1. Introduction

The reversible phenomena of photoconductivity and phototropy (or photochromism) have been known for a long time. Most of the studies reported have been on crystalline solids and until recently relatively little is known concerning these two interesting electronic properties for non-crystalline solids. Although both organic and inorganic materials can exhibit photoconductivity and phototropy, this survey paper will be restricted to inorganic systems. Most published work on non-crystalline solids, in particular those on photoconductivity, have been concentrated on the understanding of the mechanisms only rather than a correlation of the phenomena with the structures of the materials involved. In this review, attempts will be made to indicate the equal importance of the understanding of material structures. Before we proceed to review the observed properties, therefore, it is pertinent to clarify the meaning of "non-crystalline" solids.

II. Non-Crystalline Solids

Non-crystalline solids can be prepared by a large number¹ of grossly different methods. The two most important methods, particular for the present review, are (a) by cooling the melt until it is rigid in the absence of crystallization, and (b) by condensation of the vapor on a solid substrate at some temperature at which the condensate is rigid. In either case, absence of crystallinity is usually assumed if diffuse x-ray

or electron diffraction patterns similar to that given by a liquid are obtained. It is generally accepted by workers in the field of glass science and technology that the non-crystalline solid obtained by method (a) termed a glass or a ²vitreous solid. This glassy solid is a metastable phase whose frozen-in structure corresponds to the structure of a liquid or a supercooled liquid at some higher temperatures. A non-crystalline solid obtained by vapor deposition is generally referred to as an amorphous solid. The structure of an amorphous solid is dependent on many factors some of which are interrelated. For example, the structures of the vapor species, the substrate temperature, the rate of deposition and the duration of deposition. If a substance can be rendered into a non-crystalline state by both methods (a) and (b), for instance selenium, it is unlikely that the structures of the two non-crystalline solids will be the same. This will be further clarified when selenium is discussed below. Although there appears to be some evidence that non-crystalline oxides obtained by different methods are structurally similar, this is to be regarded as anomalous ³at present. In any study of the properties of non-crystalline solids, therefore, the preparation history must be considered as an important factor.

III. Photoconductivity

(a) Semiconducting Non-Crystalline Solids

Electronic conduction in semiconductors is not confined to crystalline solids. Ioffe and Regel⁴ have presented extensive data which has shown conclusively that semiconduction is primarily governed by short-range order and not long-range order. Thus the mechanism of semiconduction in a molten semiconductor may be similar to that in the corresponding crystal providing the short-range order in the two phases are similar. It is of course frequently difficult to define exactly the meaning of short-range order. Semiconducting behavior has been reported long ago for amorphous films of elementary solids such as antimony, germanium, silicon and tellurium. More recently, semiconducting behavior has been found in many oxide glasses⁵ as well as non-oxide glasses⁶ based on mixtures of elements such as S, Se, Te, P, As, Tl, Si and Ge. Photoconductivity has only been reported for the latter materials. In general, these semiconducting glasses have relatively low electrical conductivity ($10^{-2} \text{ ohm}^{-1} \text{ cm}^{-1}$ or less) and the mobility of the carriers is small ($1 \text{ cm}^2 \text{ V}^{-1} \text{ sec}^{-1}$ or less). There is at present little quantitative understanding concerning such low-mobility solids. Both n-type and p-type conduction have been reported. It is interesting to note that for some of these glasses, whereas

thermoelectric power measurements indicate that the major carriers are positive holes, Hall measurements suggest that electrons are the primary carriers. It was suggested that this anomaly could be the result of inhomogeneities in the glass⁷. Recently, however, it was reported that this anomaly persisted when glasses of the systems As_2Se_3 and As_2Te_3 ⁸ were heated to temperatures corresponding to the liquid state. It is unlikely therefore that inhomogeneities are the dominant factor.

From a practical point of view, glasses are more flexible as an electronic material since chemical compositions are not limited by stoichiometry and also there are no grain boundaries as for polycrystalline solids. Further, unlike semiconducting crystals, the electrical conductivity of the glass is apparently insensitive to the presence of impurities. In Table I, the effect of zone-refining on the variation of electrical properties for the crystalline and glassy phases of the same material is shown.

(b) Photoconductivity of Non-Crystalline Selenium

Photoconductivity was first observed for non-crystalline selenium by Weimer in 1950.¹⁰ The sample was prepared by condensing the vapor on a substrate. The spectral response of the non-crystalline sample as compared to that of the hexagonal crystal is shown in Fig. 1. Although the photo-

currents are normally very small, because of the high dark resistivity (greater than 10^{14} ohm cm at 20°C), they are many times the dark current. From a scientific point of view, after Weimer's discovery, non-crystalline selenium immediately became a challenge with many unexplained properties; among them were:

- 1) Difference in photon energy for absorption and photoconductivity;
- 2) Origin of the carriers which are predominantly positive holes;
- 3) Mobility of the carriers.

From an industrial point of view, the high resistivity of non-crystalline selenium was desirable for the Xerographic printing process¹². In the past 15 years it has therefore been widely studied. An excellent summary of published work has been made by Pell¹³. Almost without exception, research has been concentrated on the mechanism of photoconduction and or attempts to explain electrical and optical properties by band theory. Important experimental data were obtained from drift mobility measurements, particularly by Spear¹⁴, and from studies of space-charge limited currents¹⁵. The electronic states in non-crystalline selenium at room temperature as indicated by optical, photoconductivity, and charge-transport measurements have been summarized recently by Hartke and Regensburger¹⁶ and reproduced in Figure 2.

(c) Structure of Non-Crystalline Selenium

17,18

Selenium exists in three known crystalline modifications :

- 1) A common hexagonal form which is known as grey or metallic

selenium. The structure of this is made up of parallel infinite spiral chains. (2) α -monoclinic; and (3) β -monoclinic. These latter two modifications are made up of puckered Se_8 rings. The hexagonal form is the high temperature stable form and is insoluble in carbon disulphide whereas the monoclinic forms will dissolve in CS_2 . Molten selenium probably consists of a mixture of Se_8 rings, Se_6 rings, larger rings and chains of varying lengths^{19,20,21}. The distribution of these various units is dependent on temperature and controversy exists between different workers regarding the polymeric units as well as their distribution. The melting temperature of selenium is 217°C . A glass obtained by quenching the melt from different temperatures will therefore have different structures. It is also to be noted that if a Se_8 ring were to open there will be two unpaired electrons at the two ends of the resultant chain. Thus the number of unpaired electrons in a glass, say, will depend on the equilibrium distribution of the chain lengths for that particular sample. Unambiguous information on the detailed structures of glasses is not available from X-ray diffraction experiments. This is exemplified by the controversy which exists, for example, between Krebs¹⁹ who suggested Se_8 rings and larger rings of about 1000 Se atoms to be the basic units of glassy selenium and Richter²¹ who postulated Se_6 rings. The glass is

metastable with respect to the crystalline phases and will devitrify through nucleation and subsequent crystal growth. The temperature at which devitrification will occur and the particular crystalline phase which forms are both sensitive to impurities, atmosphere and mechanical stresses. The glass transition temperature for selenium is approximately 30°C which means that above which, viscous flow will be perceptible.

The vapor species of selenium are temperature dependent.

At low temperatures, molecular weight measurements²² and electron diffraction²³ indicate that the vapor species are likely to be Se_6 rings. When the vapor is condensed on a substrate at 20°C, say, it is unlikely that the amorphous film which is formed will have a structure similar to that of a glass formed by quenching the melt to 20°C. Many workers who studied the photoconductivity of non-crystalline selenium considered their vapor-formed films to be glassy or vitreous.²⁴ Lanyon, for example, considered his vapor-formed films as a "supercooled liquid". Amorphous selenium films have been deposited at various temperatures as high as 90°C. At this temperature, the viscosity of selenium is 1×10^6 poise. It is a supercooled liquid since the glass transition temperature is only 30°C. On the other hand, many films were deposited on substrates at 20°C. This will of course make the meaningful correlation of film properties even more difficult. As for

the glassy selenium, amorphous films will undergo transfor-
10

mation. Weimer, for instance, mentioned that his vapor-
formed amorphous films contained some monoclinic crystals.

25,26

Keck deposited amorphous films at temperatures between
30° and 75°C and reported that at lower temperatures, mono-
clinic crystals were present but at above 65°C, some hexagonal
crystals were formed. Further, crystal growth could occur
even at 20°C, the rate being 2700A per day. It is known that
the electrical properties of the film are dependent on
12
temperature, duration and rate of deposition. Figure 3 is
a reproduction of the recent work of Griffiths. The bottom
figure shows that the electron diffraction pattern of selenium
film deposited on the (100) cleavage face of MgO at 90°C is
diffuse. However, the transmission electron-micrograph shows
widely separated spherical particles of about 2000A in diameter.
Presumably these are non-crystalline droplets. Their separa-
tion certainly does not resemble the transmission picture of
an ordinary glassy sample.

Further progress in understanding the electrical properties
of non-crystalline semiconductors will be difficult if the
structures of the materials themselves are neglected.

(d) Photoconductivity of Chalcogenide Glasses

Besides selenium, many chalcogenide glasses have been
demonstrated to be photoconductors. Most of the pioneer work

in this field have been carried out by B. T. Kolomiets of
28 Russia . Examples of some such glasses are shown in Table II.
The results showed that the conductivity of a glass increases
when the content of the heavier element is increased. In the
glass-forming system of As, Se and Te, for example, the
activation energy also decreases with increasing As_2Te_3 . In
Table III, it is seen that the activation energies determined
from absorption and photoconductivity are similar although
they differ somewhat from that obtained from conductivity.

In Figure 4, it is seen that the conductivity of glasses
of the system As, Se and Te varies smoothly from the glassy
state to the supercooled liquid state. In Figure 5, the
photoconductivity of glassy and liquid $4\text{As}_2\text{Se}_3 \cdot \text{As}_2\text{Te}_3$ is seen to
be quite similar. Photoconducting amorphous As_2Se_3 films
29 have been made by vapor deposition . The vapor deposition
of a polycomponent system can generate an extra degree of
complexity since the composition of the condensate may deviate
from that of the original material. In Table IV, it is seen
that the composition of condensed amorphous films are influenced
30 by evaporation temperature as well as substrate temperature .

IV. Phototropy

(a) Arbitrary Definition

Phototropy or photochromism generally refers to the
phenomenon whereby a material changes color when exposed to

radiation but reverts to its original color in the dark ³¹ . Both organic and inorganic materials can exhibit phototropy. The phenomenon of solarization, for example, can be included within this broad definition. Results on solarization have ³² been summarized by Weyl . In a silicate glass containing small amounts of Mn^{2+} and Fe^{3+} ions, for instance the absorption of a light quantum results in a purple coloration in which can be explained by the reactions:

Such processes are extremely slow. For practical applications, both the coloration and fading should be controllable. The coloration, in particular should be instantaneous and be sensitive to sunlight. Two types of phototropic inorganic glasses have been developed recently. They have both generated many interesting scientific questions. We will confine this survey to these two types of glasses.

(b) Phototropic Glasses containing Silver Halides

Glasses can be melted with some silver nitrate and sodium halides to give a homogeneous liquid. On controlled cooling and heat treatment, silver halide crystals can be precipitated. ³³ Recently, Armistead and Stookey reported that for some glass compositions, if the silver content is between 0.2 to 0.7 percent, and if the silver halide crystals are controlled to 50 to 100A in diameter, a transparent glass is obtained. On

exposure to sunlight or radiations in the UV, darkening will occur rapidly. This so-called activation and subsequent fading of the glass is exemplified by the results of Fig. 6 and Fig. 7 according to Smith³⁴. The activity of the glasses, typical compositions of which are shown in Table V, are enhanced by small amounts of copper ions.

Apparently, under irradiation, three processes occur simultaneously: darkening or creation of color centers; optical bleaching; and thermal bleaching. The darkening rates, and the optical components of fading rates, are considered to be described by first-order kinetics³³. The spectral sensitivity is dependent on the particular halide. Thus a glass with AgCl is sensitive in the 3000-4000A region whereas one with a mixture of AgCl and AgBr will be sensitive from 3000-5500A and one with a mixture of AgCl and AgI will be sensitive to about 6500A. The darkening rate is apparently not very sensitive to temperature but the fading rate increases rapidly with increasing temperature. The advantage of this inorganic phototropic system is that even after 300,000 cycles, no fatigue was noticed³⁵. This is far superior to organic systems.

A tentative model to explain this interesting reversible phenomena has been given by Armistead and Stookey³³. The primary photolytic reaction can be represented by:

Thus an electron is freed from the Cl^- and is trapped by the Ag^+ . Such silver atoms, or very small aggregates of them, are the color centers. Sensitization by copper ions is attributed to:

The reaction products are metastable and will return to the original state when the incident radiation is terminated. This suggests that the Cl atoms cannot diffuse away nor will extensive aggregation of the silver atoms occur. The phenomenon is thus reversible as contrast to the normal photographic process which is irreversible. Aggregation of silver and the loss of chloride do occur in the latter process. Further support of this model is available from the similarity of the optical absorptions curves of such glasses to those for crystalline silver halides³⁴. The model is admittedly oversimplified and many observations are not yet explainable. For example, the composition of the base glass, and the thermal history are critical factors. Their roles are not yet understood. In addition to silver halides, it has been reported that silver molybdate and silver tungstate crystals can also³⁶ yield phototropic glasses similar to those described above.

(c) Phototropic Glasses Prepared under Highly Reducing Conditions.

Soda-silica glasses of high purity and melted under

highly reducing conditions also show phototropic behavior
when exposed to UV radiations³⁷. It appears that the reducing
conditions are necessary and that traces of impurities can
have large effects on the optical properties. Very careful
experiments have been reported recently by Swarts and Pressau³⁸.
For soda-silicate glass, the color center generated is located
at 5700A and no deliberately added impurities is necessary
although cerium and europium will enhance phototropy. Inhibition
of phototropy can also be caused by about 200 ppm of titanium,
vanadium or iron. The effects of cerium and europium are
shown in Table VI. The parameter K^1 is defined by:

$$K^1 = 1/d \log (T_0/T)$$

where d is the thickness of the sample, T is the percent
transmission of colored glass at peak of absorption band, and
 T_0 is percent transmission of uncolored glass. Under sustained
irradiation, the saturation value of K^1 is designated K_0^1 .
Although the rare-earth ions can supply photoelectrons, their
exact role is unclear since phototropic coloring is not
accompanied by a reversible change in absorption of the
reduced rare earth ions.

The change in transmittance of a typical soda-silica
glass on UV irradiation is shown in Fig. 8. In Fig. 9, the
effects of changing the alkali ions are shown. The position
of the peak is apparently unaffected by the concentration of

the alkali ions. For $\text{Na}_2\text{O-SiO}_2$ glasses, for instance, it is constant even when the Na_2O content is varied by as much as 22%. This observation suggests that the color centers in question is dependent on the structure of the glass. It is possible that the reduction reaction during melting generates oxygen-deficient sites which subsequently trap electrons and that the nature of this site is dependent on the nature of the alkali ion.

Typical photoresponse of this type of glass is shown in Figure 10. The formation of the color center is described by first-order kinetics whereas the fading mechanism follows a second-order relation³⁸. The coloration was not studied as a function of temperature although the fading rate is very temperature sensitive. For instance, the fading rate at room temperature is about thirty times greater than that at -150°C . Unlike the silver halide phototropic glasses, these "reduced" glasses show fatigue on repeated irradiation. It is known that fatigue is partially due to an acceleration of fading rate. Since no information exists on the effect of fatigue on coloration, the exact causes are unknown.

A number of models to explain this phenomenon has been discussed by Cohen³⁹. A trapped electron in an oxygen vacancy near an alkali ion or near a cation donor is considered unlikely. Cohen considers that the most likely mechanism is one involving

the photoreduction of a cation trace impurity, most probably the reduction of Ti^{4+} to Ti^{3+} . In view of the large effects of minute traces of impurities and the difficulty in preparing glasses totally void of impurities, the validity of any model must await further research.

Acknowledgments

I am grateful to Dr. S. Sakka and Mr. Roger Haskell for their assistance in the preparation of this review and to the National Aeronautics and Space Administration for support under Contract no. NSG-100-60.
