics:

$$R = \left(\frac{C_L \rho_L \Delta T \sqrt{\pi \alpha_L}}{\lambda p_V} \right) \left(\frac{2\sigma}{p_V - p_\infty} \right)^{1/2} \left(\frac{\rho_L}{p_V - p_\infty} \right)^{1/4} \quad (38)$$

The final Forster-Zuber correlation is

$$Nu = 0.0015 (Re)^{0.62} (Pr)^{1/3} \quad (39)$$

$$\text{or } \left(\frac{C_L \rho_L \sqrt{\pi \alpha_L} q/A}{k_L \lambda \rho_V} \right) \left(\frac{2\sigma}{\Delta p} \right)^{1/2} \left(\frac{\rho_L}{\Delta p} \right)^{1/4} = 0.0015 \left[\frac{\rho_L}{k_L} \left(\frac{C_L \rho_L \Delta T \sqrt{\pi \alpha_L}}{\lambda \rho_V} \right)^2 \right]^{0.62} \\ \times \left[\frac{C_L \mu_L}{k_L} \right]^{1/3} \quad (40)$$

This equation can be written to show the dependence of the heat transfer coefficient on the other variables:

$$h = 0.0012 \frac{(\Delta T)^{0.24} (p_V - p_\infty)^{0.75} k_L^{0.79} C_L^{0.45} \rho_L^{0.49}}{\sigma^{0.5} \lambda^{0.24} \mu_L^{0.29} \rho_V^{0.24}} \quad (41)$$

A comparison between the Forster-Zuber and Rohsenow equations, Equations (40) and (26) respectively, shows that the Reynolds number is raised to about the same exponent in both cases but that the exponent for the Prandtl number varies greatly.

It should be noted however that the Reynolds numbers in both expressions are completely different both in meaning and in numerical values.

Furthermore a comparison between the Equations (27) and (41) shows that the prediction of the effects of variables on h is quite different for both equations, even though both are derived from theories which are based on the assumptions of single bubble formations departing from the heated surface. Zuber (70) also considers other models of boiling in which bubbles leave the hot surface either in conjunction with several other bubbles or in columns. The analysis for each case requires basic modifications to the derivations based on the single bubble concept.

McNelly's Correlation

Several semi-empirical and empirical correlations have also been derived to describe nucleate boiling. McNelly (49) offers the following equation to cover the entire range of nucleate boiling.

$$\frac{h_b d}{k} = 0.225 \left(\frac{C\mu}{k} \right)^{0.69} \left(\frac{H d}{L\mu} \right)^{0.69} \left(\frac{\rho_d}{\sigma} \right)^{0.31} \left(\frac{\rho_L}{\rho_V} - 1 \right)^{0.31} \quad (42)$$

This equation similarly to the ones obtained by Rohsenow, and Forster and Zuber is based on the assumption that the main transfer resistance is in the thin liquid layer adjacent to the heat surface. Turbulence in the liquid layer is caused by the rapid formation of vapor bubbles. The dimensionless terms of Equation (42) were obtained by dimensional analysis. The constant and the exponents of the equation have been calculated from data obtained with different configurations of heating surfaces. These configurations have been found to have no effect on heat transfer coefficients so long as the bubble formation was not

upset by external agitation or by confined space. The author points out that the condition of the heating surface has a great influence on bubble generation and therefore on the overall rate of heat transfer. McNelly uses available boiling data to test the validity of his equation and to establish the constant and exponents. He explains the importance of the surface by pointing out that the pressure difference to initiate a bubble in a very still liquid will be infinite as per Lord Kelvin equation

$$\pi r^2 P = 2 \pi r \sigma \quad (43)$$

and therefore a considerable amount of superheat must be attained before boiling commences. However, if small crevices and irregularities appear on the surface they will promote bubble formation and therefore will have an important effect on the boiling performance.

Levy's Generalized Equation

Levy (45) offers the following generalized equation to describe surface boiling.

$$\frac{Q}{A} = \frac{k_L C_L \rho_L^2}{\sigma T_s (\rho_L - \rho_V)} \frac{1}{B_L} (\Delta T)^3 \quad (44)$$

The starting point for the derivation of this equation is the original equations of Forster and Zuber describing bubble growth.

$$R_i = \frac{2 \sigma T_s (\rho_L - \rho_V)}{\rho_V \rho_L h_{fg} (T_w - T_s)} \quad (45)$$

and

$$\frac{dR}{dt} = \frac{(T - T_s)^2 C_L^2 \rho_L^2 \pi \alpha}{R h_{fg}^2 \rho_V^2} \quad (46)$$

Equation 46 can be rewritten to give the rate of heat transfer from the liquid to the bubble per unit bubble area.

$$\frac{q_b}{A_b} = h_{fg} \rho_V \frac{dR}{dt} = \frac{(T - T_s)^2 C_L \rho_L \pi k_L}{R h_{fg} \rho_V} \quad (47)$$

All the heat transferred at the heated surface must be carried by the bubbles as they reach their maximum size R_s ,

$$Q = n f \frac{4}{3} \pi R_s^3 h_{fg} A \rho_V \quad (48)$$

The heat carried by bubbles of radius R is

$$Q_b = n f \frac{4}{3} \pi R^3 \rho_V A h_{fg} \quad (49)$$

By putting $T = T_w$, $q_b/Q_b = 1$, $A_b = A_{b,i}$, $R = R_i$, combining Equations (47), (48), and (49), and substituting the original bubble Equation (45), the following equation is obtained

$$\frac{Q}{A} = \frac{k_L C_L \rho_L^2}{\sigma T_s (\rho_L - \rho_V)} \frac{\pi}{2} \left(\frac{R_s}{R_i} \right)^3 \frac{A_{b,i}}{A} (T_w - T_s)^3 \quad (50)$$

which can be simplified to the following form

$$\frac{Q}{A} = \frac{k_L C_L \rho_L^2}{\sigma T_s (\rho_L - \rho_V)} \frac{1}{B_L} (\Delta T)^3 \quad (51)$$

It should be noted that

$$\frac{Q}{A} = \frac{1}{B_L} \frac{q_b}{A_b} \tag{52}$$

and that according to Rohsenow, and Forster and Zuber, Q/A is proportional to q_b/A_b and therefore B_L must be a constant. The value of the coefficient B_L must be obtained from experimental data. Levy offers a curve relating $1/B_L$ to $\rho_V \times h_{fg}$ which has to be used in conjunction with his general correlation.

There are several other similar empirical correlations for nucleate boiling in which the heat transfer coefficient is a function of temperature driving force and physical properties of the fluids.

Cryder and Gilliland's Generalized Equation

The generalized equation of Cryder and Gilliland (15) is interesting since it is one of the few equations that incorporate the diameter of the tube where boiling takes place. The equation was derived from tests made with water, salt solutions, and five organic liquids boiling on the outside of a 1.04-inch brass tube.

$$h = \text{const.} \frac{(\Delta T)^{2.39} k_L^{2.97} C_L^{0.43} \rho_L^{3.1} D^{2.1}}{\sigma^{1.65} \mu_L^{3.45}} \tag{53}$$

Hughmark's Statistical Approach

Hughmark (33) statistically analyzed nucleate pool boiling experimental data and derived the following eight-variable equation for heat flux:

$$\bar{q} = 2.67 \times 10^{-9} \frac{\Delta P^{1.867} (\rho_L - \rho_V)_w^{2.27} (C_L)_w^{0.945} T_w^{1.618}}{(\rho_V)_w^{1.385} L_w^{1.15} (\mu_L)_w^{1.630} P_R^{0.202}} \quad (54)$$

This equation which describes experimentally measured heat flux with an average absolute deviation of 40% considers only the thermodynamic properties of the liquid and vapor. It neglects the effects of the condition, geometry, and orientation of the surface. The author states that the equation has no theoretical justification but that it gives the best attainable agreement with experimental data when only thermodynamic properties are considered as products of powers.

Chen's Theory of Additive Mechanisms

Chen (9) using a different approach to solve the problem, postulated an additive mechanism of micro and macro convective heat transfer to represent boiling heat transfer with net vapor generation to saturated non-metallic fluids in convective flow. He defined two dimensionless functions, S and F, to account for the suppression of bubble growth due to flow and for the increase in convective turbulence due to the presence of vapor. Both S and F are functions of a two-phase Reynolds number and a Martinelli parameter respectively. The derivation of Chen's equation is based on the assumption that

$$h = h_{mic} + h_{mac} \quad (55)$$

The micro-convective heat transfer in convective boiling is derived from the Forster-Zuber equation

$$h_{mic} = 0.00122 \frac{k_L^{0.79} C_{pL}^{0.45} \rho_L^{0.49} g_c^{0.25}}{\sigma^{0.5} \mu_L^{0.29} \lambda^{0.24} \rho_V^{0.24}} \times (\Delta T_e)^{0.24} (\Delta P_e)^{0.75} \quad (56)$$

By the use of the Clausius and Clapeyron equation and the simplification resulting from $\Delta T/T \ll 1$ a final suppression term is derived

$$S = \left(\frac{\Delta T_e}{\Delta T} \right)^{0.24} \left(\frac{\Delta P_e}{\Delta P} \right)^{0.75} \quad (57)$$

Combining this suppression factor with equation 56 a final expression for the micro-convective coefficient in terms of the suppression factor and total superheat is obtained.

$$h_{mic} = 0.00122 \frac{k_L^{0.79} C_{pL}^{0.45} \rho_L^{0.49} g_c^{0.25}}{\sigma^{0.5} \mu_L^{0.29} \lambda^{0.24} \rho_V^{0.24}} (\Delta T)^{0.24} (\Delta P)^{0.75} S \quad (58)$$

The Dittus-Boelter equation

$$h_{mac} = 0.023 (Re)^{0.8} (Pr)^{0.4} \left(\frac{k}{D} \right) \quad (59)$$

is modified by Chen to represent effective values associated with the two-phase fluid as follows:

$$\beta = Pr/Pr_L \quad (60)$$

$$\gamma = k/k_L \quad (61)$$

$$F = (Re/Re_L)^{0.8} = \left(Re \times \frac{ML}{DGz} \right)^{0.8} \quad (62)$$

In the case of ordinary fluids the Prandtl numbers of the liquid and the vapor are normally of the same magnitude and therefore the term β is equal to 1. Furthermore since the heat is transferred through an annular

film of liquid it is expected that the liquid properties would be dominant and that γ should also be close to unity. Therefore the Dittus-Boelter modified equation is

$$h_{\text{mac}} = 0.023 (\text{Re}_L)^{0.8} (\text{Pr}_L)^{0.4} \left(\frac{k_L}{D} \right) F \quad (63)$$

and the total heat transfer coefficient is then the summation of both the micro and the macro convective heat transfer coefficients. Chen verified the validity of his equation with nine experimental cases. An average deviation between calculated and measured boiling coefficient of $\pm 11\%$ was obtained.

Sydoriak and Roberts' Derivation for Boiling N_2 and H_2 in Narrow Channels

Sydoriak and Roberts (66) derived the following equation relating heat flux to annular area and physical properties of the fluid based on their experimental work with nitrogen and hydrogen. They assumed a homogeneous frictionless two-phase flow in the annulus.

$$Q = AL \left(\rho_V^2 \rho_L Z_e \bar{g} f_2 \right)^{1/2} \quad (13)$$

V. EXPERIMENTAL INVESTIGATION

The following discussion of the experimental work consists of a description of the test equipment and of the experimental procedure, a tabulation of the data, and a review of the important experimental observations.

Apparatus for Cryogenic Confined Space Boiling Studies

Introduction

Design, construction, and operation of the apparatus used in the boiling studies incorporated one main objective: the simulation of boiling conditions experienced in the operation of confined space boiling devices, such as cryomagnets (42). The design of the test equipment allowed for either liquid nitrogen or liquid neon testing. A detailed description of the design and construction of the test apparatus follows. The neon liquefier built as a part of this project was described at the semi-annual meeting of ASHRAE in 1963 (41).

For purposes of discussion, the study apparatus has been classified into two groups, namely, experimental test section, and auxiliary equipment. These equipment groups will be considered separately.

Experimental Test Section

A major effort in the overall program was that of design and construction of an experimental test section. The test section design incorporated three major objectives:

- a. geometric simulation of confined space boiling channels,
- b. thermodynamic and hydrodynamic simulation of confined space boiling mechanisms, and
- c. obtaining significant experimental information through use of suitable instrumentation.

Geometric Configuration Considerations in Design of Test Section

As noted, simulation of confined space boiling channels was a major requirement in the test section design. The channels to be simulated, the cooling channels of a cryomagnet for example, have the following typical dimensions:

10 inches - 30 inches vertical length

3 inches - 10 feet circumferential length

0.005 inches - 0.060 inches gap dimension.

The devices incorporating the narrow channels are fully submerged in a cryogenic fluid in normal operation. Boiling then occurs in these vertically oriented channels.

In the boiling test section design, the narrow channel simulation could have been accomplished in either of two ways: (a) by accurately spacing apart two flat plates, or, (b) by accurately spacing apart two concentric cylinders to form an annular gap. It was felt that the concentric cylinders would be preferable, so the annular gap as a simulation of the narrow thickness channels was used.

At the outset it was decided that capability for visual observation of the annular boiling mechanisms during operation would be incorporated in the test section design. To accomplish this, the outer cylinder forming the annular gap was specified as precision formed Pyrex glass pipe, and the inner cylinder as the heating surface which would cause boiling when the pair of concentric cylinders were submerged in liquid nitrogen or liquid neon. To permit studies with various gap widths, it was decided that a single size of precision bore glass tube would be used with six different sized heaters. The heaters would differ from each other only in respective outside diameter dimensions. The outside diameter variation would affect the variation in gap size.

Availability of liquid neon was an important factor in sizing the test section. An average neon boil off rate equivalent to about 6 liquid lt/hr was acceptable. Based on calculation of boil off rate included in the appendix, a test heater nominally 3-inch OD x 7 1/2-inch long was specified as an insertion in a nominal 3 ± 0.0003 -inch precision Pyrex pipe.* Channel gap sizes of 0.005-inch to 0.080-inch were also specified.

The preliminary design dimensions and the annular space between a glass outer tube and an inner heater element were taken as

* Commercially available - G. K. Porter, Hatfield, Pennsylvania

the basis of geometric simulation of the narrow thickness channels. Heat transfer and fluid flow considerations now were to be incorporated in the test section design

Thermodynamic and Hydrodynamic Consideration in Design of Test Section

The thermodynamic considerations associated with the test section design were those of simulating the mode of heating found in the narrow thickness channels of cryomagnets. In those situations one surface of the channel was effectively insulated while the other surface was heated by electric resistance heating. That is, while the field producing electric current passed through the conductor which formed one face of the channel, I^2R heating occurred, resulting in a uniform heat generation.

To simulate this heating method in the test section, a resistance element of nominal 3-inch OD was considered. Electrical characteristics of suitable resistance materials at low temperatures indicated that the resistance heating scheme was impractical. Instead, a concept of a boiler-condenser heater was instituted. The boiler condenser heat transfer scheme would involve a small electric heating element to boil liquid nitrogen or liquid neon inside of a pressure vessel having a nominal 3-inch outside diameter. The outer surface of the pressure vessel would form

the heating face of the annular gap. A simple thermosyphon pump, (vapor lift pump), installed inside the pressure vessel would pump liquid nitrogen or liquid neon in a fashion so that the inner wall of the pressure vessel would be "splashed," that is, completely washed by the "percolating" fluid and therefore maintained at a constant temperature. Under test conditions, the test heater is submerged in either liquid nitrogen or liquid neon. Resistance heating by means of the partially immersed electric element would result in simultaneous vapor generation and condensation inside the 3-inch vessel, and boiling on its outer wall. At a given electric power input, the heater pressure will rise until the temperature driving force resulting from the difference between the saturation temperature of the boiling-condensing liquid inside the heater at the heater pressure, and the saturation temperature of the boiling liquid outside the heater, is sufficient to dissipate the heat input.

In this fashion, the power input to the resistance element would effectively result in heat transfer from the vessel's outer surface to the fluid in the narrow thickness channel. The thermosyphon pumping insured that the inner surface of the vessel wall would be continuously wetted with a fluid at a higher saturation temperature. The wetting in turn assured the existence of a uniform temperature potential

through the vessel wall, thus resulting in the uniform heat generation simulation desired. Having decided on the boiler-condenser heat transfer scheme, various design problems became apparent. At the outset, it was deemed desirable to maintain little contraction of the vessel diameter when cooled from ambient temperature to liquid nitrogen and neon temperatures. For this reason, a pressure vessel made from invar material (36% Ni, 69% Fe) was considered. A.S.M.E. Boiler and Pressure Vessel code (2) calculations showed a wall of 0.0407-inch thickness to be sufficient from the standpoint of internal pressure, however a wall thickness of 0.250-inch was considered more practical. Unfortunately, heat transfer calculations showed that an unreasonably high temperature difference of 40°F across the 0.250-inch thick wall would exist at the higher heat flux value anticipated in this study.

Because of the heat transfer problem posed, it was decided that the desirable contraction characteristics of the pressure vessel material would be compromised for high thermal conductivity. For this reason OFHC (oxygen free high conductivity) copper pipe would be specified as the pressure vessel wall material. At liquid neon temperatures, the OFHC material, certified ASTM Specification B-75 (3), has a thermal conductivity value of 695 Btu/hr-ft-°F which compares with 1.5 Btu/hr-ft-°F

for invar (35). The higher thermal conductivity copper would reduce the 40°F temperature difference across the 0.250-inch wall to approximately 0.2°F, at the higher heat fluxes.

A.S.M.E. Boiler and Pressure Vessel Code calculations showed that an OFHC copper wall thickness of 0.102-inches would be sufficient for 400 psia vessel pressure. Deflection consideration, however, indicated that a wall thickness of 0.125 would provide a 6.4% error between gap sizes for a given geometric configuration with 0 psia and 400 psia vessel pressures respectively. To minimize the error in gap under various vessel pressures, a heavier nominal wall thickness of 3/8-inch was specified. (Calculations noted above are included in Appendixes B and C.)

In order to minimize thermal end effects, end closures were specified as 1/4 - 5/16 nominal thickness stainless steel plates. The plates would be soldered into appropriately machined recesses at the respective ends of the OFHC copper pipe length. One plate would have a centrally located access hole while the remaining closure was solid. Each end plate would have a short length of stainless steel rod attached to it, this making the pressure vessel much like a rolling pin in appearance. One of the rods would be bored out to provide access to the pressure vessel cavity through the respective end plate.

The heating element, a Watlow Fire Rod Heater, had a nominal heating capacity of 550 watts at 120 volts AC when operated in liquid nitrogen or liquid neon, and sized 1/2-inch outside diameter, 2 1/8-inch length. The element was mounted inside a 5/8-inch outside diameter, thin wall stainless steel tube. The heater element-tube assembly inserted into the pressure vessel cavity through the access tube constituted the thermosyphon pump.

Figures 4, 5, 6, and 7 show the parts of the test heater and the assembled test section.

Experimental Data Collection Consideration in Test Section

Design

Data collection, or instrumentation, considerations in the test section design were directly related to the desired observations to be made, based on the experimental concept shown in the schematic diagram of the test section, Figure 8.

The observations deemed necessary were as follows:

- a. Saturation pressure of fluid in heater cavity (pressure vessel cavity). Saturation pressure in the pressure vessel cavity would be measured on a bank of manometers and a precision pressure gauge. The various manometers and pressure gauge were specified so as to allow accurate

TEST SECTION**

pressure readout from 0.02 psig to 600 psig. The pressure measurement bank would tap into the gas fill line of the heater and would allow continuous monitoring of the cavity saturation pressure. An auxiliary piping circuit employing the precision high pressure gauge was specified to permit metering of the gas introduced into the vessel cavity.

- b. Temperature of heater surface (pressure vessel wall) and of liquid bath into which test section is immersed.

Measurement of temperature indicated posed problems since the measurements were to be made at temperatures as low as liquid neon temperature. At this temperature level, 50°R, elaborate sensing equipment is generally employed, e.g., platinum resistance thermometers. Copper-constantan thermocouples, frequently used in cryogenic research, exhibit a very low ratio of electromotive force to temperature change at liquid neon conditions. At 50°R, a copper-constantan thermocouple has a response ratio of approximately 4 μ volts per °R temperature change.

Space limitations and practicality of instrumentation eliminated all but copper-constantan thermocouples for temperature measurement considerations. It was also decided that the measurement of the boiling liquid temperature was of secondary importance since boiling occurred at atmospheric pressure. The primary measurement would be, therefore, a

direct measurement of the temperature difference between the wall and boiling liquid. Copper-constantan thermocouples mounted in the wall of the pressure vessel and referenced to a copper-constantan junction submerged in the liquid nitrogen or neon bath would yield the desired electromotive force output corresponding to the temperature difference between the pressure vessel wall and the liquid bath. The small signal obtained from the thermocouples would require amplification to provide the desired accuracy for temperature measurements of $\pm 0.1^{\circ}\text{F}$. The temperature measurement instrumentation shown in Figure 9 was therefore specified:

1. Copper-constantan differential thermocouple circuit
 2. Sanborn 86-1500 PA preamplifier unit
 3. Brown Electric multiple point recorder 0-1 mv full scale
 4. Precision Rubicon box potentiometer for suppression voltage.
- c. Rate of heat input to the heater, this in turn being heat transferred in annular gap boiling. As shown in Figure 10, the power input to the electric heating element was measured by means of a multiple range precision wattmeter. The assumption was made that all power indicated by the wattmeter was transferred through

FIGURE 16, WIRING DIAGRAM OF THERMOCOUPLES

FIGURE 7 , WIRING DIAGRAM OF ELECTRIC HEATING ELEMENT

the walls of the pressure vessel. This implied that a negligible amount of heat would be lost through the vessel end plates and in I^2R heating of the heater element lead-in wires.

- d. Rate of gas generation or gas flow rate out of annular gap channel. Vapor generation rate or vapor flow rate out of the channel could be measured in two independent ways. The separation chamber above the test heater which would separate vapor and entrained liquid, would also collect and channel the vapor through an access tube to a rotameter for direct measurement. Secondly, the wattmeter employed in measurement of power input would also serve as a rate of vapor generation monitor. That is, if the assumption that all heat input to the test section were consumed in vaporization of channel fluid, the vapor generation rate, then, would be directly proportional to the power consumption; the constant of proportionality being the latent heat of the liquid.

Trial operations of the test section yielded a very good agreement between vapor flow rate measurements by the two independent methods. It was then decided that the wattmeter measurement of vapor flow would suffice since the flowmeter method introduced an undesirable back pressure on the boiling fluid.

- e. Liquid entrainment, mass of liquid moving with generated vapor, at exit end of annular channel. Measurement of liquid entrainment at the channel exit posed a major problem because of space limitation in the glass dewars. Ideally, the entrained liquid collected in the phase separator located on top of the test heater, would drain by gravity into a graduated glass container and would therefore be easily measured. However, reduction to practice of this idea was not feasible. The graduated container would have had to be located 2 to 3 inches below the top of the heater, thus submerging it completely. A sealed line between the phase separator and the container would be required. In order to allow for gravity flow a vent would also be needed. The main complication, however, resulted from the need of piping and appropriate valves to regulate the liquid flow to the graduated container and to allow emptying it prior to each run. It was impossible to physically fit the graduated container, all this piping and valves, and the test section in the glass dewars containing the liquid bath. Therefore measurement of liquid entrainment was not carried out, but visual observations regarding the type of entrainment and estimating its amount were made for each run.
- f. Wetted area, wetted by liquid gas mixture, of heated surface in annular channel, and liquid head driving force

for flow in annular channel. The fact that the external parts of the test apparatus were to be glass provided a straight-forward method of measuring wetted area of heated surface and liquid head driving force. It was planned that the heater surface would be visible for visual observation. A graduated scale, appropriately positioned proximate to the visible area of heated surface would permit visual measurement of the wetted length. Similarly, the scale would permit direct visual measurement of the liquid head driving force.

Composite Design, Fabrication and Assembly of Test Section

The test section therefore consists of the following basic elements:

- a. Copper heater containing a small electric element
- b. Precision glass sleeve forming the outer surface of the narrow channel
- c. Instrumentation (described in previous section)

Precision machining of the copper heater was necessary in view of the small gap sizes desired: 0.005- to 0.080-inch. Machining of the heater was therefore performed in two steps. The first one, rough machining, brought the heater outside diameter to within about 0.010-inch of the final diameter of

the heater. At that point, the wall thermocouples were installed in the heater wall and soldered, and the end plates were also installed and soldered. The second step of machining reduced the outside diameter of the heater to the exact desired diameter. The assembly of the test unit was done with specially designed flanges. Figures 6 and 7 show an assembled section. Location collars and a specially built tapered gauge were used to insure exact concentricity during assembly. The surface finish of each heater was carefully checked and its roughness was measured with a Profilometer (50). The two plated heaters, heaters no. 9 and 10, were machined like the copper heaters. They were, then, sent out for plating with about 4 mils of nickel and cadmium respectively. The plated surface was finally machined again to the required diameter which removed about 2 mils of the plating. This concept was used in order to insure the same type of surface finish for all the heaters tested.

Another important consideration was the determination of the exact gap size at the liquid nitrogen and neon temperatures. This was accomplished by accurate measurements of the outside diameter of the heater and the inside diameter of the precision Pyrex sleeve at ambient temperature. The best available coeffi-

coefficients of thermal expansion as a function of temperature for the OFHC copper and the Pyrex sleeve (1, 35) were used to calculate the contraction of both materials from ambient to liquid nitrogen and neon temperatures. Detailed calculations show that a contraction of 0.004 inch occurs for both the liquid nitrogen and neon cases. The gap dimension at liquid nitrogen and neon temperature is therefore, the gap size measured at ambient conditions plus the contraction correction of 0.004 inch. Refer to Appendix D for calculations.

Since the tests are to be carried out at cryogenic temperatures, heat leak to the test section is an important factor. Calculations show that the precision glass sleeve offers sufficient resistance to render the heat leak effect negligible. However, it was decided to minimize this effect further by the addition of a second Pyrex pipe around the precision Pyrex pipe, thus forming a vapor barrier.

Auxiliary Equipment

Auxiliary equipment was required in conjunction with the main test section. Figures 11 and 12 are views of two components: dewar assembly and gas recovery bag.

FIGURE 11

Experimental Procedure

The experimental program was divided into two parts, the first one related to the study of boiling liquid nitrogen and the second one to the study of boiling liquid neon.

Liquid Nitrogen Boiling Study

Two complete sets of runs were made with each heater: one set of runs under pool boiling conditions and the second one under annular flow boiling conditions.

The test section was assembled and introduced into the glass dewars shown in Figure 11. In the case of pool boiling, the heater was introduced alone without the precision tube glassware forming the annular space. The heater cavity was evacuated and the whole section was then cooled down with liquid nitrogen. The shield section of the dewars assembly was also filled with liquid nitrogen. The heater cavity having a volume of about 500 cc, was filled with about 250 cc of liquid nitrogen. This was accomplished by introducing enough gaseous nitrogen in the heater and condensing it.

After the heater was filled with the desired amount of liquid nitrogen the system was assumed to have reached equilibrium when the heater pressure was below 3 to 4 inches of water for over 15 minutes, with zero heat input to the test section.

A complete series of runs for pool boiling consisted of varying the electrical power input to the heating element from 0 watts to about 400 watts at at least two different submergences, submergence being defined as the depth of the lower edge of the heating surface below the surface of the liquid. A 7 1/2-inch submergence corresponds to 100% submergence since the heaters have a 7 1/2-inch effective heating surface. The following readings were taken for each run: heater pressure, wattage, heater wall temperature measurements, and submergence. A total of 6 heaters were tested under pool boiling conditions: four copper heaters, nos. 12b, 6, 7, and 8; and heaters nos. 9 and 10 which were nickel and cadmium plated respectively. The pool boiling runs were made in order to establish a datum plane for the annular gap boiling studies. The experimental procedure for the annular gap boiling was identical except for the fitting of the heater with the precision glassware that formed the annular gap. Four major gap sizes were tested, namely, 6, 20, 53, and 80 mils measured at liquid nitrogen temperature. Two additional gap widths of 21 and 22 mils were also tested in the case of the nickel plated and cadmium

plated heaters respectively. In the case of the annular gap boiling, two submergences were considered: the inner submergence defined as the length of the heater surface which is wetted by the boiling liquid and the outer submergence defined as the depth of the lower edge of the heater relative to the liquid level outside the annulus. Both submergences are identified in Figure 7.

A series of runs for annular gap boiling was similar to the one for pool boiling and consisted of varying the electric power input to the electric element at at least two inner submergences. Heater pressure, wattage, wall temperatures and both inner and outer submergences were measured for each run. The six heaters tested under pool boiling conditions were tested under annular gap boiling conditions.

Liquid Neon Boiling Study

The experimental procedure used for the liquid nitrogen boiling study was also used for the liquid neon boiling study.

Since the heaters were already tested under pool boiling conditions with liquid nitrogen, only heater 12b was similarly tested under pool boiling conditions with liquid neon.

Experimental difficulties were experienced in the case of neon boiling, during the transfer of the liquid neon from storage to

the test dewar. The main difficulties were the result of freezing and precipitation as solids of trace quantities of air introduced in the liquid neon during the filling of the inner glass dewar. Solid CO₂ and air had a tendency to plug the narrow annulus. A fine screen was installed at the bottom of the test heater to prevent the occluded solids from entering the annulus. Another difficulty was the frosting of the windows which greatly reduced the visibility of the test section.

A total of five heaters were tested under annular gap boiling conditions at full submergence except for heater 7b which was tested at three different submergences. The five heaters tested consisted of the four copper heaters with 6, 20, 53, and 80 mil gap widths, and the nickel plated heater with a 21 mil gap width.

It should be noted that the heater cavity was filled with 250 cc of liquid neon in the case of the neon boiling study.

Experimental Data

The characteristic dimensions of the six test heaters are summarized in Table I. The physical properties of the two cryogenic fluids tested, nitrogen and neon, are listed in Tables II and III respectively. The experimental data covering all the runs with nitrogen and neon, are tabulated in Tables IV to XXI.

Experimental Observations

The design of the experimental section incorporated the concept of visual observation and picture taking of boiling nitrogen and neon in the narrow annuli. Unfortunately, picture taking proved to be extremely difficult on account of the seven glass surfaces between the heater surface and the camera lens. These many surfaces resulted in distortion and glare which prevented good clear pictures. However, in spite of these difficulties several pictures and about 100 to 200 feet of 16 mm movies were sufficiently clear to permit close study of the boiling phenomena.

Visual observation during the runs was possible most of the time. Efforts were made to avoid frosting of the dewar surfaces by proper purging and good sealing of the dewar assembly so that observation would not be hampered by snow or frost. This was not always possible, particularly in the case of the neon boiling experiments where frosting was a serious problem.

It should be noted, that in spite of substantial effort during the machining of the heater surfaces, to have all the surfaces identical, a variation in the surface roughness of 6 to 20 micro-inches RMS

between heaters, was measured with a Profilometer. A complete description of the surface finish of each heater is included in Appendix F.

At this time some general observations can be made regarding pool and annular gap boiling, for both nitrogen and neon runs. These observations are very similar to the ones made by other investigators with water and organic chemicals. Two of the most common behaviors reported in the literature were also observed in this study. These are described in paragraphs a and b below.

- a. The occurrence of overheated surface at the beginning of some runs where boiling did not start until the surface temperature reached a certain level. The boiling suddenly occurred over the whole surface and the surface temperature was rapidly lowered to its normal level. Whenever this behavior occurred, the heater pressure, which is directly related to the wall temperature, would vary by about 20 to 30 psi representing 4 to 8^oF. The sudden boiling was almost explosive in nature and the entire surface was covered with bubbles. This occurred even at low heat fluxes but was more prevalent at the higher heat fluxes.
- b. Patch-to-patch boiling occurred frequently at the higher heat fluxes (600 Btu/hr-ft²). This behavior consisted of having small patches of boiling surface shifting from place to place. It seemed that the whole patch moved from one location to the other. These patches were square in shape having about 1 x 1-inch sides.

Shifting of the boiling patches did not follow any pattern and was completely random.

- c. In contrast to the patch-to-patch boiling described above, it also appeared that certain sites once activated with nucleate boiling remained active throughout the run. These active sites which were usually obtained on increasing heat flux remained active even when the heat flux was reduced. The sites were random and usually occurred at different spots from run to run. It appeared that the most permanent sites were the ones obtained during the sudden boiling described in (1) above. When the violent boiling started with an overheated surface many active sites were maintained throughout this particular series of runs.
- d. The cadmium plated heater (heater no. 10) had several small patches of copper showing on the surface. Observations during the boiling runs with this heater indicated that the boiling on this heater was of the same nature as the boiling on the other heaters. There was no preferential boiling or lack of it on the copper patches.
- e. It was mentioned earlier (p. 59) that experimental difficulties prevented measurement of entrainment. Observations showed that the occurrence of entrainment depended on the outer submergence and heat flux. In general there was no entrainment with an outer submergence of about 6 inches or less at low heat fluxes of the order of 100 - 200 Btu/hr-ft². At higher heat fluxes, a lower

outer submergence was necessary to prevent entrainment.

Entrainment was easy to observe, since the liquid in the annulus was rather clear except for about 1/2 - 1 inch of cellular type clear foam. This foam was light in texture, consisting of 70-80% void space, and was clearly defined in all cases, except for the heater with the 6 mil gap. With this very narrow gap width, the foam covered 2 to 3 inches of the surface and often consisted of a large bubble flattened between the heater surface and the Pyrex pipe.

Neon entrainment appeared slightly larger than nitrogen entrainment, otherwise the two were very similar.

- f. The effect of back pressure resulting from the use of a rotameter to measure boil-off was very noticeable. When the rotameter was connected, the inner submergence was always lower than the outer one, and the foam on top of the liquid was very shallow, about 1/4-inch, and very clearly defined. There never was any entrainment in this case.

When the test section operated as a true thermosyphon reboiler, without a rotameter connection, the inner submergence was always higher than the outer one, and was topped with 1/2 - 1-inch foam made up of larger bubbles than in the previous case.

- g. Even though the foam on top of the liquid in the annulus was rather sharply defined, it did fluctuate by about 1/4 to 1/2-inch depending

on the heat flux. Measurements of the inner submergence were obtained at the maximum height of the foam throughout the particular run. This therefore gave a maximum wetted surface for each run, resulting in minimum calculated heat flux. Any error resulting from this fluctuation was small at the higher submergences but could be quite significant at the very low inner submergences of 1 to 2 inches. At the 2-inch level an error of 1/4 inch would result in an error of wetted surface calculation of 12 1/2%, while it would be about 3% at the 7-inch level.

- h. The pool boiling runs showed about the same type of bubbling as the annular gap boiling. In the case of pool boiling a small crown of liquid surrounded the heater surface at the free liquid surface. The crown about 1/4 to 1/2-inch high acted as a shower around the heater. This was the result of thermal pumping generated by the surface bubbling. In this case calculation of the wetted surface was based on the height of the crown rather than on the height of the liquid free surface.
- i. The heater design consisted of a 7 1/2-inch copper surface or copper plated with nickel or cadmium surface with two formica sleeve insulators at both ends of the heater. The formica sleeves were epoxied to the heater and efforts were made to avoid any cracks and/or crevices between the formica and the heater. It was hoped that this area would not offer any areas of preferential boiling. However, boiling did occur preferentially

at this location with a ring of bubbles originating at this section between the formica sleeve and the heater element. It was noted that in general a substantial fraction of the boiling took place at the intersection of the formica and the heater with scattered boiling on the surface. However, as the heat flux increased the amount of boiling taking place on the surface increased. It was mentioned earlier that under certain conditions active sites would remain active regardless of the changes in heat fluxes. When this occurred it was noticed that the same heat flux was obtained at the same ΔT whether boiling originated at the formica-heater joint or elsewhere on the surface.

- j. There were only two behaviors which occurred exclusively in the case of gap boiling. One of them related to the oscillation of bubbles in the gap. Very tiny bubbles forming on the surface or at the bottom of the heater at the formica joint, appeared to dance in the annulus prior to rising to the surface. This appeared to be a more frequent occurrence with neon boiling than with nitrogen. However, it did very clearly occur with both liquids. The second behavior was of the same nature as the bubble oscillation except that it was more extreme. It was a case of slugging during which the vapor being formed on the surface forced all the liquid downward and the heater was then completely dry for a fraction of a second. Liquid then re-entered the gap and the slugging recurred. This slugging occurred only at high heat fluxes in the order of 1000 Btu/hr-ft². It is interesting

to note that slugging was not always reproducible even when high heat fluxes were reached. It was noticed that at a given heat flux the driving force was about the same with and without slugging.

- k. Preliminary testing performed with a 4-mil gap heater showed that the gap was so small that the heater itself could not be wetted, thus resulting in a very high resistance to heat flow which prevented the reaching of equilibrium conditions. This condition was partially remedied by increasing the gap size to 6 mils, which indicates that a 5 to 6-mil gap is a minimum gap size consistent with annular gap boiling.
- l. Maximum heat fluxes were reached with nitrogen only with the 6 mil gap heaters. Whenever a heat flux exceeded 850 Btu/hr-ft^2 the heater temperature kept rising without reaching equilibrium. With neon, maximum heat fluxes were reached with both the 6 mil and 20 mil gap heaters. These were 350 and 1600 Btu/hr-ft^2 for the 6 and 20 mil gap heaters.
- m. Liquid neon boiling runs introduced several difficulties which were not experienced with nitrogen. The main difficulty was due to the freezing out of air, and CO_2 impurities and creating a snowy surface on the dewar windows. This made visual observation of the neon runs quite difficult. Furthermore the solid air at times plugged the annulus shut and runs could not be made until the whole section was warmed and the plug thawed. In order to prevent this difficulty a very fine screen was attached to the

bottom of the heating section to trap out all the solid CO_2 and air. In spite of the screen, plugging did occur several times and runs had to be repeated. The neon data are much more scattered than the nitrogen data, and it is believed that this scattering may be due to the effect of these solid particles partially plugging the heater or even possibly covering some of the heater surface and therefore changing the available heating surface for boiling. All efforts were made to prevent this from occurring and whenever this effect could be seen on the surface the data were rejected and the runs repeated.

VI. TREATMENT OF EXPERIMENTAL DATA

Pool Boiling

The experimental data for the pool boiling runs consisted of: wattage, heater pressure, electromotive force generated by the wall thermocouples, and heater submergence.

Since the main purpose of the pool boiling runs is to establish a basis for the evaluation of the annular gap boiling, the data are treated in the conventional manner, i.e., relating heat fluxes to driving force, for each heater tested. The calculations involved in the reduction of the pool boiling data are identical to the first steps involved in the calculation of the annular gap boiling data, therefore a complete calculation of a typical annular gap boiling run will also demonstrate the data reduction method for pool boiling. Calculations for run A-6-5 which follow, will suffice.

Annular Gap Boiling

Observation of the annular gap boiling showed the existence of a convective type of heat transfer disturbed by bubbles rising to the surface. Actually, the heater surface was completely covered by a layer of liquid which was interrupted only at the bubble sites. Furthermore, it was noted that the actual bubble site area was a small fraction of the total heating area. It appeared that the only effect of the rising bubbles was to increase the turbulence of the liquid flowing in the annulus.

In view of these observations, it is reasonable to treat the annular gap boiling case in a manner similar to the one used for convective heat transfer. This approach was used by other investigators (49, 52, 56) and was the starting point of most theoretical derivations (9, 27, 62). However, factors affecting bubble formation and behavior should also be considered.

The following factors affecting convective heat transfer, bubble formation and behavior should be considered:

h_b	heat transfer coefficient for boiling
u	fluid velocity
ρ_L	liquid density
ρ_V	vapor density
C_{pL}	liquid specific heat
C_{pV}	vapor specific heat
D	characteristic dimension
k_L	liquid thermal conductivity
k_V	vapor thermal conductivity
L	wetted length of surface
μ_L	liquid viscosity
μ_V	vapor viscosity
σ	surface tension
K_H	conversion from kinetic energy to heat
G_c	conversion from force to mass
P_V	vapor pressure
λ	latent heat

Since it was observed that heat is transferred through a liquid film, only liquid properties for thermal conductivity, density, and heat capacity should be considered in addition to vapor density, surface tension and the rate of change of vapor pressure which influence bubble formation on growth.

The rate of change of vapor pressure with temperature is defined by the Clausius-Clapeyron equation which approximates to

$$\frac{dP_V}{dT} = \frac{\lambda P_V}{R T^2} \quad (64)$$

Since the vapor pressure is directly related to the boiling temperature, only one of the variables of equation 64 need be considered.

The rate of boil-off is directly related to latent heat and heat input, $W = Q/\lambda$, and W in turn is directly related to the fluid velocity, $u = (W/\rho)/A_t$, therefore only one of the factors u or λ is needed.

The change in specific volumes ($\frac{1}{\rho_V} - \frac{1}{\rho_L}$) affects the bubble behavior. This expression can be rewritten as $\left[\frac{1}{\rho_L} \right] \left[(\rho_L/\rho_V) - 1 \right]$, and the density ρ_L and dimensionless term $\left[(\rho_L/\rho_V) - 1 \right]$ can be considered separately.

A dimensional analysis of all factors mentioned above results in the

following dimensionless groups:

$$\text{Nusselt Number: } \frac{h_b D}{k_L} \quad (65)$$

$$\text{Reynolds Number: } \frac{D u \rho}{\mu_L} = \frac{D G}{\mu_L} \quad (66)$$

$$\text{Prandtl Number: } \frac{C_{pL} \mu_L}{k_L} \quad (67)$$

$$\text{Length to Characteristic Dimension Ratio: } L/D \quad (68)$$

$$\text{Ohnesorge Number: } \frac{\mu_L^2}{\rho_L g_c D \sigma} \quad (69)$$

$$\frac{\mu_L^2}{\rho_L g_c D^2 P_V} \quad (70)$$

and generalized equation

$$\begin{aligned} \frac{h_b D}{k_L} = a' & \left(\frac{D G}{\mu_L} \right)^b \left(\frac{L}{D} \right)^c \left(\frac{C_{pL} \mu_L}{k_L} \right)^d \left(\frac{\mu_L^2}{\rho_L g_c D \sigma} \right)^e \\ & \times \left(\frac{\mu_L^2}{\rho_L g_c D^2 P_V} \right)^f \left(\frac{\rho_L}{\rho_V} - 1 \right)^g \end{aligned} \quad (71)$$

It should be noted that other relations between σ and P can be obtained such as $(P_V D/\sigma)$ which assumes that $e = -f$. The dimensionless group $(P_V D/\sigma)$ was actually used by McNelly in his generalized correlation (49).

The present experimental work covering liquid nitrogen and neon only, does not permit determination of the exponents for all the terms of Equation (71). It is proposed to combine all the groups affecting bubble behavior in a new term

$$a = a' \left(\frac{\mu_L^2}{\rho_L g_c D \sigma} \right)^e \left(\frac{\mu_L^2}{\rho_L g_c D^2 P_V} \right)^f \left(\frac{\rho_L}{\rho_V} - 1 \right)^g \tag{72}$$

and to modify Equation (71) as follows:

$$\frac{h_b D}{k_L} = a \left(\frac{D G}{\mu_L} \right)^b \left(\frac{L}{D} \right)^c \left(\frac{C_{pL} \mu_L}{k_L} \right)^d \tag{73}$$

An additional modification to Equation (73) is necessary, namely, the substitution of a significant dimension for the characteristic length D.

The conventional equivalent diameter, D_e , for annular gaps was selected

$$\text{where } D_e = \frac{4 \times \text{flow area}}{\text{wetted perimeter}} .$$

The final equation is now:

$$\frac{h_b D_e}{k_L} = a \left(\frac{D_e G}{\mu_L} \right)^b \left(\frac{L}{D_e} \right)^c \left(\frac{C_{pL} \mu_L}{k_L} \right)^d \tag{74}$$

This equation includes the most important properties affecting heat transfer, as well as the characteristic dimensions of the annular gap. The coefficient and exponents of this equation can now be calculated from the experimental data obtained in this work.

Since heat transfer coefficients are a derived quantity, it is important to discuss the operations required in the reduction of data.

The experimental data consisted of the following: wattage, heater pressure, electromotive force generated by the wall thermocouples, heater inner and outer submergences, and gap size. Measurements of the surface roughness, and heater plating, if any, were also reported for each series of runs. A complete calculation for run A-6-5 will demonstrate the data reduction method.

Experimental Data - Run A-6-5

Heater 12b, heater OD 2.9975-inches at ambient temperature,

Precision Pyrex sleeve ID 3.0015-inches at ambient temperature

Copper heater - surface roughness as determined by Profilometer measurement: 9-10 micro-inches

Fluid tested: nitrogen

<u>Wattage</u>	<u>Heater Pressure</u>	<u>Outer Submergence</u>	<u>Inner Submergence</u>
60 watts	9.4 " Hg	7 1/2 "	7 1/2 " +

Wall Thermocouples - emf mv

TC #1	TC #2	TC #3	TC #4	TC #5	TC #6
0.086	0.069	0.073	-----	0.059	-----

Gap Size

$$t = \frac{3.0015'' + 2.9975''}{2} + 0.004'' = 0.006''$$

where 0.004" is the correction due to contraction (Calculations for the contraction correction are detailed in Appendix D).

Heat Input: $Q = 3.413 \text{ Btu/watt-hr} \times 60 \text{ watts} = 204.8 \text{ Btu/hr.}$

Wetted Area:

$$A_w = \frac{\pi \times 2.9975''}{12} \times \frac{7.5''}{12} = 0.4905 \text{ ft}^2$$

The area A_w , used to calculate heat fluxes was the heater area which was actually wetted by the boiling liquid. As mentioned earlier, the liquid in the annular gap was topped by a well defined foam. The top of the foam was visually measured to $\pm 0.1''$ and this measurement defined as inner submergence, was used in the calculation of A_w . In the case of fluctuation in the foam level, the maximum wetted height was always measured.

Heat Flux:

$$Q/A_w = \frac{204.8 \text{ Btu/hr}}{0.4905 \text{ ft}^2} = 417.5 \text{ Btu/hr-ft}^2$$

Heat transfer coefficient to the nitrogen vapor phase across a natural convective film, is less than $1 \text{ Btu/hr-ft}^2\text{-}^\circ\text{F}$. The assumption that all power input to the electric element is dissipated by boiling and transferred through the wetted surface only, results in a negligible error of less than 1%.

In view of the above, it was decided to calculate all heat fluxes on the basis of wetted area only and to ignore the negligible heat transfer from the non-wetted surface. The calculated heat flux was always a minimum value since it was based on a maximum wetted area.

Overall Temperature Driving Force: $\Delta T_t = 4.4^\circ\text{F}$

The overall temperature driving force is the temperature difference between the temperature of the boiling-condensing nitrogen inside the heater, and the saturation temperature of the liquid nitrogen surrounding the test section. In other words, it is the sum of the temperature drop across the condensing film inside the heater, the copper wall, and the boiling film outside the heater. Since the temperature drop across the heater is in the order of 0.01 and 0.2°F for 50 and 1300 Btu/hr heat input respectively, the wall resistance to heat transfer can be neglected.

ΔT_t is obtained from the heater pressure curves, Figures 13 or 15, which are calculated from vapor pressure data for nitrogen (1). The vapor pressure data for neon (1) have also been reduced in a similar manner, i.e., pressure as a function of temperature difference between the temperature of the boiling-condensing liquid inside the heater and the normal boiling temperature of the liquid surrounding the heater. Figures 13 and 14 represent the neon pressure curves.

Boiling Temperature Driving Force: $\Delta T_b = 2.8^\circ\text{F}$

The boiling temperature driving force is the temperature drop across the boiling film surrounding the heater, i.e.,

$$\Delta T_b = \text{wall temperature} - \text{normal boiling temperature of liquid.}$$

This temperature difference was measured directly by means of wall thermocouples, having their cold junctions immersed in the liquid being tested. A zero point for each thermocouple was

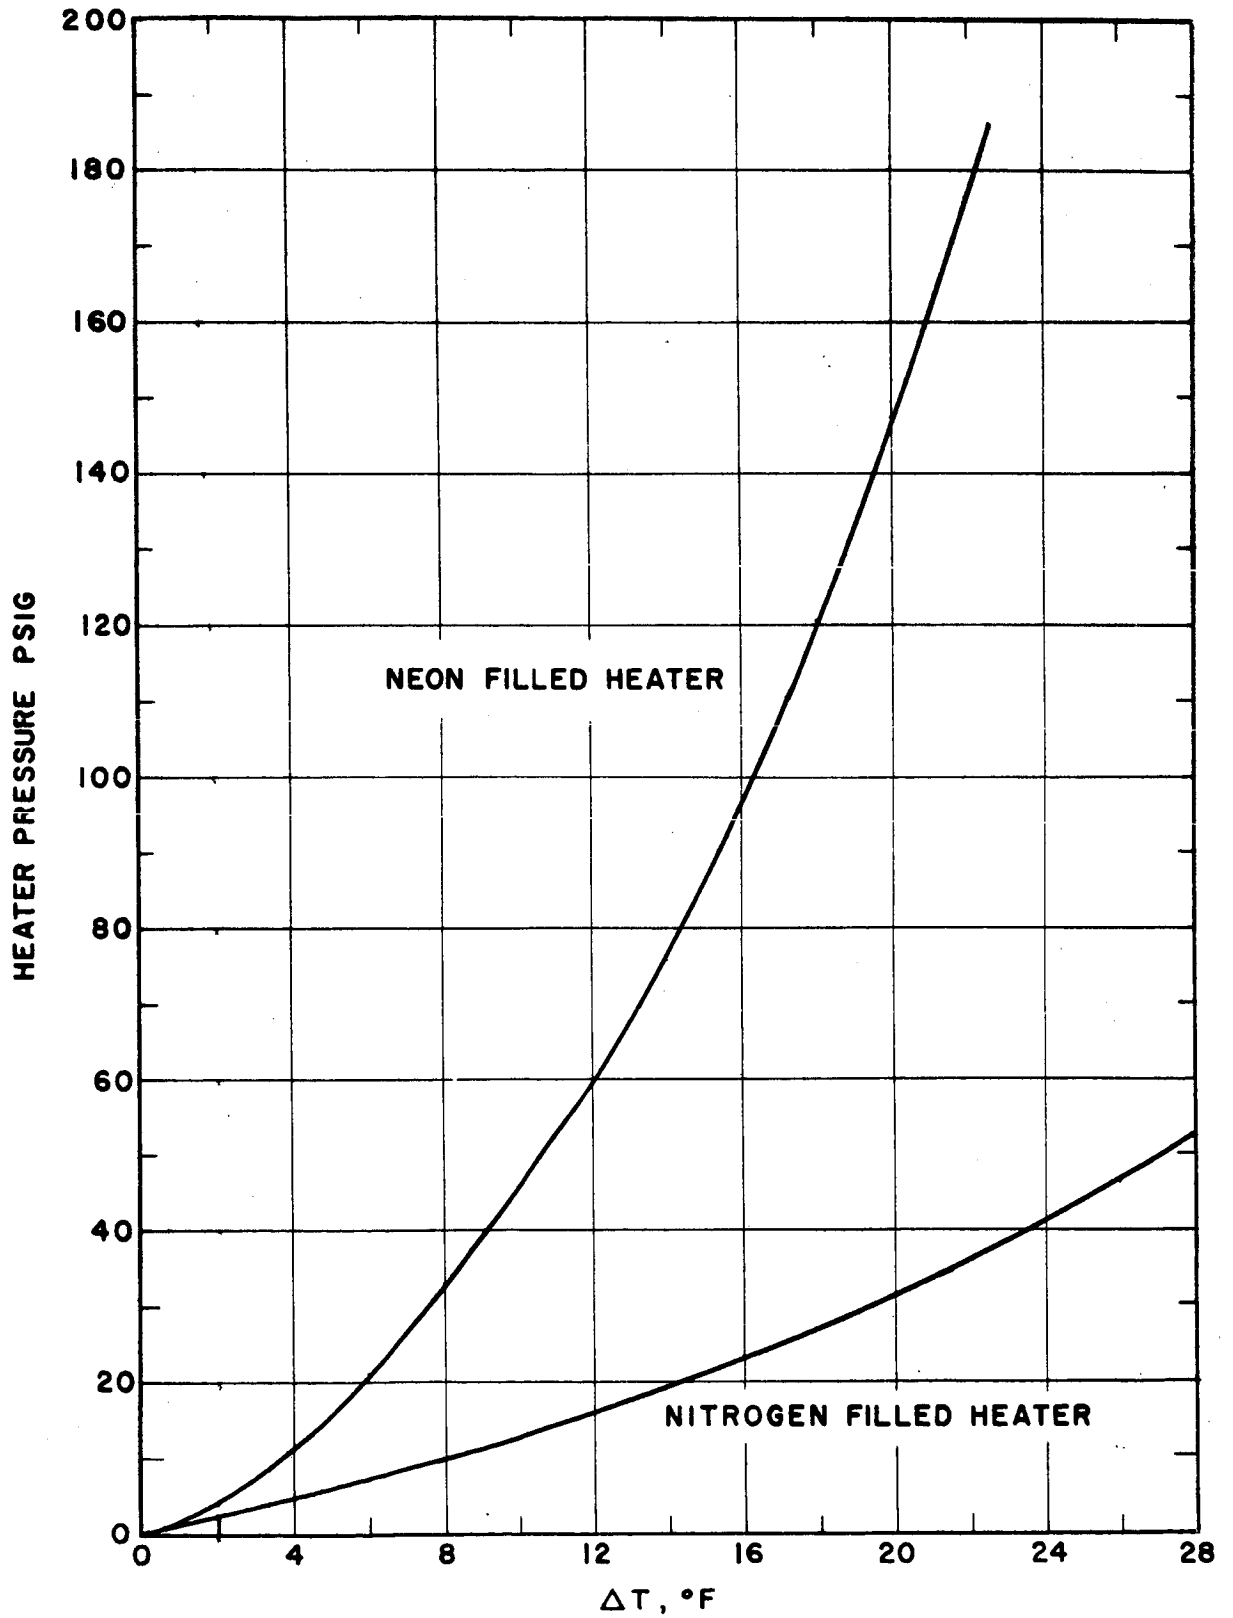

**FIGURE 13, HEATER PRESSURE VERSUS
TEMPERATURE DIFFERENCE**

FIGURE 14, HEATER PRESSURE VERSUS TEMPERATURE DIFFERENCE

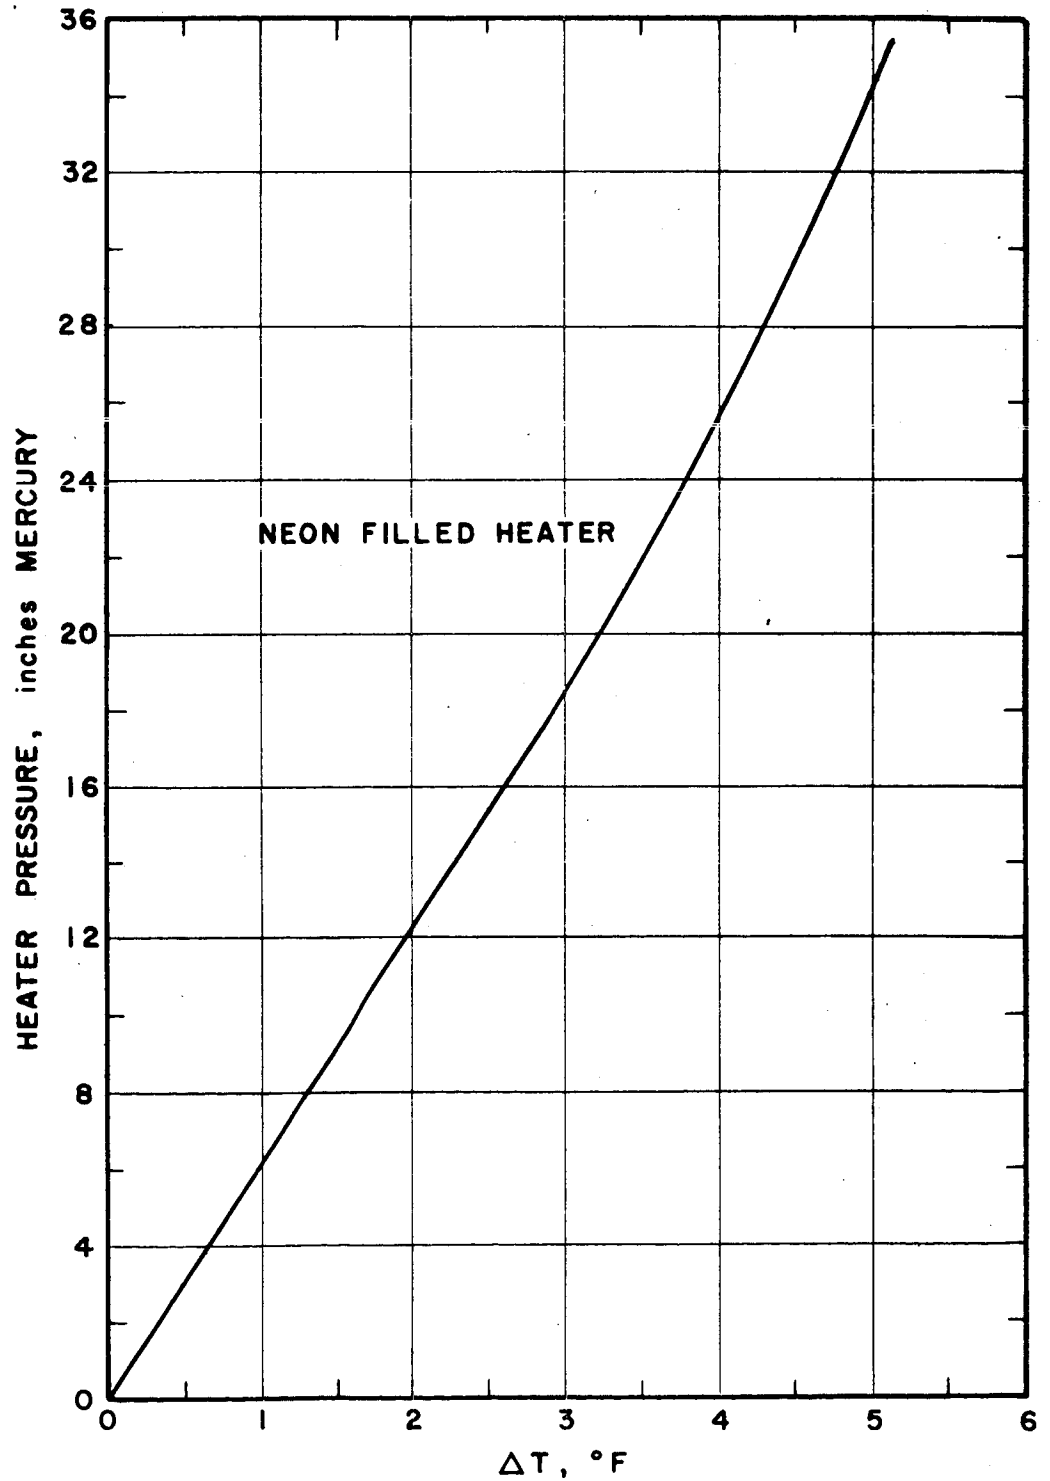

FIGURE 15, HEATER PRESSURE VERSUS
TEMPERATURE DIFFERENCE

obtained by recording the emf generated by the thermocouples at the condition of no heat input. The difference between the emf recorded for the run and the one obtained at zero power input was the Δ mv used to determine the boiling temperature driving force, ΔT_b . Figures 16 and 17 are emf curves for copper-constantan thermocouples as a function of temperature difference between the hot junction and the cold one immersed in liquid nitrogen and neon respectively. These curves were calculated from the data published by Powell, et.al. (57).

The original intent was to have an isothermal heater. It was expected that the violent boiling occurring inside the heater, and the complete wetting of the inside heater wall resulting from the thermosyphon action would maintain the heater wall at a constant uniform temperature. Indeed, preliminary tests performed with a duplicate thermosyphon heating element in a glass dewar containing liquid nitrogen were successful and proved the feasibility of the concept. However, actual performance of the 3-inch heater showed that the heater wall was not isothermal. This can be seen by examining the boiling temperature driving force profile plotted in Figure 18. This profile, which is typical for most runs, indicates that the temperature at the top of the heater is always highest. This behavior is caused by two types of heat transfer occurring simultaneously inside the heater because of its being only partially filled with liquid.

FIGURE 16, E M F VERSUS TEMPERATURE
DIFFERENCE FOR COPPER-CONSTANTAN
THERMOCOUPLES

FIGURE 17, E M F VERSUS TEMPERATURE
DIFFERENCE FOR COPPER-CONSTANTAN
THERMOCOUPLES

FIGURE 18, TYPICAL HEATER WALL TEMPERATURE BOILING DRIVING FORCE PROFILE

This partial filling was necessary to prevent burnout of the electric element. As a result of this condition, the top half of the heater was subjected to condensation heat transfer, while the lower part was subjected to convective heat transfer. The higher condensing film coefficient at the top resulted in a small inside temperature driving force, while the smaller convective heat transfer coefficient in the lower half caused a larger inside temperature driving force than in the top section. The violent agitation of the boiling-condensing fluid inside the heater, maintained it at a uniform temperature. Similarly, the fluid outside the heater was at constant temperature. This results in a larger boiling temperature driving force at the top of the heater than at its bottom. The several boiling temperature difference profiles of Figure 18 clearly show this behavior.

The explanation that the heater wall temperature profile was the result of the two types of heat transfer coefficient inside the heater has been experimentally verified. Runs A-P6-2, A-P6-4, and A-P6-6 are identical to runs A-P6-19, A-P6-17, and A-P6-18 respectively, except for the amount of liquid inside the heater. The heater was half full with liquid nitrogen during the first three runs and two-thirds full during the last three runs. The overall temperature driving force, being the sum of the individual boiling (external) and condensing (internal) temperature driving forces, is proportional to the internal temperature driving force,

when the boiling one is constant. Since the boiling driving force is independent of the internal temperature driving force, it will remain constant when the heat flux is constant. Therefore at a given heat input, one would expect that the heater with condensation over a larger internal surface, would have a lower overall temperature driving force than the one with condensation over a smaller internal surface. This is actually substantiated since the runs with the heater half full of liquid show a substantially lower overall temperature driving force and top boiling temperature driving force than the ones measured for the runs having the heater two-thirds full of liquid. These results are shown in Table V.

It should be noted, that the high thermal conductivity of the copper wall (580 Btu/hr-ft-°F at -320°F and 695 Btu/hr-ft-°F at -410°F) has a beneficial effect in reducing the temperature difference along the heater wall.

Since the boiling temperature driving force, ΔT_b , is not constant over the heater length, an average boiling temperature driving force was used in all calculations. This average was obtained by integrating ΔT_b over the wetted wall length.

Boiling Heat Transfer Coefficient:

$$h_b = \frac{(Q/A_w) \text{ Btu/hr-ft}^2}{\Delta T_b \text{ } ^\circ\text{F}} = \frac{417.5}{2.8} = 149.1 \text{ Btu/hr-ft}^2\text{-}^\circ\text{F}$$

Nitrogen Boil-off:

$$\begin{aligned}
 W &= \frac{Q \text{ Btu/hr}}{\lambda \text{ Btu/lb}} = \frac{Q \text{ Btu/hr} \times 28 \text{ lb/lb-mole}}{2405 \text{ Btu/lb-mole}} \\
 &= 0.01164 Q \text{ lb/hr} \\
 &= 0.01164 \times 204.8 = 2.38 \text{ lb/hr}
 \end{aligned}$$

Runs A-80-5 to A-80-10 were used to establish the validity of determining the rate of boil-off by dividing the electric power input by the fluid latent heat and assuming negligible heat leak to the test section. A rotameter was connected to the 6-inch glass chamber on top of the test heater, and rotameter, temperature of the vapor entering the rotameter, and wattmeter readings were taken simultaneously. Temperature and density correction, $C = \sqrt{\frac{520}{T} \times \frac{28}{29}}$ where $T^{\circ}R$ is the vapor temperature, were made to the reading of the rotameter scale which was calibrated for air at $60^{\circ}F$.

The results of the flow check are summarized in Table XXII and the comparison between the calculated and measured boil-off rates is shown in Figure 19.

It was assumed that the same relationship existed for the neon runs. Observation of the test section at zero heat input showed no bubble formation for both the nitrogen and neon cases, thus substantiating the assumption of zero heat leak to the test section.

Annular Gap Flow Area:

$$A_t = \frac{\pi}{4} \frac{(D_2^2 - D_1^2)}{144} = \frac{\pi}{144} (D_2^2 - t^2) \text{ ft}^2$$

TABLE XXII
COMPARISON BETWEEN CALCULATED AND MEASURED NITROGEN BOIL-OFF

VII. RESULTS AND DISCUSSION

Nitrogen Pool Boiling

The nitrogen pool boiling data reduced to heat flux and boiling temperature driving force, are tabulated in Tables XXV to XXX and plotted in Figures 20 to 26.

The data for full submergence case, can be correlated satisfactorily by the equation $Q/A_w = a (\Delta T_b)^b$. (75)

The coefficient and exponent of equation 75, for each individual heater, which were obtained by the "method of least squares" with a GE 225 computer (except heater no. 10) are listed in Table XXXI.

It is interesting to note that the exponents vary between 0.99 to 1.50, a value which is substantially lower than the 3 to 4 value suggested by other investigators (15, 43, 47, 62). However, exponents having a value of 0.98 and 0.94 can be calculated for liquid helium and liquid nitrogen respectively from the experimental data presented by Richards et.al (61) in Figures 2 and 8. Furthermore, the level of heat flux obtained in this study is in excellent agreement with some of the data presented by Richards. For example, at $\Delta T_b = 1.8^\circ\text{F}$, the heat flux equals 174 Btu/hr-ft^2 for heater 12b (run A-P12b-3); and 160 Btu/hr-ft^2 for Haselden and Peters data covered in Figure 8 of Richards' survey.

TABLE XXXI
 CORRELATION
 NITROGEN POOL BOILING
 (Full Submergence - 7 1/2-inches)

$$Q/A_w = a (\Delta T_b)^b$$

Heater No.	a	b	Average % Deviation
12b	94.0	1.16	4
6	139	0.99	6
9 (Ni)	52.7	1.50	6
10 (Cd)	30.0	1.20	22
7b	57.4	1.32	7
8	98.5	1.18	11
All Cu Heaters	94.7	1.18	14
All Heaters Except Heater No. 10 (Cd)	87.2	1.20	16

The full submergence data for all the copper heaters can be correlated by a single equation with an average percent deviation of 14%.

$$Q/A_w = 94.7 (\Delta T_b)^{1.18} \quad (76)$$

The average percent deviation is the average of the absolute value of all individual percent deviations calculated from the expression:

$$\frac{\text{observed value} - \text{calculated value}}{\text{observed value}} \times 100.$$

The full submergence data for all the heaters, except heater no. 10 (cadmium plated), can be correlated by the following equation

$$Q/A_w = 87.2 (\Delta T_b)^{1.20} \quad (77)$$

with an average percent deviation of 16%. The lines for both equations are shown in Figure 26.

There is no apparent reason for the large difference between the results for the cadmium plated heater and those for the other heaters. All the heaters were machine finished in an identical manner using the same tools and the same type Bahr-Manning craucus cloth. Profilometer measurements for surface roughness showed a total range of 6-20 micro-inches for all the six heaters, with a maximum range of 4 micro-inches for each individual heater. This variation in surface roughness is important as shown by the work of Corty and Foust (13), however it does not explain the

presents results, since the cadmium plated heater has a roughness which is intermediate between the roughness of the nickel plated and copper heaters.

For the purpose of this study, it will be assumed that all copper heaters are identical, the nickel plated heater similar, and the cadmium plated one different. Since the main purpose of the pool boiling runs was to establish a relationship between heaters, which was done with the full submergence condition, no effort was made to correlate the data obtained at other submergences. These data are reported and plotted together with the full submergence data. Examination of Figures 20 to 25, shows that at a given temperature driving force, the lower the submergence, the higher the heat flux. This can be explained by the appearance of preferential boiling at the joint between the insulation cap and the bottom of the heater. Figures 26a and 26b show this effect.

Examination of the data shows that heat flux decreases with increasing submergence, reaches a minimum at about 100% submergence, and then increases with increasing submergence. Some of the factors that may explain this behavior are surface blanketing with vapor, turbulence, number of bubbling sites, and bubble size. It seems that the blanketing effect is the controlling one for the case of partial and full submergence. The bubbles being formed in the lower part of the heater blanket the upper surface with vapor and reduces its effectiveness. However, when

FIGURE 26a

NITROGEN POOL BOILING

FULL SUBMERGENCE

FIGURE 26b

NITROGEN POOL BOILING

HALF SUBMERGENCE

submergence increases beyond the 100% point, the other effects offset the detrimental effect of blanketing and heat flux increases with increasing submergence. It is believed that further study of this problem is necessary to develop a proper understanding of the several effects involved and to establish their magnitude (42).

Neon Pool Boiling

The neon pool boiling data were correlated in the same manner as the nitrogen data except that the overall temperature driving force was used instead of the boiling temperature driving force. For comparison purposes, the nitrogen pool boiling data for heater 12b were also correlated on the basis of overall temperature driving force. The equations for the neon and nitrogen cases are shown in Table XXXII and the two lines are compared in Figure 34.

TABLE XXXII

COMPARISON BETWEEN NITROGEN AND NEON POOL BOILING

(Full Submergence 7 1/2-inches)

Heater 12b

Nitrogen $Q/A_w = 66.0 (\Delta T_t)^{1.11}$

Neon $Q/A_w = 135 (\Delta T_t)^{1.11}$

Annular Gap Boiling - Nitrogen and Neon

The experimental data for annular gap boiling were reduced to Nusselt and Reynolds numbers using liquid properties and the equivalent diameter for the annulus. The calculated data are presented in Tables XXXIII to XXXVIII for liquid nitrogen and XXXIX to XLIII for liquid neon. These data are presented graphically as heat flux versus boiling temperature driving force, and as Nusselt number versus Reynolds number in Figures 27 to 33, 35 to 51.

The data were correlated by means of Equation (74) which was derived in pages 106-110:

$$\frac{h_b D_e}{k_L} = a \left(\frac{D_e G}{\mu_L} \right)^b \left(\frac{L}{D_e} \right)^c \left(\frac{C_{pL} \mu_L}{k_L} \right)^d \quad (74)$$

$$\text{or } Nu_L = a (Re_L)^b (L/D_e)^c (Pr_L)^d$$

The coefficient and exponents were obtained by the method of least squares with a GE computer resulting in the following equation:

$$Nu_L = 150 (Re_L)^{0.18} (L/D_e)^{-0.82} (Pr_L)^{0.95} \quad (78)$$

which represents all the experimental data with an average percent deviation of 23%. The measured Nusselt numbers are compared with the calculated ones in Figure 52.

FIGURE 52, COMPARISON BETWEEN MEASURED AND CALCULATED NUSSELT NUMBER FOR ALL NEON AND NITROGEN ANNULAR FLOW BOILING DATA

Equations for each individual heater can be easily calculated. For example, equations for annular gap nitrogen boiling at full submergence are:

$$\text{Nu}_L = 17.3 (\text{Re}_L)^{0.18} \quad \text{for 0.053-inch gap} \quad (79)$$

and

$$\text{Nu}_L = 24.4 (\text{Re}_L)^{0.18} \quad \text{for 0.080-inch gap} \quad (80)$$

These equations are shown in Figures 45 and 46 respectively.

The agreement between the correlation and the experimental data is noteworthy in view of the wide range of experimental conditions.

The following discussion briefly reviews the effect of the important experimental conditions on the boiling coefficients.

1. Surface Roughness and Finish

The measured root mean square roughness and surface finish appear to have no effect on boiling coefficients in annular gap boiling, at least within the limits of this work. Even the data for the cadmium plated heater are correlated quite well by Equation (78). Based on the pool boiling data, it would have been anticipated that this would not be possible. This apparent independence of annular gap boiling from surface effect has also been observed with respect to surface oxidation. Runs A-53-2 to A-53-27 were made with a copper heater having about 15% of its surface badly oxidized. These runs were repeated with the heater surface completely cleaned and the coefficients calculated from the new data were the same as the ones calculated from the old data.

2. Back Pressure Created by the Rotameter

Runs A-20-2 to A-20-22 were performed with the rotameter line connected to the vapor liquid separator located above the heater section. The effect of the back pressure created by the rotameter on the system was very noticeable. The liquid level inside the annulus was immediately lowered to a point about 1-inch below the outer liquid level. The appearance of the foam was also changed. Its height was reduced from 1 inch or so to about 1/4 inch or less. Entrainment, if any, was completely stopped. Vapor bubbles appear to become smaller. All in all, the back pressure effect on the nature of the gap boiling was significant.

However, in spite of the different appearance of boiling, the heat transfer coefficients calculated for the cases of connected and unconnected rotameter were the same. This suggests that the assumption of convective type heat transfer made in the derivation of Equation (74),

$$Nu_L = a (Re_L)^b (L/D_e)^c (Pr_L)^d, \quad (74)$$

the use of the physical properties for the liquid phase, and the selection of the terms used in the equation are justified.

3. Entrainment

Entrainment occurred when the combination of heat input and outer submergence was sufficient to raise liquid droplets into the

entrainment collector. Examination of data taken with and without entrainment shows, that at a given heat flux, the boiling temperature driving force is slightly smaller for the case having entrainment. This is caused by the larger flow existing in the annulus during entrainment resulting in a better performance. The effect, however, was usually small. Differences in temperature driving forces were usually of the order of 0.2-0.4°F at the higher heat fluxes, or the equivalent of 2-3% of the temperature driving force.

4. Length to Diameter Ratio

The L/D_e ratio was varied two ways:

- a. by varying the submergence L with a fixed gap size, i.e. a fixed D_e , and
- b. by varying the gap size, D_e , for a given submergence.

L/D_e was varied from 9.4 to 313 by means of the two methods a and b.

There is actually a basic difference between methods a and b for varying L/D_e ratios. The heat flux is a function of the submergence L , but is independent of the gap size, or its equivalent diameter D_e . Therefore, when method a is used, a change in L/D_e ratio will result in a change in heat flux even though the heat input to the test heater remains unchanged. This results in a condition of constant boil-off. However, when

L is fixed and D_e is varied, then a change in L/D_e will not affect the heat input, the heat flux, nor the boil-off rate.

In spite of this basic difference between the two ways of varying L/D_e , the data correlates well regardless of how L/D_e was changed.

5. Comparison Between Neon and Nitrogen Boiling

There was no detectable difference between neon and nitrogen, either in pool or in annular gap boiling. Data, however, showed that at a given temperature difference, heat flux for neon was higher than for nitrogen. Figure 34 clearly shows this fact for pool boiling condition. The same conclusion can be reached for annular gap boiling by comparing Figures 33 and 40: at a given ΔT_b , heat fluxes for neon are higher than the ones for nitrogen.

6. Maximum Heat Flux

Maximum heat fluxes due to gap size were experienced in four cases only:

- a. 850 Btu/hr-ft² at $\Delta T_b = 5.8^\circ\text{F}$ for liquid nitrogen
flowing in a 6 mil gap heater
- b. 350 Btu/hr-ft² at $\Delta T_b = 1.1^\circ\text{F}$ for liquid neon flowing
in a 6 mil gap heater
- c. 1600 Btu/hr-ft² at $\Delta T_b = 6.5^\circ\text{F}$ for liquid neon and a
20 mil gap heater

- d. 1600 Btu/hr-ft² at $\Delta T_b = 3.0^\circ\text{F}$ for liquid neon and a 21 mil gap heater.

In all other cases, limit on heat flux was the result of heat input limitation rather than gap size effect.

7. Evaluation of the Sydoriak and Roberts Correlation

A comparison between heat fluxes calculated by means of the Sydoriak and Roberts equation and measured ones are summarized in Table XLIV.

It is apparent that the Sydoriak and Roberts equation is not valid for gap sizes larger than 22 mils. The agreement between measured and calculated heat fluxes for nitrogen is better than 2 to 1 for the 20 and 21 mil gap and 2.2 to 1 for the 22 mil gap condition. Comparison could not be made for the 6 mil gap heater nor for neon boiling in view of the reaching of maximum heat fluxes with temperature driving forces smaller than 18°F .

0.080	27500	4000	19850	7500

VIII. CONCLUSIONS

An investigation of neon and nitrogen boiling both under pool boiling conditions and in narrow annuli, was completed. The study covered the case of a 7 1/2-inch long vertical heater with a nominal 3-inch outside diameter and gap sizes ranging from 0.006 to 0.080 inch.

The experimental design concept allowed for visual observation simultaneously with data collection, which made it possible to relate data directly to behavior.

The following equation correlating the nitrogen pool boiling data for all heaters, except the cadmium plated one, with an average percent deviation of $\pm 16\%$ was obtained:

$$Q/A_w = 87.2 (\Delta T_b)^{1.20} \tag{77}$$

A generalized equation for annular gap boiling was derived on the assumption of convective type heat transfer. The concept of equivalent diameter was used to modify the characteristic dimension in the Nusselt and Reynolds numbers.

The following equation correlated all annular gap boiling data obtained with nitrogen and neon with an average percent deviation of $\pm 23\%$.

$$\frac{h_b D_e}{k_L} = 150 \left(\frac{D_e G}{\mu_L} \right)^{0.18} \left(\frac{L}{D_e} \right)^{-0.82} \left(\frac{C_{pL} \mu_L}{k_L} \right)^{0.95} \tag{78}$$

The validity of the correlation over the wide range of parameters involved in the experimental work substantiates the assumptions made and concepts involved in the derivation of the equation.

However, caution should be exercised in the use of Equation (78) outside the range of the experimental work. It is believed that while this equation would be satisfactory for cryogenic fluids in general, certain size limitations should be considered, namely, vertical height less than 15 inches and annular gap sizes in the order of 0.006 to 0.080 inch. It should be noted, however, that this range of gap sizes effectively covers the practical range for narrow annuli. The lower limit of 0.006 inch is very nearly a practical minimum. A gap size exceeding the upper limit of 0.080 inch will result in a condition equivalent to pool boiling.

θ	Time, hr	28,31,33,34,36
θ	Contact angle	5
λ	Latent heat of vaporization, Btu/lb	20,21,26,27,31,33,34,36,38,40,41,56,58,64
λ	Thermal conductivity, kcal/m/hr/grad	5
λ_i	Difference in heat content between vapor at its arithmetic average temperature and liquid at its boiling point, Btu/lb	2
μ	Viscosity, lb/ft-hr	1,42
μ_L	Viscosity of liquid, lb/ft-hr	19,21,24,26,27,36,40,41,53,56,58,62,66,67,69,70,71,72,73,74,78 Table III
μ_{L_w}	Viscosity of liquid at wall temperature, lb/ft-hr	54
μ_v	Viscosity of vapor, lb/ft-hr, used in f_{tt}	4
ρ	Density, lb/ft ³	66
ρ, ρ_v	Density of vapor, lb/ft ³	1,17,19,21,23,26,27,28,31,33,34,36,40,41,42,44,45,46,47,48,49,50,51,71,72
ρ_L	Density of liquid, lb/ft ³	1,11,13,17,19,21,23,26,27,31,33,34,36,38,40,41,42,44,45,46,47,50,51,53,56,58,69,70,71,72
ρ_{L_w}	Density of liquid at wall temperature, lb/ft ³	54

Symbol	Meaning	Equation Where Used
ρ_{v2}	Exit vapor density, lb/ft ³	13
ρ_{vw}	Density of vapor at wall temperature, lb/ft ³	54
σ	Surface tension kg/m	5
σ	Surface tension, lb/ft	1, 11, 14, 17, 19, 21, 23, 26, 27, 28, 38, 40, 41, 42, 43, 50, 51, 53, 56, 58, 69, 71, 72
σ	Parameter in intermolecular potential function	Table III
ϕ	Correction term = $\frac{(2 - \cos \beta)(1 + \cos \beta)^2}{4}$	11
$F_{tt,f}$	Martinelli two-phase parameter, gas phase evaluated at film temperature	4
	$F_{tt} = \left(\frac{\dot{w}_1}{\dot{w}_g}\right)^{0.9} \left(\frac{\mu_L}{\mu_v}\right)^{0.1} \left(\frac{\rho_v}{\rho_L}\right)^{0.5}$

XI. APPENDIXES

APPENDIX A

CALCULATION OF NEON BOIL OFF RATE FOR PRELIMINARY DESIGN OF TEST SECTION

The neon boil off rate calculation incorporates the following:

1. heated surface 10 inches long, 4 inches diameter
2. assumption that maximum heat flux in annular boiling is 10% burn-out heat flux for pool boiling (66)
3. prediction of pool boiling burn out by Forster-Zuber correlation (20)

$$(q/A)_{\max} = C \rho_V \lambda \left[\frac{\sigma g (\rho_L - \rho_V) g_0}{\rho_V^2} \right]^{\frac{1}{4}}$$

$$(q/A)_{\max} = \text{burn out heat flux, pool boiling}$$

$$C = 0.131, \text{ empirical coefficient}$$

$$\rho_L = 75.35 \frac{\text{lb.}}{\text{ft.}^3}, \text{ liquid neon density}$$

$$\rho_V = \rho_0 \frac{T_0}{T}, \text{ gaseous neon density}$$

$$\rho_0 = 0.0522 \frac{\text{lb.}}{\text{ft.}^3}, \text{ std. gaseous neon density}$$

$$T_0 = 530^\circ\text{R}, \text{ std. temp.}$$

$$T = 50^\circ\text{R}, \text{ gaseous neon temp. at boil off}$$

$$\therefore \rho_V = 0.554 \text{ lb./ft.}^3$$

$$g = 32.17 \text{ ft/sec}^2, \text{ gravitational acceleration}$$

$$g_0 = 32.17 \frac{\text{lb.m ft.}}{\text{lb. F sec}^2}, \text{ gravitational constant}$$

$$\sigma = 0.00036 \frac{\text{lb. F}}{\text{ft.}} \text{ surface tension of liquid neon at N.B.P.}$$

$$\lambda = 37.05 \frac{\text{BTU}}{\text{lb.m}}, \text{ latent heat of vaporization at neon N.B.P.}$$

Substituting and solving,

$$(q/a)_{\max} \text{ pool boiling} = 29,100 \frac{\text{BTU}}{\text{ft}^2 \text{ hr}}, \text{ and}$$

$$(q/A)_{\max} \text{ annular boiling} = 2,910 \frac{\text{BTU}}{\text{ft}^2 \text{ hr}} .$$

Consider heated surface, A, as

$$A = \frac{10 \text{ in} \times \pi \times 4 \text{ in.} \times \text{ft}^2}{144 \text{ in}^2}$$
$$= 0.872 \text{ ft}^2$$

Solving from (q/A) max and A,

$$q = 2,910 \frac{\text{BTU}}{\text{hr ft}^2} \times 0.872 \text{ ft}^2$$
$$q = 2,545 \frac{\text{BTU}}{\text{hr}}$$

Boiling rate w is then determined, knowing volume latent heat

λ_{vol} .

$$w = \frac{q}{\lambda_{\text{vol}}}, \quad \text{where } \lambda_{\text{vol}} = 98.8 \text{ Btu/lt}$$

$$w = \frac{2,545 \text{ BTU/hr}}{98.8 \text{ BTU/lt}}$$
$$= 25.8 \text{ lt/hr}$$

Recalculation using 7 1/2 inch length and 3 in. diameter heater yields a maximum boil-off rate

$$w = 14.5 \text{ lt/hr}$$

Assuming that the average heat flux for a complete run will approximate 40% of the maximum heat flux, average boil-off is then estimated to be:

$$w_{\text{avg}} = 0.40 \times 14.5 = 5.8 \text{ lt/hr}$$

APPENDIX B

CALCULATIONS FOR INVAR PRESSURE VESSEL IN TEST SECTION DESIGN

Preliminary conditions used in the design calculations of the pressure vessel:

1. heating surface, 7 1/2 inches long, 3 inches nominal outside diameter
2. 400 psia max operating pressure at -410°F. (400 psia is approximately critical pressure of neon)

A.S.M.E. Boiler and Pressure Vessel Code information:

$$t = \frac{PR}{SE - 0.6P}$$

t = design thickness

P = 400 psia, operating pressure

R = 1.5 inches, vessel radius

S = 15,000 psia (approx Factor of Safety, 5, based on 75,000 tensile strength)

E = 1, joint efficiency of seamless tube

$$t = \frac{400 \times 1.5}{15,000 - 240} \text{ inches}$$

$$= \frac{600}{14,760} \text{ inches}$$

$$= 0.0407 \text{ inches}$$

Heat transfer characteristics calculated for invar pressure vessel:

1. wall thickness taken as 0.250 inches, surface area 7 1/2 length, 3 π inches circumferential length.
2. average heat flux of 1,455 BTU/hr ft²
3. thermal conductivity at liquid neon temperatures 1.5 BTU/hr ft^{0R} (24% Ni Stainless Steel) (Ref. 36)
4. assume inner and outer surface temperatures are the same as the respective fluid saturation temperatures

Conduction heat transfer formulation:

$$q/A = k \frac{\Delta T}{t}$$

$$t = 0.250 \text{ in. thickness}$$

$$k = 1.5 \text{ BTU/hr ft R, thermal conductivity (36)}$$

$$q/A = 1,455 \text{ BTU/hr ft}^2, \text{ heat flux}$$

Solving for the temperature difference ΔT

$$\Delta T = \frac{1,455 \times 0.250}{1.5 \times 12} \text{ } ^\circ\text{R}$$

$$\Delta T = 20.2^\circ\text{R}$$

APPENDIX C

CALCULATIONS FOR OFHC COPPER PRESSURE VESSELS IN TEST SECTION

Preliminary dimensions of pressure vessel:

1. heating surface 7 1/2 inches long, 3 inches nominal outside diameter
2. 400 psia max operating pressure at -410°F (400 psia approximately critical pressure of neon)

A.S.M.E. Boiler and Pressure Vessel Code Information

$$t = \frac{PR}{SE-0.6P}$$

t = design thickness

P = 400 psia, operating pressure

R = 1.5 inches, vessel radius

S = 6,000 psia, A.S.M.E. Boiler and Pressure Vessel Code Material Specification SB-75

$$t = \frac{400 \times 1.5}{6000-240} \text{ inches}$$

$$= \frac{600}{5760} \text{ inches}$$

$$= 0.102 \text{ inches}$$

Calculation of deflection for outer surface of copper pressure vessel

using wall thickness of 0.125 in. and thick walled cylinder formula

$$U_o = \frac{1 + \nu}{E} \left(1 + \frac{R_I^2}{R_o^2 - R_I^2} \right) R_o P$$

ν = 0.33 Poisson ratio for copper

R_o = 1.5 inches, outside diameter

R_I = 1.375 inches, inside diameter

E = 17,000,000 psia, modulus of elasticity

$P = 400$ psia, internal pressure

U_o = deflection of outer surface in radial direction

$$U_o = \frac{1.33}{17,000,000} \left(1 + \frac{1.89}{2.25-1.89} \right) 1.5 \times 400 \text{ inches}$$

$$= \frac{1.33 (6.29) 1.5 \times 400 \text{ inches}}{17,000,000}$$

$$= 0.000294 \text{ inch}$$

Error involved for operation with 0.0050 inches gap at two pressure levels, 0 psig and 400 psig

1. $P = 0$ psig

$$U_o = 0$$

$$\text{gap} = 0.0050$$

2. $P = 400$ psig

$$U_o = 0.0003 \text{ inches}$$

$$\text{gap} = 0.0047 \text{ inches}$$

Error of difference

$$\frac{0.0050 - 0.0047}{0.0047} = 6.4\%$$

APPENDIX D

CALCULATION OF CONTRACTION CHARACTERISTIC OF TEST SECTION MATERIALS

In general, thermal contraction of a material is accounted for in the formula

$$L_{\Delta T} = L_0 (1 + \alpha \Delta T)$$

where L_0 = original length at temperature T_0

$L_{\Delta T}$ = length after temperature change from T_0 to T or $\Delta T = (T - T_0)$

α = average coefficient of linear thermal expansion for temperature change ΔT .

For the large temperature change experienced by the test section, it is erroneous to consider an average coefficient of linear thermal expansion. Instead, a temperature dependency of the coefficient should be considered. Including the temperature dependency of the coefficient in a formulation for contraction is accomplished by using a stepwise calculation. The stepwise calculation assumes a constant value of the expansion coefficient over a small temperature change, the total temperature change of concern being the sum of the small step changes.

Let $L_{\Delta T_{total}}$ and L_0 be the final and initial length respectively. A calculated length for a small temperature change ΔT_n would be represented by L_n . Noting this then, the formulation is as follows:

$$L_1 = L_0 (1 + \alpha_1 \Delta T_1)$$

$$L_2 = L_1 (1 + \alpha_2 \Delta T_2) = L_0 (1 + \alpha_1 \Delta T_1) (1 + \alpha_2 \Delta T_2)$$

$$\text{or } L_n = L_0 (1 + \alpha_1 \Delta T_1) (1 + \alpha_2 \Delta T_2) \dots (1 + \alpha_n \Delta T_n).$$

The n^{th} temperature change step would end at T_n such that $T_n = T_f$,

where
$$\Delta T_{\text{total}} = T_f - T_o = \sum \Delta T_n,$$

Thus, when $T_n = T_f$, L_n corresponds to $L_{\Delta T_{\text{total}}}$, and the formulation

is then
$$L_{\Delta T_{\text{total}}} = L_o (1 + \alpha_1 \Delta T_1) (1 + \alpha_2 \Delta T_2) \dots (1 + \alpha_n \Delta T_n).$$

A stepwise calculation of coefficients of thermal expansion of Pyrex glass and copper for temperature changes of ambient temperature to liquid nitrogen and liquid neon temperatures is made. Graphical representation of the stepwise breakdown is presented in Figure 53.

Stepwise Calculation of Contraction Characteristic for Copper.

Step n	T_n ($^{\circ}\text{F}$)	ΔT_n ($^{\circ}\text{F}$)	$\alpha_n \times 10^6$ (in. $^{\circ}\text{F}/\text{in.}$)	$1 + \alpha_n \Delta T_n$
0	70	0		
1	-28	-98	9.1	0.99911
2	-152	-124	8.5	0.99895
3	-252	-100	7.5	0.99925
4	-292	-40	6.25	0.99975
5	-320.5	-28.5	5.0	0.99986
6	-353	-32	3.25	0.99989
7	-410.7	-57.7	1.25	0.99993

For the liquid nitrogen temperature level

$$L_{\Delta T_{\text{total}}} = L_o (1 + \alpha_1 \Delta T_1) \dots (1 + \alpha_n \Delta T_n), n = 5$$

$$= L_o (0.99695)$$

For the liquid neon temperature level

$$L_{\Delta T_{\text{total}}} = L_o (1 + \alpha_1 \Delta T_1) \dots (1 + \alpha_n \Delta T_n), n = 7$$

$$= L_o (0.99674)$$

Nominal diameter (L_o) of copper being 3.0 inches, nominal contraction will then be:

$$L_{\text{Cu, N}_2} = 3.0000 (0.99695 - 1.00000) \text{ in.}$$

$$= -0.00915 \text{ in.}$$

$$L_{\text{Cu, Ne}} = 3.000 (0.99674 - 1.00000) \text{ in.}$$

$$= -0.00978 \text{ in.}$$

FIGURE D.1, COEFFICIENT OF LINEAR THERMAL EXPANSION FOR COPPER AND PYREX

Stepwise Calculation of Contraction Characteristics for Pyrex

Step n	T _n (°F)	ΔT _n (°F)	α _n × 10 ⁶ (in.°F/in.)	1 + α _n ΔT _n
0	70	60		
1	4	-66	2.20	0.99985

5	-248	-56	1.25	0.99993
6	-320.5	-72.5	1.00	0.99993
7	-383.0	-62.5	0.40	0.99997
8	-410.7	-27.7	-0.15	1.00000

For the liquid nitrogen temperature level:

$$L \Delta T_{total} = L_0 (1 + \alpha_1 \Delta T_1) \dots (1 + \alpha_n \Delta T_n), n = 6.$$

$$= L_0 (0.99940)$$

For the liquid neon temperature level:

$$L \Delta T_{total} = L_0 (1 + \alpha_1 \Delta T_1) \dots (1 + \alpha_n \Delta T_n), n = 8$$

$$= L_0 (0.99937)$$

Nominal diameter (L₀) of Pyrex being 3.0 inches, nominal contraction will then be:

$$\Delta L_{(Pyrex, N_2)} = 3.0000 (0.99940 - 1.00000) \text{ in.}$$

$$= -0.00180 \text{ in.}$$

$$\Delta L_{(Pyrex, Ne)} = 3.0000 (0.99937 - 1.00000) \text{ in.}$$

$$= -0.00189 \text{ in.}$$

Net Total Differential Contraction is calculated to be:

for liquid nitrogen

$$\Delta L_{Net, N_2} = \Delta L_{(Pyrex, N_2)} - \Delta L_{(Cu, N_2)}$$

$$= (-0.00180 + 0.00915) \text{ in.}$$

$$= 0.00735 \text{ in.}$$

and for liquid neon

$$\begin{aligned}\Delta L_{\text{Net, Ne}} &= \Delta L_{(\text{Pyrex, Ne})} - \Delta L_{(\text{Cu, Ne})} \\ &= (-0.00189 \quad 0.00978) \text{ in.} \\ &= 0.00789 \text{ in.}\end{aligned}$$

Net Differential Annular Gap, Contraction used in data calculations:

for liquid nitrogen

$$\begin{aligned}\Delta_{\text{N}_2} &= 1/2 \Delta L_{\text{Net, N}_2} \\ &= 0.00368 \text{ in.} = 0.004 \text{ in.}\end{aligned}$$

for liquid neon

$$\begin{aligned}\Delta_{\text{Ne}} &= 1/2 \Delta L_{\text{Net, Ne}} \\ &= 0.00395 \text{ in.} = 0.004 \text{ in.}\end{aligned}$$

APPENDIX ETest Section Auxiliary Equipment

The auxiliary equipment required to complement the test heater assembly consisted of the following.

1. Test Section Dewars:

Since visual observation was one of the basic concepts for the boiling study, it was necessary to use glass dewars to contain the boiling liquid and the test heater. In order to minimize heat leak to the system, a set of two silvered glass dewars with four windows was specified and manufactured by H. S. Martin and Sons, Evanston, Illinois. The specifications for the set were:

Inner dewar:

outer wall 10 1/4" $\pm 1/8$ " OD x 1/9" thick
inner wall 9 1/8" $\pm 1/8$ " OD x 1/4" thick
evacuated length 54"
pipe flange, standard 9" glass pipe flange with 12" length
of pipe attached to the top of the dewar
evacuated section silvered except for four windows 4" wide,
full dewar length, and located every 90°

Outer dewar:

outer wall 14 $\pm 1/8$ " OD x 5/16" thick
inner wall 12 1/2" $\pm 1/8$ " OD x 5/16" thick
evacuated length 48"

pipe flange, standard 12" glass pipe flange with 12" length of pipe attached to top of dewar evacuated section silvered, except for four windows 4" wide, full dewar length, and located every 90°.

The dewar set was "hung" in appropriate collars held by a frame. Styrofoam was used to protect the bottom sections of the two dewars and to act as locating spacers. Figure 11 is a picture of the dewars assembly.

2. Gas Recovery Bag:

In view of the high cost of neon, it was necessary to provide a means to recover the neon boil-off. A rectangular shaped polyethylene gas bag, 3' x 9' x 12', was connected to the inner dewar by means of a 1 5/8" copper line. A frame allowing the bag to "breathe" was designed and constructed. Figure 12 is a picture of the inflated bag.

3. Test Section Structure:

Because of the length of the dewar set, a large tower-like structure was designed for the experimental setup. The frame, 4' x 8' x 16' in size, provided support for the respective outer dewar and inner dewar collars such that the mouth of the inner dewar was located 7' above the floor. To permit ease of

access, a floor was fabricated within the tower framework 7' above the floor. This then provided entrance to the inner dewar through a "hole in the floor." An overhead winch was provided to move the test section in and out of its operating position inside the inner dewar.

The tower also supported a shatterproof glass enclosure around the outer dewar to protect it from accidental contact and to prevent possible violent implosion of the glassware.

4. Liquid Neon Storage and Transfer Equipment:

The neon liquefaction plant was operated in a batch type process, each batch consisting of approximately 20-25 liters of liquid. Several 25 liter standard liquid nitrogen shielded dewars were used for neon storage.

Transfer of liquid neon from the neon plant to the 25 liter dewars and from the 25 liter dewars to the test section dewar was accomplished through a commercially available vacuum insulated flexible transfer line.

APPENDIX FExamination of Test Heater Surfaces

All heaters were machined, finished, and polished in a similar manner. They all appeared identical, except for a few minor faults that generally affected less than 5% of the total surface. A close examination of each heater was made to determine the type and extent of these faults.

The results of each examination are briefly summarized below.

Heater 6

1. OFHC copper
2. Highly polished with regular polishing scratches around circumference
3. Six thermocouple indication points in each of two longitudinal lines 180° apart
4. Multiple longitudinal scratches of zero apparent depth around 120° of circumference
5. Surface roughness - 16-20 micro-inches RMS

Heater 7b

1. OFHC copper
2. Regularly polished, highly burnished
3. Six thermocouple indication points
4. Longitudinal spotty corrosion spots 1 inch from one line of thermocouples - zero depth

5. Wide scratches in three areas around periphery $1/3$ length of cylinder - zero apparent depth
6. Isolated scratches of $1/16$ - $1/4$ inch length, usually longitudinal randomly oriented around periphery
7. Surface roughness 11-13 micro-inches RMS

Heater 8

1. OFHC copper
2. Regular circular machine indications resulting in a highly burnished surface
3. Six thermocouple indication points
4. Two longitudinal areas of corrosion attack (zero apparent depth) $1/4$ " wide at 110° to each other along complete length, with stain marks (slight color difference) at top and bottom
5. Checkerboard imprints (zero apparent depth) $2\ 1/4$ " x $3/4$ ", $2\ 1/2$ " and 4" from top
6. One z-shaped scratch at midpoint, zero apparent depth
7. Surface roughness 13-15 micro-inches RMS

Heater 9

1. Nickel plated OFHC copper
2. Extremely high polish with regular circumferential burnishing
3. Six thermocouple indication points
4. Slight discoloration over 10% of surface
5. Isolated pitting (25 to 50 points) over $3/4$ of surface

6. Slight, almost invisible, longitudinal scratches, zero depth, over entire surface
7. One area $1/4 \times 1$ " in midpoint looking like corrosion in alligator pattern (cause unknown)
8. Surface roughness 6-8 micro-inches RMS

Heater 10

1. Cadmium plated OFHC copper
2. Highly polished surface with irregular burnish marks
3. Six thermocouple indication points
4. Three areas, (approximately $1/2 \times 3/4$ "), $3/4$ " from top land, at 120° , with copper showing
5. Approximately $1/16$ " over $1/2$ circumference at top land with copper showing
6. One area, about $3/4 \times 3/4$ ", $1/2$ " from bottom with copper showing
7. Copper showing for $1/16$ " at lower land
8. Longitudinal scratches over $1/2$ to $1 1/2$ " of circumference
9. Pitting over 3" of circumference for middle 80%
10. Surface roughness 8-11 micro-inches RMS

Heater 12b

1. Electrolytic tough pitch copper (almost identical to OFHC)
2. Highly polished with irregular polishing scratches around circumference
3. Six thermocouple indication points
4. Six gross (approximately 0.005" deep) irregularities, longitudinal alignment $1/4$ to $1/2$ " long

240

5. Tear marks visible all over under 48X, but not 1X magnification
6. Surface roughness 9-11 micro-inches RMS
