ION DISTRIBUTION AND TEMPERATURE

IN THE TOPSIDE IONOSPHERE

OBTAINED FROM THE ALOUETTE SATELLITE

ABSTRACT

13334

Electron density distributions are obtained from Alouette topside soundings recorded at Stanford University. Plasma scale height profiles are then determined, and from these profiles information can be deduced about relative ion concentrations, electron temperature and ion temperature. Results are obtained for dip latitudes between 48°N and 78°N, and altitudes from 400 km to 900 km.

It is found that the lower latitude nighttime data can be interpreted in terms of a three-constituent (O^{+}, H_e^{+}, H^{+}) diffusive equilibrium model with an (O^{+}) - (H_e^{+}, H^{+}) transition occurring at about 550 km in the summer and 500 km in the winter. The variation of this transition altitude with local time and with latitude is obtained. It is found that the transition level rises with increasing latitude, rising above 900 km at about 62° dip latitude. The transition level is also observed to rise very quickly at local sunrise and to descend quickly at local sunset. The data suggest that the (O^{+}) - (H_e^{+}, H^{+}) transition is at least as high as 1000 km during the day. Under these conditions the daytime scale heights at all observed latitudes and the nighttime scale heights at dip latitudes north of 63° can be interpreted in terms of temperature variations in an O^{+} ionosphere.

Author

I. INTRODUCTION

It is believed that the most abundant ions in the upper ionosphere are O^+, H_e^+, and H^+. There is little doubt that O^+ is the dominant ion at least between 200 km and 500 km (Johnson, et al., 1958, Taylor, et al., 1963). At altitudes above about 1500 km it is generally believed that H^+ is the dominant ion. Recent measurements of hybrid resonances at 1,000 km by Barrington, et al, (1964) suggest comparable ratios of H^+ to O^+ at this altitude. On the other hand, the relative abundance of H_e^+ in the ionosphere is not yet fully established. Nicolet (1961) suggested that neutral helium might be an important constituent of the upper atmosphere. King, et al (1964) present topside sounder data recorded at Singapore in October 1962 suggesting a nighttime $O^+ -$ to $- H_e^+$ transition at about 600 km. Bowen et al (1964) show midlatitude results obtained during the summer of 1962 from the Ariel satellite, indicating that, at night, H_e^+ is a dominant ion at 800 km, with O^+ and H^+ also present in significant quantities.

In this paper we consider a detailed analysis of topside electron density profiles. Since the electron density distribution in the topside ionosphere varies as a function both of relative ion concentration and the electron and ion temperature, such an analysis provides information about charged particle temperatures as well as distributions.

The relationship between electron density, electron and ion temperature and relative ion concentration can perhaps best be described in terms of the parameter "plasma scale height." In this paper we wish to define plasma scale height as the negative reciprocal of the normalized height gradient of electron density. Symbolically, this is

$$\mathcal{H} = - \frac{n_e}{\partial n_e / \partial h} \qquad (1)$$

where $\mathcal{H}$ is plasma scale height and n_e is electron density. Integration of Eq. (1) yields

$$n_e(z) = n_o \exp[- \int_o^z \frac{dh}{\mathcal{H}}] \tag{2}$$

which, for the special case $\mathcal{H}$ = constant, reduces to

$$n_e(z) = n_o \exp[- \frac{z}{\mathcal{H}}] \tag{3}$$

where z and h are both height variables and n_o is electron density at a reference height defined by $h = 0$.

We will show that, for a statistically neutral mixture of particles in diffusive equilibrium, plasma scale height is given by

$$\mathcal{H} = \frac{T_e + T_i}{T_e' + T_i' + <m_i> g/k} \tag{4}$$

where T_e and T_i are electron and ion temperatures respectively, primes indicate derivatives with respect to height, $<m_i>$ is the mean mass of all ions present, g is the acceleration of gravity and k is Boltzmann's constant. Thus, using plasma scale height profiles obtained from Alouette topside soundings, information can be obtained about electron temperature, ion temperature and relative ion concentration in the topside ionosphere.

It can be seen that for the case in which no height gradients of temperature are present, Eq. (4) reduces to a form which appears to be in very common usage today. As is apparent by inspection of Eq. (4), however, if significant height gradients of temperature exist, their omission will lead to serious errors in deduced values for electron and ion temperature.

Since December 4, 1962, signals from the Alouette have been monitored on a routine basis by the satellite receiving station at the Radioscience Laboratory of Stanford University. Details of the acquisition of the telemetered data by the recording station are described in Thomas and Sader (1964). The reduction of these data to electron density [N(h)] profiles is described by Thomas, et al (1965a,b).

The reduction of ionograms has been performed through a joint effort of the Space Sciences Division of Ames Research Center and Stanford Research Institute. The format of each profile was that of a tabulation of values of electron density at heights of 1000 km, 950 km, 900 km, etc., down to the level of maximum electron density, below which no data were obtained. As part of the same computer program, a corresponding tabulation of scale height values at the same true heights was easily obtained in accordance with the definition of Eq. (1). Published tables of these data are now in press (Thomas, Rycroft and Colin, 1965).

Data were obtained for the periods May-July 1963 and November 1963 - January 1964 and these groups are called "summer" and "winter" respectively. During each three-month period a complete diurnal spectrum of data was obtained. Data obtained for local mean satellite times (LMT) between 2300 and 0400 were considered "nighttime" data; data for the period 0800 LMT to 1700 LMT were classified as "daytime" data. We will derive Eq. (4) and the corresponding expressions for the distributions of number densities, after which we will examine the data in detail.

II. THEORY

We are here considering the theoretical distribution of ions and electrons in the region bounded by heights of 400 km and 900 km, and dip latitudes of 48° and 78° North.

The following simplifying assumptions are appropriate:

1. The ionosphere consists entirely of neutral particles and a statistically neutral mixture of electrons and singly charged ions of oxygen (O^+), helium (H_e^+), and hydrogen (H^+).

2. The medium is in a state of diffusive equilibrium, thus diffusion is the dominant process controlling the distribution of electrons and ions, and we can neglect the effect of production, loss, and time derivatives of all quantities.

3. The ionosphere is horizontally stratified, i.e. horizontal gradients of all quantities are much smaller than vertical gradients.

4. There is no net transport velocity associated with any species.

5. In any small region of space, all ions are in thermal equilibrium among themselves.

For conditions such as these, in which there is no production or loss, the equilibrium distribution of any species can be obtained by forming a balance of all forces present. For this case the appropriate force equation for each species is obtained by balancing the pressure gradient against all other forces, as:

$$\nabla p = nq\overline{E} + \overline{F} \qquad (5)$$

where

$$p = nkT \qquad (6)$$

Here p is the partial pressure of any species of particle, T is particle temperature, $\overline{E}$ is any electric field present, and $\overline{F}$ accounts for all non-coulomb forces present. In the case of a rotating earth, $\overline{F}$ is the sum of gravitational and centrifugal forces, but for altitudes less than 1000 km, it can be easily shown that the centrifugal force is negligible, and Eq. (5) may be expressed as

- 4 -

$$\frac{dp}{dh} = nq\overline{E} - nmg \tag{7}$$

where h is a coordinate in the radial direction.

Combining Eqs. (6) and (7), we have:

$$\frac{d}{dh} (n_e k T_e) = - n_e m_e g - n_e |q| E \tag{8}$$

for electrons, and:

$$\frac{d}{dh} (n_i k T_i) = - n_i m_i g + n_i |q| E \tag{9}$$

for each ion species.

Performing the differentiation on (8) and (9), we have:

$$k T_e \frac{dn_e}{dh} + k n_e \frac{dT_e}{dh} = - n_e m_e g - n_e |q| E \tag{10}$$

$$k T_i \frac{dn_i}{dh} + k n_i \frac{dT_i}{dh} = - n_i m_i g + n_i |q| E \tag{11}$$

Summing (11) over all ions, we have

$$k T_i \frac{d}{dh} \Sigma n_i + k \frac{dT_i}{dh} \Sigma_i n_i = - \Sigma_i n_i m_i g + \Sigma_i n_i |q| E \tag{12}$$

since, by assumption (5), all ions have the same temperature. Noting that $n_e = \Sigma_i n_i$, $m_i \gg m_e$ for any ion, and defining mean ionic mass as

$$\langle m_i \rangle = \frac{\Sigma_i n_i m_i}{n_e} ,$$

we can add Eqs. (10) and (12) and obtain

$$k(T_e + T_i) \frac{dn_e}{dh} + kn_e \frac{d}{dh} (T_e + T_i) = - n_e <m_i> g \qquad (13)$$

Solving for $-n_e/n_e{}'$, we easily obtain Eq. (4). Integrating Eq. (9) from $h = 0$ to $h = z$, we obtain

$$n_i(z) = \frac{n_{io} T_{io}}{T_i(z)} \exp \left[\int_o^z \frac{|q| E - m_i g}{kT_i} \, dh \right] \qquad (14)$$

From Eq. (14) we can express the fractional proportion of any constituent as;

$$p_i = \frac{n_i}{\sum\limits_i n_i} = \frac{n_{io} \exp \left[- \int_o^z \frac{m_i g}{kT_i} \, dh \right]}{\sum\limits_i n_{io} \exp \left[- \int_o^z \frac{m_i g}{kT_i} \, dh \right]} \qquad (15)$$

where all common factors have been removed. Mean ionic mass can now be expressed as;

$$<m_i> = \sum\limits_i p_i m_i = \frac{\sum\limits_i n_{io} m_i \exp \left[- \int_o^z \frac{m_i g}{kT_i} \, dh \right]}{\sum\limits_i n_{io} \exp \left[- \int_o^z \frac{m_i g}{kT_i} \, dh \right]} \qquad (16)$$

From Eqs. (15) and (16) we see that both p_i and $<m_i>$ are independent of electron temperature.

III. OBSERVATIONS OF THE DATA

The Stanford station does not have a command capability and
thus can obtain data only when the sounder is commanded on by
certain nearby command stations. In addition, the sounder is
not commanded on especially for the benefit of the Stanford re-
ceiving station. The stations providing the most advantageous
commands are College, Alaska and Grand Forks, Minnesota. The
geographic location of these stations tended to concentrate most
of the data acquisition to the higher latitudes, i.e. from 48°
dip latitude to 78° dip latitude.

The height limits are set by other considerations. Consider-
ation of the data is limited to heights greater than 100 km above
the ionization maximum in order to avoid the complicating effects
of recombination. Reasonable lower limits were set at 400 km for
both summer and winter results. The upper limit in height is set
by practical problems. In the vicinity of the satellite the
virtual depth of the signal penetration increases very rapidly
with a small increase in sounding frequency. The result is that
the ionogram trace has a very steep gradient in the vicinity of
the satellite, so steep that it becomes difficult to scale vis-
ually. Paul and Wright (1964) have examined this problem and
have shown that the ionogram trace approaches an infinite grad-
ient at the satellite, thus making the records difficult to in-
terpret. The scale height profiles we have analysed have shown
the effect of this problem, being reasonably consistent up to
850 km or 900 km, and showing randomly erratic behavior above
there, thus determining our upper limit of 900 km.

In general, data acquired during the summer period were more
plentiful and of higher quality than the winter data. This was
true especially of nighttime passages. There were more passages
actually recorded in the summer period than in the winter, and
the percentage of nighttime recordings was higher in the summer
than in the winter. On many of the ionograms the plasma fre-

quency at the vehicle could not be determined due to noise or other effects. The net result was that the accuracy of the winter nighttime analysis suffers to some extent from insufficient data.

Figure 1 is a plot of scale height as a function of height at a series of latitudes obtained from a typical nighttime passage. The data are typical for periods from 2300 to 0400 LMT and for both summer and winter records. Each curve, or H profile, is associated with a certain latitude and is actually an average of all profiles occurring within ± 1.5 degrees of that latitude.

Figure 2 represents data from a passage occurring June 10, 1963, from 1130 to 1250 LMT. It is typical, however, of daytime (0800-1700 LMT) data for both summer and winter. Only two profiles are plotted because, at least between 450 km and 850 km, virtually all the data occurred within the narrow region indicated by the dotted lines.

Figures 3 and 4 emphasize the difference in diurnal variation at two different latitudes for summer and winter respectively. Each curve is obtained by averaging the data from 15 or more passages. The daytime curves represent the average of all data recorded from 0800 to 1700 LMT. The nighttime curves represent the average of all data recorded from 2300 to 0400 LMT. It can be seen from the figure that diurnal variation is strongly dependent on latitude.

Figures 5 and 6 illustrate the variations of daytime scale heights with latitude for summer and winter respectively. Each of these plots was obtained from the average of a series (15 to 20) of passages occurring between 0800 and 1700 LMT. The summer profiles are seen to increase slightly with latitude at all altitudes, while the winter profiles are nearly independent of latitude at 500 km and decrease with latitude at the higher latitudes.

Figures 7 and 8 illustrate the variations of nighttime scale heights with latitude for summer and winter respectively. These plots were obtained by averaging the data from a series of passages occurring between 2300 and 0400 LMT. The latitudinal variation suggested by Fig. 1 is apparent here also.

Nearly all the Figs. 1-8 show the effects of the presence of an ionization maximum. Most of the profiles tend to increase with decreasing altitude below about 400 km. In the latter part of this paper it is convenient to approximate daytime plasma scale height profiles with a straight line. In this case we will limit our consideration of the data to the region above 500 km.

IV. INTERPRETATION OF RESULTS

The results of Brace, et al (1963), Evans and Loewenthal (1964) and others suggest that midlatitude nighttime temperature gradients are small. For this situation, a first order approximation to Eq. (4) becomes

$$\mathcal{H} \approx \frac{K}{<m_i>} \tag{17}$$

since in this case

$$\frac{\partial <m_i>}{\partial h} \gg T_e' + T_i'.$$

Figure 9 illustrates an isothermal solution to Eq. (24) corresponding to the summer nighttime scale profile occurring at 48 deg, shown in Fig. 3. It can be easily verified that the distribution of Fig. 9 yields a scale height profile which agrees with the experimental profile within 4% at any height. If we define the transition level by the condition that $P(O^+) = 50\%$,

it may be seen that, in the vicinity of the transition level, i.e., 550 km, that $\langle m_i \rangle$ does indeed vary quite rapidly, so rapidly in fact that variations in scale height must be due almost entirely to variations in $\langle m_i \rangle$, as suggested by Eq. (26). In addition, it may be seen that as little as 200 km below the transition level, O^+ so completely dominates the mixture, the assumption may be made, with little error, that the only ions present are O^+. Finally, consideration of experimental values of scale height and reasonable values of temperatures indicates that the transition must indeed be from O^+ to lighter ions.

It is easily shown that a similar analysis may be performed on the winter nighttime scale height profile at 48 deg as shown in Fig. 4, yielding similar temperature and distribution results, with a transition level at about 500 km.

A.   VARIATIONS OF THE TRANSITION LEVEL

We have seen that the deflection of an experimental scale height profile identifies a transition from O^+ to He^+ and/or H^+ ions. We have estimated that the height of this transition can be determined to within an accuracy of, perhaps, ± 25 km. It is now convenient to attempt to describe this transition level in a different manner than previously used.

Since a transition is defined by the condition $P(O^+) = 50\%$, then at the transition level for any arbitrary concentrations of He^+ and H^+, $\langle m_i \rangle$ must lie between 8.5 amu and 10 amu. If temperature gradients are not too large we can say that transition corresponds approximately to the conditions;

$$H(h_T) \approx 1.6\, H(h_{min}) \tag{18}$$

$$h_T \approx 200 \text{ km} + h_{min} \tag{19}$$

$$\frac{d}{dh}\mathcal{H}(h_{min}) \ll \frac{d}{dh}\mathcal{H}(h_T) \qquad (20)$$

where h_T is the transition level and h_{min} is a height below which $\mathcal{H}$ variations are small. Obviously the application of conditions (18), (19), and (20) requires some judgement but it is easily verified that a plasma scale height profile in the vicinity of a transition does satisfy these conditions and that conversely, only a sharply deflecting plasma scale height profile can satisfy these conditions. Finally, it can be argued that such a deflection can arise only from an ion transition or from unacceptably large local temperature gradients. It can thus be reasoned that the successful application of conditions (18), (19) and (20) to any plasma scale height profile does indeed establish and locate a transition.

When these conditions were applied to each plasma scale height profile for each satellite passage, and the resulting transition height for each profile plotted against the latitude at which it occurred, it was seen that in all cases the resulting plot showed a monotonic increase with latitude. In Fig. 10 we have shown the results of drawing a smooth curve through values of transition level which were obtained at three degree latitude intervals by averaging the results of a series of summer passages and a series of winter passages. These curves have also been plotted as dashed lines in Figs. 7 and 8.

There are two other important conclusions we can draw from the curves in Fig. 10. First, as pointed out earlier, the relative ion concentration is independent of electron temperature. The curves indicate therefore, that ion temperature increases with increasing latitude. Second, at depths as small as 200 km below the transition level, O^+ concentration completely dominates, so that at higher latitudes variations in scale height must be due almost entirely to temperature effects.

Using the same method we can study the variation of transition level with time. Figure 11 shows a plot of transition level as a function of time for all profiles obtained at $48^{\pm}$ 1.5 deg dip latitude. The trend of variation of the transition level suggested by Fig. 11 is that the level rises rather quickly at dawn, descends quickly at sunset, and remains fairly constant through most of the night. One should be cautious about attempting to draw quantitative conclusions from the curve since at sunrise and sunset, neither time derivatives nor transport velocities are likely to be negligible, but the evidence that the transition level is higher by day than by night is quite strong. If we assume that the daytime transition level is at least as high as 1000 km, then the approximation can be made that the ion composition in the region below 800 km is only O^+, and we can interpret changes in daytime scale height entirely in terms of electron temperature and ion temperature.

B. THE O^+ APPROXIMATION

Within the O^+ region, i.e., more than 200 km below the transition level, we can make the approximation that mean ionic mass is constant at a value of 16 amu. Scale height variations can thus be interpreted entirely in terms of temperature variations.

As a matter of convenience, then, we introduce the definition

$$H = \frac{k(T_e + T_i)}{2m(O^+)g} \tag{21}$$

so that, upon neglecting the small variation in gravity, we can express Eq. (4) as

$$\mathcal{N} = \frac{H}{H' + \frac{1}{2}} \tag{22}$$

- 12 -

It may be seen from Figs. 3, 4, 5, and 6 that the daytime and high latitude nighttime data are quite linear with height, at least above 500 km. On this basis we approximate any such profile with a straight line form; i.e.

$$\mathcal{N} = a + bz \tag{23}$$

where a and b are obtained from the data and $z = 0$ at 500 km. For example, the Day (48 deg) profile of Fig. 3 is given approximately by $\mathcal{N} = 185 + 0.5z$.

Equation (22) can now be expressed as

$$H' = \frac{H}{a + bz} - \frac{1}{2} \tag{24}$$

for which a solution is

$$H = C(z + {}^a/_b)^{\frac{1}{b}} + \frac{b/2}{1-b}(z + {}^a/_b) \tag{25}$$

where C is an arbitrary constant.

To determine values for T_e and T_i from Eq. (25), we can appeal to the theoretical work of Hanson (1963) and Geisler and Bowhill (1965) and the experimental results of Evans and Loewenthal (1964). Following the results of these workers we assume that T_e is isothermal and that T_i increases with height, approaching T_e as an upper limit such that $T_i'(800) = 0$ and $T_i(800) = T_e$.

These conditions provide the boundaries needed to solve Eqs. (24) and (25) for values of T_e and T_i. For the scale heights shown in Figs. 5 through 8, the corresponding solutions for T_e and T_i are shown in Figs. 12 through 15 respectively.

Estimates of midlatitude nighttime temperatures were obtained on the assumption that electron and ion temperatures were

equal and isothermal. Estimates of high latitude nighttime temperatures are here obtained on the assumption that mean ionic mass is independent of height. In the latitude region between 48 deg and 63 deg, however, neither assumption is likely to be appropriate. For this reason the solutions obtained in the two regions have been connected with smooth dashed lines as shown in Figs. 14 and 15, where the temperatures at 48 deg are consistent with the 48 deg nighttime profiles of Figs. 3 and 4.

A comparison of Figs. 14 and 15 shows that for both summer and winter nighttime conditions, temperatures appear to increase with increasing latitude, reaching a maximum at between 65 deg and 70 deg latitude, although summer temperatures appear to be a bit higher. The apparent trough in the winter temperatures may not be genuine. The winter data in this region was rather sparse, and it is entirely possible that the indication of another temperature increase north of 72 deg might be caused by an increasing ratio of lighter ions to O^+ ions in this region.

A downward flux of energetic particles from sources such as the solar wind or the Van Allen Belts might account for this, although it seems that particles depositing appreciable energy at these altitudes would have to be of fairly low energy. Thus far, the measurement of energetic particle fluxes appears to have been limited to particles with energies greater than about 40 kev.

From purely geometric considerations, the region above about 65 deg latitude is sunlit nearly all night during the summer period. The summer night high latitude temperatures are thus likely to be the result of both solar flux and whatever heating mechanism is producing the winter conditions. Such an assumption would explain both the higher temperatures during the summer, and also the fact that the temperature peaks occur at about 5 deg higher latitude in the summer than in the winter.

V. CONCLUSIONS

Under the assumption that the topside ionosphere is in a state of diffusive equilibrium, the measured parameter scale height bears a simple relationship to the electron temperature, ion temperature and relative ion concentration.

A midlatitude nighttime transition from O^+ ions to lighter (i.e., H_e^+, H^+) ions is shown to exist at about 550 km in the summer and 500 km in the winter. The accuracy of this determination is estimated to be ±25 km. The transition is shown to be characteristically narrow, such that, as little as 200 km below the transition, it is a reasonable approximation that the only ions present are O^+. Using this approximation, the daytime and the high latitude nighttime scale height variations are interpreted in terms of temperature variations.

Daytime temperatures for both summer and winter are observed to vary only slightly with latitude, while the more pronounced height variations are seen to agree reasonably well with the theoretical results of Hanson (1963) and Geisler and Bowhill (1965).

Nighttime temperatures for both summer and winter show a much greater latitudinal effect, with both a fairly sharp peak and a pronounced upward gradient at about 65-70 deg dip latitude, suggesting a significant source of heat energy in this region.

occurring between 2300 and 0400 LMT. The dotted line
represents the transition level ($O^+ - H_e^+$, H^+). May -
July 1963.

Fig. 8. Winter nighttime scale height as a function of dip
latitude at a series of altitudes. Each curve repre-
sents the average of data obtained from at least 15
passages occurring between 2300 and 0400 LMT. The
dotted line represents the transition level (O^+ -H_e^+,
H^+). November 1963 - January 1964.

Fig. 9. Percentage compositions of O^+, H_e^+, and H^+ as
functions of height for an ionosphere in which
$T_e = T_i = 928^\circ K$ and percentage concentrations at
550 km are specified as % (O^+) = 50%, % (H_e^+) = 32%,
% (H^+) = 18%.

Fig. 10. Nighttime transition level as a function of latitude
for summer (May - July 1963) and winter (November 1963 -
January 1964). Transition level is defined as the
height at which the percentage concentration of O^+
is 50%. Each curve is obtained from the average data
from at least 15 passages occurring between 2300 LMT
and 0400 LMT.

Fig. 11. Transition level at 48 deg dip latitude as a function
of time for summer (May - July 1963) and winter (Nov-
ember 1963 - January 1964). Transition level is de-
fined as the height at which the percentage concentra-
tion of O^+ is 50%. The dotted portions of the curves
represent incomplete data.

Fig. 12. Electron and ion temperatures as functions of dip
latitude for daytime summer (May - July 1963). Elec-
tron temperature is assumed everywhere independent of
height and is represented by the 800 km curve. Ion
temperatures are shown at four heights and $T_e = T_i$
at 800 km.

Fig. 13. Electron and ion temperatures as functions of dip
latitude for daytime winter (November 1963 - January
1964). Electron temperature is assumed everywhere
independent of height and is represented by the 800
km curve; ion temperatures are shown at four heights
and $T_e = T_i$ at 800 km.

Fig. 14. Electron and ion temperatures as functions of dip
latitude for nighttime summer (May - July 1963).
Electron temperature is assumed everywhere independent
of height and is represented by the 800 km curve. Ion
temperatures are shown at four heights and $T_e = T_i$
at 800 km. Below 63 deg dip latitude, temperatures
are represented approximately by the dotted extensions
to the curves.

Fig. 15. Electron and ion temperatures as functions of dip
latitude for nighttime winter (November 1963 - Jan-
uary 1964). Electron temperature is assumed every-
where independent of height and is represented by the
800 km curve. Ion temperatures are shown at three
heights and $T_e = T_i$ at 800 km. Below the 63 deg
dip latitude, temperatures are represented approx-
imately by the dotted extensions to the curves.
