PUBLICATIONS OF GODDARD SPACE FLIGHT CENTER 1964

Volume I
SPACE SCIENCES

FOREWORD

This publication is a collection of articles, papers, talks, and reports generated by the scientific and engineering staff of Goddard Space Flight Center in the year 1964. Many of these articles were originally published in scientific or engineering Journals or as official NASA technical publications, while others are documents of a more informal nature. All are reprinted here as nearly verbatim as typography and format will permit.

These articles are grouped into broad subject categories, but no detailed subdivision has been made. Within each category, the articles are arranged alphabetically by author. An overall author index is given in the back of the volume.

The years 1963, 1964, and 1965 are being published as whole-year issues, and the resulting size dictates the use of two volumes; the first volume is titled Space Sciences, and the second Space Technology. It is anticipated, however, that future issues will be quarterly single volumes.

CONTENTS

FOREWORD iii

I. ASTRONOMY AND ASTROPHYSICS

"B STAR COLORS BETWEEN 2000 AND 3000 ANGSTROMS," *by* A. Boggess, III 1
"INTERSTELLAR EXTINCTION IN THE MIDDLE ULTRAVIOLET," *by* A. Boggess, III, *and* J. Borgman 4
"ORIGIN OF THE SOLAR SYSTEM," *by* A. G. W. Cameron 7
"GRAVITATIONAL COLLAPSE," *by* H.-Y. Chiu 13
"SUPERNOVAE, NEUTRINOS, AND NEUTRON STARS," *by* H.-Y. Chiu 27
"SURFACE X-RAY EMISSION FROM NEUTRON STARS," *by* H.-Y. Chiu *and* E. E. Salpeter 55
"ESCAPE OF STARS DURING THE COLLISION OF TWO GALAXIES," *by* G. Contopoulos *and* G. Bozis 58
"DYNAMICS AND EVOLUTION OF CLOSE BINARY SYSTEMS," *by* S.-S. Huang 67
"EFFECT OF NON-SYNCHRONOUS ROTATION ON CLOSE BINARY STARS," *by* S.-S. Huang 108
"AN INTERPRETATION OF ϵ AURIGAE" *by* S.-S. Huang 113
"THE MOTION OF GASEOUS STREAMS IN THE BINARY SYSTEM," *by* S.-S. Huang 120
"ROTATIONAL BEHAVIOR OF THE MAIN-SEQUENCE STARS AND ITS PLAUSIBLE CONSEQUENCES CONCERNING FORMATION OF PLANETARY SYSTEMS," *by* S.-S. Huang 129
"SEQUENCE OF EVENTS IN THE EARLY PHASE OF THE SOLAR SYSTEM," *by* S.-S. Huang 137
"PLASMA NEUTRINO EMISSION FROM A HOT, DENSE ELECTRON GAS," *by* C. L. Inman *and* M. A. Ruderman 142
"MAGNETOGRAVITATIONAL INSTABILITY OF ANISOTROPIC PLASMA WITH HALL EFFECT," *by* G. L. Kalra *and* S. P. Talwar 155
"THE DETECTION OF SOLAR NEUTRINOS," *by* H. Reeves 160
"ACCRETION OF INTERSTELLAR MATTER BY MASSIVE OBJECTS," *by* E. E. Salpeter 165
"C_2 SWAN BANDS IN COMETS." *by* R. E. Stockhausen *and* D. E. Osterbrock 169
"EVOLUTION OF O STARS. II. HYDROGEN EXHAUSTION AND GRAVITATIONAL CONTRACTION," *by* R. Stothers 174
"THE RV TAURI POPULATION," *by* R. Stothers 184

II. CELESTIAL MECHANICS AND GEODESY

"LONG-PERIOD CONTRIBUTIONS TO THE DISTURBING FUNCTIONS OF THE EARTH FROM THE SEVENTH, NINTH, AND ELEVENTH ZONAL HARMONICS," *by* T. L. Felsentreger *and* W. J. Wickless 191
"NOTES ON VON ZEIPEL'S METHOD," *by* G. E. O. Giacaglia 196
"A SERIES SOLUTION FOR SOME PERIODIC ORBITS IN THE RESTRICTED THREE-BODY PROBLEM ACCORDING TO THE PERTURBATION METHOD," *by* S.-S. Huang 206
"ON THE APPLICATION OF PFAFF'S METHOD IN THE THEORY OF VARIATION OF ASTRONOMICAL CONSTANTS," *by* P. Musen 215
"ON THE SIMULTANEOUS COMPUTATION OF THE SECULAR AND RESONANCE EFFECTS IN THE MOTION OF CELESTIAL BODIES," *by* P. Musen 233
"DETERMINATION OF THE TRIAXIALITY OF THE EARTH FROM OBSERVATIONS ON THE DRIFT OF THE SYNCOM II SATELLITE," *by* C. A. Wagner 243
"INTRODUCTION TO THE APPLICATION OF VON ZEIPEL'S METHOD," *by* W. J. Wickless 282

PRECEDING PAGE BLANK NOT FILMED.

III. SOLAR PHYSICS

"COMMENTS ON HIGH ENERGY X-RAYS BURSTS OBSERVED BY OSO-1," *by* K. J. FROST 291
"TEMPERATURE OF A GRAY BODY MOST CLOSELY FITTING THE SOLAR EXTRATERRESTRIAL SPECTRUM," *by* W. B. FUSSELL *and* J. B. SCHUTT 294
"DISTRIBUTION IN HELIOGRAPHIC LONGITUDE OF FLARES WHICH PRODUCE ENERGETIC SOLAR PARTICLES," *by* D. E. GUSS 299
"THE EFFECT OF A CORONAL EXPANSION ON THE COMPUTATION OF AN ELECTRON TEMPERATURE FROM EMISSION-LINE INTENSITIES," *by* W. M. NEUPERT 301
"TIME VARIATIONS IN THE SOLAR EXTREME ULTRAVIOLET SPECTRUM OBSERVED BY OSO-1," *by* W. M. NEUPERT 306
"THE UV LINES OF FE XIV IN THE SOLAR CORONA," *by* R. E. STOCKHAUSEN 315
"SOLAR X-RAYS: A COMPARISON WITH MICROWAVE RADIATION," *by* W. A. WHITE 319

IV. IONOSPHERE AND RADIO PHYSICS

"D REGION FORMATION," *by* A. C. AIKIN 325
"SOME RESULTS OF ROCKET EXPERIMENTS IN THE QUIET *D* REGION", *by* A. C. AIKIN, J. A. KANE, *and* J. TROIM 335
"HYDROGEN IONS," *by* S. J. BAUER 343
"MEAN DIURNAL VARIATION OF THE TOPSIDE IONOSPHERE AT MID-LATITUDES," *by* S. J. BAUER *and* L. J. BLUMLE 348
"ELECTRON DISTRIBUTION IN THE IONOSPHERE," *by* R. E. BOURDEAU 355
"RESEARCH WITHIN THE IONOSPHERE," *by* R. E. BOURDEAU 363
"THE TEMPERATURE OF CHARGED PARTICLES IN THE UPPER ATMOSPHERE," *by* R. E. BOURDEAU 376
"POSITIVE ION TEMPERATURES ABOVE THE F-LAYER MAXIMUM," *by* R. L. F. BOYD *and* W. J. RAITT 384
"GEOMAGNETIC CONTROL OF DIFFUSION IN THE UPPER ATMOSPHERE," *by* S. CHANDRA *and* R. A. GOLDBERG 387
"THE EFFECT OF A VARIABLE ELECTRON TEMPERATURE ON THE EQUATORIAL ELECTRON DENSITY DISTRIBUTION IN THE UPPER IONOSPHERE," *by* R. A. GOLDBERG 397

I. ASTRONOMY AND ASTROPHYSICS

B STAR COLORS BETWEEN 2000 AND 3000 ANGSTROMS*

ALBERT BOGGESS III

Ultraviolet fluxes at 2200 and 2600 Angstroms have been measured for about 180 B and A stars using filter photometers in rockets. Forty-eight of these stars have been observed more than once, and an analysis of these data show the uncertainty of a single observation to be less than 20 percent. A UV-color versus B-V plot of luminosity class III, IV, and V stars with little reddening shows a degree of correlation consistent with the observational uncertainty. The data appears to be of sufficient quality for use in deriving B star temperatures and interstellar scattering curves.

Ultraviolet astronomical observations have suffered due to limitations in detector systems, limitations in photometric standards, the problem of obtaining precision data with miniature instrumentation in the rocket environment, and the inability to: select the stars to be observed. It is these restrictions which have dictated the kinds of observations that have been made. The first program to be undertaken was broadband ultraviolet color and flux measurements using small, simple photometers that scanned the sky with the rocket motion. This data is of value in its own right and also has been particularly useful in the design of more sophisticated experiments. As instrumentation techniques improved, it became possible to fly medium resolution objective grating spectrometers to record ultraviolet flux distributions. This data is discussed in the following paper. Now that rocket pointing systems are becoming available, a relatively high resolution scanning spectrometer is being designed to study selected stars in greater detail.

Perhaps the two greatest difficulties associated with the work done to date are that the rockets could not be pointed and that the equipment is destroyed after each flight. Because of the inability to point the rockets, an essentially random selection of stars is obtained on any given flight, and it is necessary to combine the data from a number of flights to produce a useful set of observations. But here the second difficulty is encountered. Since the instruments are destroyed at the end of flight, the internal consistency of the results is totally dependent upon the maintenance of laboratory photometric standards which can be used to calibrate each set of rocket instrumentation and to transfer the calibration from one flight to the next. Because of the emphasis that has been placed on these standards, and because they can be maintained only by repeated absolute calibration, the uncertainties in the absolute calibration of the data are generally smaller than the random uncertainties within the observations themselves. Only by paying careful attention to these calibrations and by demonstrating their consistency from one flight to the next can it be argued that the data is worth interpreting. My principal aim here is to state what kind of accuracy has been achieved.

In obtaining the filter photometry data, two wavelengths have been used: 2600 and 2200 Angstroms; and the photometers have been flown in pairs: one with a 2600 Angstrom filter and one with a 2200 Angstrom filter. The photometers in a pair have parallel optical axes so that simultaneous flux measurements are made at both wavelengths. Originally 60 mm diameter quartz or calcium fluoride lenses were used as objectives; more recently 150 mm diameter Cassegrain telescopes have been employed as collectors. In either case, the filter is placed behind the collector, a field stop and field lens are placed at the focal plane, and a quartz windowed photomultiplier is

*Published in *Annales d' Astrophysique*, 27(6): 805-808, 1964.

used as a detector. The filter characteristics are shown in Figures 1 and 2.

The first filter has an effective wavelength of 2200 Angstroms with a 210 Angstrom effective width. It is a first order interference filter and exhibits a long wavelength tail which contributes

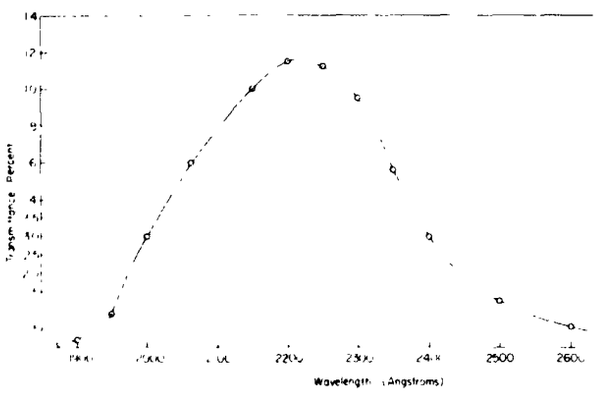

FIGURE 1.— Response curve for 2200 Angstrom photometer.

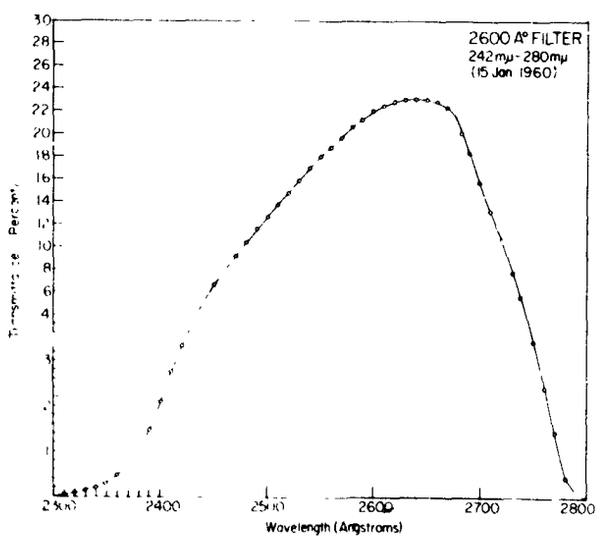

FIGURE 2. —Response curve for 2600 Angstrom photometer.

significantly to the transmitted energy. On the short wavelength side the tail is chopped by the transmission of the optical system. Since the long wavelength tail extends into the bandpass of the 2600 Angstrom filter, its effect on the 2200 Angstrom flux can be allowed for by subtracting a fixed percentage of the flux seen by the 2600 Angstrom filter. This procedure is accurate to within a percent or so for a wide range of spectral gradients. The filter shown in Figure 2 is a sandwich of lead doped potassium bromide-potassium chloride and nickel sulphate hexahydrate crystals together with various high silica glasses. It has an effective wavelength of 2600 Angstroms with a 250 Angstrom bandpass. The calibration of the photometers is fairly straightforward. The transmission of the optical train is measured with a spectrophotometer, and the relative spectral efficiency of the photomultiplier is compared against a known phosphor. Since both filters pass the 2537 Angstrom line of mercury, this line can be used conveniently as an absolute standard in an inverse square law calibration. The mercury standard is maintained by periodically using a thermocouple to compare it to the total radiation from a tungsten lamp calibrated by the National Bureau of Standards.

Three pairs of photometers are flown in a rocket, each pair looking in a different direction in order to cover as much sky as possible. As the rocket spins and processes, the photometers scan the sky, typically seeing an individual star for about two-tenths of a second. In four flights some 300 two color observations on about 180 different stars have been recorded. Forty-eight of these stars have been observed with more than one pair of photometers. Therefore, there are approximately 120 observations, covering forty-eight stars, from which the internal reliability of the data can be judged. Of these forty-eight stars, all observations clustered within 20 percent for forty of them, within 10 percent for seventeen. The uncertainties in this data should be representative of the accuracy of all the observations, so that even for those stars observed only once the data should have an uncertainty of less than 20 percent

It is interesting to see the colors derived for the 48 well observed stars, and to compare them with conventional B-V colors. Here again, one is subjected to a severe selection process. When the selection is restricted to those whose B-V is available, to luminosity classes III, IV, and V, and to those with color excess of .02 magnitude or less, only thirteen of the original forty-eight stars are left, and they are shown in Table 1 and Figure 3. β Per and β Cep are variable, but the variability in (B-V) is small compared to the uncertainty in the ultraviolet colors. ϵ UMa is a peculiar star showing chromium and europium lines; however, with such a small group of stars to work with,

TABLE 1.—*Ultraviolet Colors of Stars With Little Color Excess*

		Sp	B-V	$m_{2200}-m_{2600}$
ζ	UMa	A2V	+.02	−.06
γ	UMa	AOV	.00	.00
α	CrB	AOV	−.02	−.14
ϵ	UMa	AOp	−.03	−.08
β	Per	B8	−.07	−.32
β	Lib	B8V	−.11	−.35
ζ	Dra	B6III	−.12	−.45
τ	Her	B5IV	−.15	-.66
ι	Her	B3V	−.18	−.53
η	UMa	B3V	−.20	−.37
ϵ 1, 2	Sco	B3, 2	−.20	−.36
β	Cep	B2III	−.22	−.49
η	Lup	B2V	−.23	−.55

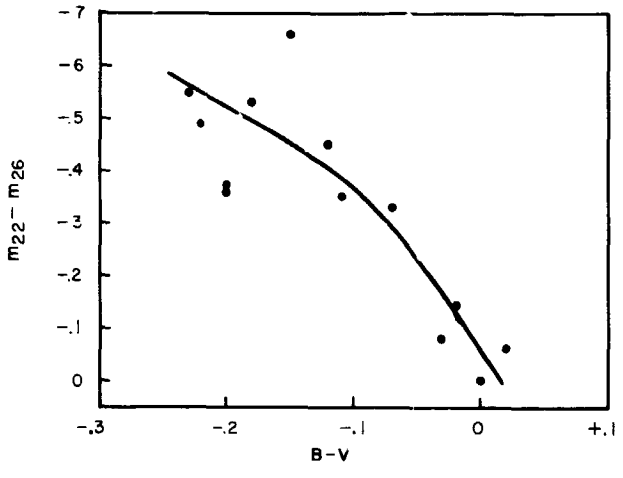

FIGURE 3.—Color-Color diagram for well observed stars of luminosity classes III, IV, and V having $E \leq .02$.

beggars can't be choosers. Finally, η_1 Sco and η_2Sco appear in the photometer field together and this observation must be considered the average of the two stars. Since they are similar in spectral type and color, the observation should still have weight.

The ultraviolet colors listed are absolute. That is, they represent true ratios of the 2200 Angstrom and 2600 Angstrom fluxes. It is fortuitous that early A stars have roughly equal fluxes at these two wavelengths, making the zero point of the ultraviolet color scale nearly correct. The curve drawn in Figure 3 is arbitrary. However, all but three of the stars are within one-tenth magnitude of that curve, and those three are within two-tenths. This degree of correlation appears to be comparable to the accuracy of the data. Such a correlation is very encouraging. It means, for instance, that it should be possible to derive information on interstellar scattering in the ultraviolet, and, of course, to derive a temperature scale for the B stars based on the observed ultraviolet spectral gradient. This phase of the work is just starting, but Stecher will describe some of the first attempts in the following paper in connection with the spectrophotometric data. There again, the matter of calibration is all important. Fortunately there are seven stars in common between the broadband and the spectrophotometric data, so that spectrophotometric fluxes at 2200 and 2600 Angstroms can be compared with fluxes from the filter photometry. The seven stars are ϵ and η UMa, λ Cas, β Cep, τ; ζ and π Sco. The two sets of data, which are obtained by quite different techniques, agree within 20 percent for all seven of these stars, and for four out of the seven there is agreement within 10 percent. In other words, we are now at the stage where the observations are sufficiently reliable to be used with confidence in deriving information on stellar atmospheres and interstellar scattering.

INTERSTELLAR EXTINCTION IN THE MIDDLE ULTRAVIOLET*

ALBERT BOGGESS III AND JAN BORGMAN†

Recently, Boggess (1964) obtained photoelectric photometry of a number of stars in two wavelength bands centered at 2600A and 2200A. A detailed description of the instrumental system will be found in his paper. The accuracy of this rocket-based photometry, as checked by the repeatability of the measurements, is very satisfactory. The observations include six stars in the narrow spectral range 09.5–B1, which appear suitable for deriving a first reliable estimate of the interstellar extinction in the middle ultraviolet. These stars are γ Sco, π Sco, δ Sco, β Sco, ζ Oph, and α Cam, in order of reddening.

The first seven lines of Table 1 give the UBVRIJK photometry of these stars, as far as available at the moment. The data have been taken from Johnson and Borgman (1963) and from more recent work that is in the process of publication. The color excesses E_{B-V} in line 9 have been derived from the MK classification in line 8, using Johnson's (1963) calibration. These color excesses are rather small and an independent deter-

†Kapteyn Laboratory, Groningen, The Netherlands.

mination seems desirable. For this purpose the intrinsic colors $(N-M)_o$ given by Borgman and Blaauw (1964) have been combined with the observed colors N–M to obtain the color excesses E_{N-M}. Line 12 gives $2.66E_{N-M}$, which is on the E_{B-V} scale as shown by Borgman and Blaauw. In the following, the color excesses $\overline{E_{B-V}}$ of line 13 are adopted; these are the mean values of the entries on lines 9 and 12.

Lines 14 through 17 of Table 1 contain Boggess' 2600A observations and some inferred quantities. F_{2600} is the observed flux in units of 10^{-9} ergs $sec^{-1}cm^{-2}A^{-1}$. The numbers are followed by a weight designation, of which the first figure is the number of observations and the second figure is a weight estimate based on the average quality of the observations. These weight estimates are intended only as a guide when evaluating the data; the relation with mean errors has not been considered. Line 15 gives the color index $m_{26}-V$, based on lines 1 and 14. Though not necessary for the present purpose, some attempt has been made to set the zero point of the color system at AO V. The range in spectral type among the six stars is quite small (09.5–B1); nevertheless the small corrections $\Delta(m_{26}-V)$ were computed in an attempt to remove the intrinsic color differences. Underhill's (1962) models, which were differentially calibrated in $(N-M)_o$, have been used for this purpose. The corrections on line 16 were obtained by interpolating between the models on the basis of the intrinsic colors of line 10 and adopting a zero correction for the intrinsically bluest star, ζ Oph. Hence, line 17 gives the color indices which would have been observed if each star had been intrinsically similar to ζ Oph. It should be pointed out that the corrections of line 16, being small in comparison to the range of m_{26}–V, have little influence on the final result. However, the intended improvement is probably not unrealistic in view of the accuracy of the present observations as well as the very satisfactory agreement between the observed flux and the theoretical atmospheric radiation field in the 2000–3000 Angstrom region (Strömgren 1964, Stecher 1964).

Lines 18 through 21 show the same steps in the reduction of the 2200A photometry as those described above for the 2600A observations. As in line 16, the corrections in line 20 are small.

Giving the same weight to each observation, the following least squares solutions have been derived:

$$^{(m}26^{-V)}\ \text{corr.} = 2.67\,\overline{E_{B-V}} - 2.80 \qquad (1)$$
$$\pm 0.34\ \text{(p.e.)} \quad \pm 0.08\ \text{(p.e.)}$$

and

$$^{(m}22^{-V)}\ \text{corr.} = 4.91\,\overline{E_{B-V}} - 3.12 \qquad (2)$$
$$\pm 0.25\ \text{(p.e.)} \quad \pm 0.06\ \text{(p.e.)}$$

Rejecting the only observation which is single (the 2600A flux of α Cam), solution (1) changes to

$$^{(m}26^{-V)}\ \text{corr.} = 3.33\,\overline{E_{B-V}} - 2.84 \qquad (3)$$
$$\pm 0.26\ \text{(p.e.)} \quad \pm 0.08\ \text{(p.e.)}$$

The uncertainty of the 2600A observation of α Cam is confirmed by the peculiar position of this star in the $^{(m}26^{-V)}$ corr.[9] $\overline{E_{B-V}}$ diagram, which may also be partly caused by uncertain intrinsic colors of this supergiant. We prefer to adopt solution (3) instead of (1). The last terms in each of the relations (1), (2), and (3) are the intrinsic colors of an 09.5V star. The probable errors do not include any zero point error of the color system.

An investigation of the color excess ratios $E_{V-I}/\overline{E_{B-V}}$ and $E_{V-K}/\overline{E_{B-V}}$, based on lines 5, 7 and 13 and the intrinsic colors given by Johnson and Borgman (1963) leads to the conclusion that the reddening law in the direction of ζ Oph and α Cam is probably the "normal" case, which results in $A_V/E_{B-V}=3.1$. The reddening of the other four stars is too small for an evaluation in this respect. It is not unlikely that some of the other stars are affected by an extinction law which is characterized by $A_V/E_{B-V}=4$ as appears to be the case for the most reddened region in the Scorpio-Centaurus group (Borgman 1964). However, the reddening of these four stars is small and the result of the reduction will largely be determined by the reddening of ζ Oph and α Cam. Hence, it is assumed that the reddening law derived from the six stars in Table 1 is essentially a "normal" one which can be represented in other wavelength regions by the Cygnus reddening law given by Johnson and Borgman (1963) (excluding the U-point where the adopted effective wavelength is subject to reconsideration), by the mean

reddening law of Borgman (1961), and by the statistical determination of $A_V/E_{V-B}=3.1$ (see *e.g.* Schmidt-Kaler 1961). These observational results are listed in Table 2 and are illustrated in Figure 1, together with Van de Hulst's dielectric grain extinction curve No. 15 (Van de Hulst 1949). Everything has been normalized to $A_V=3.1$ mag., corresponding to $E_{B-V}=1$ mag. It is evident that Van de Hulst's extinction curve fits the observations quite well to about 4000A but fails to explain the extinction at shorter wavelengths, particularly the new results at 2600A and 2200A. A better fit can probably be obtained with extinction models based on composite particles. A preliminary computation by Greenberg (1964) shows that this may indeed be the case for the carbon core-ice mantle grains suggested by Wickramasinghe (1963).

ORIGIN OF THE SOLAR SYSTEM*

A. G. W. CAMERON

The question of the origin of the solar system might for convenience be opened with ideas advanced by Descartes a little more than three centuries ago, just about the time the concept of the scientific method as a way of investigating nature was being formulated.

Descartes suggested that the solar system arose from a large vortex containing primitive matter, some going to form the Sun and some, involved in smaller eddies, going to form the planets and their satellites. Considering the state of knowledge of fluid dynamics and science three centuries ago, this was not a bad picture. It is not even grossly different from the picture that many of us have today.

Over the last three centuries, there have been two basic schemes suggested for the formation of the solar system. Each has had ups and downs. Why has this problem been with us so long, and so little progress made with it?

Most of the discussion in the last three centuries has tried to explain a very small number of facts—a few regularities in the solar system: The Sun rotates and the planets are in the same plane around the Sun, and so on. It all amounts to saying merely that the angular momentum vectors in the solar system tend to be aligned. Also, there does seem to be a regular increase in the spacing of planet orbits in the solar system, something that has been called the Titius-Bode law, if it is a law, and no one is sure.

Until recently, that is about all cosmogonists had upon which to base answers to the problem. It is only in the last decade that the solid base of facts needed to make some real progress has been built. This base has come partly from the intensive investigations of meteorites now going on, and from the chemical boundary conditions to the theories of the origin of the solar system that can be set from analysis of the chemical composition and mineralogical properties of meteorites. It has come from new techniques in astronomy, particularly radio astronomy, giving us great insight into the properties of planets and the Moon. And it has come from direct spacecraft explorations, particularly the Mariner flight toward Venus and the discovery that that planet does not have a magnetic field like the Earth's.

But, at the same time, the more discovered about the present composition and properties of the solar system, the more are the facts that need explaining, and the more difficult it is to do this.

Figure 1 (a) will help in reviewing briefly one of the two main ideas about the formation of the solar system. First, there is the idea, about two centuries old, and very popular early in this century, that there was a close passage of two stars that raised huge tides and pulled out filaments of gas. In some way the planets were to have condensed out of the filaments. It is now fairly certain that nothing like this happened, for a variety of reasons. Spitzer, for example, has shown that gas drawn out of a star in this way would be so hot that solids would not condense from it, but the gas would disperse in space instead. Moreover, Lyttleton showed that most material drawn out from a star in this way—more than 99 percent of it—would fall back on the star. Perhaps most important, it is now fairly certain that the Sun cannot contain any appreciable amount of deuterium; it would all have been destroyed by thermonuclear reactions early in its history. But quite large amounts of deuterium, relatively speaking, do occur in the Earth. It cannot have once been in the Sun. Why should other planetary constituents have been?

*Published in *Astronautics & Aerospace Engineering*, August 1964.

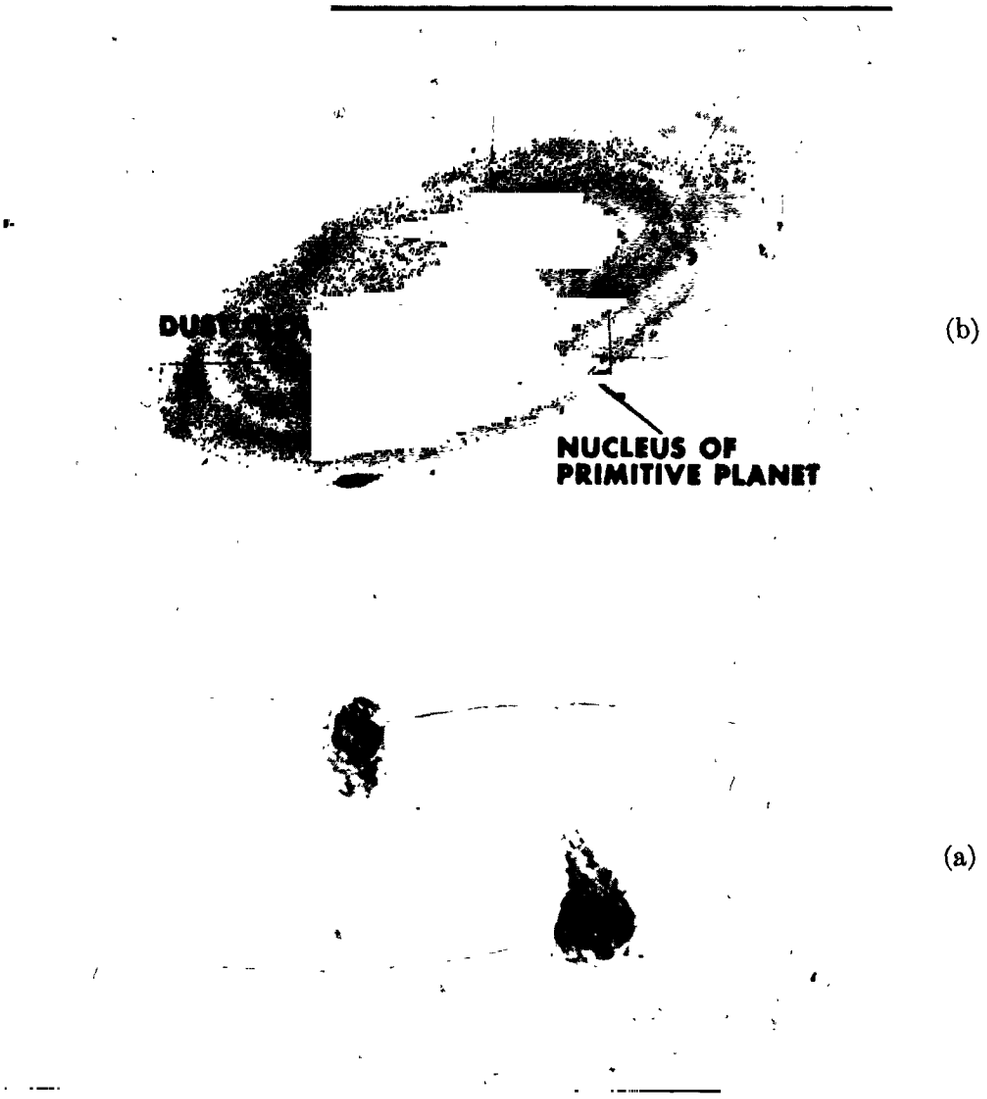

FIGURE 1.—The "fried egg" concept of formation of the solar system (b) is believed generally today, while the once popular supposition that filaments of gas became planets after an encounter of two stars (a) is considered unlikely.

What of the other idea? Figure 1 (b) shows the fried-egg concept which I think most of us tend to believe today, in some form or other, and which is essentially the picture Descartes introduced three centuries ago. There is some sort of a primitive nebula of gas and dust surrounding the Sun, formed as a part of the process which generated the Sun itself.

Figure 2 shows a typical spiral galaxy. Seen in color, the light from the center is reddish, and the light from the distant parts of the disk is bluish. This color difference indicates that the stars in those different parts of the galaxy have quite different characteristics. The reddish color comes from rather old, red giant stars in the central portion of galaxies of this sort, and the blue light from young stars with high surface temperatures.

The outer, bluish stars evolve quite rapidly through their thermonuclear history, and live only a few million years. However, presence of the central red giant stars indicates that the galaxy has been around for a few billion years at least. Thus there is evidence that star formation continues in the outermost parts of the disk in this kind of galaxy, in the region of young stars, where we find the Sun in the Milky Way.

We are beginning to know something about the age of our own galaxy from the study of how stars

FIGURE 2.—Light on the age of our own galaxy is being shed by studies of typical spiral galaxies such as this. When seen in color, light from the center is reddish and that from distant parts of the disc has a blue hue, indicating characteristics of stars in various areas of the galaxy.

have evolved in the star clusters of the Milky Way. Its age seems at least 10-billion years and perhaps as much as 25-billion; say, nominally, 15-billion—much older than the age of the Earth and the meteorites and, presumably, the solar system as a whole, which only goes back some 4½-billion years.

Because the galaxy is much older than the solar system, and because we would expect that star formation should take place much more rapidly in the early stages of the history of our galaxy than at the present time, it is fair to postulate that the conditions in the disk of the Milky Way at the time the Sun was formed were certainly not qualitatively different, and perhaps only slightly different quantitatively, from what we see in space today.

Consider the gas between the stars in the Milky way out of which new stars would have to form. This gas is being continually replenished from the evolution of older stars. There may be some still remaining from the very earliest days of our own galaxy that never formed into stars. But, at any rate, there is certainly a replenishing going on, for instance, through supernova and the less-catastrophic nova explosions. Moreover, some stars throw off continuously a great deal of mass as a very intense stellar "wind." We can look at the regions in our own galaxy where we see very massive hot stars. Because these stars live for such a short time, just a few million years, we know that where we see them must be the position, or very close to the position, where they formed.

Figure 3 shows the Orion Nebula, revealing some details of its structure. In particular, it exhibits patchiness due to dark absorbing regions which are quite inhomogeneously distributed. This is important. The gas, which presumably has to condense to form stars, shows quite large fluctuations in density.

FIGURE 3.—This revealing photo of Orion Nebula shows fluctuation in density of gas, which presumably has to condense to form stars.

There are, then, regions of gas in space having variation in density. The average density overall of the galactic plane is probably about one particle per cubic centimeter. But a typical interstellar cloud may have a density of 10 particles per cc. The upper extreme observed for the particle density in some clouds can be of the order of 1000 particles per cc.

When considering what conditions must be satisfied for gas to become gravitationally unstable and condense, or collapse, to form stars, it is necessary to compare the gravitational potential energy of such a cloud with its internal thermal and magnetic energies. The collapse can take place only if the gravitational potential energy, intrinsically a negative quantity, becomes sufficiently greater than the positive internal energies.

When conditions are attained under which that can take place has been a puzzling question, and has led to different approaches to the subject. These different approaches, in turn, have led to different suggestions as to the primitive solar nebula.

One important approach takes the following tack. Hoyle, Fowler, Greenstein, and others look for cloud complexes large enough to exhibit the necessary gravitational potential energy for collapse. This generally requires some 10^5–10^6 solar masses of material becoming gravitationally unstable and starting to contract as a whole.

Such a region of space, a complex of clouds of gas in space, cannot contract very far before it starts running into difficulties that prevent it from contracting further. One of these may be the magnetic energy contained within it. But a more probable one is the rotation that the cloud possesses.

It is thought that some sort of a general magnetic field exists in space, and that this field's lines of force are reasonably well glued to the material in the cloud. Even in a cloud where the hydrogen and the helium are neutral, starlight keeps such atoms as carbon ionized all the time. These ions will then stay with the lines of force, and the friction of the neutral atoms with these ions will tend to keep the entire mass of the cloud glued to the magnetic lines of force.

So the magnetic field in space can exercise some control over such a large cloud. It probably exerts one main control by requiring the cloud to rotate once during the time it makes one revolution around the center of the galaxy. For the distance of the Sun, that would take about 200-million years.

The rotation may be a bit larger than that, or a bit smaller; but as long as the magnetic field exercises any reasonable degree of control, it cannot be even one order of magnitude different. The conservation of angular momentum will cause the cloud complex to spin more rapidly as it contracts, and the contraction will be halted when the centrifugal force at the equator becomes equal to the gravitational forces.

For this cloud complex to contract further, rotation must twist the lines of force of the general interstellar magnetic field, and in this way transmit angular momentum from the cloud to the surrounding regions. This action will slow the rotation and allow a further contraction of the cloud.

After some period, and the removal of a great amount of angular momentum, the cloud can shrink by a large factor, and small parts of it become unstable toward separate gravitational contraction. Density fluctuations should exist in such a cloud complex and it should fragment into smaller and smaller sub-units, eventually getting down to fragments about the order of one solar mass.

According to the other general point of view, which I advocate, the optimum condition for obtaining the contraction of an initial interstellar cloud does not involve a large cloud complex, but rather a typical cloud, which may have a mass of the order of 1000 solar masses. Assuming this typical cloud, one can calculate that it becomes gravitationally unstable when the density becomes as high as something like 1000 particles per cc—the highest density which is actually observed in space. Such a high density, it should be expected, can only be formed by sliding the material along the lines of force of the interstellar magnetic field. Otherwise, the internal magnetic pressure would be so high that at a density of 1000 particles per cc the cloud would immediately expand to a much smaller density.

When such a cloud becomes gravitationally unstable, difficulties concerning rotational instability tend to disappear, and there is no need to invoke a transmission of angular momentum from

the cloud to the surroundings to bring about a collapse to quite small dimensions and a fragmentation into units of the order of the Sun in mass. Furthermore, collapse takes only about 1 percent of the time it would have taken in the initial state to go through one revolution. So there is in fact no opportunity to twist the lines of force sufficiently to transmit angular momentum to the surroundings, and it is necessary to conserve the initial angular momentum all the way down.

What, then, is the state of the fragment of about one solar mass, the ultimate unit which can result from this general contraction of the cloud in space?

In the picture he put forward, Hoyle assumes sufficient loss of angular momentum to cause his ultimate fragments to contract down as far as about the orbit of Mercury before they start spinning rapidly enough to shed mass in the equatorial plane. Continuing to contract, the Sun would shed more and more mass in the equatorial plane, its initial magnetic field being retained to some extent within the material as it shrank, but linking the gas in the equatorial plane of the Sun to the central body. As the central body shrinks, it spins more and more rapidly, and thus tends to get ahead of the gas in the equatorial plane, which is going around with Keplerian orbital motion. The magnetic linkage acts to spin more rapidly the material shed in the equatorial plane, giving it more angular momentum, and so causing the material to go farther and farther away from the central body itself. In this manner the material in the nebula formed inside the orbit of Mercury eventually passes over the entire region now occupied by the solar-system's planets.

This view of the development of the planets, proposed by Hoyle in conjunction with Fowler and Greenstein, requires that small bodies will chemically condense out of the gas shed in the equatorial plane and accumulate to planetesimals of some tens of meters in dimension. And eventually these "metric planetesimals," as they call them, will accumulate to form the plants.

The inner planets, they explain, form largely out of metals and silicate material—much the sort of thing now observed—because they believe that the first objects to grow and accumulate in space should be the bodies that condense out at the highest temperatures. Then, as the gas goes farther and farther out in space, it drops icy materials—H_2O, NH_3, CH_4—and eventually, by the time the gas has gotten to the outskirts of the solar system, the general region of Uranus and Neptune, the remaining material, mainly hydrogen with some helium, may tend to exaporate into space, or, as Gold has suggested, be blasted out by streams of particles from the Sun.

The other principal feature of the ideas put forward by Hoyle, Fowler, and Greenstein is that during the time that the objects have dimensions of the order of some tens of meters, the Sun exhibits considerable magnetic activity, due to its linkage with the solar nebula, which it is pushing farther and farther away into space. This causes very intense flares, accelerating particles to hundreds of millions of electron volts. These particles intensively bombard the surfaces of the metric planetesimals, thus producing some interesting nuclear effects, such as the lighter elements—the deuterium, lithium, beryllium, and boron—that one finds in the solar system, as well as producing certain isotopic variations observed in meteorites and the Earth. It becomes a very complicated story.

A contrasting view to all this involves my own hypothesis. It starts with a smaller cloud in space, one unable to get rid of any angular momentum. A typical fragment that arises from its contraction will tend to become rotationally unstable at dimensions of the order about 100 AU—quite a bit larger than the dimensions of the solar system. When this object contracts further; it forms a disk of gas only, with no body at the center in hydrostatic equilibrium—that is, no central body to be the Sun.

Given such a primitive disk, how does the solar system form? Here again, we must rely in some way on the magnetic field which spreads through the interstellar medium to begin with, and which has been trapped in the material as the body has shrunk out of space. As there is still a fairly strong density concentration toward the center of the nebula, the material moving about the center of the mass has a shear. Adjacent layers thus tend to go at different speeds, pulling out the lines of force of the magnetic field, so that they lie more and more parallel to the direction of the shear. This squeezes the lines of force together, making the magnetic field stronger, and thus containing more energy.

The energy has to come from somewhere. Since the shearing motion is pumping energy into the magnetic field it has to come at the expense of the shearing motion itself. But the shearing motion in turn depends entirely on the mass distribution in the primitive disk, and the only way in which energy can come from the shear is to redistribute the mass in disk. This would require that most of the matter in the disk flow inward, and some at the outer edge of the disk of course flow outward so that the disk as a whole conserves its angular momentum.

How the Sun would form seems fairly clear. But the only chance to form the planets in this picture comes before there is much redistribution of mass; for the motion of the gas inward to form the Sun—no matter how long it takes, a million years, or what have you—will draw with it all of the little solids, unless they have grown into a large enough body to withstand such motion.

How large must such bodies be to withstand inward movements? It turns out that in the inner part of the solar system they have to be larger than the largest asteroids.

This disk, on the other hand, very clearly has chemically condensed-out material to the extent of at least a hundred times the mass of the present planets. So the planets need not represent a very efficient collection of solid debris in this massive primitive solar nebula. It is only necessary to get 1 percent of the material into the form of planets. So we are interested in a very inefficient method of accumulation. And presumably the great bulk of the material does not grow into bodies at least asteroidal in size.

Accumulating bodies in space presents an extremely difficult problem. If very small bodies come together gently enough, then it may be that they can adhere one to another. The presence of a thick solar nebula can greatly assist such an accumulation process. But take the gas away and let the bodies start colliding with an appreciable relative velocity, and there will tend to be a general shattering and diminishment of bodies rather than an accumulation

There are a number of other points that one might discuss in connection with either of these theories; and they have been discussed in depth in special conferences. Aside from any potential correctness, they have served as grounds for experiments, and in particular have defined some particular things to look for in the scientific investigation of the Moon and the planets.

Earth, of course, presents a disconcerting problem. Its surface record goes back only about 3-billion years, only about two-thirds the age of the Earth. There can be no first-hand investigation of the home planet in its formative stages, only a surmising. And clever theory will not substitute for direct observations in shedding light on the origin of the solar system. We must go to the Moon and to the asteroids and the other bodies in space, particularly the smaller bodies, before we can really try to pin down how it all happened.

GRAVITATIONAL COLLAPSE*

HONG-YEE CHIU†

With the exception of a few supernova remnants which are in our galaxy, most cosmic radio sources are "radio galaxies." Although flare stars do emit radio waves occasionally, no ordinary stars with strong, steady radio emission have been found. The typical optical power of stars is from 10^{30} ergs/sec (white dwarfs) to 10^{38} ergs/sec (super giants). For comparison, the optical power of the sun is 4×10^{33} ergs/sec. The typical radio power of supernova remnants is around 10^{36} ergs/sec. For a giant galaxy (containing approximately 10^{11}–10^{12} stars with a total mass of around $10^{11}\odot$, where $\odot$ = solar mass = 2×10^{33}g), the optical power is around 10^{44} ergs/sec. Radio emission from normal galaxies is generally weaker, the power ranging from 10^{37}–10^{39} ergs/sec. For certain peculiar galaxies, the so-called "radio galaxies," the radio emission rate ranges from 10^{41}–$10^{44.5}$ ergs/sec.

However, since 1960, another kind of strange object has been found — "quasi-stellar radio sources"; these formed the center of discussion at the symposium. Their radio power is around 10^{44} ergs/sec and their optical power is around 10^{46} ergs/sec, *which is 100 times the total energy output rate of a giant galaxy!* To date nine of these objects have been found. On photographic plates, these peculiar radio sources have star-like appearances, and one of them showed erratic light variations with a time constant of the order of one year and a long-term quasi-period of ten years. A modest estimate of the total energy content of each of these objects (in the form of the kinetic energy of electrons of 1 BeV energy) gives a minimum of 10^{60} ergs, which is the *rest energy* of about 10^{6} suns.

Are "quasi-stellar radio sources" stars? Ordinary stellar-structure theory precludes stars of mass greater than 100$\odot$. In such stars, radiation pressure dominates and because of the thermodynamic properties of radiation, these stars will pulsate with large amlitudes as a result of this pulsation, mass will be ejected, thereby reducing the mass of the star. Are "quasi-stellar radio sources" galaxies? Their angular size is less than 0.5″, while normal galaxies at corresponding distances (determined by their red shift) will have an angular size of the order of 3″. In several cases, the light variation precludes this possibility because galaxies do not have light variations.

So far, the clumsily long name "quasi-stellar radio sources" is used to describe these objects. Because the nature of these objects is entirely unknown, it is hard to prepare a short, appropriate nomenclature for them so that their essential properties are obvious from their name. For convenience, the abbreviated form "*quasar*" will be used throughout this paper.

The idea of having a meeting on gravitational collapse came after the discoveries of the enormous energy output of quasars and the subsequent gravitational-collapse theory of F. Hoyle of Cambridge University and W. A. Fowler of the California Institute of Technology to explain this enormous energy output. When the symposium met, the original hypothesis of Hoyle and Fowler (reviewed at the meeting by E. M. Burbidge of the University of California at La Jolla) was abandoned and was replaced by those to be reported later. Meanwhile, new observational data had been accumulated and were presented at the meeting. It seems safe to say that, at the present time, the interior structure and the physical mechanism of the energy production of quasars are still not understood.

Fusion of hydrogen into heavier elements will yield an energy of about one percent of the rest energy of matter. If the energy source of the quasars were nuclear in nature, it would be necessary that $10^{5}\odot$ of hydrogen be burned in around 10^{8} years. It is rather unlikely that nuclear energy could be released in unison on such a large scale. Moreover, nuclear reactions usually take place in the interior of a star; the energy released gradually diffuses out, and finally is radiated thermally as black-body radiation, peaked at an energy of around 2 eV. How can the energy of electrons be elevated from a few eV to a few BeV without violating the second law of thermodynamics? Using the most efficient thermodynamic cycle, a nuclear-energy source many orders of magnitude higher is needed[8] Therefore, there is only one energy source left for us to consider: gravitational energy. Incidentally, the gravitational field is the weakest field in nature, but it is the only one that allows us (at least theoretically) to extract up to 8/9 of the rest energy of matter.

After this brief introduction to the central theme of the discussions, I shall now report the individual papers that were presented at the symposium. In order to have continuity in this report, I shall not report the talks chronologically, but in a logical manner.

Reviewing the common properties of radio sources, T. Matthews of Caltech pointed out that radio emission from normal galaxies is rather weak compared with their optical emission. Their radio power is around 10^{37-39} ergs/sec while their optical power is around 10^{44} ergs/sec. Some rare, peculiar spiral galaxies may have a radio emissive power of around 10^{40} ergs/sec. Strong radio galaxies with a radio power of 10^{41-44} ergs/sec are most frequently found among the so-called D systems. These are galaxies with excessively bright nuclei (Seyfert galaxies). Some strong sources are also identified with elliptical galaxies. The optical emission rate of quasars is around 10^{46} ergs/sec and their radio emission rate is around 10^{44} ergs/sec. (See Fig. 1 for a plot of radio and photographic magnitudes of galaxies and quasars.)

To date, a total number of nine quasars have been identified from the contents of the revised 3C catalogue (3C stands for the *Third Cambridge Catalogue of Radio Sources*) which contain about 470 radio sources, many of them still unidentified optically. This catalogue was compiled by a group working under M. Ryle of the University of Cambridge. The two quasars which have been extensively studied and which were extensively discussed at the meeting have catalogue numbers 3C273 and 3C48 respectively.

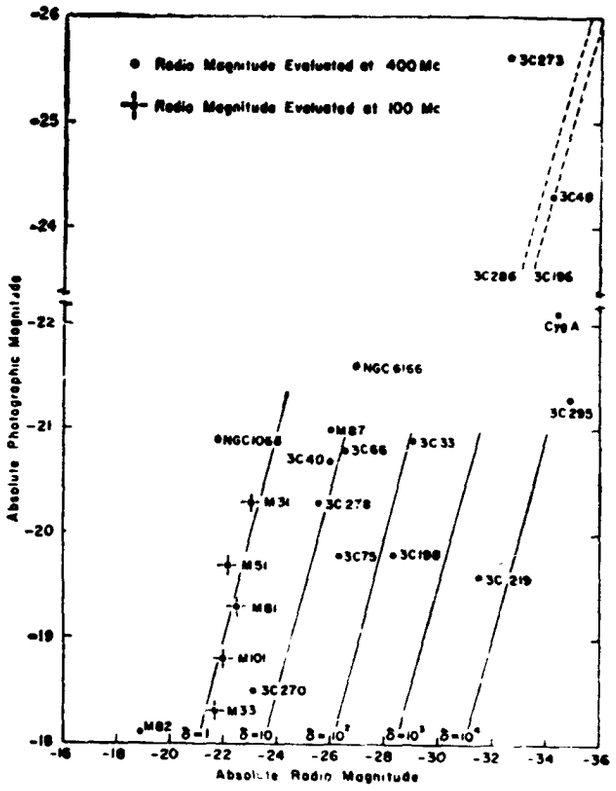

FIGURE 1.—Above, a plot of absolute radio magnitudes and absolute photographic magnitudes of galaxies and quasars. The absolute photographic magnitude, a measure of the optical power, is defined in the footnote on p. 22. The absolute radio magnitude M_r is defined to be $M_r = -54.1 - 2.5 \log_{10} S$ where S is the radio power in watts per second per cycle bandwidth at 400 Mc/sec, with the exception of a few normal galaxies where S is evaluated at 100 Mc/sec; δ is the ratio of radio power to optical power normalized to unity for normal galaxies. Other radio galaxies have a value of δ up to 10^4. Quasars 3 C 273 and 3 C 48 are found in a region in the graph where no galaxies are found. The distance of two other quasars (3 C 286 and 3 C 196) have not been determined and their possible position in this graph are indicated by the dotted lines. The sources of data used here are references 1 and 2.

Radio interferometers with a resolution of the order of 1″ of arc were first used to study the shape of some of the stronger quasars. This method also enables one to locate accurate positions for these sources. This was done chiefly by the

Manchester group (R. P. Allen, B. Anderson, R. G. Conway, H. P. Palmer, V. C. Reddish, and B. Rowson) and by the Caltech group (P. Maltby, T. A. Matthews, and A. T. Moffet). In the radio position of 3C48, an object resembling a 16^m star was found on the photographic plates.* This "star" was surrounded by a nebula measuring $5'' \times 12''$ which does not resemble any galaxy. (See Fig. 2.)

FIGURE 2.—Below, an actual photograph of 3 C 48 (shown in enlarged image at upper right). Objects D and B are reference stars from which the magnitude of 3 C 48 is determined. A faint nebulosity can vaguely be seen. (Photo by T. A. Matthews and A. R. Sandage taken with Hale Telescope, Mt. Palomar, Ref. 3).

At the same time, lunar occultation observations of 3C273 were carried out by the Australian group (C. Hazard, M. B. Mackey, and A. J. Shimmins). This other method of observation provided an optical identification for 3C273. Because of gravitational perturbations, the orbital plane of the moon is not fixed in space but precesses with a period of around 19 years. Thus, the moon, with an angular size of 30 minutes of arc, can occult stars within a belt of 20° as it moves around the earth. When a radio source is occulted, one can learn from the diffraction pattern about the location, shape, and size of the radio source. Fig. 3 shows some observed diffraction patterns of 3C273. In particular, it is easy to tell if a source is an extended one. It was found that 3C273 consists of two sources, *A* and *B;* their separation is $19.5''$ (see Fig. 4). Component *B* is slightly elliptical and four times weaker than component *A*. Using the $200''$ Hale telescope, A. Sandage of Mt. Wilson and Palomar Observatory obtained photographs which show, at the radio position of *A*, a nebula shaped as a jet, pointing away from a 13^m star-like object which is identified as component *B*. One of Sandage's photographs appears in Fig. 5.

Radio spectra for both components of 3C273 and for 3C48 have been obtained. Briefly, the mechanism for radio emission and the nature of radio spectra can be described in the following way. The optical radiation of stars and nebulae is chiefly emitted by thermally excited ions. The spectra of stars and nebulae are rich in absorption or emission lines; their over-all features can be understood in terms of black-body radiation peaked around certain optical wavelengths. The radio spectra that are normally observed can be broadly classified into two categories: thermal and synchrotron emission. In the thermal spectrum, the intensity per unit frequency increases towards shorter wavelengths for emission from "optically thick" emitters. This kind of spectrum resembles that of the long-wavelength end of a black-body thermal radiation, hence its name. Most likely it is produced by electron bremsstrahlung, which occurs when electrons pass very near ions. In the synchrotron spectrum, the intensity decreases towards the shorter wavelengths, and usually the intensity per unit frequency is proportional to $\nu^{-\alpha}$, where ν is the frequency and α is a positive number usually between 0.3 and 1.2 (for most sources, α has a value of around 0.8).

The paths of electrons in a magnetic field are not straight lines but curves. Hence these electrons suffer acceleration while traveling on a

*Superscript *m* stands for the magnitude; $m = -2.5 \log_{10} F + C$ where F is the observed energy flux and C is a constant. At a distance of 32.5 light years the sun has a magnitude of +4.85. This is also the distance at which the absolute magnitude of an object is defined. A 6^m star is just barely visible to the eye. A difference of 5 magnitudes amounts to a difference in measured energy flux of 100.

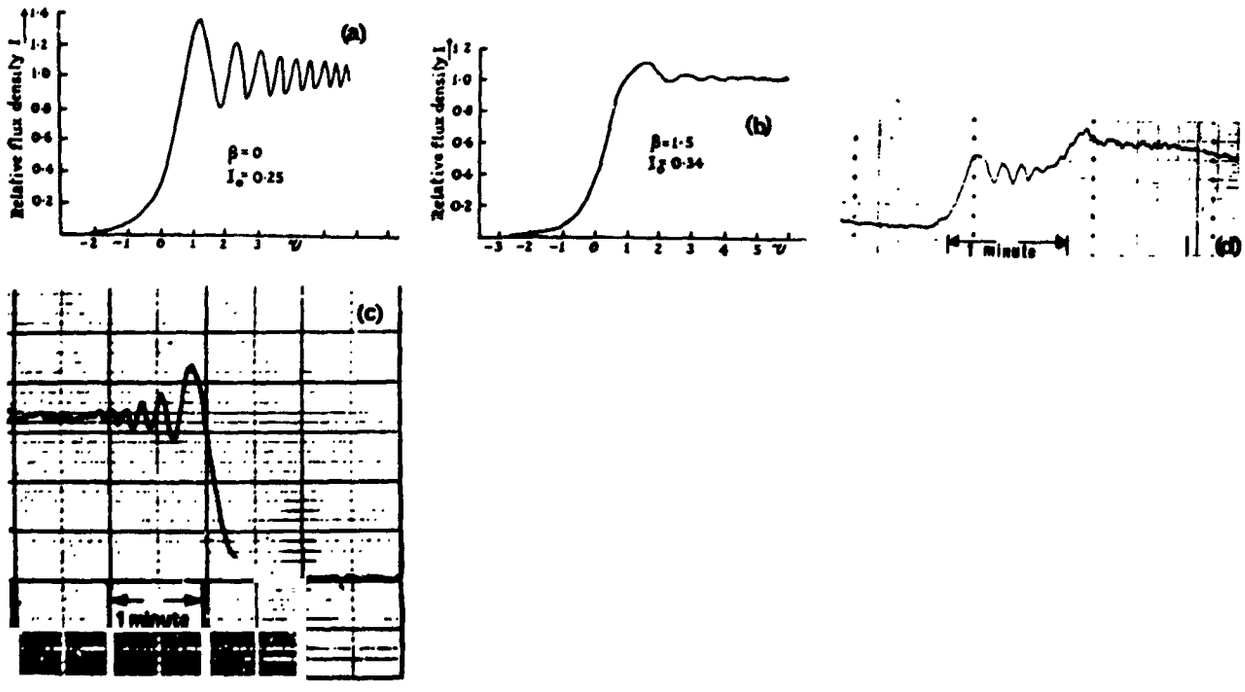

FIGURE 3.—Intensity observed as function of time in lunar occulation: (a) shows diffraction pattern calculated for a point source; (b) shows that of an extended object. Note decrease in amplitude for an extended object. Angular diameter w is related to β by $w=\beta/(C\lambda/2d)^{\frac{1}{2}}$ where λ is the wave length and d the distance to the moon; v is proportional to the time; $v=0$ corresponds to the geometrical shadow. An actual emersion diffraction pattern of 3 C 273 at 410 Mc/sec on August 5, 1962, is shown in (c). Note the similarity to that for a point source (a). Immersion diffraction pattern of October 26, 1962, at 1420 Mc/sec, is shown in (d). Note resolution of 3 C 273 into point source and extended source (Ref. 6, 7).

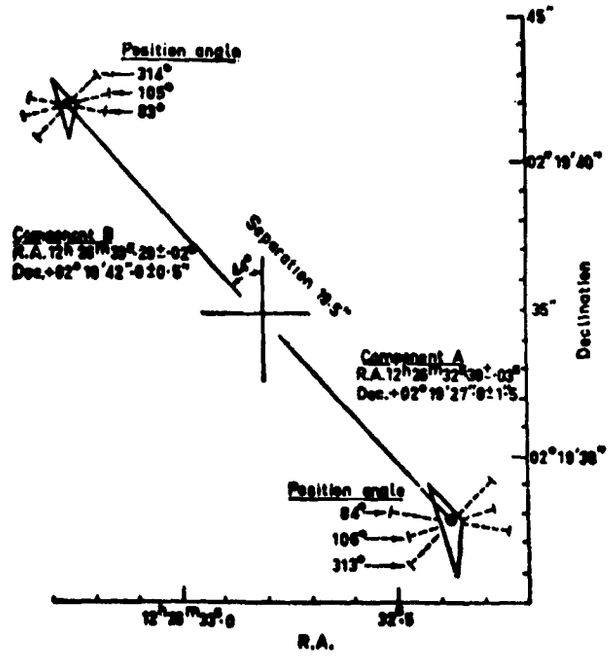

FIGURE 4.—Diagram of the radio source 3 C 273. Sides of full triangles represent widths of equivalent strip source as measured at 410 Mc/sec for each of three position angles indicated (Ref. 6).

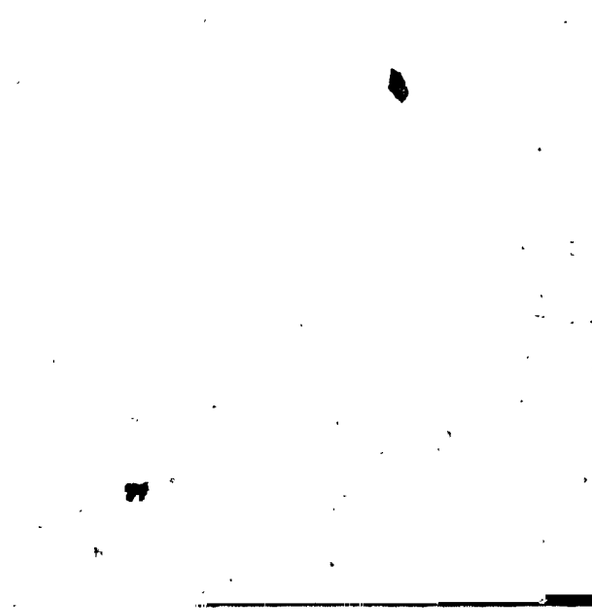

FIGURE 5.—Photograph of 3 C 273. Note the jet which points away from the starlike object. Although its distance is 1.8×10^9 light years, this object is easily seen through an amateur's 6-inch telescope. (Photo by A. R. Sandage with Hale telescope at Mt. Palomar.)

curved path. These "accelerated" electrons then radiate polarized electromagnetic waves, primarily in the radio region. Such radiation from monoenergetic electrons was first observed in electron synchrotrons, hence the name synchrotron radiation. The observed cosmic-ray spectrum is usually

$$N(E)dE = E^{-k}dE$$

where $N(E)dE$ is the flux in the energy band dE and k is a positive number; $k = 1.5$ for high-energy cosmic-ray particles. We may assume that the relativistic electron component of cosmic rays also obeys this law. Then the synchrotron radiation intensity per unit frequency is proportional to $\nu^{-\alpha}$.

The radio spectrum of 3C273 shown in Fig. 6 is a composite of the two sources A and B, and can

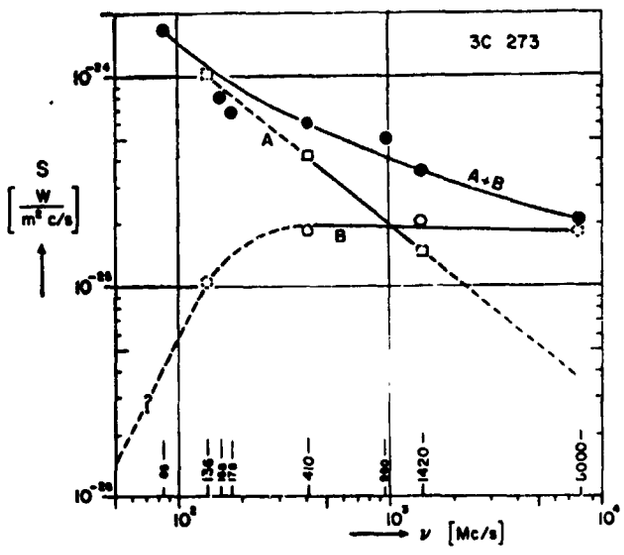

FIGURE 6.—Radio spectrum of 3 C 273. Black dots are measurements of both components. Squares give spectrum of component A; the open circles of component B. The line through the open circles shows how one could fit a thermal spectrum to it. But this interpretation seems highly unrealistic. (Courtesy of W. Priester.)

be resolved as indicated. This resolution was obtained from lunar occultation observations. The spectrum of A seems to belong to the synchrotron type, and that of B to the thermal type. However, this interpretation of the observed spectrum of source B would require a temperature of the order of 10^9 °K. Such a high temperature contradicts the lifetime estimated by present theory.

The optical spectrum of 3C48 has also been available for some time. Several emission lines were found, but no unequivocal identification with lines of known atoms or ions could be made. Moreover, J. Greenstein of Caltech found that the spectra of some fainter quasars, 3C147, 3C196, and 3C286 (also showing somewhat weaker emission lines), looked quite different from that of 3C48.

M. Schmidt studied the spectrum of the bright object, 3C273. He found four emission lines which formed a simple harmonic pattern with separation and intensity decreasing towards the ultraviolet. This series of lines looks like that of any hydrogen-like atoms. Unfortunately, they correspond to no elements found on earth. A unique interpretation can only be made by assuming a red shift ($\Delta\lambda/\lambda$) of 0.16 and that the emitting element is hydrogen. (A far greater red shift has to be assumed if the emitting element consists of other hydrogen-like atoms.) Indeed, with this interpretation, a red-shifted Hα line (shifted from 6563A to 7590Å) was found in the infrared by J. B. Oke of Caltech. Similarly, the line spectra of all other quasars can be interpreted as red-shifted emission lines and forbidden lines. In 3C48 the emission line identified corresponds to that of [Mg II] and the forbidden lines to those of [O II], [Ne III], and [Ne IV]. In 3C48 the red shift is 0.37. The corresponding velocity (if the red shift is interpreted as the Doppler shift) is around 0.15 c and 0.3 c for 3C273 and 3C48, respectively.* Fig. 7 shows the red-shift interpretation of a number of quasars.

Another feature of quasars is that they show a strong ultraviolet excess even at a red shift of $\Delta\lambda/\lambda = 0.8$. Using filter techniques, A. R. Sandage and M. Ryle have successfully identified a few more quasars (3C9, 3C216, 3C245) from a number of objects showing strong ultraviolet excess.

Could quasars be stars in our galaxy with a high receding velocity? This is extremely unlikely. First, the gravitational field of our galaxy cannot retain stars with a velocity $> 10^{93}\,c$. Second, the proper motion (apparent motion of stars with respect to background stars) would appear

*The Doppler shift is $d\nu/\nu = (-\nu/c)\ (1-\nu^2/c^2)^{-1/2}$, where ν is the relative velocity of the source and the observer. For the same velocity most cosmological theories predict a shift $d\nu/\nu$ in between $(-\nu/c)\ (1-\nu^2/c^2)^{-1/2}$ and $-\nu/c$ (linear).

large compared with other stars of much smaller velocity.

W. H. Jefferys of Wesleyan University (Connecticut) studied the proper motion of 3C273. Since 3C273 is fairly bright, its image was found among many sky-patrol plates dating back to 1888. Plates from many observatories using different telescopes, accumulated over the past fifty years, were used to determine the proper motion.

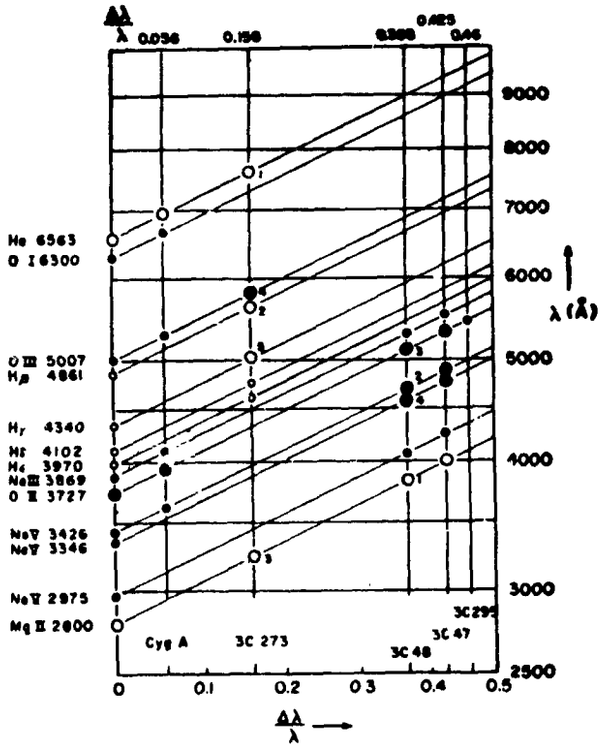

FIGURE 7.—Schematic spectra of 3C 273, 3C 48, and 3C 47 together with Cygnus A and 3C 295. The ordinate is the red shift $\Delta\lambda/\lambda$. Forbidden lines are represented by black dots. The numbers underneath the dots indicate the relative strength of the lines, number 1 being the strongest line in the spectrum. (Courtesy of W. Priester).

The inertial system used is the so-called FK3 system. This refers to a group of more than 900 stars catalogued in the *Dritter (Third) Fundamental-Katalog des Berliner Astronomischen Jahrbuchs* (Kopff, 1934) with the highest precision then available.* The measured proper motion of 3C273 is 0.001 ± 0.0025 seconds of arc per year. The standard deviation is from uncertainties associated with the accuracy of the absolute position of stars in the FK3 system. From the value of proper motion and the velocity derived from the differential rotation of our galaxy, the distance of 3C273 is $>65\,000$ light years, and this puts 3C273 on the border of our galaxy (the size of our galaxy is 10^5 light years). A similar result was also obtained by W. J. Luyten of the University of Minnesota, using more recent plates.

Can the red shift be gravitational in nature? The red shift of light from a self-gravitating body of radius R, mass M, is of the order of $GM/Rc^2 = 10^{96}(M/\odot)(R/R_\odot)^{-1}$. ($R_\odot$ = solar radius $= 7\times10^{10}$ cm). In order to have a red shift as large as 0.1, $(M/\odot)(R/R_\odot)^{-1} \approx 10^5$. For a star of one solar mass and an $R \backsim 10^6$ cm, a density of about 10^{15} g/cm^3 would be required. (E. E. Salpeter of Cornell University reviewed the equilibrium configuration of superdense stars. It is not possible for superdense stars of mass $>>\odot$ to exist, nor can the red shift of light from superdense stars exceed 0.3.) The presence of spectral lines implies a surface temperature of the order of 10^4 °K. From the radius of superdense stars, one can estimate the total radiative power, and thus deduce the distance from the observed flux. If 3C273 were a superdense star, its distance would be 0.3 light years and it would be practically inside our solar system! From the intensity of the forbidden lines J. Greenstein further concluded that the distance would be even smaller. Such stars would have been discovered by Kepler through the failure of Kepler's laws!

One may also assume that quasars have bigger masses and bigger radii than superdense stars. For example, one can assume that 3C273 is a star at a distance of 1000 light years. In order to be compatible with the energy output rate, the radius has to be 10^{13} cm. Then, in order to account for the red shift, the mass has to be $10^7\ \odot$! W. A. Fowler pointed out that such stars cannot even burn hydrogen, because they would fall within their gravitational radius before the temperature would be high enough (10^7 °K) to burn hydrogen!

D. Williams of the University of California at Berkeley reported the observation of interstellar absorption lines in 3C273. When radio waves of distant galaxies reach us, part of the energy at the 21-cm wavelength is absorbed by hydrogen in our

*Recently, the FK 4 Catalogue, containing more than 1,500 stars, has been published.

galaxy. A very weak 21-cm absorption line was found in the radio spectrum of 3C273 with a line shift corresponding to a velocity of 1 km/sec ± 10km/sec. This effect, however, is very marginal.

Since no other rational interpretation can be given to the red shift, one can only attribute it to the cosmological red shift. Using Hubble's law, the distance of 3C273 is placed at 1.8×10^9 light years. This gives an energy output rate for 3C273 of 10^{46} ergs/sec at optical frequency. Some people will question whether Hubble's law is well established. Hubble's law states that the distance of galaxies to us is linearly related to their red shift:

$$\text{Distance} = \frac{\text{Recession velocity}}{H}$$

The proportionality constant $H(\approx 100\text{km-sec}^{-1}\text{-megaparsec}^{91})$* is known as Hubble's constant. $H^{-1}c$ is a measure for the dimension of our universe; at a distance $\approx H^{-1}c$ the red shift is total. One often hears that astronomical observations are not accurate enough to distinguish one type of cosmological theory from another, and many have expressed doubts about applying Hubble's law to obtain the distances of unknown objects from their red shift. The answer is that these two problems are somewhat different in nature. Assuming that the local density of galaxies is the same throughout the universe *at a given time* and that the curvature of the universe is everywhere constant, different cosmological theories will predict different galactic densities as a function of the distance (this galactic density is observed from a single space-time point) and the distance is obtained from the red shift by the above equation. The galactic density observed at a single space-time point would be different for different cosmological theories because of the expansion of the universe, and because the expanding rate as a function of the distance is different in different theories. Unfortunately, the various cosmological theories predict measurable differences in galactic densities only at distances much beyond the reach of the world's most powerful telescope—the 200″ Hale telescope at Mt. Palomar. Hubble's law, however, is established accurately for neighboring galaxies by applying knowledge of the period-luminosity relation of Cepheid variables. (Cepheids are bright variables of luminosity $\backsim 10^5\ L_\odot$, and their period is related to their luminosity by a simple law. Hence, by observing the period and the apparent brightness of Cepheid variables of other galaxies, one can obtain a distance.) Then the absolute brightness of more distant galaxies is related to the red shift through a complicated statistical analysis eliminating the difference in intrinsic luminosities of individual galaxies. The result is a law that can be trusted to within a factor of 2 in distance estimates. Hence we believe that Hubble's law may be applied to quasars to obtain their distance accurately.

H. J. Smith of McDonald Observatory took a bold look at quasars. Is there light variation in these objects? Sky-patrol plates from Harvard University Observatory are available back to 1888. Although a large number of old plates have aged and become unreliable, some of them are still in fairly good condition. In measuring light variations, one only needs to compare the image of 3C273 with neighboring stars. Smith and D. Hoffleit of Yale found a large light variation with an amplitude up to 50 percent and a quasi-cycle of fifteen years (see Fig. 8). A. R. Sandage observed 3C273, 3C48, and 3C196 more recently with a photoelectric device and found some erratic variations up to a few tenths of a magnitude. From statistical theory, if 3C273 were a galaxy with a nominal number of stars ($\backsim 10^{10}$), the expected annual variation would be much less than 10^{-5} of the variation of any star. This limit is obtained by assuming that all stars in the galaxy are variables of the same period. Hence it is not possible that 3C273 and other quasars are compact galaxies. Further, in order that the light from such an object can vary with a time constant $\backsim$ 1 year (the shortest variation observed), the physical dimension of 3C273 cannot be much bigger than the time it takes light signals to go across it—namely, one light year.

Having established that quasars are neither local stars nor galaxies, the next thing to do was to study further the details of their spectra. J. Greenstein reported that these lines have been identified with the forbidden lines O^+, Ne^{++}, and Ne^{++++}. Certain atomic excited states decay through higher-order interactions, and their lifetimes are long ($\sim$1 second). Under ordinary lab-

*1 parsec = 3.25 light years.

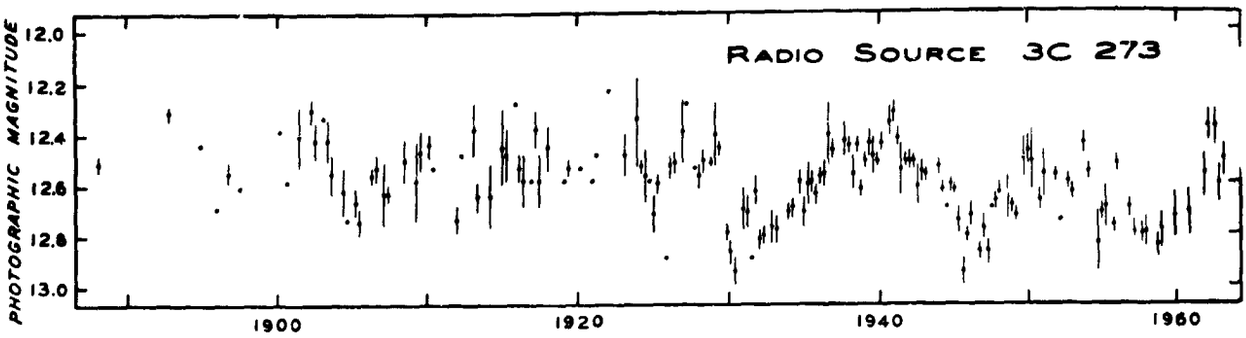

FIGURE 8.—Light variation curve of 3 C 273 as analyzed by H. J. Smith and D. Hoffleit from old sky patrol plates. Data represent statistical average over a few days of observations, and standard deviation is as indicated by vertical line segments. (H. J. Smith pointed out that a big light crash of 3 C 273 occurred towards the end of October 1929. It was a big year for crashes.)

oratory discharge-tube density ($\gtrsim 10^{15}$ particles/cm^3), collisional de-excitation takes place before atoms in these excited states can decay, and the corresponding lines are ordinarily unobservable in the laboratory (forbidden). The presence of forbidden lines indicates low electron density ($< 10^7$/cm^3). As the density increases, forbidden lines gradually disappear.

The observed forbidden lines are [O II], [O III], and [Ne III], but [Mg II] is not a forbidden line. Incidentally, a sizable fraction of energy radiated ($\sim$20%) is contained in these lines. From their observed relative strength the electron number density N_e may be established. Knowing the distance from the red shift, the absolute intensity of the strength of these lines and hence the total number of atoms emitting them may be determined. The table lists Greenstein's results.

Quasar	N_e/cm^3	*Radius (parsec)*	$M/\odot$ *(of emitting parts)*
3C273	10^7	0.6	2×10^5
3C48	10^5	5	2×10^6

If quasars were superdense stars, the differential red shift at different layers would limit the thickness of the emitting layer to that corresponding to the observed width of forbidden lines. This would limit the total number of emitting ions. From this limit and the observed intensity of forbidden lines, Greenstein concluded that quasars would have to be as close as the moon! Such large gravitational perturbations on the solar system could not have escaped the keen eye of Kepler. Hence, from the presence of forbidden lines one can argue indirectly but strongly that the red shift cannot be gravitational.

The lower limit for the masses of 3C273 and 3C48 can be estimated as follows: From the line broadening, we can estimate the kinetic velocity of emitting atoms. It turns out to be 1500 km/sec. In order that these atoms be bound gravitationally at a distance of 0.6 parsec, the center of 3C273 must contain a mass of at least $10^8\odot$. This is the lower limit for the masses of 3C273 and 3C48.

One can also obtain the mass from energy estimates. To know the total energy radiated, one needs to know the age of quasars. The energy output rate is 3×10^{46} ergs/sec, equivalent to the nuclear energy output from the burning of one solar mass of hydrogen in one day. In 3C273, there is a jet, component *A*, 150 000 light years away from the other component, component *B*. It is most likely that the jet was ejected from 3C273. If one accepts this interpretation, then the age of 3C273 must be at least 150 000 years. This gives a value of 10^{59} ergs for the total energy radiated.

But this is not the whole story about the energy content of quasars. The optical emission can be interpreted as resulting from collisional excitation caused by the thermal motion of ions. From the shape of the radio spectrum (Fig. 6), the radio emission is most likely from synchrotron radiation. Thermal radiation with such strong intensity would require a temperature of the order of 10^9 °K and at this temperature its lifetime against neutrino loss is less than a few days. Relativistic electrons moving in a magnetic field can radiate predominantly in the radio region. To date, we do not know of any way of accelerating high-energy electrons with high efficiency, and it seems con-

sistent with known cases (e.g., the Crab Nebula) at about 1 percent of the energy stored in all high-energy particles may be in the form of high-energy electrons. Also, magnetic fields contain energy. A minimum estimate of the total energy consistent with radio data is at least 10^{60} ergs.

The presence of a magnetic field is further supported by the discovery of polarization in the optical region. One does not expect a very large polarization, because the plane of polarization of electromagnetic waves will be rotated while passing through a plasma; the rotation angle is different for different frequencies (Faraday rotation). Hence, for a given band width, the polarization decreases as electromagnetic waves pass through a plasma. At a wavelength of 4500 angstroms, a polarization of 0.45 (± 0.15) percent, based on twelve observations, has been obtained by McDonald. The angle of polarization is defined to $\pm 5°$. This indicates that there is a small component of synchrotron radiation in the optical region as well.

To summarize the discussion on the observed features of quasars, we conclude that (1) quasars are massive objects with a mass $\gtrsim 10^8 \odot$ which are confined to a space of about one parsec; (2) they are not composed of stars but seem to be coherent masses; (3) their lifetime is at least 10^5 years; (4) they radiate radio waves strongly, but radiate most strongly in the optical region; (5) their surface is composed of very tenuous matter of a particle-number density of the order of $10^7/\text{cm}^3$; and (6) their total energy content is larger than the rest energy of $10^6 \odot$.

Now I shall report some theoretical speculations based mostly on the energy requirement of quasars. All of the 10^{60} ergs of energy ($=10^6 \odot c^2$) are in the form of magnetic fields and high-energy particles, and a possible energy source is gravitational energy, which can be released in violent events (e.g., collapse); thus all the energy released may be in the form of high-energy particles. The prevalent theory of gravitation is general relativity. General relativity predicts some singularities, one of which, the Schwarzschild singularity, will be discussed briefly below.

Classically, if one is able to accumulate matter indefinitely and statically, the escape velocity at the surface will eventually exceed the light velocity. As an interesting historical sidelight, I remind the reader that in conjunction with the corpuscular theory of light, Laplace demonstrated in 1795 that a body of the dimension of the orbit of the earth around the sun, with a density of that of the earth, would not allow any of its rays to escape. Hence, he concluded that the most luminous object in the universe may not be visible.

The same conclusion holds in relativity theory. In fact, the mass limit calculated according to Newtonian theory is exactly the same as that predicted in general relativity theory! The light emitted at a distance R from a sphere of mass M is red-shifted by the factor $(1-2GM/Rc^2)^{-\frac{1}{2}}$ as observed by distant observers; for light emitted at the surface, defined by $R^*=2GM/c^2$, the red shift is infinite. R^* is called the gravitational radius or the Schwarzschild radius. The time dilatation factor is also $(1-2GM/Rc^2)^{-\frac{1}{2}}$. To an outside observer, a body falling toward R^* will never reach it, since in approaching it, the time dilatation factor $(1-2GM/Rc^2)^{-\frac{1}{2}}$ diverges and the motion will slow down and eventually stop (time machine!). Signals sent out by the falling body will be more and more red-shifted to very long wavelengths. To a local observer falling towards the center, however, the time of descent is finite. In fact, from the present radius of the sun (7×10^{10} cm), the time of descent towards the center, assuming the sun is within its gravitational radius, is less than one day. For a proton, $R^*=10^{-33}$ cm; for the sun, $R^*=2.6\times 10^5$ cm; and for a massive object $M\sim 10^8 \odot$, $R^*\sim 10^{13}$ cm. For a collapsing star in which the pressure can be neglected, J. R. Oppenheimer and H. Snyder, then of the University of California at Berkeley, found in 1939 that the above conclusion was still valid.

Although no light can cross the gravitational radius, the gravitational field and the electrostatic field of the gravitational singularity (those carried by the so-called longitudinal gravitons and photons) can be felt by external observers. Thus, the Schwarzschild singularity can be detected through its gravitational field, but it cannot be seen. Also, because for a comoving observer the Schwarzschild singularity does not seem to exist, many relativists believe it is just a singularity introduced by the particular coordinate one chooses to describe the gravitational field. Various efforts have been made to find a coordinate system free of the Schwarzschild singularity, including a modification of the topology of the space-time continuum,

but in all cases, singularities always reappear at other places.

In practice, the Schwarzschild singularity sets an ultimate limit on how far a body can collapse gravitationally. This limit is actually approached in the model proposed by F. Hoyle and W. A. Fowler. In a bold attempt, F. Hoyle analyzed the conditions for the formation of large coherent masses. The difficulties of forming large masses are (1) angular momentum and (2) breaking up of large masses to smaller ones prematurely. The period of rotation is proportional to R^{-2} (R is the dimension of the object), but all other time scales (the free-fall time, the time of transit of hydromagnetic waves across a body) are proportional to $R^{-3/2}$ in the nonrelativistic case. Hence, rotation will prevent matter from condensing further when the speed of rotation at the equator equals the escape velocity. As a comparison, rotation becomes important during the formation of the sun when the radius of the protosun is around 10 to 100 times the present value.

In the relativistic region, all time scales have the same dependence on R. Other physical characteristics of the body (density, mass, magnetic field, and so on) then determine which time scale becomes the most important one. In order that a large coherent mass may be formed, the gravitational time scale must be the shortest one. A comparison of the gravitational time scale $[\sim(3\pi/32G\rho)^{\frac{1}{2}}]$ and the hydromagnetic time scale $[\sim(4\pi\rho)^{\frac{1}{2}}R/H]$, where H is the magnetic field, shows that, for a magnetic field of 10^{-6} gauss and a density of 10^{-21} g/cm^3, the gravitational time scale is shorter than that of the hydromagnetic wave when the mass is greater than $10^6\odot$. (As a comparison, the galactic magnetic field is in between 10^{-6} gauss and 10^{-5} gauss, the interstellar matter density is 10^{-24} g/cm^3, and the density of nebulae is 10^{-21} g/cm^3.) From a similar comparison of the rotation time scale ($\sim\omega^{-1}$) with the gravitational time scale, one finds that for $\omega=10^{-15}$ sec^{-1} (the angular velocity of a galaxy), the condition is $\rho>5\times10^{-24}$ g/cm^3. Thus one need not have a spectacular density in order to overcome the limit imposed by angular momentum.

In this simple argument, one does not consider the transfer of angular momentum from one part of the body to the other. If considerable amounts of angular momentum are transferred, the previous argument is not valid. It is not known whether angular momentum may be transmitted in large quantities. Optimistically, one hopes the inner part can fall a great way before transfer of angular momentum becomes important.

Thus, conceivably, a large mass ($\gtrsim10^6\odot$) can condense to a density of around 10^{-16} g/cm^3. At this density, due to rotation, the body becomes appreciably flattened (see Fig. 9). Let the thickness of the disc be W, the diameter be D. Now the time scale for the vertical direction is determined by W and this gravitational time scale is much larger than the hydromagnetic time scale. Fragmentation can now take place in the outer

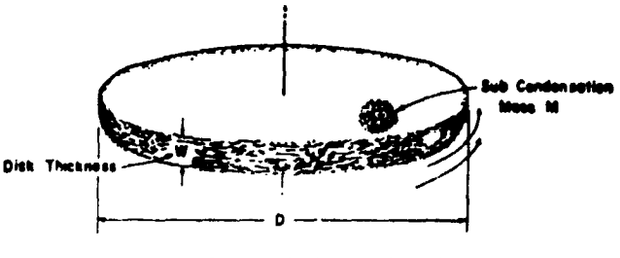

FIGURE 9.—Flattened disc in Hoyle's theory.

part. The mass m in each fragmented blob is given by $m/M\sim(W/D)^2$; for $W/D=10^{-2}$ and $M=10^6\odot$, we have $m=10^2\odot$.

The temperature of the gas can be calculated by applying the virial theorem (which equates the thermal energy of a self-gravitating sphere to its self-gravitational energy). The calculated value for this case is around 10^4 °K, somewhat below the ionization temperature of hydrogen at the corresponding density. Further contraction (now taking place individually in smaller blobs) will raise the temperature, and hence ionize the gas. The ionization of hydrogen requires an energy of about 10^{13} ergs/g and the thermal (and gravitational) energy is about 10^{12} ergs/g at 10^4 °K. The gravitational energy is proportional to R^{-1}. To obtain an energy of 10^{13} ergs/g, a contraction by a factor of ten, or an increase in density by a factor of 10^3 is needed. The density suddenly increases from 10^{-16} g/cm^3 to 10^{-13} g/cm^3.

The gas cloud becomes opaque to radiation only until $\rho\sim10^{-11}$g/cm^3. During the contraction phase, energy has to be supplied to the radiation field as well. Hence the contraction cannot stop until a density of 10^{-11} g/cm^3 is reached. As I

have mentioned earlier, stars of masses $\gtrsim 10^2 \odot$ are not stable against pulsation. A check on the thermodynamic mechanical properties of a $100\odot$ star shows that it is only marginally in stable equilibrium. Now a rapid contraction takes place almost like a collapse, suddenly raising the density from 10^{-16}g/cm^3 to 10^{-11}g/cm^3 in a time comparable to the gravitational free-fall time. Will the collapse stop? In a star of a few solar masses, we are quite sure that the collapse will stop before nuclear energy generation runs wild. The kinetic energy associated with the collapse will be damped out in the subsequent oscillations. In a 10^2 ⊙ star, the collapse will probably overshoot, and the accompanied oscillation will have very large amplitude.

The most efficient damping mechanism is the electron-pair annihilation process of neutrino production. But this is important only when $T > 10^9$ °K; at lower temperature, there is no damping. Since the temperature fluctuation of the star is very large, nuclear reactions (hydrogen burning) will proceed in a somewhat erratic manner. An estimate of the actual time scale for nuclear burning is difficult; but, in order to fit those sporadic light variations in 3C273, the time scale for nuclear burning should be around one year. This rate also fits the observed energy flux (3×10^{46} ergs/sec).

S. A. Colgate of Lawrence Radiation Laboratory and A. G. W. Cameron of Goddard Institute for Space Studies pointed out, however, that F. Hoyle's mechanism does not provide enough high-energy particles for radio emission. Shock waves generated by supernovae, traveling in the very tenuous matter in which these stars are embedded, will accelerate particles to relativistic velocities. A considerable amount of gravitational energy will be released during supernova collapse. Moreover, shock waves will generate hydromagnetic waves throughout the medium, which may explain the long-term light variations (15 years) of 3C273.

Remnants of these massive stars may be in the form of neutron stars or a Schwarzschild singularity, either of which may accelerate particles to relativistic speeds. This may be the mechanism that produced a jet in M87, a galaxy. The idea of acceleration was advanced by Ya. B. Zel'dovich of the USSR.

Another alternative suggested by Hoyle is that the inner region of the big body can collapse gravitationally to extreme density; rotation can either be crushed by gravitational force or dissipated by radiating gravitational waves, assuming a noncylindrical shape was achieved through fission. F. Dyson of the Institute for Advanced Study remarked that the difficulty associated with a gravitational-collapse theory is that it would be over in one day (the local time it takes for a test particle to cross the Schwarzschild singularity of $10^2 \odot$). How can a state of collapse be maintained for over 10^6 years, which would be required in quasars?

T. Gold of Cornell pointed out that in supernova explosions the light output increases rapidly but declines slowly, and this is in contradiction to what is observed in quasars (see Fig. 8).

Hoyle summarized his talk with a diagram which is reproduced here as Fig. 10.

W. A. Fowler then discussed a similar mechanism for massive objects. As condensation takes place, the inner part begins to rotate rapidly, and fission can take place. When the inner part bifurcates into a nonsymmetrical form, gravitational radiation will take place, radiating away an appreciable amount of rotational energy (which is comparable to the total rest energy). This raises the potential energy outside, and part of the matter will have a positive binding energy. Mass will be ejected. The difficulty here, as pointed out by a number of others, is that one cannot avoid a coupling between inside and outside if fast nonsymmetrical rotation takes place.

T. Gold presented the idea that if stars escaping from star clusters can carry away enough angular momentum, star clusters can collapse, and collisions between stars will occur more frequently. Energy released in such collision processes is fairly large, and certain radio phenomena can be explained.

A number of other topics not related to massive objects, but relevant to gravitational collapse or to galactic structure were also discussed.

E. M. Burbidge reviewed several proposed mechanisms for strong radio sources. Originally, a radio source in Cygnus was identified with a pair of galaxies appearing to be in collision. R. Minkowski of the University of California at Berkeley postulated that collision between normal galaxies could generate high-energy particles responsible

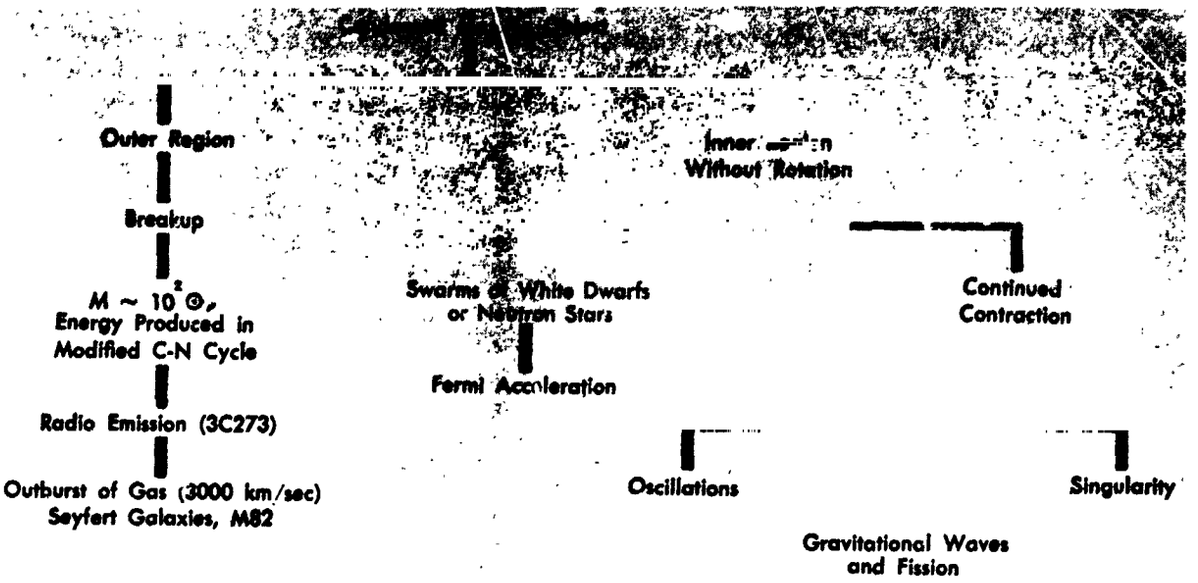

FIGURE 10.—Chart summarizing possible mechanizing of gravitational collapse proposed by F. Hoyle.

for radio emission, but this idea was later rejected because the energy thus released would be far too small. Also, the known number of radio sources is much greater than would be expected from the frequency of galactic collisions for most optically identified sources not associated with clusters of galaxies. G. R. Burbidge of the University of California at La Jolla and F. Hoyle proposed that collisions between galaxies and anti-galaxies (composed of antimatter) might give enough energy. However, there are many inconsistencies in this proposal. For example, why should matter and anti-matter be separated until the right moment to annihilate? Another mechanism is the emission of radio waves through the interaction of a turbulent magnetic field with gases. One can perhaps explain the radio emission from M82 by this mechanism, but in an elliptical galaxy, there is practically no gas! The existence of large scale, strong magnetic fields in elliptical galaxies is also unlikely.

If one accepts supernova remnants as the only radio emitters in a galaxy, one needs a total number of 10^8 supernovae spreading over 10^8 years. I. Shklowsky of the USSR suggested that during the early stages of galactic evolution, rapid star formation can take place, and supernova activities may be stronger than at present. A. G. W. Cameron modified Shklowsky's idea, proposing that in regions rich in gas and low in magnetic field, massive stars can condense simultaneously. After going through their normal evolutionary sequence, they become supernovae—all in around 10^6 years. Remnants of these supernovae can account for the radio emission. The difficulty is the same as in the proposal of G. R. Burbidge and F. Hoyle: in elliptical radio galaxies there appears to be very little gas.

G. R. Burbidge postulated that in the center of a galaxy, if the separation between presupernova stars is around a few light days, the supernova explosion of one of them may trigger the rest of them to become supernovae. In order that his mechanism may work, a stellar density of 10^7 stars/cubic parsec is needed. Such a high density may exist and escape detection. However, one does not know of any trigger mechanism.

H.-Y. Chiu of Goddard Institute for Space Studies reported on a study of the evolution of presupernova stars in which it was found that a very dence core will develop before a star undergoes callapse. Almost all the energy released during collapse will be dissipated in the form of neutrinos, and the dense core will become neutron matter.

E. E. Salpeter reviewed the equilibrium configuration of neutron stars. At a density greater than 10^{12} g/cm^3, matter is composed predominantly of neutrons, and at an even higher density ($> 10^{14}$

g/cm³) hyperons may exist. These neutrons cannot decay because all electron states are filled up. There exists a mass limit for neutron stars, and no static equilibrium configuration is possible if the mass exceeds this limit. This limit for a perfect Fermi gas is 0.76⊙ (Oppenheimer-Volkoff mass limit). If real gases are considered, the limit varies somewhat, but in no case does it exceed 3⊙.

H. Bondi of King's College, London (reported by E. E. Salpeter), derived a rigorous upper limit ($\Delta\lambda/\lambda < 0.615$) for the red shift of light emitted from the surface of neutron stars. A more realistic limit is found to be around 0.3, which incidentally also excludes the possibility that the large red shift (>0.3) of some quasars is a gravitational red shift. In principle, this is the upper limit of the red shift for light emitted from any self-gravitating body.

J. A. Wheeler of Princeton discussed another kind of gravitational singularity. He assumed that one can accumulate matter *statically* until at the center, the time metric g_{00} vanishes (this corresponds to a classical situation in which the gravitational potential *at the center* of the body is equal to its rest energy). Any matter dropped through hole to the center will give away energy equivalent to its rest energy and thus the total gravitational mass (as observed by external observers through its gravitating effect) cannot increase. Such a singularity acts as a gravitational machine, converting all matter into energy. Since the number of nucleons is conserved, Wheeler postulated the existence of a class of new massless bosons, the δ ray, which carries the nucleon number. One of the chairmen remarked that δ rays, if they exist, may be used to transport ponderable matter at the speed of light.

However, it is not known if one can really accumulate matter statically until this kind of gravitational singularity comes into existence. All neutron-star models studied so far indicate that a dynamical collapse will take place when the mass exceeds the critical mass limit (the mass limit was reviewed by Salpeter).

A spirited discussion then took place, reemphasizing some of the points discussed during the meeting. E. L. Schucking of the Southwest Center for Advanced Studies pointed out that other discussions relevant to massive objects, cosmic rays, and cosmic x and γ rays had been omitted from the discussion. P. Bergmann of Yeshiva University remarked that in the past general relativistic effects had been observed only in the weak field limit. Now new developments of astrophysics have made relativity a more physical theory. He expressed hope that a quantized version of relativity theory may play an important part in understanding massive objects. R. Minkowski expressed satisfaction that within the past ten years the technique of optically identifying radio sources had made great progress. On the other hand, a theoretical understanding of the structure of large masses is lacking. In one context, J. R. Oppenheimer, who pioneered the study of neutron stars and gravitational collapse, remarked that the present situation in interpreting quasars resembled that of quantum electrodynamics eighteen years ago, when all one had was confusion and lots of data. If the meeting taught us anything, it has taught us that those two dark clouds in the otherwise clear sky of physics (Kelvin, at the turn of the last century, was referring to natural radioactivity and X rays) are still there. But they are now to be found at the very edge of our universe.

ACKNOWLEDGMENT

The author wishes to thank T. A. Matthews, A. R. Sandage, C. Hazard, M. B. Mackey, A. J. Shimmins, H. J. Smith, D. Hoffleit, W. Priester, and Miss Jane Woodbridge for their help in preparing this report. Thanks are also due to the editors of the *Astrophysical Journal*, *Sky and Telescope*, and *Nature* for permission to use a number of previously published illustrations.

SUPERNOVAE, NEUTRINOS, AND NEUTRON STARS*

HONG-YEE CHIU†

The final evolution of a pre-supernova star is reviewed. It is now believed that the supernova explosion of a star is first triggered by the collapse of its core, followed by the sudden release of gravitational energy or the sudden ignition of nuclear fuel in the envelope. Among the subjects discussed herein are the causes for stellar collapse, the static structures of white dwarfs and neutron stars, the dynamic collapse of oversized neutron stars, angular momentum and stellar collapse, and the observable features of neutron stars.

1. INTRODUCTION‡

It is now accepted with reasonable assurance that the supernova explosion of a star is first triggered by the collapse of its core,** followed by the sudden release of gravitational energy or the sudden ignition of nuclear fuel in the envelope (References 2–6). A number of suggestions have been made as to the physical processes which may cause the core to collapse suddenly. Among the most promising mechanisms are the disintegration of iron (the then most abundant element) into helium at a temperature of 7×10^{9}°K (Reference 3), and the neutrino process which dissipates stellar energy at a drastic rate of 10^{23} ergs/cm^3-sec at the same temperature (this rate is to be compared with the stellar energy density which is 10^{24} ergs/cm^3 at the same temperature and a density of 10^{6} gm/cm^3) (Reference 5).

As we shall see later, although these two physical processes give rise to different kinds of instabilities, nevertheless they are capable individually of triggering the sudden release of either gravitational or nuclear energy of a star. A detailed computation is underway to determine the range of masses for which either of these two processes comes into play first.***

A sudden release of nuclear or gravitational energy in the envelope will cause it to expand quickly (References 3 and 4). The expanding envelope is directly observable. Owing to its complexity and its dynamical nature, only qualitative conclusions have been presented. Even so, interesting results regarding the origin of cosmic rays (Reference 7) and the origin of elements have been obtained, and qualitative agreements with observational results are quite satisfactory (References 3 and 6).

What is left as the core collapses is not immediately clear. In the past, it was usually assumed that ordinary white dwarfs (whose mean density is around 10^{6} gm/cm^3) are remnants of supernova explosions. The large number of white dwarfs discovered (around 10 percent of the stars in the solar neighborhood are white dwarfs), however, cannot be explained by the relative scarcity of supernovae per galaxy (which occur at a rate of around 1/50—300 years) (References 8 and 9). The other alternative that neutron stars may be the remnants of supernovae has so far been accepted only with skepticism§ (References 10 and

‡A more complete description of stellar evolution along the present trend of thought may be found in Reference 1.

**The concept of stellar collapse was first introduced by G. Gamow and M. Schonberg (Reference 2).

***H. Y. Chiu and E. E. Salpeter, work in progress.

§However, W. Baade and F. Zwicky believed that supernova explosions are resulted from the formation of a neutron star (Reference 12). This belief is no longer supported by other evidences; see Reference 3.

11). Moreover, there is *no astronomical evidence* yet that such stars even exist.

Theoretically there are also some difficulties. At least one type of pre-supernova stars is believed to have a mass of around $30M_\odot$ ($M_\odot$ = solar mass = 2×10^{33} gm) of which around $20M_\odot$ belongs to the core? Since there exists an upper limit ($\approx0.8M_\odot$) for the mass of a neutron star (and also white dwarfs) beyond which no stable configuration exists, what will be the fate of the massive stellar core? It is unlikely that a large fraction of the $20M^\odot$ which the core possesses will be blown away by any reasonable means. Since the composition of the core is believed to be mainly iron—the end product of thermonuclear evolution, no nuclear energy is available and gravitational energy is incapable of doing so (Section 3.1).

It was also suggested that the collapse would initiate, in addition to an outward shock which ejects matter, also an inward shock wave which compresses the core quickly (Reference 4). When the density reaches 10^{14} gm/cm^3, the inter-nucleon distance will be of the order of the size of the repulsive core ($\approx10^{-14}$cm), and the shock wave will be rebounded by the hard nuclear core. The rebounded shock wave will expand the star to the normal density possessed by a white dwarf, and will eject more mass from the star. This hope, however, was relinquished recently because of neutrino processes. Neutrino processes involving electron neutrinos and μ-neutrinos are extremely efficient in dissipating energy—the relaxation time being around 10^{-5} sec at $T=10^{12}$°K. This would be the temperature of a medium if it is compressed adiabatically to a density of 10^{13} gm/cm^3. This relaxation time (10^{-5} sec) is extremely short as compared with the time the compression takes place, which is calculated to be around 10^{-2} sec. Hence, once compressed to such high densities ($\gtrsim10^{13}$ gm/cm^3), the star will lose all its energy; and it cannot restore itself to a normal density. This is discussed in more detail in Section 3.4.

So far, no stars in any way resembling neutron stars have been discovered. We would like to point out that this is not evidence against the existence of neutron stars. Our atmosphere strongly absorbs electromagnetic radiation whose wavelengths are less than 3000A. The total energy output by a neutron star is proportional to the fourth power of its effective surface temperature T_e. The part of neutron star radiation that will pass through our atmosphere, however, increases only as T, when $T\gg10^4$°K (Section 8.3). For a surface temperature of 10^6°K, the total energy output of a neutron star is around that of the sun, but the part of radiation that can pass through our atmosphere is about 10^{-5} of that of the sun at the same distance. This is too faint to be seen at even a reasonable distance (say, 10 light years).

We shall discuss the nature of various problems related to the formation and detection of neutron stars. Although in the past, several pieces of excellent and wonderful work have been done,† the problem in the large is still unsolved. In this paper we do not attempt to solve this problem. We should like, however, to emphasize the difficulty of the problem and the possible direction of a solution.

Since rotational energy may be quickly dissipated by gravitational radiation when the collapse takes place, we shall ignore rotational effects in our discussions. This is discussed in particular detail in Section 7.

2. CAUSES FOR COLLAPSE OF A STAR

A star is, in the large, a mechanical system in quasi-hydrostatic equilibrium. It has a negative total energy and, in order to be in a stable equilibrium, its total energy must also be a minimum on its energy surface with respect to small perturbations. Moreover, the energetics of a stable star must be such that hydrostatic equilibrium has a useful meaning. When either of these two conditions is not fulfilled, the star will be unstable and, since its total energy is negative to start with, collapse will take place.

When the first condition is not fulfilled, the star is said to have *hydrostatic instability*. When the second condition is not fulfilled, the star is said to have *dynamical instability*. In the following we study them in more detail.

2.1. Hydrostatic Instability

Here we are concerned only with the stability of a star in hydrostatic equilibium under small

†These works are summarised in Section 5.6. References to these works may also be found there.

adiabatic perturbations (Reference 13).* Let E_T be the total energy of a star. E_T is given by

$$E_T = -G\int_0^M \frac{m\,dm}{r} + \int_0^M \epsilon\,dm \quad , \qquad (2.1)$$

where the first term represents the gravitational energy and ϵ is the thermodynamic energy per unit mass, G is the gravitational constant, m is the mass of the star within a sphere of symmetry of radius r, and M is its total mass. In order that the star be in equilibrium, it is necessary that the first variation of E_T be null:

$$\delta E_T = 0 \quad ; \qquad (2.2)$$

and, in order that the equilibrium be a stable one, the sign of the second variation must be positive —that is,

$$\delta^2 E_T > 0 \quad . \qquad (2.3)$$

One can demonstrate that Equation 2.2 gives rise to the equation of hydrostatic equilibrium and Equation 2.3 gives rise to the following inequality:†

$$\int\left(\Gamma - \frac{4}{3}\right) P\,dV > 0 \quad , \qquad (2.4)$$

where P is the hydrostatic pressure and V is the volume of the star; Γ is the adiabatic exponent and is defined as

$$\Gamma = -\frac{v}{P}\left(\frac{dP}{dv}\right)_{ad} \qquad (2.5)$$

The subscript means that this differentiation is carried out under an adiabatic process.

One form of Γ is‡ (see footnote, page 3)

$$\Gamma = \frac{Pv + v\left(\frac{\partial\epsilon}{\partial v}\right)_P}{P\left(\frac{\partial\epsilon}{\partial P}\right)_v} \qquad (2.6)$$

where v is the specific volume (volume per unit mass) and P is the gas pressure. Assuming that ϵ and P_v are all functions of temperature alone, and approximating Δv by v, one obtains the following form for Γ:

$$\Gamma = 1 + \frac{\Delta(Pv)}{\Delta\epsilon} \quad . \qquad (2.7)$$

Normally, for a non-relativistic gas, $Pv = 2/3\epsilon$; hence $\Gamma = 5/3$. For a relativistic gas, $Pv = 1/3\epsilon$; hence $\Gamma = 4/3$.** If, in a particular temperature regime phase transition takes place, the energy of transition has to be included in ϵ., Thus when phase transition occurs (such as ionization dissociation or nuclear disintegration) the value of Γ will drop to below 4/3. For iron-helium transition, the heat of transition ϵ_t is roughly 2.2 Mev/nucleon. The transition occurs at a temperature of 8×10^9°K, at which the thermal energy is around 1 Mev/particle. Since the electrons are quite relativistic, $Pv \approx 1/3\epsilon_e$, where ϵ_e is the thermal energy for the electrons. Using the value $\epsilon_e \approx 1$ Mev, and writing $\epsilon \approx \epsilon_e + \epsilon_t$ (thermal energy of nuclei and radiation energy may be neglected), we find that

$$\Gamma = 1 + \frac{\frac{1}{3}\epsilon_e}{\epsilon_e + \epsilon_t} \approx 1.1 \quad . \qquad (2.8)$$

We remark that the dissociation of iron into helium is not the only mechanism that will cause Γ to drop to below 4/3. Figure 1 shows Γ as a function of temperature for a number of densities for a gas in equilibrium with electron pair creation (Reference 14).*** One finds that the value of Γ may drop to below 4/3 if the density is low enough. For the density-temperature region one usually considers inside a star, the creation of electron-positron pairs will not cause a star to collapse. Only for extremely massive objects, which Flower and Hoyle considered as possible radio sources, will the creation of electron-positron pairs be responsible for the collapse of a star (Reference 15).

The disintegration of iron into helium, however, occurs over an extensive (though narrow) tem-

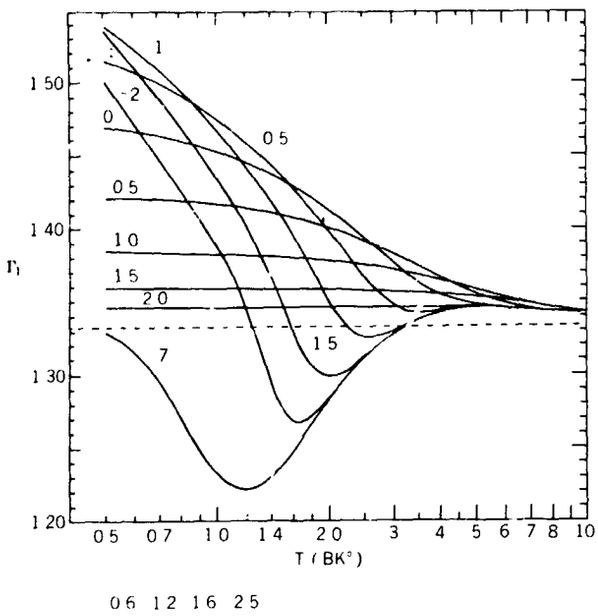

FIGURE 1.—The adiabatic exponent $\Gamma \equiv -\frac{v}{P}\left(\frac{dP}{dv}\right)_{ad}$ for an electron gas in equilibrium with radiation and pair creation is plotted as a function of temperature for a number of densities. The number on the curves refer to $\log_{10} p/p_0$, where $p_0 = 2\times10^6$ gm/cm³.

perature-density region as indicated in Figure 2. Hence, every star which evolves with increasing temperature will come across such a region. In these regions instabilities may occur. Although the sign of the integral in Equation 2.4 has not been proven to be generally negative for a star in

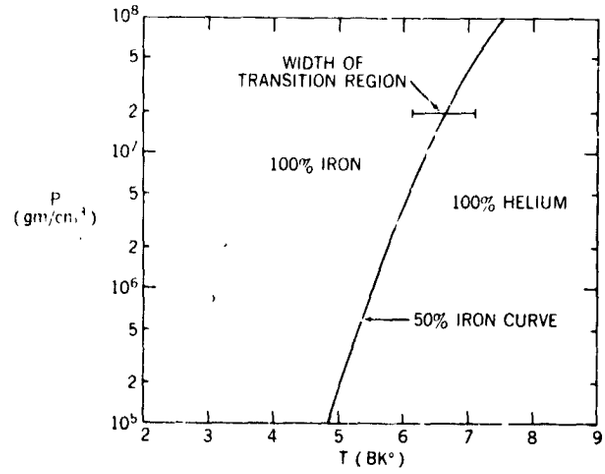

FIGURE 2.—The temperature-density relation, for which the equilibrium ratio Fe^{56} to He^4 is unity, is plotted. The transition region has a width of around $\Delta T \approx 10^9$ °K.

this density-temperature region, in certain simple cases (References 4 and 5) it has negative values. A more extensive work to study this kind of instability is underway.†

2.2. Dynamical Instability of a Star

While a star is stable in a hydrostatic sense, it may still be unstable dynamically, and vice versa. The dynamical stability of a star is related to the energy flow inside a star.

From the condition for hydrostatic equilibrium ($\delta E_T = 0$) one may obtain the equation for hydrostatic equilibrium:

$$\frac{dP}{dr} = -\rho\frac{Gm}{r^2}, \qquad (2.9)$$

where ρ is the density and m was defined previously and is given by

$$m = \int_0^r 4\pi r^2 \rho\, dr \ . \qquad (2.10)$$

A more detailed discussion of Equations 2.9 and 2.10 may be found in standard textbooks (Reference 16). Equation 2.9 is valid only when all matter inside a star does not have macrosopic motion. When a star is contracting rapidly, one must include the acceleration $\dot{v}$ (where v is the velocity and $\dot{v}$ its hydrodynamic derivative). In the absence of relativistic effect, and assuming spherical symmetry, both v and $\dot{v}$ are in the direction of r (notation: v_r). Hence, the equation for hydrostatic equilibrium becomes

$$\frac{dP}{dr} = -\rho\frac{Gm}{r^2} - \rho\dot{v}_r \ ; \qquad (2.11)$$

$\dot{v}_r$ is given by

$$\dot{v}_r = \frac{\partial v_r}{\partial t} + v_r\frac{\partial v_r}{\partial r} \ . \qquad (2.12)$$

It is more convenient to use m as one of the two independent variables since m is independent of t. Then Equation 2.11 becomes (we now drop the subscript r on v and $\dot{v}$).

$$\frac{dP}{dm} = -\frac{G}{4\pi}\frac{m}{r^4} - \frac{\dot{v}}{4\pi r^2} \ . \qquad (2.13)$$

†See footnote *** on, page 1.

Differentiating Equation 2.10, one obtains a relation between r and m:

$$\frac{dr}{dm} = \frac{1}{4\pi r^2 \rho} . \qquad (2.14)$$

Further, we also have the equation of continuity:

$$\dot{\rho} + \rho \operatorname{div} v = \dot{\rho} + \rho \frac{\partial v}{\partial r} = 0 . \qquad (2.15)$$

The contraction of the star is caused by some fast energy dissipation process (like the neutrino process) which depends only on the density ρ and the temperature T. Let the rate of energy dissipation per unit mass be $\epsilon_d(\rho,T)$. The energy balance equation is

$$-T \frac{dS}{dt} = \epsilon_d(\rho,T) , \qquad (2.16)$$

where S is the entropy per unit mass.* Further, thermodynamics supplies us with the following relations:

$$\left.\begin{aligned} S &= S(\rho,T) , \\ P &= P(\rho,T) . \end{aligned}\right\} \qquad (2.17)$$

Hence, the four equations, Equations 2.13 through 2.16, with their four unknown variables (ρ,T,r,v), can now be solved in terms of m and t (which are the independent variables). The boundary conditions are:

$$\left.\begin{aligned} &\text{At } m=0: \\ &\quad r=v=\dot{v}=0, \ \rho \text{ and T are finite,} \\ &\quad \text{and } \frac{dP}{dm} \propto m^{-1/3}; \\ &\text{At some value of r: v, } \dot{v} \text{ are finite;} \\ &\quad \text{and } \rho \text{ and T tend to zero} \\ &\quad \text{simultaneously;} \\ &\text{At } t=0: \\ &\quad \rho=\rho_0(m), \ T=T_0(m), \ v=v(m), \\ &\quad \dot{v}=\dot{v}(m). \end{aligned}\right\} \qquad (2.18)$$

These boundary conditions are physical restrictions on the type of solutions one expects from the set of nonlinear differential equations, Equations 2.13 through 2.16. Their meaning is almost self-evident. Equations 2.13 through 2.16 with the boundary condition Equation 2.18 describe the non-relativistic collapse of a star. If v approaches a certain limit which will be discussed below, it may happen that no solutions could be found which are continuous in both m and t and satisfy the boundary condition (Equation 2.18). In such cases a shock wave will be developed. The behavior of some simple shock wave solutions has been studied by Colgate el al. (Reference 4).

We now study the sign of $\dot{v}$ and the physical limit on v. Let W be the gravitational energy of the star and E its total thermodynamic energy; then the total energy of the star E_T is given by

$$E_T = W + E . \qquad (2.19)$$

The virial theorem gives†

$$-W = (1+\eta) E , \qquad (2.20)$$

where ϵ is a slowly varying constant depending on the gross thermodynamic properties of a star. For all cases, $1>\eta>0$. At $T \approx 6\times10^9$ °K, $\eta \approx 0.1$.†

Approximately one can write

$$W = -G \int \frac{m\,dm}{r} \approx -\frac{GM^2}{R} , \qquad (2.21)$$

where R is the radius of the star, and also

$$E = \int \epsilon \, dm \approx M \cdot R_g T , \qquad (2.22)$$

where ϵ, the thermodynamic energy per unit mass, is approximated by the expression for a per gas:

$$\epsilon \approx R_g T \qquad (2.23)$$

and R_g is the gas constant ($R_g = 8.2\times10^7$ in cgs units). From Equations 2.21 and 2.22, the following relations are obtained:

$$T = \frac{GM}{R_g(1+\eta)} \frac{1}{R} , \qquad (2.24)$$

$$W = -\eta E_T = -\eta M R_g T = -\frac{\eta G}{1+\eta} \frac{M^2}{R} . \qquad (2.25)$$

*This equation is derived on the assumption that the rate of energy transfer by photon is very small compared with the rate of energy dissipation by neutrinos. For the justification of this assumption, see Reference 5.

†See Appendix A.

Since gravitational contraction is the only energy source available at $T \gtrsim 4\times10^9$ °K, above this temperature the energy balance equation becomes

$$-\frac{dW}{dt} = \int \epsilon_d \, dm \approx M\epsilon_d(\rho, T) \, . \quad (2.26)$$

The energy dissipation function ϵ_d for the annihilation process (which is the most important one in this temperature density region) is

$$\epsilon_d = \epsilon_o \frac{T^9}{\rho} \, , \quad (2.27)$$

where $\epsilon_o = 4\times10^{-75}$ ergs/(°K)^9-sec-cm^3.

From Equation 2.24 we can also obtain a dynamical relation between Y and ρ. Since

$$\rho = \frac{4}{3}\pi R^3 \, ,$$

the relation is

$$\rho = \left[\frac{Rg^3}{4G^3M^2}\right] T^3 \equiv AT^3 \, . \quad (2.28)$$

A is a constant defined by the above equation.

From Equations 2.25 through 2.28, we obtain the following relations:

$$-\frac{dR}{dt} = \frac{1+\eta}{\eta GM} \epsilon_o \frac{1}{A}\left[\frac{GM}{R_g(1+\eta)}\right]^6 \frac{1}{R^4} = \frac{C}{R^4} \quad (2.29)$$

and

$$-\frac{d^2R}{dt^2} = -\frac{4C}{R^5}\frac{dR}{dt} = +\frac{4C^2}{R^9} \, . \quad (2.30)$$

C is a constant depending on M and other gas characteristics. We now identify v with dR/dt and $\dot{v}$ with d^2R/dt^2. They both have unchanging negative signs which indicate that the star is collapsing inward, with rapidly increasing speed. Although Equations 2.29 and 2.30 are only approximate solutions, they do indicate strongly that a stellar collapse will eventually occur.

The limit for $\dot{v}$ is set by the gravitational field of the star. Thus,

$$\dot{v} < \frac{MG}{R^2} \, . \quad (2.31)$$

Equation 2.31, together with Equation 2.30, sets a lower limit on R below which no hydrostatic equilibrium is possible:

$$R > \left[\frac{4C^2}{MG}\right]^{1/7} \equiv R_l \, . \quad (2.32)$$

A similar result may be obtained by considering the upper limit for v. The upper limit for v is set by the gravitational energy available at radius R:

$$\frac{1}{2}Mv^2 < \frac{M^2G}{R} \, . \quad (2.33)$$

Equation 2.33 is identical with Equation 2.32 apart from a numerical factor close to unity.

Let $M = 20M_\odot$, $\eta = 0.1$; we find the limiting radius R_l to be

$$R_l \approx 10^9 \text{ cm} \, ,$$

$$C \approx 6.8 \times 10^{31} \text{ (in cgs units)} \, .$$

The corresponding temperature as estimated from Equation 2.28 is roughly 3×10^9 °K. This temperature is below the iron-helium disintegration temperature ($\approx 6\times10^9$ °K.) However, we remark that the above estimate is very crude. The only conclusion we can draw is that both the *annihilation neutrino process* and the *iron-helium disintegration process* are capable of causing a massive star to collapse. To answer this question more quantitatively, one needs to find out the sign of the integral (Equation 2.4) and to solve Equations 2.13 through 2.17 with the boundary condition Equation 2.18 and appropriate input parameters.

The steep dependence of $\dot{v}$ on 1/R ($\propto$ T) as shown in Equation 2.30 indicates that the collapse may take place suddenly.

3. PHYSICAL EVENTS AND CONSEQUENCES OF STELLAR COLLAPSE

We have demonstrated in the last section that, when the gravitational contraction of a star (carried by neutrino emission process) reaches a certain stage, collapse must take place and the concept of hydrostatic equilibrium loses its meaning. We shall find out whether the collapse will

stop and whether the star can eject enough mass so as to become an ordinary white dwarf.

3.1. Impossibility of Ejecting Enough Matter To Become a White Dwarf

In order that a massive core may eject enough mass to become a white dwarf, some physical mechanism must be present to eject almost all of its mass into space.

It is difficult to imagine a practical mechanism to achieve this. However, we shall now demonstrate on energetic grounds that a star cannot eject enough matter into space so that the remaining star becomes a white dwarf. The gravitational energy of a star is GM^2/R. Since no cold star of mass $>1.4M_\odot$ may exist (see Section 4), an energy of the amount

$$\frac{G\left(M^2 - M_\odot{}^2\right)}{R}$$

is needed to dissociate the star from its gravitational binding. This energy must be supplied gravitationally by the remaining core of the star of mass around $M_\odot$, radius r. Hence, to the first approximation

$$\frac{G\left(M^2 - M_\odot{}^2\right)}{R} \approx \frac{GM_\odot{}^2}{r} \quad . \tag{3.1}$$

Consider $M \approx 20M_\odot$, and a radius of 10^9 cm (which corresponds to a temperature of around 1 Mev when instability occurs); we find $r \approx R/400$. The density of the remaining core will be $(400)^3 = 6.4 = 10^7$ higher than that of the star before collapse takes place. From Equation 2.28 the density at the instant of collapse is estimated to be roughly 10^7 gm/cm^3. Hence the remaining core will have a density of at least 10^{13} gm/cm^3, which is the density of a neutron star.

This example is cited just to demonstrate that, when a massive star collapses, there is no possibility that the remaining core will be a white dwarf.

Moreover, most of the energy released during the gravitational collapse of a star will be in the form of neutrinos and cannot be of any practical use. This will be discussed in more detail in Section 3.4.

We now examine the thermodynamic properties of dense matter and the corresponding stars.

3.2. Thermodynamic Properties of Degenerate Matter at Near Zero Temperatures

At zero temperature and reasonably low density ($\rho \lesssim 10^{12}$ gm/cm^3) the energetics of an ionized gas are dominated by the electrons. The available energy states are occupied up to a Fermi momentum p_F corresponding to a Fermi energy E_F. The relation between the electron number density n_e and Fermi momentum p_F and density ρ are as follows:*

$$x = \frac{p_F}{m_e c} \quad , \tag{3.2}$$

$$n_e = \frac{8\pi m_e{}^3 c^3}{3h^3} x^3 = 5.9 \times 10^{29} x^3/\text{cm}^3 \quad , \tag{3.3}$$

$$\rho = 10^6 \frac{A}{Z} x^3 \text{ gm/cm}^3 \quad , \tag{3.4}$$

where A and Z are average values for the mass number and the atomic number for the gas. The electron Fermi energy E_F is given by

$$E_F = m_e c^2 \left[\left(1 + x^2\right)^{1/2} - 1\right] \quad . \tag{3.5}$$

Salpeter (Reference 18) found that in the stellar regime the pressure energy density relation is very well described by that for a perfect Fermi gas All other corrections (Coulomb correction, exchange effect, ion motion, etc.) are very small. These relations for a perfect Fermi gas are (Reference 17):

$$P = \frac{\pi m^4 c^5}{3h^3} f(x) = 6.01 \times 10^{22} f(x) \text{ d/cm}^2 \quad , \tag{3.6}$$

$$E_{kin} = \frac{\pi m^4 c^5}{3h^3} g(x) \quad , \tag{3.7}$$

$$f(x) = x\left(2x^2 - 3\right)\left(x^2 + 1\right)^{1/2} + 3 \sinh^{-1} x \quad , \tag{3.8}$$

$$g(x) = 8x^3\left[\left(x^2 + 1\right)^{1/2} - 1\right] - f(x) \quad , \tag{3.9}$$

where E_{kin} is the kinetic energy density of the electrons. We have the following asymptotic expression:

$$\left.\begin{aligned} f(x) &\to \frac{8}{5} x^5 \\ g(x) &\to \frac{12}{5} x^5 \end{aligned}\right\} \quad x \to 0 \quad , \tag{3.10}$$

*For a description of the theory of a perfect Fermi gas, see Reference 17.

and

$$\left.\begin{aligned} f(x) &\to 2x^4 \\ g(x) &\to 6x^4 \end{aligned}\right\} \quad x \to \infty , \qquad (3.11)$$

Hence

$$P \to \frac{2}{3} E_{kin} \qquad x \to 0 , \qquad (3.12)$$

$$P \to \frac{1}{3} E_{kin} \qquad x \to \infty , \qquad (3.13)$$

and

$$P = \frac{1}{20}\left(\frac{3}{\pi}\right)^{2/3} \frac{h^2}{m} n_e^{5/3} \qquad x \to 0 , \qquad (3.14)$$

$$P = \frac{1}{8}\left(\frac{3}{\pi}\right)^{1/3} hcn_e^{4/3} \qquad x \to \infty . \qquad (3.15)$$

3.3. Composition of Degenerate Matter at Near Zero Temperatures

If the energy of an electron is greater than the ϵ_z, the beta-decay energy for electron emission (counting only the kinetic energy) of the nucleus (Z–1, A), then inverse beta reactions involving (Z, A) will occur:

$$e^- + (Z,A) \to (Z-1,A) + \nu. \qquad (3.16)$$

If $E_F > \epsilon_z$, then the nucleus (Z, A) ceases to be stable and undergoes inverse beta decay to the nucleus (Z–1, A). The nucleus (Z–1, A) cannot decay because all electronic states are occupied up to the Fermi energy $E_F > \epsilon_z$. If the nuclei are in equilibrium, the composition is easily calculated. By minimizing the quantity

$$b^* = \frac{B(Z,A) - ZE_F'}{A} \qquad (3.17)$$

(where E_F' is the Fermi energy of the electron gas minus the neutron-hydrogen atom rest mass energy difference), Salpeter (Reference 18) calculated the equilibrium composition for cold degenerate mater. His result is shown in Table 1.

When $\rho \gtrsim 10^7$, Γ for the electron gas is already very close to 4/3 (Figure 1). The gas sphere is only marginally stable against hydrostatic instability. The inverse beta reactions will cause Γ to be less than 4/3 for the density region $\rho = 10^7$ to $\rho = 10^{12}$ gm/cm^3. Wheeler (Reference 19) has computed the ratio of P to $\rho^{4/3}$; he finds that the ratio actually decreases with ρ in the above density region.* His result is shown in Figure 3.

Table 1

Equilibrium Composition of Cold Matter*

(Z, A)	(26,56)	(28,62)	(28,64)	(28,66)	(28,68)
E_F	0.6	2.5	3.9	6.1	7.0
$\log_{10}\rho$	7.15	8.63	9.15	9.69	9.87
(Z, A)	(30,76)	(30,78)	(30,80)	(32,90)	(38,120)
E_F	8.5	9.5	14.8	20.6	24.0 Free neutrons
$\log_{10}\rho$	10.13	10.28	10.84	11.28	11.53

*ρ is measured in gm/cm^3, E_F in Mev.

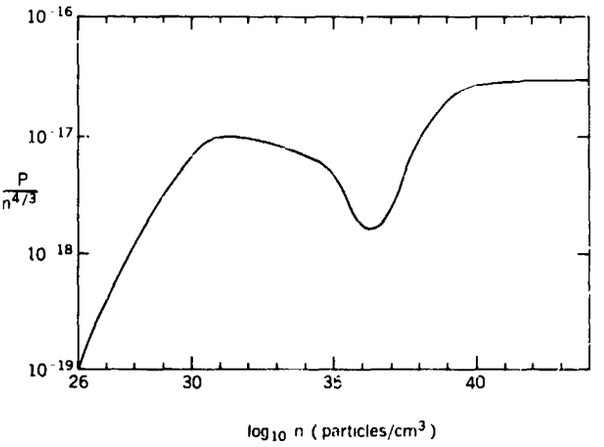

FIGURE 3.—The ratio $P/n^{4/3}$ (where n is the total number density of nucleons) is plotted as a function of n. In between $n = 10^{31}$/cm^3 and $n = 10^{38}$/cm^3 ($\rho = 10^7 \to 1.67 \times 10^{13}$gm/cm^3) $P/n^{4/3}$ decreases as n increases, indicating that the power dependence of P on n is less than 4/3; this result is due to Wheeler.

If all nuclei are not in thermodynamic equilibrium, then the transition may not take place as described by Table 1. Cameron (Reference 20) has studied the rate of nuclear reactions at high density (pycno nuclear reactions). He found that most nuclear reactions leading towards equilibrium state will take place spontaneously even at zero temperature when the density is greater than 10^9 gm/cm^3.

*At zero temperature $\Gamma = (\rho/P)(dP/d\rho)$. If P is expressed as $P = P_0 \rho\Gamma$, where P_0 is a proportionality constant, then Γ is the adiabatic exponent.

We may therefore safely expect that the composition of matter at $\rho > 10^9$ gm/cm^3 will be reasonably given by Table 1 under equilibrium conditions. Wheeler's result (Figure 3) indicates that in-between the density-temperature region $\rho = 10^8$ to $\rho = 10^{12}$ gm/cm^3 there are no equilibrium configurations for a star. Harrison, Wakano, and Wheeler (Reference 19) have also studied the structure of stars at zero temperature; the result is shown in Figure 4, in which the mass as a function to stellar density is plotted. In certain

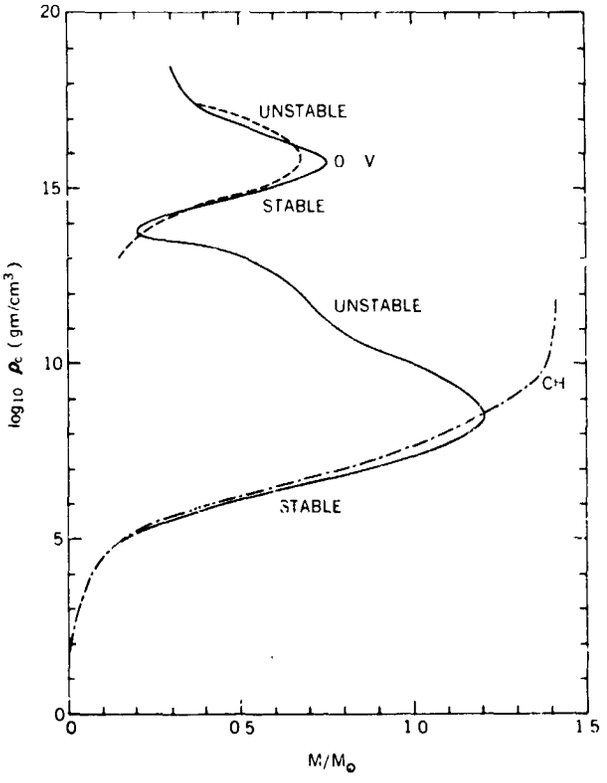

FIGURE 4.--The mass-central density ρ_c relation for zero temperature stars. Given a central density, with the equation of state described in Figure 3 and Section 3.3, the mass may be integrated by using Equations 2.9 and 2.10 or Equations 5.2 and 5.3. Curves marked CH show the nongeneral-relativistic result of Chandrasekhar (Ref. 17), and the curve marked O-V is the general relativistic result of Oppenheimer and Volkoff for an ideal Fermi gas (Ref. 27). This solid curve is due to Wheeler et al. (Refs. 19 and 25.)

density regions where inverse beta reaction occurs, the mass of the star decreases with increasing central density, indicating that such configurations are unstable.

3.4. Neutrino Production at Near Zero Stellar Temperatures

We now turn to the energetics of dense matter at non-zero temperatures. As long as $kT \ll E_F$, the thermodynamic properties of matter are not different from that for the zero temperature case. Hence we shall only consider the case where $kT \approx E_F$. It may be pointed out that, as long as Γ is close to 4/3, the relation $T \propto \rho^{1/3}$ (Equation 2.28) is expected to hold for the temperature and density of a star during its evolution. If $E_F \gg mc^2$, $E_F \propto \rho^{1/3}$. Hence the ratio kT/E_F will be roughly a constant if energy dissipation is not substantial; otherwise it will decrease.

In the following we shall assume that the ratio kT/E_F will be roughly 1. With this assumption, if we find the relaxation time for losing energy to neutrinos is short compared with the time for the star to restore to its original density, then we are back to the zero temperature case.

At $T = 6 \times 10^9$ °K ($kT \approx 0.5$ Mev) the most dominant neutrino process is the annihilation process (References 21, 22, and 23):

$$\gamma \rightleftarrows e^- + e^+ \longrightarrow \nu_e + \bar{\nu}_e \quad . \tag{3.18}$$

At higher temperatures then neutrino processes also must be considered. At low density ($\rho < 10^7$ gm/cm^3, say) the mean free path of neutrinos is longer than the physical dimension of the star. At higher density, the mean free path of neutrinos is no longer compared with the physical dimension of the star. The rate of dissipation of neutrinal energy is then less than the production rate.

At $kT \approx m_\mu c^2$, the creation of π meson pairs and μ meson pairs is not negligible. Because the neutrinos associated with the μ meson do not interact with electrons to the lowest order, the dissipation of stellar energy through μ-neutrino production is more important. We shall also include this in our discussion.

(a) Electron-Positron Pair, π and μ Pair Densities

The number density for the electron pair created, under the condition $E_F/kT \gg 1$, is roughly given by (see, for example, Reference 23)

$$n_e = \frac{8\pi m_e^3 c^3}{h^3} \int_0^\infty \frac{x^2 dx}{\exp\left[(1+x^2)^{1/2}/\theta_e\right] + 1} \tag{3.19}$$

where

$$\theta_e = \frac{kT}{m_e c^2} = \frac{T}{T_e} . \quad (3.20)$$

Numerically

$$T_e = 6 \times 10^9 °K . \quad (3.21)$$

Since $T \gg T_e$, we may use the approximation $(1+x^2)^{1/2} \approx x$. Changing variables from x to $u\mu_m/\theta_e$, we have

$$n_e = \frac{8\pi m_e^3 c^3}{h^3} \theta_e^3 \int_0^\infty \frac{u^2 du}{\exp u + 1} . \quad (3.22)$$

Since

$$\int_0^\infty \frac{u^2 du}{\exp u + 1} = \zeta(3) = 1.2202 , \quad (3.23)$$

where $\zeta(z)$ is the Riemann's zeta function, we find numerically that

$$n_e = 4.4 \times 10^{30} \theta_e^3 \quad (3.24)$$

For the case of π or μ mesons we may define

$$\theta_\mu = \frac{kT}{m_\mu c^2} = \frac{T}{T_\mu} , \quad (3.25)$$

$$\theta_\pi = \frac{kT}{m_\pi c^2} = \frac{T}{T_\pi} , \quad (3.26)$$

$$T_\mu = 1.24 \times 10^{12} °K , \quad (3.27)$$

$$T_\pi = 1.65 \times 10^{12} °K . \quad (3.28)$$

If we neglect the factor unity in Equation 3.19, we have

$$n_\pi = 5.8 \times 10^{37} \theta_\pi K_2\left(\frac{1}{\theta_\pi}\right) , \quad (3.29)$$

$$n_\mu = 1.54 \times 10^{37} \theta_\mu K_2\left(\frac{1}{\theta_\mu}\right) . \quad (3.30)$$

where $K_2(z)$ is the modified Hankel function with the following asymptotic expression:

$$K_2(z) \longrightarrow \frac{2}{z^2} \qquad z \ll 1 , \quad (3.31)$$

$$K_2(z) \longrightarrow \sqrt{\frac{\pi}{2z}}\, e^{-z} \qquad z \gg 1 . \quad (3.32)$$

Table 2 lists the number density of electron pairs and μ meson pairs for $T = 10^{10}°K$ to $10^{12}°K$.

Table 2

Electron, π Meson, and μ Meson Number Densities as a Function of Temperature

(T is measured in °K; n in particles/cm^3).

(b) Neutrino Cross Sections at High Energy

When the energy difference between neutron and proton can be neglected, the cross section for first order neutrono process is given by

$$\sigma \frac{v}{c} = CG^2 p_\nu^2 , \quad (3.33)$$

where G is the weak interaction constant, v is the relative velocity of the initial system of particles ($\approx c$), and p_ν is the final neutrino momentum. C is a numerical constant listed for a number of reactions in Table 3.

3.5. Relaxation Time for Cooling of a Collapsing Star

At high temperature the energy difference between proton and neutron may be neglected. If

Table 3

Neutrino Reactions

	Reaction	$c \equiv \nu/G^2P_\nu^2$
e - 1	$e^- + e^+ \rightarrow \nu_e + \bar{\nu}_e$	$1/3\pi$
e - 2	$e^- + p \rightarrow n + \nu_e$	$5.5/\pi$
e - 3	$e^+ + n \rightarrow p + \bar{\nu}_e$	$5.5/\pi$
e - 4	$e^- + \gamma \rightarrow e^- + \nu_e + \bar{\nu}_e$	α/π
μ - 1	$\mu^- + \mu^+ \rightarrow \nu_\mu + \bar{\nu}_\mu$	$1/3\pi$
μ - 2	$\mu^- + p \rightarrow n + \nu_\mu$	$5.5/\pi$
μ - 3	$\mu^+ + n \rightarrow p + \bar{\nu}_\mu$	$5.5/\pi$
μ - 4	$\pi \rightarrow \mu + \nu_\mu$	Lifetime $= 2.2 \times 10^{-8}$ sec
μ - 5	$\mu \rightarrow e + \nu_\mu + \nu_e$	Lifetime $= 2.2 \times 10^{-6}$ sec

the relation between the temperature T and the density ρ is given by*

$$\frac{T}{10^{12}\,^\circ K} = \left(\frac{\rho}{10^{13}\ \mathrm{gm/cm^3}}\right)^{1/3}. \qquad (3.34)$$

the neutrino yield from electron-neutrino processes will be roughly the same, except the photo-neutrino process e–4 which is down by a factor of $\alpha/\pi \approx 1/400$. The μ-neutrino processes show a wider variation. All μ capture or annihilation processes have roughly the same cross section as the electron process, as is expected from the theory. However, π and μ mesons can decay into electrons and neutrinos. The rate of decay, to the extent that degeneracy is neglected, is independent of the energy (apart from a time dilatation factor). Up to a temperature of $\approx 10^{12.2}$K, μ-neutrino emission from π-decay is the most important process.

As the density of the star increases, the mean free path of neutrinos becomes smaller. Once the mean free path of the neutrinos becomes smaller than the dimension of the star, the neutrino energy loss rate is no longer the same as the production rate. Let the radius of the star be R, the mean free path for neutrinos be λ, the total stellar neutrino energy content U_ν; then the neutrino luminosity L_ν for a star is

$$L_\nu = \frac{U_\nu}{\frac{R}{c}\cdot\frac{R}{\lambda}}. \qquad (3.35)$$

Equation 3.35 has the following interpretation: When $\lambda = R$, the neutrinos leave the star with the velocity of light and the time constant for doing this is just R/c, the time of transit across the star with a velocity of light. When $\lambda < R$, neutrinos on the average scatter R/λ times before they leak out of the star. Its path length is approximately increased by a factor of R/λ. Hence Equation 3.35 describes the rate of decay of stellar neutrinal energy. The neutrinal energy content of the star may be estimated in the following way: The average energy of each neutrino is around kT. If all neutrinal states are filled up, further neutrino emission processes are inhibited. The total energy content allowable to neutrinos is of the same order as the energy content of the electron pairs, which is of the same order of magnitude as the total energy content.

A recent experiment demonstrated that the neutrino associated with electrons (e-neutrino) and the neutrino associated with μ mesons (μ-neutrino) have different quantum numbers (Reference 24). That is, a μ-neutrino cannot

*Equation 3.34 is consistent with the assumption that $E_F/\tau k \approx 1$.

induce an inverse beta reaction:

$$\left.\begin{aligned} &\bar{\nu}_\mu + p \not\rightarrow n + e^+ , \\ &\nu_\mu + n \not\rightarrow p + e^- , \end{aligned}\right\} \qquad (3.36)$$

nor can an e-neutrino induce inverse μ capture reactions:

$$\left.\begin{aligned} &\bar{\nu}_e + p \not\rightarrow n + \mu^+ , \\ &\nu_e + n \not\rightarrow p + \mu^- . \end{aligned}\right\} \qquad (3.37)$$

Since the average energy of μ-neutrinos coming from π-decay and μ-decay is of the order of mc_μ^2 (or less), inverse μ capture reaction cannot occur. Until $kT \approx m_\mu c^2$ ($T \approx 10^{12}$°K), the number density for μ mesons is small. At the temperature ($T = 1.6\times10^{11}$°K) when the loss of energy due to π decay becomes very important, the mean free path for ν_μ–μ scattering is 10^8 cm, which is around the radius of the star ($\approx 7\times10^7$ cm). Hence μ-neutrinos can dissipate stellar energy rapidly while e-neutrinos cannot. Table 4 summarizes our results. The relaxation time for dissipating stellar energy is shortest at roughly $T = 6.3\times10^{10}$°K, and again at $T \approx 4\times10^{11}$°K. The corresponding relaxation times are roughly 3×10^{-3} and 10^{-4} seconds, respectively. This is roughly the time scale for the star to relax to the zero temperature configuration discussed previously.

Since this time scale is of the same order of magnitude for light to travel across the star, we conclude the core collapses under zero temperature conditions ($E_F/kT \gg 1$). Colgate's proposal (Reference 4) that a shock wave will first compress the star into neutron star density, that it will be rebounded to restore the core to normal density, is somewhat unrealistic.

We have not included in our calculations the red shift of neutrinos due to the gravitational field of the star. The red shift caused by the gravitational field of the star will at most decrease the net loss energy rate by a factor of 2 (Section 8.2, and also Reference 48). If the red shift becomes much larger, then the star approaches a singular position which we shall soon discuss.

4. STATIC STRUCTURE OF WHITE DWARFS AT ZERO TEMPERATURE

Using Equations 3.6 and 3.7 as equations of state, Chandrasekhar (Reference 17) integrated Equations 2.9 and 2.10 to obtain the static structure of white dwarfs. His result is shown in Figure 4 together with Wheeler's, and Oppenheimer and Volkoff's, results. The most interesting feature is that the central density (and the central pressure) become infinite when the mass is still finite. The limiting mass he obtained is $5.75M_\odot/\mu_e^2$ where $\mu_e = \mathbb{A}/\mathbb{Z}$. Taking the most popular value of $\mu_e = 2$, the limiting mass is around $1.44M_\odot$.

Salpeter* worked out an intuitive derivation of the limiting mass, which is reproduced below. The virial theorem tells us that (Equation 2.20)

$$E_G \tilde{=} E .$$

Let E_e be the kinetic energy per electron. Then

$$\left.\begin{aligned} E_G &\approx \frac{GM^2}{R} , \\ E &\approx NE_e \end{aligned}\right\} \qquad (4.1)$$

and

$$M = N\mu_e m_p . \qquad (4.2)$$

Hence

$$E_e = \frac{GM_p^2 \mu_e^2 N}{R} . \qquad (4.3)$$

Let r_e be the average value of the inter-electron spacing and p_e be the average momentum; then the uncertainty principle gives

$$r_e p_e \geq \hbar . \qquad (4.4)$$

Considering only the equal sign case, we find, from the definition of E_e and Equation 4.4, that

$$\begin{aligned} E_e &= \frac{p_e^2}{2m_e} = \frac{m_e c^2}{2}\left(\frac{r_o}{r_e}\right)^2 \qquad p_e \ll m_e c , \\ E_e &= p_e c = m_e c^2\left(\frac{r_o}{r_e}\right) \qquad p_e \gg m_e c , \end{aligned} \qquad (4.5)$$

*Private communication.

where $r_o = \hbar/m_e c$ is the Compton wavelength for an electron. Combining these two equations, letting $s = r_e/r_o$, one can write

$$E_e = mc^2 \left[\frac{1}{s + 2s^2}\right] . \qquad (4.6)$$

Wheeler (Reference 25) has checked the accuracy of Equation 4.6 against the more complete formula Equations 3.6 and 3.7; he finds the maximum deviation is around 8 percent. Since $R \approx N^{1/3} r_e$, in substituting Equation 4.6 into Equation 4.3, one obtains the following expression:

$$\frac{1}{1 + 2s} = \left[\frac{G m_p^2 \mu_e^2}{r_o mc^2}\right] \cdot N^{2/3} \equiv \mu_e^2 \left(\frac{N}{N_o}\right)^{2/3} , \qquad (4.7)$$

where

$$N_o = \left[\frac{G m_p^2}{\hbar c}\right]^{-3/2} \approx 2N_\odot ; \qquad (4.8)$$

N_o is a characteristic number and $N_\odot$ is the number of particles of the sun. When $N < N_o$, it is possible to find a value of s such that Equation 4.7 is satisfied. When $\mu_e^3 N > N_o$, it is not possible to satisfy Equation 4.7 with a positive value of s Hence, there exists a limiting value of mass beyond which no static equilibrium structure is possible.

Long before the density ρ becomes infinite, inverse beta reactions described in Section 3.3 will occur and Chandrasekhar's description will *no longer* be valid. However, this occurs at a mass very close to his limiting mass; this is shown in Figure 4.

We believe the structure of white dwarfs is well understood. Although the density and the pressure may become infinite at a finite mass, this divergence never occurs in nature as demonstrated by Wheeler (Figure 4). This is, however, not true in the case of neutron stars.

5. THE STATIC STRUCTURE OF NEUTRON STARS

5.1. The Equation of Stellar Structure

Since the numerical value for GM/Rc^2 (the ratio of gravitational energy to rest energy) for a neutron star is close to unity, it is necessary to consider the structure from a general relativistic point of view. Because of neutrino energy dissipation (Section 3.4), the temperature of the

neutron core may always be taken to be zero. The pressure P may be taken to be a function of material density only (P and ρ are all measured in proper coordinates). Further, we consider only the static structure of neutron stars with complete spherical symmetry and no rotation. Under these circumstances, the stress energy tensor becomes

$$T_{\mu\nu} = \begin{pmatrix} -P & 0 & 0 & 0 \\ 0 & -P & 0 & 0 \\ 0 & 0 & -P & 0 \\ 0 & 0 & 0 & \rho c^2 \end{pmatrix} . \qquad (5.1)$$

The equation of stellar structure is a solution of Einstein field equations with a time static and spherically symmetric metric (References 26 and 27). The equation is:

$$\frac{dP}{dr} = \frac{\left(\frac{P}{c^2} + \rho\right) G\left(4\pi r^3 \frac{P}{c^2} + m^*\right)}{r\left(r - \frac{2Gm^*}{c^2}\right)} \qquad (5.2)$$

and

$$\frac{dm^*}{dr} = 4\pi r^2 \rho \, . \qquad (5.3)$$

Neglecting $1/c^2$ terms, Equation 5.2 reduces to that for a not-relativistic gas sphere. At the radius of the star, m^* is actually the gravitational mass observed by a distant observer (by the gravitational field the star produces). In the following we denote the proper mass (the mass before it was assembled into a star) by m, the mass observed by distant observers by an asterisk*.

The analytical properties of Equations 5.2 and 5.3 have been discussed by Oppenheimer and Volkoff (Reference 27). They found that the boundary conditions for an ordinary star apply (e.g., at $r=0$, $m^*=0$, and the central pressure $P_c>0$, etc.).

5.2. The Equation of State

In order that a unique solution for Equations 4.2 and 4.3 be possible for a given set of boundary conditions, P must be a known function of ρ. We shall discuss the equation of state $P(\rho)$ in greater detail. Because the interparticle spacing is of the order of 10^{-13} cm or less, which is roughly the size of elementary particles, it is not possible to exclude the structure of elementary particles from our discussion as in the case of the white dwarfs.

Before we proceed to the detailed structure of the equation of state, we would like to examine the limitations on the equation of state.

5.3. The Unimportance of Quantum-Gravitational Effects

Since the gravitational field inside a neutron star is extremely strong, one might wonder if quantum effects of the gravitational field may interfere with normal interactions among particles. However, quantum effects of gravitational field will, in general, not be important, as we shall show below.

A well-known theorem in Riemannian geometry* states that, in a given space with a non-Euclidean metric, it is always possible to find a coordinate transformation such that locally at any given point the metric $g_{\mu\nu}$ may be reduced to that for a Minkowskian space; that is,

$$g'_{\mu\nu} = \begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & +1 \end{pmatrix} . \qquad (5.4)$$

Unless the $g_{\mu\nu}$'s change considerably over the dimension of elementary particles ($\approx \hbar/m_\pi c \approx 10^{-13}$ cm), it is not necessary to consider quantum effects of gravitational fields. Even in the extreme case when the mass of a neutron star is close to its critical mass, when the time metric g_{00} vanishes at the center, quantum effects may still not enter. According to Oppenheimer and

*This is easily proven. The line element ds may be written as:

$$ds^2 = \sum_{i,j} g_{ij} dx^i dx^j \, ,$$

where $\{g_{ij}\}$ is the metric tensor and $\{x^i\}$ is a general set of coordinates. Since $\{g_{ij}\}$ is a symmetric tensor, at a particular point $\{g_{ij}\}$ can be diagonalized by "rotating" the $\{x^i\}$ coordinate system at this point. An additional scale change in the rotated $\{x^i\}$ system reduces the line element to

$$ds^2 = \sum_{i,j} \pm \delta_{ij} dx^i dx^j \, ,$$

where δ_{ij} is the Kronecker delta and the sign ($\pm$) is chosen as to be consistent with the signature of Equation 13.1. Since g_{ij} varies with position, obviously this transformation is valid only at the particular point chosen.

Volkoff one can write generally, in the center of a neutron star:

$$g_{oo} = \left(1 - \frac{2Gm^*}{Rc}\right)^{1/2} \exp\left[-\frac{1}{c^2}\int_o^{P_c} \frac{dP}{\frac{P}{c^2} + \rho}\right]; \quad (5.5)$$

when the mass of a neutron star approaches the critical mass, $P_c \to \infty$, the integral in the exponential diverges logarithmically as one approaches the center, and g_{00} vanishes as $1/P$ ($P \to \infty$). Unless $P \to \infty$ abruptly over a dimension of an elementary particle, g_{00} cannot change substantially. This would not occur since the pressure is itself a macroscopic concept. Hence the center of neutron stars is not likely to be the dwelling place of quantum gravitational field theory.

It might be questioned that, since the trajectories of particles with spin are not geodesics (References 28 and 29), this might be an indication that quantum-gravitational effects play an important role. However, the spin-gravity interaction depends on the gradient of the gravitational field (spin-orbit type coupling) (References 28 and 29). Unless g_{00} changes substantially over the dimension of an elementary particle, this interaction may be treated classically. Thus the criteria for replacing a gravitational field by an acceleration is the same for particles with spin or without spin. As long as the pressure retains its macroscopic meaning, locally we can always replace gravitational fields, however strong, by a uniform acceleration. In the following, we therefore neglect the quantum gravitational effects.

5.4. Relativistic Limits on the Equation of State

General relativity does set up certain limits for the equation of state on the basis of positive (or negative, depending on which convention to follow) definiteness of the stress energy tensor, and that signals cannot propagate at a speed faster than light speed.

The speed of sound v_s for a given medium is given as

$$v_s = c\sqrt{\frac{dP}{d\epsilon}} < c, \quad (5.6)$$

where ϵ is the energy density. Integrating Equation 5.6 one obtains

$$P < \epsilon. \quad (5.7)$$

That is, the pressure must not exceed the energy density.

This is more relaxed limit for P.

In the case of a non-interacting ideal gas (including photon gas) the trace of the energy momentum tensor T_{ij} may be demonstrated to have a positive definite value (see, for example, Reference 30); T_{ij} is given by:

$$T_{ij} = \begin{pmatrix} -P & 0 & 0 & 0 \\ 0 & -P & 0 & 0 \\ 0 & 0 & -P & 0 \\ 0 & 0 & 0 & +\epsilon \end{pmatrix}. \quad (5.8)$$

Thus we have a more stringent condition on P:

$$P \leq \frac{1}{3}\epsilon. \quad (5.9)$$

Only in the case of a photon gas one can have $P = \epsilon/3$. This sets an upper limit for the speed of sound to be $(1/\sqrt{3})c$.

Recently, however, Zel'Dovich (Reference 31) constructed an example of a relativistically invariant theory for a classical vector field with a mass, interacting with stationary classical point charges. In this theory the energy density ϵ and the pressure P are

$$\epsilon = nM + \frac{2\pi g^2 n^2}{\mu^2}, \quad (5.10)$$

$$P = \frac{2\pi g^2 n^2}{\mu^2}, \quad (5.11)$$

(units: $\hbar = c = 1$) where M is the mass of the heavy particle, μ the mass of the field quanta, g the charge of the field quanta, and n the number density of heavy particles. In the limit of large n, $\epsilon \propto n^2$ and $\epsilon \approx P$.

One might argue that, since for a particle with mass the stress energy tensor is

$$T_{\mu\nu} = \left(\rho + \frac{1}{c^2}P\right) U^\mu U^\nu - \frac{1}{c^2}\rho\eta^{\mu\nu}, \quad (5.12)$$

(where $\eta^{\mu\nu}$ is the Minkowskian metric, U^μ the f · velocity) and that nothing can be "ilghter" t₁ a photon (for photon the rest mass is zero), $P = 1/3\epsilon$ should be the ultimate limit for all equations of state. Zel'Dovich's example indicates that such intuitive deduction is not correct.

5.5. Detailed Structure of Matter at High Density

The composition of matter at high density was considered in detail by Ambartsumyan and Saakyan (References 32 and 33). When the Fermi energy (including the rest energy) of neutrons exceeds the rest energy of strange particles, strange particles will be created in equilibrium with neutron gas. Although it is necessary to preserve the strangeness conservation law in the production process, in the decay process such a law need not be preserved and the number density for strange particles is governed by their ability to decay. Thus, we do not need to worry about the seemingly strangeness non-conserving character of reactions of the following type:

$$n + n \rightleftarrows \Lambda^\circ + \Lambda^\circ \cdot \qquad (5.13)$$

With this fact in mind, we now write down the reactions we will consider:*

$$\left.\begin{aligned} Y^\circ &\rightleftarrows n \,, \\ e^- + Y^+ &\rightleftarrows n \,, \\ Y^- &\rightleftarrows n + e^- \,, \\ e^- + P &\rightleftarrows n \,, \\ e^- &\rightleftarrows \mu^- \,, \\ e^- &\rightleftarrows \pi^- \,, \end{aligned}\right\} \qquad (5.14)$$

where Y denotes one or more type of strange particles. Let the Fermi energy of particle x be denoted as E_x, its number density by N_x. Since at zero temperature the Fermi energy is the same as the chemical potential, the equilibrium condition for Equation 5.14 is:

$$\left.\begin{aligned} E_{Y^\circ} = E_n = E_e + E_{Y+} = E_e + E_p \,, \\ E_{Y-} = E_n + E_e \,, \\ E_{e-} = E_{\mu-} = m_\pi c^2 \,. \end{aligned}\right\} \qquad (5.15)$$

The reason for setting the chemical potential of π meson to its rest energy is because it is a boson which allows infinite condensation at zero kinetic energy. Further, the charge neutrality condition gives an additional constraint:

$$\Sigma N_{Y+} - \Sigma N_{Y-} - N_e - N_\mu - N_\pi = 0 \,. \qquad (5.16)$$

No π^+, μ^+ are allowed because they will annihilate with π^-, μ^- to become photons (or neutrinos) which subsequently will escape.

From Equations 5.15 and 5.16 the following conclusions may be drawn:

(1) The number density for e and μ are fixed independent of the material density once the Fermi energy of electrons reaches $m_\pi c^2$. At extremely high density only baryons contribute to the pressure. The threshold for π meson creation occurs at a baryon density of 5.86×10^{40} particles/cm³, or a material density of 10^{17} gm/cm³.

(2) π meson is the only boson that can be present. It represents an energy reservoir without contributing to the pressure. Other bosons created (e.g., the intermediate boson) will decay into π mesons directly or indirectly.

The composition of matter becomes very complicated at high energy. Particles become extremely densely packed. At a density of 10^{17} gm/cm³ the interparticle spacing is around 4×10^{-14} cm, which is about the radius of the repulsive core for protons and neutrons. Hence at such high density the interaction among particles is by no means negligible. The interacting energy is around 10 Bev in the cm system (which corresponds to a laboratory energy of 100 Bev). Experimental study of interactions at such a high energy is somewhat beyond the present capability. Our knowledge of the equations of state for closely packed neutron matter is therefore highly uncertain.

*The present approach is due to Ambartsumyan et al. (References 32 and 33).

5.6. Models for Neutron Stars

We have seen that nuclear interactions among elementary particles at extremely high energy play an important role in the macroscopic behavior of dense neutron stars. In the following we shall demonstrate that there may exist a paradox between a very fundamental conservation law (baryon conservation law) and general relativity. From neutron star models with a hypothetical equation we may study the properties of this paradox which, if resolved, should yield us important information on extremely high energy interactions.

We are mostly interested in the singular character of the metric g_{00}. In the following we shall review work done by other physicists on this subject.

(a) Oppenheimer-Volkoff Theory

The very first relativistic model for neutron stars was constructed by Oppenheimer and Volkoff (Reference 27). They assumed an equation of state of an ideal Fermi gas. Their mass-radius relation is demonstrated in Figure 4. The equilibrium mass m* (Equation 5.3) as a function of density shows a maximum of 0.76 $M_\odot$ at a density of around 10^{16} gm/cm^3 and then declines to $0.3M_\odot$ when the pressure P and the density ρ diverge at the center.* Since at the center $m^*=0$, we have, from Equation 5.5,

$$g_{00} = \exp\left[-\frac{1}{c^2}\int_0^{P_c}\frac{dP}{\frac{P}{c^2}+\rho}\right], \qquad (5.17)$$

g_{00} approaches zero when $P_c \to \infty$. Thus a singularity develops at the center when the mass is still finite. This singularity, unlike the Schwarzschild singularity, *cannot* be removed by a mere coordinate transformation (see Section 6). It may be a real singularity.

*(b) Cameron's Model**

Following Oppenheimer-Volkoff's model, several other models have been constructed. Cameron (Reference 10), in particular, used an equation of state computed by Skyrme according to many-body theory, taking into account the unclear interaction at low energy. Salpeter worked out a more complete equation of state computed on the basis of effective range theorgy. It agrees with Skyrme's theory in the low energy limit for which Skyrme's theory applies. Cameron's result is shown in Figure 5. Again, a singularity ($g_{00}=0$) develops at the center of his model star at a finite mass. The value of the critical mass is around $2M_\odot$.

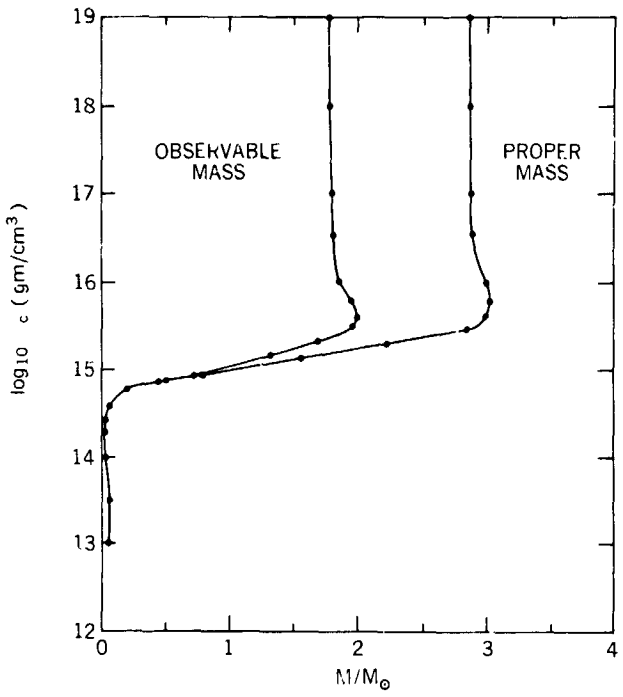

FIGURE 5.—The mass-central density P_c relation in Cameron's model (Ref. 10). Observable mass is m*; the proper mass is m as defined in Section 5.1.

(c) Wheeler et al. Hard Sphere Model

Motivated by the use of repulsive core to interpret low energy nuclear interactions, Wheeler et al. (Reference 19) studied the extreme case: the incompressible fluid for which the equation of state is

$$\left.\begin{aligned} P &= \text{finite} \\ P &= \infty \end{aligned}\right\} \quad \rho < \rho_0 , \qquad (5.18)$$

where ρ_0 is some density. Despite this kind of equation of state if the mass is not too large, in general no singularities will appear; but, for a

*The masses we talk about are masses observed by observers at large distances.

given value of ρ_o, there exists a critical mass for which a singularity ($g_{00}=0$) appears at the center. Moreover, they found that

$$\frac{dM^*}{dM} = \left[1-\left(\frac{M^*}{M_{cr}}\right)^{2/3}\right]^{1/2}, \qquad (5.19)$$

where M^* is the mass of the star observed by distant observer, M is the mass of the material that composes the star before the star is assembled, and M_{cr} is a critical mass depending on the value of P_o. Hence $dM^*/dM=0$ when $M^*=M_{cr}$. Moreover, they found that the ratio M^*/M has a non-zero finite value even when $M^*=M_{cr}$. We shall explore the meaning and implications of this result in the following discussions.

(d) Ambartsumyan-Saakyan Model

Ambartsumyan and Saakyan (References 32 and 33) studied the neutron star models on the basis of their equation of state, taking into account strange particles. Their result is shown in Figure 6. Essentially there is no change in the conclusion that g_{00} vanishes at the center of a finite mass.

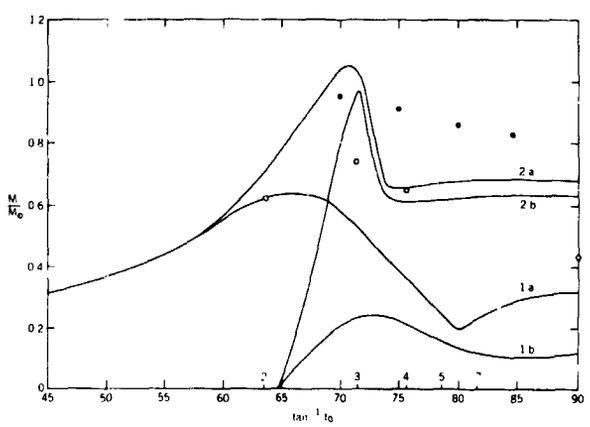

FIGURE 6.—The mass–t relation in Ambartsumyan and Saakyan's model; t_o is the value of t at the center of the star, where

$$t=4\ln\left\{\frac{P_F}{m_n c}+\left[1+\left(\frac{P_F}{m_n c}\right)^2\right]^{\frac{1}{2}}\right\}.$$

Curves 1a and 1b depict the mass of the star and its hyperon core in the case where elementary particles form an ideal gas at any densities. Curves 2a and 2b present the same picture for the case where repulsive forces acting between baryons at high densities (real gas) are taken into account. Black dots indicate the mass of configurations consisting of neutrons, with repulsive forces taken into account. Hollow dots indicate the mass of those configurations consisting of an ideal neutron gas. (Calculations by Oppenheimer and Volkoff, Ref. 27.)

*G. S. Saakyan (Reference 34) recently has repeated the computation by Cameron as described here. He found a mistake in Cameron's paper, and that the value of the critical mass is not as high as Cameron claimed.

6. DYNAMIC COLLAPSE OF OVERSIZED NEUTRON STARS

Although the four treatments of neutron star models have not exhausted the possibility of all types of equation of states, they do indicate that inevitably g_{00} vanishes at the center for a finite neutron star mass. The question arises: Is this singularity unavoidable? Is there no way to save the face of physics by avoiding infinite pressure and density? In this section we would like to examine the problem of the dynamical collapse of a star more closely, and the nature of the singularity with which we are faced.

6.1. Schwarzschild Singularity and the Ultimate Mass Limit

For a point mass, the Schwarzschild solution for the metric has the form (Reference 26):

$$ds^2 = g_{ij}\,dx^{ij} = -\frac{dr^2}{1-\frac{2GM}{rc^2}} - r^2\,d\theta^2 - r^2\sin^2\theta\,d\phi^2 + \left(1-\frac{2GM}{rc^2}\right)dt^2 . \qquad (6.1)$$

For a mass m, a singularity occurs at $r_s=2GM/c^2$. That is, $ds^2=\infty$. Consequently no light signal can cross this boundary defined by $r=r_s$.* For a proton, $r_s\approx 10^{-53}$ cm. Since the radius of a proton is 10^{-13} cm, it does seem that the Schwarzschild singularity may not play as important role in the structure of a proton For massive objects like the sun, the Schwarzschild radius is around 2.6 km, which is about the size of a neutron star of the same mass with a density of around 10^{16} gm.

This singularity has been a subject of discussion among relativists ever since the solution was found. Is it a real singularity? Or is it just a singularity related to a particular coordinate system?

*We might remark that such behavior was first predicted by Laplace on the basis of a corpuscular theory of light. See Reference 35.

By a change of coordinates of $r \to \bar{r}$, $\theta \to \theta$, $\phi \to \phi$, $t \to \bar{t}$, where $\bar{r}$ is related to r by the following relation†:

$$r = \left(1 + \frac{GM}{2\bar{r}c^2}\right)^2 \bar{r} . \qquad (6.2)$$

Equation 6.1 becomes

$$ds^2 = -\left(1 + \frac{m'}{2\bar{r}}\right)^4 \left(d\bar{r}^2 + \bar{r}^2\, d\theta^2 + \bar{r}^2 \sin^2\theta\, d\phi^2\right) + \frac{(1 - m'/2\bar{r})^2}{(1 + m'/2\bar{r})^2}\, dt^2 , \qquad (6.3)$$

where

$$m' = \frac{GM}{c^2}$$

is the geometrized mass. In Equation 6.3 the singularity in r coordinates disappears. Hence it seems that the singularity at $r = r_s$ is a coordinate singularity.

Further, Robertson (Reference 36) has demonstrated that, by a coordinate transformation, one can eliminate this singularity in the following sense: An observer in the flat space observes the free fall of a test particle towards the singularity. The time it takes the test particle to cross the boundary (which is at $r_s = 2GM/c^2$) is infinite; this is because $g_{00} = 0$ at the boundary and the test particle suffers infinite time dilatation as it approaches the singularity. However, if the observer moves with the test particle, the time duration that he observes for the test particle (and himself) to cross the boundary is *finite*. Hence, in the opinion of many relativitists, this singularity is a *coordinate* singularity since it can be removed by a proper choice of coordinate systems (transformation to a co-moving frame).

We regard the Schwarzschild singularity as a *physical singularity* in the following sense. Given a matter distribution such that initially nowhere within the matter distribution is $r_s \leq 2GM/c^2$. An observer observes this distribution of matter in a nearly flat space (since almost all points of the universe are locally nearly flat). Since it takes an infinite time for this distribution of matter to cross the Schwarzschild singularity, we may regard the Schwarzschild singularity to be a real, physical singularity. Once matter is found in a non-singular state, within the finite lifetime of the universe it will remain in the non-singular state. Similarly, if a Schwarzschild singularity were found in nature, it was created with the universe.

Since all massive stars undergo supernova explosion, their cores will inevitably collapse to extremely high densities. It might be worthwhile to investigate whether they collapse asymptotically into within Schwarzschild singularity or not. It is of more importance to investigate, first, whether a singularity similar to Schwarzschild singularity exists in neutron stars with all possibilities of equation of state.

As an interesting episode, we quote a paragraph from Eddington's momumental work on "The Internal Constitution of the Star" (Reference 37):

"The great bulk of these giant stars is due to low density rather than great mass . . . It is rather interesting to notice that Einstein's theory of gravitation has something to say on this point. According to it a star of 250 million km radius could not possibly have so high a density as the sun. Firstly, the force of gravitation would be so great that light would be unable to escape from it, the rays falling back to the star like a stone to the earth. Secondly, the red-shift of the spectral lines would be so great that the spectrum would be shifted out of existence. Thirdly, the mass would produce so much curvature of the space-time metric that space would close up round the star, leaving us outside (i.e., nowhere). The second point gives a more delicate indication and shows that the density is less than 0.001; for even at that density there would be a red-shift of the spectrum too great to be concealed by any probable Doppler effect.

Lest this argument should be regarded by our more conservative readers as ultra-modern, we hasten to add that it is to be found in the writings of Laplace*:

'A luminous star, of the same density as the earth, and whose diameter should be two houndred and fifty times larger than that of the sun, would not, in consequence of its attraction, allow any of its rays to arrive at us; it is therefore possible that the largest luminous bodies in the universe may, through this cause, be invisible.' "

3.2. Will a Massive Star Collapse into a Neutron Star Without Being Singular?

We have surveyed the work of many authors (which by no means exhausted all possible equations of state) and we find that it seems inescapable that g_{00} will vanish at the center of a neutron star if its mass approaches a certain limit, which is around $1M_\odot$.

†This coordinate system is known as the isotropic coordinate system.

*Reference 35

There are several properties characteristic to this kind of treatment of a neutron star:

(1) The rest energy of a particle is $\sqrt{g_{00}}\,mc^2$ and at $g_{00}=0$ it takes no energy to create a pair of particles, nor does one gain any energy by annihilating a pair of particles. All photons emitted at points where $g_{00}=0$ will suffer infinite red shift and there will be no energy associated with such photons.

(2) The ratio of M^*/M_f is a well-defined number even when $M^*=M_{cr}$ in all cases. In Wheeler's work (Reference 19) this ratio is 2.8, and in Cameron's work (Reference 10) this ratio is 1.5.

(3) Although only the simple incompressible fluid case can one calculate $dM^*/dm=0$ at $M^*=M_{cr}$, we believe the result $dM^*/dM=0$ at $M^*=M_{cr}$ is universal because, in the case of incompressible fluid, this is due to $g_{00}=0$ at the center. Thus consider a star at the critical mass. If one adds to it one more gram of mass, this mass will not add to the observed mass of the star, but will be converted into energy—into a kind that can escape, namely, radiation.

5.3. Wheeler's Theory

One may be perturbed by the fact that the star now becomes a gravitational machine by which matter is converted into energy, thus violating the baryon conservation law. Gravitational machines converting mass into energy are nothing new. Any gravitating body, in some sense, is a gravitational machine in the above sense. If we drop matter from infinity to the surface of the sun; roughly 10^{-6} of its mass will be converted into energy which escapes, and this piece of matter will be gravitationally bound to the sun. However, if we pump energy into the sun to disintegrate it, we will reobtain nucleons. There is no ambiguity.

In the case of neutron stars this does not seem to be so. At the critical mass limit the ratio of M^*/M is a fixed constant of the order of 1/3. According to Equation 5.19, the stellar mass approaches the critical mass when the original mass is finite. Beyond this point the star becomes a gravitational machine converting mass into energy. Thus the total number of nucleons is not a well-defined number. When we pump energy into the system to dissociate the star from its gravitational binding, we do not get all nucleons back —we only get a definite number ($\approx 3\cdot M_{cr}/m_p$) back. Thus, the baryon number may not be a meaningful concept for a neutron star.

From this example Wheeler (Reference 19 and 25) concluded that the baryon number conservation law must break down in a very dense star. We are open-minded to this kind of suggestion. Although the baryon conservation law has been demonstrated to high precision to be a valid concept in an ordinary nuclei (Reference 38), it has always been postulated only as an empirical law (e.g., Reference 39).

The origin of this law is still unclear. Moreover, we do not know what this law actually means when baryons are closely packed to within their structure ($\leq$ repulsive core radius). It certainly poses an extremely interesting and meanwhile difficult problem. The final solution, as we have seen in Section 5.3, must come from extremely high energy physics.

6.4. Oppenheimer-Snyder Theory

Oppenheimer and Snyder (Reference 40) had approached the problem of collapse in the following manner: In the absence of the pressure, the collapse may be treated analytically. They computed the world trajectories of material bodies falling towards a common center under the gravitational field produced by these material bodies. They obtained the following result: To an external observer these particles fall toward the Schwarzschild singularity asymptotically and the total time of fall is infinite. This is because of the infinite time dilatation effect mentioned earlier. To a local observer, the time is finite; and, for the case of the sun, it is of the order of 1 day. Since the star continues to fall indefinitely, the star is always in some dynamical motion and this is consistent with the fact that no static structure of such a star exists if its mass exceeds a certain limit.

We do not regard this resolution as satisfactory, since the pressure P cannot be neglected in the case of a neutron star; from what others have demonstrated (References 19, 31, 32, and 33), $P\approx\rho c^2$ and therefore cannot be neglected. Their solution, however, may be of cosmological significance. We shall discuss further possible solutions to this problem in Section 9.

7. ANGULAR MOMENTUM AND STELLAR COLLAPSE

We have delayed the discussion of the effect of angular momentum up to now—not because it is not important, but because it leads to very interesting consequences: namely, the possibility of gravitational radiation from a rapidly rotating neutron star, and the possibility of their detection.

The moment of inertia of a spherical body of radius R, mass M, and of uniform density ρ is:

$$I = \frac{2}{5} MR^2 . \qquad (7.1)$$

The angular momentum $I\omega$ is a conserved quantity (where ω is the angular velocity). For a normal star $R \approx 10^{11}$ cm and the period of rotation is around 1 day. Thus,

$$I\omega \propto R^2 \omega \approx 6 \times 10^{17} . \qquad (7.2)$$

The centrifugal force f_c per unit mass at the equator of the star is

$$f_c = \frac{v_{eq}^2}{R} ,$$

where $v_{eq} = R\omega$ is the speed at the equator. Since $f_c < MG/R^2$ (otherwise the star will be torn apart by rotation), we have the upper limit on R:

$$\frac{(R^2\omega)^2}{R^3} < \frac{MG}{R^3} \qquad (7.3)$$

or

$$R > \frac{(R^2\omega)^2}{MG} . \qquad (7.4)$$

This is the minimum radius to which a rotating star may collapse. Using $M = 2 \odot M$, and the value of $R^2\omega$ given by Equation 7.2, we find that

$$R > 10^8 \text{ cm} , \qquad (7.5)$$

and at this limiting value of R the angular velocity ω is around 1 rad/sec, and the period is around 0.1 sec.

Although a rotating body with cylindrical symmetry does not radiate gravitational waves, there is no reason that a rapidly rotating body should preserve its cylindrical symmetry. The classical Jacobi ellipsoid is an example: a homogeneous, uniform density fluid held together by its gravitational field can assume the shape of an ellipsoid with the axis of rotation perpendicular to the long axis of the ellipsoid. As an estimate we apply to our rotating star the formula of gravitational wave radiating power computed for a spinning rod (References 41, 42, and 43). The radiating power is

$$P = \frac{32GI^2\alpha^6}{5c^5} . \qquad (7.6)$$

The rotational energy is $1/2\ (I\omega^2)$. Hence the relaxation time τ for the star to lose its angular momentum is

$$\tau = \frac{5c^5}{64GI\alpha^4} . \qquad (7.7)$$

For the parameters we consider, we find $\tau \approx 50$ seconds. Although this is longer than the time of dynamical collapse as calculated by Colgate (Reference 7), it is quite small compared with the lifetime of a neutron star, which we shall compute.

Weber thinks such gravitational radiation is detectable (References 41 and 44).

8. OBSERVABLE FEATURES OF NEUTRON STARS

8.1. Energy Content of a Neutron Star

We now shall calculate the energy content of neutron stars. The Fermi energy of neutrons (and hyperons) averaged over the star cannot be greater than $m_n c^2$; otherwise the gravitational energy of the star will exceed its rest energy and the star will be within its Schwarzschild radius. Further, if the temperature is too high, neutrino processes will quickly dissipate its thermal energy. Hence the temperature must be below a certain limit. From these criteria the temperature of neutron stars is thus estimated to be 10^9 °K, assuming they were formed earlier at a high temperature. The relaxation time for cooling by neutrino emission at this temperature by plasma neutrino process and pair annihiliation process (References 21–23 and 45) is greater than 10^3 years, which will be the lifetime of neutron stars against optical emission (see next section).

We now apply the theory of a nearly zero temperature ideal Fermi gas to find the thermal energy. The specific heat per unit mass is given as Reference 17.

$$c_v = \left(\frac{\partial \epsilon}{\partial T}\right)_v = \frac{\pi^3 k}{m_n}\left(\frac{kT}{m_n c^2}\right)\frac{x(x^2+1)^{1/2}}{x^3}$$

$$= \frac{T}{T_0}\frac{x(x^2+1)^{1/2}}{x^3} , \qquad (8.1)$$

where $x = p_F^{(n)}/m_n c^2$ and $p_F^{(n)}$ is the Fermi momentum for the neutron gas. The total thermal energy ϵ_{th} is given by

$$\epsilon_{th} = \int_0^T c^\sigma \, dT = \frac{1}{2} \frac{T^2}{T_0} \frac{x(x^2+1)^{1/2}}{x^3} . \quad (8.2)$$

As we have remarked before, the overall average E_F is less than $m_n c^2$. Therefore x is never very much different from unity. Taking $T = 10^9$ °K and $x = 1$, we find that

$$T_0^{-1} = 0.75 \times 10^{-4} \quad (8.3)$$

and

$$\epsilon_{th} \cong 4.6 \times 10^{13} \text{ ergs/gm} \quad (8.4)$$

The total thermal energy of the neutron star is $\approx M \cdot 10^{14} = 10^{47}$ ergs, which is about the thermal energy of the sun.

The neutron core is not composed of neutrons alone. Hence the thermal energy is a sum over all particle energies. In this case, the value of x will be somewhat smaller than 1. The thermal energy of a neutron star may be several times greater than the value estimated here.

8.2. Physical Properties of the Surface of a Neutron Star

The surface of a neutron star must consist of ordinary matter since, when $\rho < 10^{12}$ gm/cm³, the composition of matter is predominantly iron group elements. Thus we can picture a neutron star as a centrally condensed neutron core, surrounded by a layer of nearly iron group elements. If the interior temperature of a neutron star is taken to be 10^9 °K, then when $\rho > 10^6$ gm/cm³ the iron group elements will become degenerate. Since the thermal conductivity of a neutron core and the degenerate layer is very high, we need only consider the nondegenerate ordinary-stellar-matter envelope which contributes mostly to the overall opacity of the star.

The iron group elements have very high values of Z and the ionization temperature in the k-shell electrons is around 0.015 Mev, which corresponds to a temperature of 10^8 °K. The absorption coefficient exhibits a very sharp edge (absorption edge). At the ionization energy the absorption cross section may be as high as 10^{-20} cm². On the average, the mean free path of radiation may be as short as 0.1 gm/cm². When $T > 10^8$ °K, the main source of opacity is due to Compton scattering. The opacity is a constant. The mean free path of photons is roughly 5 gm/cm².

As a rough estimate we now apply the theory of the white dwarf atmosphere to a neutron star (Reference 46). Assuming the main source of opacity to be due to the absorption edge of k-shell electrons, the radial dependence of temperature and density is:

$$\rho \propto \left(\frac{\gamma}{\beta} - 1\right)^{3.25} , \quad (8.5)$$

$$T \propto \left(\frac{R}{\beta} - 1\right) , \quad (8.6)$$

where R is the radius of the neutron star and the proportional constant is determined by the mean density of the star. For a neutron star of mean density $\langle\rho\rangle = 10^{15}$ gm/cm³, R is around 10^6 cm. Thus

$$\rho \approx \langle\rho\rangle \left(\frac{R}{r} - 1\right)^{3.25} = 10^{15} \left(\frac{\Delta r}{R}\right)^{3.25} . \quad (8.7)$$

Taking $\rho = 10^6$ gm, we find $\Delta r = 10^{-2.77}$ R $\approx 10^3$ cm. Material contained in the envelope in gm/cm² is *roughly* $\int_0^{\Delta r} \rho dr \approx 10^8$ gm/cm². The number of scatterings a photon suffers in leaving the envelope is roughly $\int_0^{\Delta r} \rho dr \lambda \approx 10^8$, where λ is taken to be 5 cm/gm-cm².

To estimate the luminosity, we use an intuitive theory due to J. Steinberger.* Consider the following experimental setup: A series of parallel infinite plates of perfect blackbody properties is set up as in Figure 7. Let the temperature of the nth parallel plate be T_n, and let T_1 be fixed. The energy flow is assumed to be completely radiative. When a steady state of energy flow is reached, it is easy to verify the following relation:

$$\begin{aligned} acT_1^4 - acT_2^4 &= acT_2^4 - acT_3^4 = \cdots \\ &= acT_{n-1}^4 - acT_n^4 = \cdots \\ &= acT_{n-1}^4 - acT_n^4 = acT_n^4 . \end{aligned} \quad (8.8)$$

*Private communication.

where a is the Stefan-Boltzmann constant and c the velocity of light. From this equation we obtain a relation between T_1 and T_m:

$$acT_1^4 = \frac{acT_m^4}{m} . \quad (8.9)$$

Photons are continuously absorbed and reemitted by atoms or nuclei. In the atmosphere of a star the atoms are like the parallel plate in Steinberger's model for radiative transfer. The energy flux radiated from a unit area on the surface of a neutron star is ($T_1 \approx 10^9$ °K)

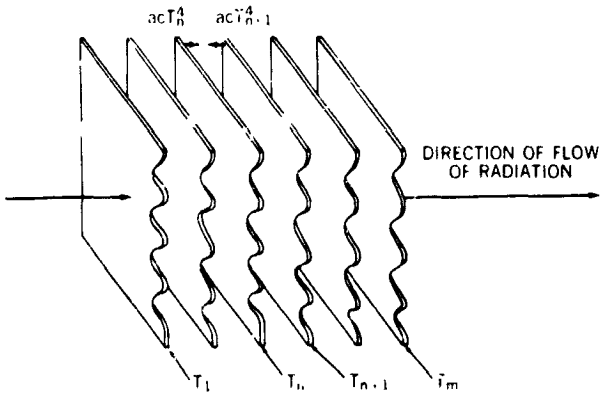

FIGURE 7.—An extremely simplified model of stellar atmospheres. The plates are made from materials with perfect blackbody properties.

$$f = \frac{acT_1^4}{14 \times 10^8} \approx 5 \times 10^{23} \text{ ergs/cm}^2\text{-sec} . \quad (8.10)$$

The overall luminosity L is thus

$$L = 4\pi r^2 f \geq 10^{37} \text{ ergs/sec} . \quad (8.11)$$

The maximum of the spectral frequency corresponds to $T \approx 10^7$ °K. We have computed the energy content of a neutron star to be 10^{47} ergs. A neutron star radiating energy at such a lavish rate will last for at most 1000 years. However, as the temperature is reduced, the rate of energy radiation will be reduced, too; when $T_1 = 10^8$ °K, the luminosity L will be reduced to around 10^{-4} of the value given in Equation 8.11 and the lifetime will be around 10^4 years, with a maximum on the spectral frequency $T \approx 10^6$ °K (0.1 kev).

8.3. Observational Problem

Our atmosphere is transparent only to radiation in the following wavelength region (e.g., Reference 47): 3000A→7000A (visible), 8000A→12,000A (infrared window), 1 cm→10 meters (microwave) 47): 3000A¼7000A (visible), 8000A→12,000A (infrared window), 1 cm→10 meters (microwave), and 200 meters→infinity (low frequency radio wave).

Interstellar matter consists mainly of hydrogen, and it is extremely opaque to radiation of wavelength near the Lyman continuum ($\approx$1000A). Since the absorption coefficient exhibits a sharp edge and has a λ^3 dependence, for frequencies other than that near the Lyman continuum it is relatively transparent.

The surface temperature of neutron stars is around $10^6 \rightarrow 10^7$ °K. Burbidge (Reference 48) has estimated the red shift and he found that, if the neutron stars have a very small envelope (as we have calculated), the light from such stars may suffer a red shift as large as $\lambda/2$. Hence the temperature observed by distant observers will be one-half the value at the surface. The red shift will therefore reduce the observable temperature by at most a factor of 2.

The maximum in Planck's formula for $T = 10^6 \rightarrow 10^7$ °K is between 100A and 10A (in-between UV and x-ray bands). Both lie in a region where interstellar absorption is not large. The mean free path is around 10^5 light years, assuming an interstellar hydrogen density of 1 particle/cm^3. We remark that this wavelength region is very difficult to observe experimentally.

The fraction of this radiation energy R_ν that will pass through our atmospheric window is easily seen to be given by

$$R_\nu = \frac{\int_0^x \frac{x^3\,dx}{e^x - 1}}{\int_0^\infty \frac{x^3\,dx}{e^x - 1}} = \frac{15}{\pi^4} \int_0^x \frac{x^3\,dx}{e^x - 1} , \quad (8.12)$$

where $x = h\nu/kT$. For small values of x, since $e^x \approx 1 + x$, we have

$$R_\nu = \frac{5}{\pi^4} x^3 . \quad (8.13)$$

For $kT = 50$ ev ($T \approx 5 \times 10^5$ °K), $h\nu = 5$ ev (corresponding to $\lambda \approx 3000$A), we find that

$$R_\nu \approx 5 \times 10^{-3} . \quad (8.14)$$

Thus, for a neutron star of internal temperature 10^8 °K it will have a luminosity of $\approx 10^{-6}L_\odot$. For such low luminosity stars, the star has to be, borrowing a comment from Greenstein,* "practically inside the solar system in order to be observable by the world's largest telescope, the 200 inch Mount Palomar telescope." Hence, it is not surprising that no neutron stars have ever been found.

Since in our picture every supernova star will inevitably become a neutron star, we can estimate their numbers in our galaxy. Taking the age of our galaxy to be 10^{10} years, and the rate of a supernova explosion to be roughly 10^{-2}/year (References 8 and 9), we find the total number of neutron stars in our galaxy to be 10^8, of which possibly ten will have a surface temperature of about 10^7 °K, and possibly 10^2 will have a surface temperature of about 10^6 °K.

With the use of proper instruments mounted in an earth satellite now available for scientific research, such neutron stars should be readily detectable. *(See footnote on page 51, however.)*

Moreover, since most stars possess rotation, the rotational energy will be dissipated, during the collapse phase, into gravitational waves. Such waves should be detectable. Instruments designed by Weber and his associates (References 41 and 44), if perfected to their expectation, should be able to detect such waves many galaxies away. Thus their instruments may be used to detect supernova explosions. We remark that their instruments are more sensitive than the neutrino monitor station suggested previously (References 1 and 21).

9. DISCUSSION

The central point of the paradox presented by Wheeler is essentially the following: Given a neutron star, assuming one can add to its mass (hence the nucleon numbers) until it reaches the critical value; then at this critical value a singularity ($g_{00}=0$) develops at the center. Unlike the Schwarzschild singularity this singularity cannot be removed by performing a coordinate transformation. Further addition of mass to the star will not increase its mass nor its nucleon number. All nucleons added to it will be converted into radiation energy. This essentially violates the empirical law that baryons cannot be destroyed in any reaction. Since the existence of the critical mass is inevitable, Wheeler concluded that the baryon conservation law must be violated in super-dense stars.

We have examined this problem and our conclusions are the following:

(a) The absence of quantum-gravitational effects: Inside a neutron star the gravitational field has to interact with the elementary particle field classically. This is because the gradient of the gravitational field is extremely small as compared with the gradients of nucleon, electromagnetic, etc. fields. By the principle of equivalence, one can replace a uniform gravitational field by a uniform acceleration. Thus the equation of state may be computed without regard to any gravitational field present.

(b) Wheeler argued that one cannot get away from this difficulty by proclaiming that the whole star falls through the Schwarzschild singularity. The problem poses, as he calls it, "a problem of principle." No one can forbid an observer from adding one extra gram of matter to a star already at the critical mass.

We would like to remark that it is by no means clear how this singularity is developed. It depends strongly on the equation of state. On the central density-mass curve (Figure 4) a maximum is found. Beyond this maximum, in most cases the gravitational binding energy of the neutron star is *positive*. This means *the critical mass cannot be reached statically.* Moreover, we know that, if the mass decreases with increasing central density, the stellar configuration is not a stable one. Hence, then the problem of the critical mass must be treated dynamically. We also note that the maximum in the mass is reached when the star is still free from singularity.

If the existence of the mass maximum is inevitable, the static problem as posed by Wheeler is irrelevant to the dynamical collapse of a star (the only way a neutron star may be formed).

Neglecting the pressure term in the stress energy tensor, Oppenheimer and Snyder (Reference 40) found that the star collapses toward the Schwarzschild singularity asymptotically. In reality the pressure cannot be neglected—in fact,

*Private communication. The author is indebted to him for an enlightening discussion on the nature of peculiar radio sources which were once considered to be neutron stars. However, J. Greenstein demonstrated that they cannot be neutron stars (Reference 49).

$\approx \rho c^2$. The essential questions are therefore: If we takes into account the pressure, does a real singularity such as $g_{00}=0$ develop at the center first? Or does the star still fall through the Schwarzschild singularity asymptotically? These are certainly relevant questions to ask. They can be answered theoretically be a further study of neutron star models.

(c) Another type of equation of state: S. Weinberg* posed the following argument. An incompressible fluid may be regarded as composed of particles with a repulsive potential between them. Although they are the hardest equations of state one can think of, they also carry an indefinitely large amount of energy. Since the *source* of gravitational field is energy itself, one gets into infinite trouble by letting the energy be infinitely large. He therefore suggested the following: Let there be an attractive force of small range. When matter is compressed hard enough, the attractive force will come into play and local clustering of particles will occur, forming quasi-bound states. The energy of the system will be decreased by the amount of the binding energy. One can thus increase the mass limit for neutron stars by letting local clustering of particles take place.

If one piles all the mass of the universe into a neutron star and considers Wheeler's static problem, then essentially, if one still wants to save the baryon conservation law, the binding energy of these clusters must be of the order of the rest energy of the particles themselves. Such a *super-strong field has not been observed* in present high energy physics experiments.

If the fine structure constant is of order unity, a number of interesting things will happen. Pairs of electrons will be created spontaneously into bound states; yet these bound pairs have zero energy. In order that such thing be possible for baryons, the strength of the coupling $f^2/\hbar c$ must be at least 100 times stronger than that for the strong interaction. In order not to conflict with the present knowledge of elementary particles, the range of this super-strong interaction cannot exceed, say, 10^{-15} cm. Since a binding among all pairs is assumed (attractive force), the interactions must be scalar or tensor in character. The quanta associated with such a field must be around 100 times the π meson mass, or 20 times the nucleon mass.

Of course, what we have suggested is purely speculative. A star which collapses to within its Schwarzschild singularity will gradually become invisible. On the other hand, if a star can get rid of its mass-energy by resorting to baryon nonconservation or the existence of such a hypothetical super-strong interaction, the remaining body should be observable with approximately the surface characteristic discussed in Section 8. They are certainly observable.

10. CONCLUDING REMARKS*

In this paper the final evolution of a pre-supernova star is reviewed. It seems inevitable that the star will end up as a neutron star with a radius of around 10^6 cm and a surface temperature of around 10^6–10^7 °K. A critical mass limit exists for neutron stars. Beyond this mass limit no static structure is possible. Neutron stars can only be detected by extra-terrestrial x-ray telescopes. If detected, they pose interesting questions on our present theory of fundamental particles.

11. ACKNOWLEDGMENTS

The author wishes to thank Professors C. W. Misner and J. A. Wheeler for discussions on the general properties of neutrons stars, and Professor L. Woltjer for a discussion on the character of the atmosphere for a neutron star. He also wishes to thank Dr. Robert Jastrow for his hospitality at the Institute for Space Studies.

*Private communication. The author first learned this idea from Professor C. W. Misner, who believed he was quoting Dr Weinberg. When the author asked Dr. Weinberg, he insisted that he was misquoted by one of us (H. Y. C. or C. W. M.). Nevertheless, he admitted later that this idea might work. His original idea applied to model universes as a whole, but he thinks this idea may work inside a neutron star too. The author feels that, although the present idea originates from misquotations, Dr. Weinberg nevertheless should deserve the credit of being the originator.

*When this article went to press, rocketbound x-ray observations made by Rossi's group (H. Gursky, R. Giacconi, F. R. Paolini, and B. B. Rossi, *Phys. Rev. Letters*, 11: 530 (1963)) and H. Friedman's group (reported in the December meeting of the American Astronomical Society, 1963) reveal the existence of discrete x-ray sources, one of them near the Crab Nebula, the remnant of the supernova of 1054 A.D. The energy flux in the 3A wavelength region is around 10^{-7} ergs/cm²-sec. If the source is indeed neutron stars in the Crab Nebula, the calculated source flux is around 10^{37} ergs/sec. This is consistent with the estimates made in this paper. However, further observations are necessary to clarify if these x-ray sources are indeed neutron stars

A more detailed evaluation of the surface properties of neutron stars has been performed by the author and also by Miss S. Tsuruta and Dr. A. G. W. Cameron. Both works are to be published elsewhere. Results indicated that the crude estimates made in this paper are correct to one order of magnitude.

Appendix A
VIRIAL THEOREM

Now we derive the virial theorem. Defining $V \equiv (4\pi/3)r^3$ and multiplying both sides of Equation 2.9 by V, we have

$$V\,dP = -\rho \frac{Gm}{r^2} \cdot \frac{4\pi}{3} r^3\,dr = -\frac{1}{3}\frac{Gm\,dm}{r} \quad . \tag{A1}$$

We now integrate Equation (A1) over the star. Partically integrating $\int V dP$, we have

$$\int V\,dP = PV \Big|_{r=0}^{r=R} - \int P\,dV = -\int P\,dV \tag{A2}$$

since, at $r=0$, $V=0$; and, at $r=R$ (radius of the star), $P=0$. Thus, we have the relation

$$3\int P\,dV = \int \frac{Gm\,dm}{r} = -E_G \quad . \tag{A3}$$

If a relation between P and E (energy density) exists, Equation (A3) relates the gravitational energy of a star to its thermodynamic energy. For a non-relativistic gas $P=2/3E$; and for a relativistic gas, $P=1/3E$. Thus the total energy E_T of a star is

$$E_T = -\eta E_{th} \ , \tag{A4}$$

where $0 \leq \eta \leq 1$.

SURFACE X-RAY EMISSION FROM NEUTRON STARS*

HONG-YEE CHIU† AND E. E. SALPETER‡

Galactic x-ray emission has been observed from rockets[1] and recently[2] two discrete sources of x-rays in the wavelength region of 1.5 to 8 Å have been found. The measured flux over this wavelength region was 10^{-7} erg/cm^2 sec for the stronger source (located near Scorpius) with an angular size less than 5°. The other source is about eight times weaker and seems to coincide with the Crab Nebula. The Crab is known to be the remnant of the supernova in A.D. 1054, three thousand light years away. The stronger Scorpius source may[3] be a (somewhat closer) supernova remnant of similar age.

During a type I supernova explosion, the core of the original star may contract into a hot "neutron star." Such neutron stars were suggested[4] as possible x-ray sources and we give analytic estimates[5] of their observable surface properties as a function of age (for central temperatures of the order of 10^9 °K).

Neutron stars can exist with masses between about $0.2M_\odot$ and $1.5M_\odot$ ($M_\odot = 2\times10^{33}$ g is the solar mass) and have a radius R close to 10 km and interior densities a few times 10^{14} g/cm^3. The neutrons are highly degenerate for central temperatures $T_c \ll 5\times10^{11}$ °K and their average Fermi energy $E_{F,n}$ is about 50 MeV. Because of the high conductivity, the neutron core is essentially isothermal and its total thermal energy E_t is[6] approximately

$$E_t = 7.6\times10^{47}(T_c/10^9\ ^\circ\mathrm{K})^2(M/M_\odot) \times(E_{F,n}/50\ \mathrm{MeV})^{-1}\ \mathrm{ergs}. \quad (1)$$

The neutrons are in equilibrium with a small amount of protons and electrons with $E_{F,n} \approx E_{F,e}$ ($E_{F,p}$ is small). Neutrinos can be emitted by a modified "Urca process" in which two neutrons with suitable momenta (near the Fermi momentum) "scatter" into a final state of $n+p+e^-+\nu$ (the inverse process releases ν). Our present[7] estimate for this Urca energy loss rate, $L_{\nu,\mathrm{Ur}}$ is

$$L_{\nu,\mathrm{Ur}} \sim 2\times10^{36}(T_c/10^9\ ^\circ\mathrm{K})^8(E_{F,n}/50\mathrm{MeV})^{-2.25} \times(M/M_\odot)\ \mathrm{erg/sec}. \quad (2)$$

At densities below 10^{11} g/cm^3, the equilibrium configuration favors "ordinary ionized matter" which constitutes a thin mantle ($\sim$1 km) around the neutron core. Throughout most of the mantle the electrons are realativistically degenerate with a high conductivity, so that the temperature is close to T_c, and one can calculate the "density scale-height" analytically. The plasma neutrino process[8] has a maximum rate at densities near $(T/10^9\ ^\circ\mathrm{K})^3\times4\times10^{10}$ g/cm^3 and we find for the integrated energy loss rate $L_{\nu,\mathrm{pl}}$

$$L_{\nu,\mathrm{pl}} \approx 2\times10^{36}(T_c/10^9\ ^\circ\mathrm{K})^{10}(R/10\ \mathrm{km})^4 \times(M/M_\odot)^{-1}\ \mathrm{erg/sec}. \quad (3)$$

When $\rho < \rho_m \approx (T/10^9\ ^\circ\mathrm{K})^{1.5}\times10^6$ g/cm^3, the electrons become nondegenerate and their conductivity low. The main temperature gradient then occurs in an outer nondegenerate layer (a few meters thick) of "ordinary matter." We assume $T = T_c$ at $\rho = \rho m$, a constant opacity ($\kappa^{-1}\rho^{-1}$ is the photon mean free path), and $A/Z = 2$ in this layer, and obtain its structure analytically. The photon luminosity L_{ph} is then

$$L_{\mathrm{ph}} = 1.6\times10^{37}(0.2/\kappa)(M/M_\odot) \times(T_c/10^9\ ^\circ\mathrm{K})^{1.5}\ \mathrm{erg/sec}, \quad (4)$$

independent of the radius R. For $T_c \geq 5\times10^8$ °K, Thomson scattering of photons by free electrons

*Published in *Physical Review Letters*, 12(15): 413–415, April 13, 1964.

†Goddard Space Flight Center and Columbia University. Mr. Chiu is a NCR–NAS Senior Research Associate, and also a Research Fellow, Academia Sinica, Republic of China.

‡Goddard Space Flight Center and Cornell University, Ithaca, New York.

dominates which gives $\kappa = 0.2$. For $T_c \leq 2\times10^8$ °K the opacity κ depends on temperature (roughly as $\rho^{0.5}T^{-3.5}$), due to photon absorption by a small admixture of bound electrons. We estimate an average value of 0.4 for κ at $T_c = 2\times10^8$ °K.

Table I gives our results for several values of the central temperature for mass $M = 0.5M_\odot$ and radius $R = 10$ km. T_e is the effective blackbody surface temperature corresponding to L_{ph} and the surface area $4\pi R^2$; λ_W is $hc/4.965\kappa T$, the wavelength of the Wien displacement law but with a gravitational red shift of 8 percent included; τ is $E_t(L_\nu + L_{ph})^{-1}$, a measure of the cooling time. A neutron star with $T_c \approx 10^9$ °K in the Crab Nebula (age$\sim10^3$ years) would produce near the earth, according to Table I, an x-ray intensity close to that observed.[2] This agreement is gratifying but in view of the large numerical uncertainties[9] in Table I may still be fortuitous.

Spectral measurements of discrete x-ray sources in the future will be very useful: At short wavelengths ($\lambda \lesssim 1$Å) the rapid fall-off of the neutron star's blackbody spectrum should be easy to distinguish from the flatter spectra expected from other[10] types of x-ray sources. If finer spectral resolution is available, intensity discontinuities may be detectable at wavelengths λ_K corresponding to K-shell absorption edges of medium-size nuclei (e.g., 6.3 Å for Mg and 1.3 Å for Fe, before applying the red-shift correction). Measurement of λ_K (or of absorption lines) would furnish a value for the gravitational red-shift and hence for M/R for the neutron star.

For x-ray wavelengths $\lambda \lesssim 5$ Å, absorption by interstellar gas is small even across the whole galactic disc. If x-ray detection sensitivity can be improved by a factor of about 100 over that in previous flights,[1,2] then any supernova explosion which produced a neutron star during the last one or two thousand years could be detected. There could have been up to about 20 such events. Much older neutron stars with $T_e \lesssim 10^6$ °K would be difficult to detect as x-ray sources because of strong absorption at $\lambda \lesssim 30$ Å by interstellar gas. Because of its small radius the energy radiated directly in visible light by a neutron star ($L_{vis} \gtrsim 4\times10^{27}$ erg/sec $= 10^{-6}L_\odot$) is far too small to be detected in most cases. If the star is situated in a gas cloud (density $\gtrsim 20$ atoms per cm^3) it will ionize a surrounding region (of radius ~ 0.2 light years for $T_e = 10^6$ °K; ~ 0.6 light years for $T_e = 10^7$ °K). Recombination of the ions results in visible light and the region's surface brightness may be (just barely) detectable by terrestrial optical telescopes.

TABLE 1. *Emission characteristics*

Core temp. T_c (°K)	Total thermal energy E_t (ergs)	Neutrino loss rate $L_\nu'_{pl}+L_\nu'_{UR}$ (ergs/sec)	Photon luminosity L_{ph} (ergs/sec)	Surface temp. T_e (°K)	Cooling time τ (years)	Optimum wavelength λW (Å)
2×10^9	1.6×10^{48}	4×10^{39}	2.3×10^{37}	1.3×10^7	10	2.4
1×10^9	4×10^{47}	5×10^{36}	8×10^{36}	1.0×10^7	1×10^3	3.1
5×10^8	1×10^{47}	8×10^{33}	3×10^{36}	8×10^6	1×10^3	3.9
2×10^8	1.6×10^{46}	1×10^{29}	3×10^{35}	4.5×10^6	1.5×10^3	6.8

The chemical composition of the atmosphere of a neutron star is uncertain at the moment, partly because the density scale-heights are so small and diffusion[11] can be much more important than in ordinary stars; H and He from the surface can diffuse in a few years to deeper layers ($T \gtrsim 5\times10^8$ °K) where they are burned up rapidly and these two elements should be completely absent in neutron stars. The equivalent diffusion time for ^{12}C is about 100 years and C is probably strongly (but not completely) depleted in a neutron star about 1000 years old, O and Ne depleted slightly, and any Mg or heavier nuclei (present at the formation of the neutron star) are unburnt. Diffusive separation can lead in a few hundred years to a strongly enhanced abundance in the photosphere of the lightest nuclei (O, Ne, or Mg), unless convection restores mixing, in which case the metals near ^{56}Fe could be most abundant.

We want to thank Dr. A. G. W. Cameron, Dr. G. W. Clark, Dr. F. J. Dyson, and Dr. D. Morton for discussions, and Miss Jane Keston for help in numerical work. One of us (E. E. S.) is indebted to the National Academy of Science for a fellowship.

ESCAPE OF STARS DURING THE COLLISION OF TWO GALAXIES*

GEORGE CONTOPOULOS AND GEORGE BOZIS†

An approximate theory is developed to find out whether a star, moving initially on the plane of symmetry of a galaxy, escapes during the collision with another galaxy of small dimensions. The escaping stars are inside an ellipse on the plane of symmetry of the galaxy. Numerical calculations in a Bottlinger model of a galaxy give results of the same order of magnitude. The total amount of the escaping matter is only a few per cent of the total mass of the galaxy, if the collision velocity is of the order of 2000 km/sec. The behavior of the escaping and non-escaping stars is described. The escaping stars do not follow the colliding galaxy and do not form a bridge or link between the two galaxies.

I. ESCAPING STARS

The purpose of this paper is to consider the effects of the collision of two galaxies on stars moving initially on the plane of symmetry of one galaxy.

If we assume a relative velocity of collision of about 2000 km/sec (Spitzer and Baade 1951), the collision lasts about 10^7 years. During that time the perturbations due to the ellipticity of the first galaxy are insignificant for stellar orbits close to its plane of symmetry (Contopoulos and Bozis 1962; hereafter referred to as "Paper I"). Therefore in order to study approximately the effects of the collision on these orbits we may use a spherical model of a galaxy. The colliding galaxy is also assumed to be spherical but of small dimensions. We will see that, if its diameter is less than 2 kpc, its effects are essentially the same as those of a point mass. In the numerical examples below the mass of both galaxies is assumed to be about 10^{11} $M_\odot$, and the radius of the first galaxy is taken 10 kpc.

In Paper I it has been proved that, if two such galaxies collide with a relative velocity $v=2000$ km/sec, their relative motion may be considered as uniform; in fact the change of velocity is of the order of 30 km/sec and the change of the direction of the velocity is less than 5°.

Further, during the collision, a star moving in a circular orbit on the plane of symmetry of the first galaxy O with radius 8 kpc describes only about 1/20 of a revolution, i.e., about 18°; therefore, we may consider, in a rough approximation, the unperturbed orbit of S to be a straight line, $x'=x_0'$, perpendicular to the axis x', which is directed away from the center O (Fig. 1), and parallel to the axis y'. Under these assumptions the perturbation may be considered as a two-body encounter that lasts as long as the collision itself.

The galaxy O' is assumed to move along the axis z' with uniform velocity $\bar{v}$, reaching the point O_1 on the plane xOy at $t=t_0$. The initial velocity of the star is $\bar{v}_e$; if the perturbing galaxy was not present, S would reach the axis x' at $t=t_1$.

The velocities v and v_e are of the order of 2000 km/sec and 200 km/sec, respectively; therefore, during 10^7 years the galaxy O' moves approximately from $z'=10$ kpc (initial position) to $z'=-10$ kpc (final position), while S moves about 2 kpc along a parallel to the y'-axis. The influence of O' on S when the distance OO' is larger than 10 kpc is very small. In fact, as we will see below, the escaping stars are inside an ellipse whose dimensions are of the order of 4 kpc. Therefore, their minimum distance from O' is about

*Published in *The Astrophysical Journal*, 139(4):1239–1250, May 15, 1964.

†Goddard Space Flight Center and Yale University Observatory.

2 kpc or less. When a point comes from infinity to a distance of 10 kpc the relative velocity changes only by about 1 per cent and the change of its direction is of the order of 2 percent of the angle between the asymptotes. In fact, if v_∞ is the relative velocity before the encounter and v the relative velocity at a distance r from O', then

$$v^2 = \frac{2Gm}{r} + v_\infty^2,$$

hence

$$\Delta v = v - v_\infty \simeq \frac{Gm}{r v_\infty},$$

and for $r = 10$ kpc, $v_\infty = 2000$ km/sec, and $m = 10_{11} M\odot$,

$$\Delta v = 22 \text{ km/sec}.$$

The angle 2ψ between the initial and final velocities is given by $\tan \psi = p/q$, where $x_1^2/p^2 - y_1^2/q^2 = 1$ is the equation of the relative orbit. As q is of the order of 2 kpc, and $p = Gm/v_\infty^2 \simeq 0.1$ kpc, we have $p/q \simeq 0.05$.

The tangent at a point (x_1, y_1) whose distance from the focus is 10 kpc makes an angle ψ' with the axis y_1, where

$$\tan \psi' = \tan \psi \sqrt{\left(1 - \frac{p^2}{x_1^2}\right)},$$

and $[x_1 - \sqrt{(p^2+q^2)}]^2 + y_1^2 = 100$.

Then the deviation $(\psi - \psi')$ is given by

$$\tan(\psi - \psi') = \frac{(p/q)[10 + p - \sqrt{(100+20p-q^2)}]}{10 + p + (p^2/q^2)\sqrt{(100+20p-q^2)}}$$

$$\simeq \frac{p}{q} \cdot \frac{0.05q^2}{10} = 0.005\, pq.$$

Hence

$$\frac{\psi - \psi'}{\psi} \simeq 0.005 q^2,$$

and for $q = 2$, this is 2 per cent. Therefore we may consider the initial and final relative velocities of S with respect to O as being equal to the corresponding velocities in a two-body encounter at infinite distances.

The initial relative velocity of the star S with respect to the galaxy O' is $\bar{v}_0 = \bar{v}_e - \bar{v}$; the corresponding final velocity $\bar{v}_0'$ is equal to $\bar{v}_0$ in measure but not in direction. The final velocity of S with respect to the galaxy O is $\bar{v}_f = \bar{v}_0' + \bar{v}$; if v_f is greater than the velocity of escape v_e, the star escapes from the galaxy O.

In what follows we use a frame of reference where O' is at rest. The galaxy O is moving with respect to O' with velocity $-\bar{v}$ along the axis z' that makes an angle e with the plane xOy (Fig. 1).

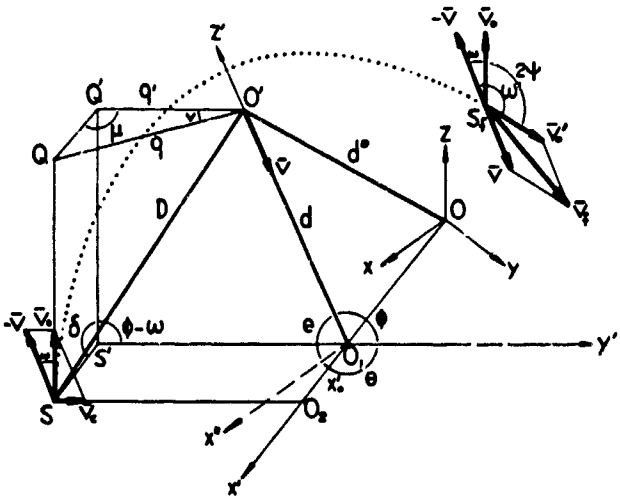

FIGURE 1.—A galaxy O' of mass m is moving downward along the axis z' toward the point O_1 in the plane of symmetry of the galaxy O, of mass M. The axis Ox is parallel to the projection O_1x'' of O_1z' on the plane of symmetry. The distances of O' from O, O_1, and S are d^*, d, and D, respectively.

The projection of z' on the plane xOy makes an angle θ with O_1y', and φ is the angle $z'O_1y'$. Then

$$\cos \varphi = \cos e \cos \theta. \tag{1}$$

At the initial time t we have

$$y' = O_1S' = v_e(t - t_1) \tag{2}$$

and

$$z' = O_1O' = v(t_0 - t). \tag{3}$$

If ω is the angle between $\bar{v}_0$ and $-\bar{v}$, we have

$$\frac{\sin \omega}{v_e} = \frac{\sin \varphi}{v_0} = \frac{\sin(\varphi - \omega)}{v} \tag{4}$$

and

$$v_0^2 = v^2 + v_e^2 + 2\, v\, v_e \cos \varphi. \tag{5}$$

The corresponding angle between $\bar{v}_0'$ and $-\bar{v}$ is ω', and the angle between $\bar{v}_0$ and $\bar{v}_0'$ is 2φ, which

is approximately equal to the angle between the asymptotes of the hyperbolic orbit. Therefore

$$\tan \psi = \frac{Gm}{qv_0^2}, \tag{6}$$

where q is the impact parameter.

The impact parameter is found as follows. Let SS' be parallel to the axis x' and $S'Q'$ parallel to $\bar{v}_0$, $O'Q$ and $O'Q'$ perpendicular to SQ and $S'Q'$, respectively; $S'Q'$ is on the plane $S'O_1O'$ and QQ' is perpendicular to SQ and $S'Q'$. The angle between the planes $QQ'S'$ and $O'Q'S'$ is μ, and the angle between the planes $QO'S$ and $Q'O'S'$ is ν. The angle $Q'S'O_1$ is equal to $\varphi-\omega$, therefore

$$\begin{aligned} q' &= -y' \sin(\varphi-\omega) - z' \sin\omega \\ &= -\left(y' + z'\frac{v_c}{v}\right)\sin(\varphi-\omega) \\ &= v_c(t_1-t_0)\sin(\varphi-\omega) = -y_0' \sin(\varphi-\omega), \end{aligned} \tag{7}$$

where

$$y_0' = v_c(t_0-t_1) \tag{8}$$

is the y' coordinate of S at $t=t_0$. The term q' is positive if $y_0'<0$, and negative if $y_0'>0$. Further

$$S'S = O_1O_2 = x_0', \qquad Q'Q = x_0' \sin\delta, \qquad \text{and } q^2 = q'^2 + x_0'^2 \sin^2\delta - 2q'x_0' \sin\delta\cos\mu. \tag{9}$$

From the trihedral angle $S'Q'SO_1$ we find

$$\cos\delta = \sin(\varphi-\omega)\cos I \tag{10}$$

and

$$\sin\delta\cos\mu = -\cos(\varphi-\omega)\cos I \tag{11}$$

where I is the angle between the planes $y'O_1z'$ and $y'O_1x'$, hence

$$\cos I = \cot\varphi \tan\theta = \frac{\cos e \sin\theta}{\sin\varphi}. \tag{12}$$

Therefore,

$$\begin{aligned} q^2 = x_0'^2[1-\sin^2(\varphi-\omega)\cos^2 I] + y_0'^2\sin^2(\varphi-\omega) \\ -2x_0'y_0' \sin(\varphi-\omega)\cos(\varphi-\omega)\cos I. \end{aligned} \tag{13}$$

A star escapes if

$$v_f^2 = v^2 + v_0^2 - 2vv_0\cos\omega' \geq v_e^2. \tag{14}$$

This is possible only if $v+v_0 \geq v_e$. Then we can set

$$\begin{aligned} -1 \leq \frac{v^2+v_0^2-v_e^2}{2vv_0} = \cos\omega_0' < \frac{v^2+v_0^2-v_c^2}{2vv_0} \\ = \frac{v+v_c\cos\varphi}{v_0} = \cos\omega < 1, \end{aligned} \tag{15}$$

because $v_c<v_e$. Therefore $O<\omega_0'\leq\pi$, and if a star escapes we have

$$\cos\omega' \leq \cos\omega_0'. \tag{16}$$

The angle ω' can be found from the trihedral angle $S_f\bar{v}_0\bar{v}_0'(-\bar{v})$;

$$\cos\omega' = \cos 2\psi\cos\omega + \sin 2\psi \sin\omega\cos(\pi-\nu), \tag{17}$$

where $(\pi-\nu)$ is the angle between the plane $S_f\bar{v}_0\bar{v}_0'$ (i.e., the plane $O'QS$ of the relative orbit) and the plane $S_f\bar{v}_0(-\bar{v})$ (which is parallel to the plane $O'Q'S'$); thus $(\pi-\nu)$ is the complement of the angle $QO'Q'$, and

$$\begin{aligned} \cos\nu = \frac{q'-x_0'\sin\delta\cos\mu}{q} = \tfrac{1}{9}[-y_0'\sin(\varphi-\omega) \\ +x_0'\cos(\varphi-\omega)\cos I]. \end{aligned} \tag{18}$$

If we use relations (6) and (17) in inequality (16) we get

$$\begin{aligned} \{x_0'^2[1-\sin^2(\varphi-\omega)\cos^2 I] + y_0'^2\sin^2(\varphi-\omega) \\ -2x_0'y_0\sin(\varphi-\omega)\cos(\varphi-\omega)\cos I\} \\ (\cos\omega - \cos\omega_0') + \frac{2Gm}{v_0^2}\sin\omega\sin(\varphi-\omega)\,y_0' \\ -\frac{2Gm}{v_0^2}\sin\omega\cos(\varphi-\omega)\cos I\,x_0' \\ \leq \frac{G^2m^2}{v_0^4}(\cos\omega+\cos\omega_0'), \end{aligned} \tag{19}$$

i.e., the escaping stars are inside the ellipse

$$\begin{aligned} x_0'^2(1-\sin^2(\varphi-\omega)\cos^2 I) + y_0'-y_c')^2\sin^2(\varphi-\omega) \\ -2x_0'(y_0'-y_c')\sin(\varphi-\omega)\cos(\varphi-\omega)\cos I \\ = \frac{G^2m^2\sin^2\omega_0'}{v_0^4(\cos\omega-\cos\omega_0')^2}, \end{aligned} \tag{20}$$

whose center is $(x_0'=0,\ y_c')$, where

$$\begin{aligned} y_c' &= -\frac{Gm\sin\omega}{v_0^2\sin(\varphi-\omega)(\cos\omega-\cos\omega_0')} \\ &= -\frac{2Gmv_c}{(v_e^2-v_c^2)v_0}. \end{aligned} \tag{21}$$

The axes of this ellipse form an angle γ with the axes x' and y', where

$$\tan\gamma = -\tan(\varphi-\omega)\cos I = \frac{-\tan(\varphi-\omega)\cos e\sin\theta}{\sin\varphi}. \quad (22)$$

For $0<\theta<\pi$, the angle γ is positive (measured counterclockwise) if $\varphi-\omega>\pi/2$ and negative if $\varphi-\omega<\pi/2$. For $-\pi<\theta<0$, i.e., if the projection of z' on the plane $x'O_1y'$ is on the negative side of the axis x', the angle γ is positive if $\varphi-\omega<\pi/2$ and negative if $\varphi-\omega>\pi/2$. For $\theta=0$ or $\theta=\pi$, the angle $\gamma=0$.

If $\theta=\pi/2$ then $\varphi=\pi/2$, $I=e$, and equations (20)–(22) become

$$x_0'^2(1-\cos^2\omega\cos^2 e)+\cos^2\omega(y_0'-y_c')^2 - 2x_0'(y_0'-y_c)\sin\omega\cos\omega\cos e = \frac{G^2m^2\sin^2\omega_0'}{v_0^4(\cos\omega-\cos\omega_0')^2}, \quad (23)$$

$$y_c' = -\frac{Gm\tan\omega}{v_0^2(\cos\omega-\cos\omega_0')}, \quad (24)$$

and

$$\tan\gamma = -\cot\omega\cos e. \quad (25)$$

From equation (20) we find easily the area of the ellipse

$$E=\pi a_x'a_y' = \frac{\pi G^2m^2\sin^2\omega_0'}{v_0^4(\cos\omega-\cos\omega_0')^2\sin(\varphi-\omega)\sin I}. \quad (26)$$

When $v\to\infty$, then $E\to0$. If $I=\pi/2$, then the ellipse becomes

$$x_0'^2+(y_0'-y_c')^2\sin^2(\varphi-\omega) = \frac{G^2m^2\sin^2\omega_0'}{v_0^4(\cos\omega-\cos\omega_0')^2}. \quad (27)$$

The semi-axes of the ellipse are then

$$a_x = \frac{Gm\sin\omega_0'}{v_0^2(\cos\omega-\cos\omega_0')} = \frac{2Gm\sin\omega_0'\sin(\varphi-\omega)}{(v_e^2-v_c^2)\sin\varphi}, \quad (28)$$

and

$$ay = \frac{Gm\sin\omega_0'}{v_0^2(\cos\omega-\cos\omega_0')\sin(\varphi-\omega)} = \frac{2Gm\sin\omega_0'}{(v_e^2-v_c^2)\sin\varphi}. \quad (29)$$

If $v\to\infty$, then $a_x\to0$ and $a_y\to0$.

The ratio of the axes is

$$a_x/a_y=\sin(\varphi-\omega)=v\sin\varphi/v_0, \quad (30)$$

and the area of the ellipse is

$$E=\pi a_xa_y=\frac{4\pi G^2m^2\sin^2\omega_0'\sin(\varphi-\omega)}{(v_e^2-v_c^2)^2\sin^2\varphi}. \quad (31)$$

Table 1 gives the values of a_x, ay, E, y_c', and ω for the model considered in Section II with $e=\pi/2$, $\varphi=\pi/2$, $v=2000$ km/sec $=2.0454$ kpc/10^6 years, and different minimum distances $r=\sqrt{(\alpha^2+\beta^2)}$ of the colliding galaxy from the center.

TABLE 1

r (kpc)	a_x (kpc)	a_y (kpc)	E (kpc)^2	y_c' (kpc)	ω (degrees)
4	1.41	1.42	6	−0.7	6.22
6	1.94	1.95	12	−1.2	6.55
8	2.41	2.42	18	−1.6	6.19
10	2.80	2.81	25	−1.9	5.74

If the effective radius of the galaxy R_G is about 10 kpc, the above area is between 2 per cent (for $r=4$ kpc) and 8 per cent (for $r=10$ kpc) of the total area.

The proportion of the escaping stars is roughly $E\rho/\pi R_G\bar{\rho}^2$ where $\bar{\rho}$ is the mean density of the galaxy and ρ is the mean density in the region of escape.

Table 2 gives the values of φ, E, y_c', ω for ($e=75°$, $\theta=0°$), ($e=45°$, $\theta=0°$) and ($e=45°$, $\theta=45°$).

The value of γ in the first two cases is zero, and in the last case varies between $-39°.8$ and $-39°.1$.

It is seen that the values of E and y_c' in all three cases are quite near the corresponding values of Table 1. Therefore, the amount of escaping matter from the plane of symmetry of a galaxy does not depend very much on the direction of the collision.

We do not give the values of E, etc., for $r<4$ because near the center the assumption of a binary collision between the star and the approaching galaxy is not even approximately satisfied.

TABLE 2

r (kpc)	$e=75°, \theta=0°, \varphi=75°$			$e=45°, \theta=0°, \varphi=45°$			$e=45°, \theta=45°, \varphi=60°$		
	E (kpc)^2	y_c' (kpc)	ω (degrees)	E (kpc)^2	y_c' (kpc)	ω (degrees)	E (kpc)^2	y_c' (kpc)	ω (degrees)
4	6	−0.7	5.85	7	−0.7	4.10	7	−0.7	5.12
6	11	−1.2	6.15	11	−1.1	4.29	13	−1.2	5.37
8	17	−1.6	5.82	17	−1.5	4.08	20	−1.5	5.09
10	23	−1.9	5 41	23	−1.8	3.80	28	−1.9	4.74

If the diameter of the colliding galaxy is 2 kpc (or less), its cross-section is small, in general, in comparison with the area E of the region of escape; therefore, the amount of escaping matter is essentially the same as in the case of a point mass. If the diameter is larger than 2 kpc, the amount of escaping matter will be smaller.

II. NUMERICAL CALCULATIONS

In order to calculate numerically the orbits of stars during the collision of two galaxies we have chosen a simple model for the first galaxy, in which the forces per unit mass are given by Bottlinger's formula

$$F=\frac{ar}{1+br^3}. \tag{32}$$

This formula has been applied by Lohmann (1953; 1954*a*, *b*) to our Galaxy, as well as to M31 and M33, and by Kerr and de Vancouleurs (1956) to the Large Magellanic Cloud. It is discussed, together with other models, by de Vaucouleurs (1959) and Perek (1962).

The values of a and b were chosen to represent approximately the force function F given by Schmidt (1956) for the plane of symmetry of our Galaxy, namely,

$$a=0.0055(10^6 \text{ years})^{-2}, \quad b=0.012 \text{ kpc}^{-3}.$$

The corresponding potential function is

$$U=-\frac{a}{bk}\left\{\frac{1}{6}\ln\left[\frac{r^2-kr+k^2}{(r+k)^2}\right]-\frac{1}{3}\cot^{-1}\left(\frac{2r-k}{k\sqrt{3}}\right)\right\}, \tag{33}$$

where $k=b^{-1/3}$ and $U_\infty=0$.

In this model the mass of the Galaxy is

$$M=\frac{a}{bG}\simeq 1.02\times 10^{11} M_\odot. \tag{34}$$

The circular velocity is

$$v_c=\sqrt{(Fr)}, \tag{35}$$

and the escape velocity is

$$v_e=\sqrt{(2U)}. \tag{36}$$

Table 3 gives the values of v_c and v_e for different distances r from the center in the above field.

Now we consider the following situation (Fig. 1): A point mass $O'(m)$ goes through a spherical galaxy $O(M)$, represented by the force function (32). This force function is assumed to be stationary; this is justified if the colliding galaxy does not come very close to the center of the galaxy O, because then the amount of escaping

TABLE 3

r (kpc)	v_c (kpc/10^6 years)	v_e (kpc/10^6 years)	r (kpc)	v_c (kpc/10^6 years)	v_e (kpc/10^6 years)
4	0.2231	0.4294	14	0.1783	0.2549
6	.2348	.3750	16	.1676	.2388
8	2220	.3321	18	.1584	.2253
10	.2057	.2997	20	0.1506	0.2138
12	0.1909	0.2748			

matter is rather small. In fact the density corresponding to the force function (32) is

$$\rho=\frac{3a}{4\pi G(1+br^3)^2},$$

and the mean density is

$$\bar{\rho}=\frac{3a}{4\pi GbR_G{}^3},$$

so that if we take a mean radius of the galaxy $R_G=10$ kpc, then the proportion of the escaping stars is

$$\frac{E\rho}{\pi R_G{}^2\bar{\rho}}\simeq\frac{0.04E}{(1+0.012r^3)^2};$$

for $r=10$ kpc this is about 0.6 per cent while for $r=4$ kpc this is 8 percent.

The motion of O' is assumed to be uniform along the line $O'O_1$ where O_1, (α, β) lies on the plane xOy. The plane xOz is taken parallel to the direction $O'O_1$ and e is the angle between this line and the plane xOy. The coordinates of the star S are x, y, z, and d, d^*, D are the distances of O' from O_1, O, and S, respectively.

The unperturbed orbit of S is, in general, a rosette on the plane xOy. In this paper, however, we consider only the case of circular orbits around O.

The perturbation acting on the star is equal to the acceleration of S due to the galaxy O' minus the acceleration of the galaxy O, taken as a whole. As the attraction between O and O' is $mF(d^*)$, the acceleration of O is $(m/M)F(d^*)$. Thus the equations of motion of S are

$$\frac{d^2x}{dt^2}=-F(r^*)\frac{x}{r^*}+\frac{Gm}{D^3}(\alpha+d\cos e-x)-F(d^*)\frac{m}{M}\frac{(\alpha+d\cos e)}{d^*},\quad(37)$$

$$\frac{d^2y}{dt^2}=-F(r^*)\frac{y}{r^*}+\frac{Gm}{D^3}(\beta-y)-F(d^*)\frac{m}{M}\frac{\beta}{d^*},\quad(38)$$

and

$$\frac{d^2z}{dt^2}=-F(r^*)\frac{z}{r^*}=\frac{Gm}{D^3}(d\sin e-z)-F(d^*)\frac{m}{M}\frac{d\sin e}{d^*},\quad(39)$$

where

$$r^*=\sqrt{(x^2+y^2+z^2)},\quad(40)$$

$$d^*=\sqrt{[(\alpha+d\cos e)^2+\beta^2+(d\sin e)^2]},\quad(41)$$

$$D=\sqrt{[(\alpha+d\cos e-x)^2+(\beta-y)^2+(d\sin e-z)^2]},\quad(42)$$

and

$$d=d_0-vt.\quad(43)$$

The numerical values used are the following: $m/M=1$, $MG=a/b$, $v=2000$ km/sec $=2.0454$ kpc/10^6 years, $d_0=100$ kpc, $\alpha=8$ kpc, $\beta=0$, and $e=90°$ (case A), or $e=45°$ (case B). The initial conditions for $t=0$ were taken in such a way that the star, moving in the unperturbed circular orbit, would reach an axis forming an angle g with the positive x-axis (g is positive if measured counterclockwise), when the colliding galaxy reaches the point O_1 (α, β), namely, at about $t=48.89\times10^6$ years.

The greatest part of the calculations was made with the IBM 7090 computer of NASA's Institute for Space Studies, New York. The Runge-Kutta integration method was used with a step 0.1 (10^6 years) and the orbits were calculated for 200×10^6 years. At $t=200\times10^6$ years the colliding galaxy is at a distance of about 300 kpc from the galaxy O and its influence is then negligible. In some cases, when the stars escaped rather fast from the galaxy O, the calculations were stopped earlier.

The initial z coordinates and velocities were all assumed to be zero. Figure 2*A* shows the positions that the stars would have in case A ($e=90°$) at $t=48.89\times10^7$ years (when the colliding galaxy reaches the point O_1), if there was no perturbation. The polar coordinates of these positions are (r, g); therefore the initial polar coordinates, for $t=0$, are

$$r_0=r$$

and

$$g_0\equiv g-48.89\frac{v_c}{r}\times57.^\circ2957795$$

The dots represent stars that are not escaping. The small circles represent escaping stars. The region of escaping stars is approximately a circle of diameter 5 kpc. From Table 1 we see that the ellipse of escaping stars for $r=\sqrt{(\alpha^2+\beta^2)}=8$ kpc is very nearly a circle of diameter 4.8 kpc; the

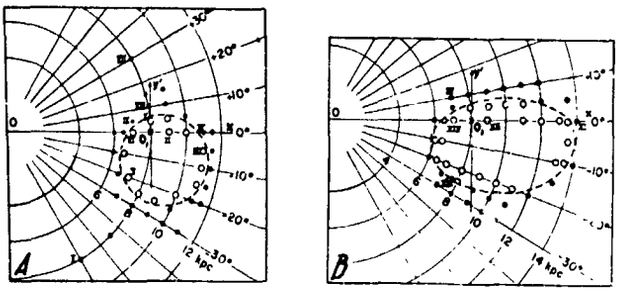

FIGURE 2.—The position (r, g in polor coordinates) of escaping (open circles) and non-escaping (solid circles) stars in their unperturbed orbits when the colliding galaxy is going through the point 0_1 ($\alpha=8$ kpc, $\beta=0$). In case A, $e=90°$; in case B, $e=45°$.

agreement with the calculations is very good in this case.

The center of the circle in Figure 2*A* is not at $x_c'=0$, as it was expected theoretically, but at about $x_c'=1$ kpc, i.e., further out than the point O_1. On the other hand, the y' coordinate of the center is about $y_c'=-1.5$ kpc, i.e., very close to the calculated value. Therefore, the only discrepancy between theory and calculations is that the actual region of escape is further out than expected; this is due, of course, to the fact that the unperturbed orbits are curved and not straight lines as they were assumed in Section I. The only consequence of this effect is that the region of escape actually includes less dense areas, therefore, the amount of escaping matter is smaller.

In case B ($e=45°$) the calculated orbits are marked in Figure 2*B*. The region of escape is approximately an ellipse of dimensions $2a=8$ kpc, $2b=5$ kpc, and the area $E=31$ kpc^2. This is bigger than expected on the basis of the simple theory developed in Section I. However, even in this case the area E is only 10 percent of the effective area in the plane of symmetry of the galaxy O, and as it includes mainly the outer parts of the galaxy the mass of the escaping matter is less than 2 per cent of the total matter near the plane xOy.

The individual orbits of stars during the collision show a number of interesting characteristics. Figures 3 and 4, copied from plots made by the NASA computer, show the main types of orbits encountered, in the case $e=90°$.

A common characteristic of all the orbits is that the perturbations are very small until the colliding galaxy goes through the galaxy O. Until that moment the orbits are practically circles on the xy-plane. After the collision the orbits may be divided into three types: (*a*) orbits of stars that remain far from the region of escape; (*b*) "escaping" orbits; and (*c*) orbits of stars near the region of escape.

If the star is far from the region of escape, its orbit is not changed much by the collision. It remains almost circular, and the z-motion is very small. Such is the case of orbit I ($r=8$ kpc, $g=-60°$).

The orbits of stars inside or near the region of escape can be divided into the following groups (cf. Figs. 2*A* and 3*A*-3*D*): (i) stars with $g\leq 0°$ and $r\geq 8$, or r smaller than 8, but g not near 0°; (ii) stars with $r<8$ and $g\leq 0°$ but g near 0°; and (iii) stars with $g>0°$. We discuss these groups separately.

i) The stars with $g\leq 0°$ that are inside or near the region of escape are accelerated toward the positive y'-axis as the colliding galaxy goes through the galaxy O. If $r>8$ kpc the orbits are deflected to the left. This deflection is bigger whenever the approach to the colliding galaxy is closer. For example, in case II ($r=9$, $g=0°$) the star is ejected abruptly to the left and down, while in case III ($r=11$, $g=-5°$) the star escapes but with smaller velocity. In case IV ($r=11$, $g=0°$) the star does not escape, but its orbit does not differ much from the escaping orbits for $t=200\times 10^6$ years. Only the fact that its velocity is less than the escape velocity makes it sure that it does not escape, but forms a very elongated orbit around the center of the galaxy O.

All orbits near the boundary of the region of escape from ($r=11$, $g=0°$) to ($r=8$, $g=-25°$) are similar to cases III and IV. The y component of the final velocity is negative for large r, while it is positive for r near 8.

The same general behavior is shown by the orbits with $r<8$ but g not close to 0°. For example, case V ($r=7$, $g=-20°$) represents an escaping orbit; the star escapes toward the positive y direction and downward.

ii) The orbits with $r<8$ and g near 0° show an abrupt deviation to the right. This is most marked in case VI ($r=7$, $g=0°$) when the star is ejected abruptly to the right and downward.

iii) The orbits with positive g are usually not escaping. In general, the additional attraction

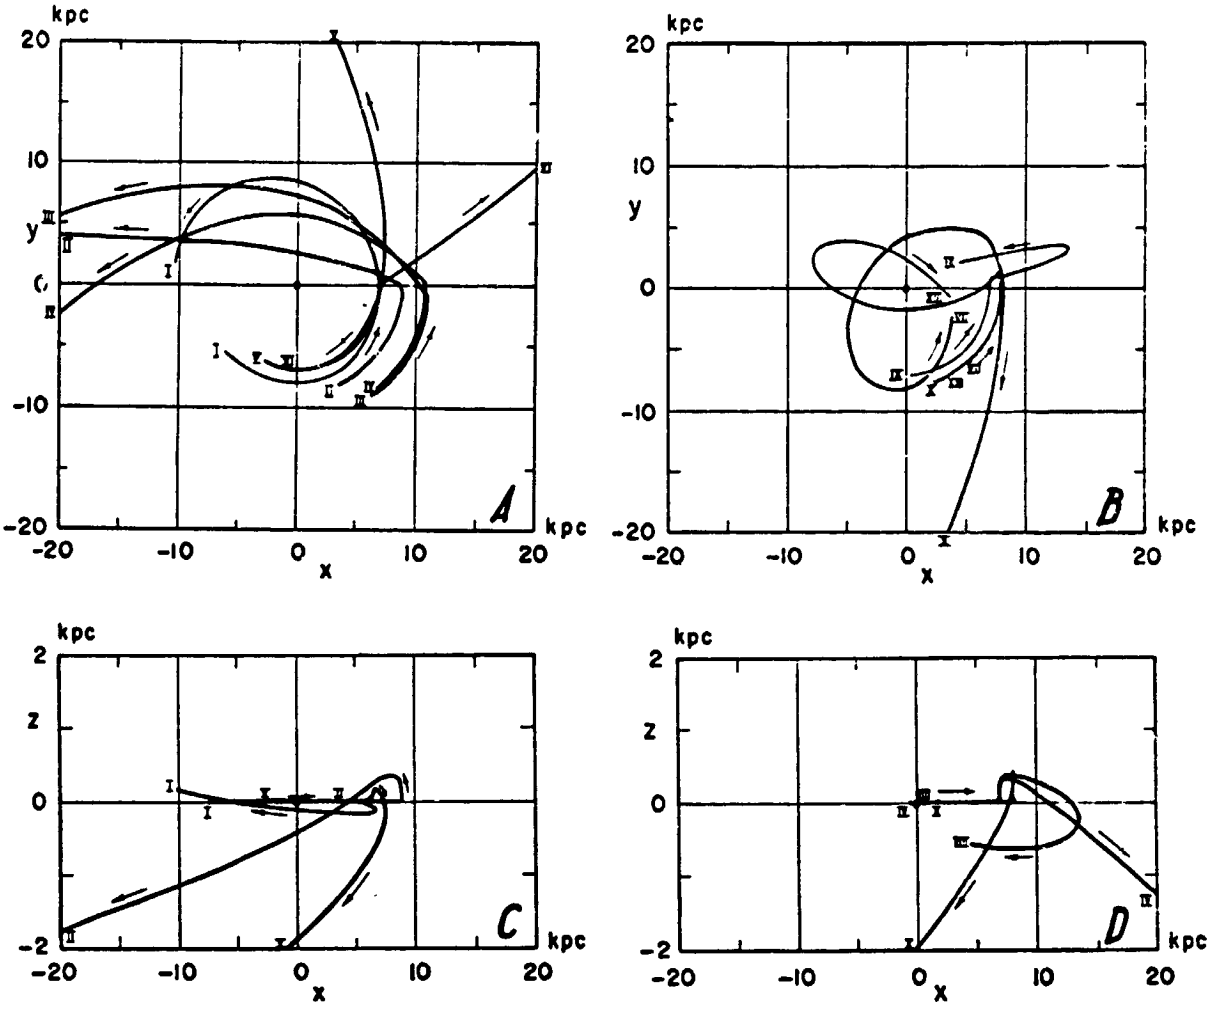

FIGURE 3.—Characteristic cases of orbits during a collision through $O_1(\alpha=8$ kpc, $\beta=0)$ with $e=90°$; I ($r=8$ kpc, $g=-60°$; non-escaping; II ($r=9$ kpc, $g=0°$; escaping); III ($r=11$ kpc, $g=-5°$; escaping); IV ($r=11$ kpc, $g=0°$; non-escaping); V ($r=7$ kpc, $g=-20°$; escaping); VI ($r=7$ kpc, $g=0°$; escaping); VII ($r=8$ kpc, $g=+30°$; non-escaping); VIII ($r=8$ kpc, $g=+10°$; non-escaping); IX ($r=7$ kpc, $g=+5°$; non-escaping); X ($r=8$ kpc, $g=+5°$; escaping). A, B give the projections of the orbits on the xy-plane, while C, D give the projections of some orbits on the xz-plane.

of the colliding galaxy makes the orbits more elongated. Such is the case VII ($r=8$, $g=+30°$), that is rather far from the region of escape. In case VIII ($r=8$, $g=+10°$), however, the deviation is so large, that the orbit reverses the sense of rotation, although the star does not escape. A large deviation, but to the right, is shown in case IX ($r=7$, $g=+5°$). Finally, case X ($r=8$, $g=+5°$) shows an abrupt reversal of the motion of the star and ejection toward the negative y-axis. Such a behavior, however, is quite exceptional.

From the above discussion we conclude that the greatest proportion of the ejected stars escapes toward the left (between the positive y-axis and the negative x-axis) and downward. The stars do not follow the colliding galaxy after the collision and they do not form a bridge or link between the two galaxies.

In case B ($e=45°$) the orbits are similar to those of case A, except as regards the z coordinate (cf. Figs. 2*B* and 4).

i) The stars with $r\geq 8$, $g\leq 0°$ have comparatively large motions upward as the colliding galaxy approaches, which are changed to downward motions later, as in case XI ($r=14$, $g=0°$). This is because in these cases the approaching galaxy comes rather close to these stars before it reaches the plane xOy at O_1.

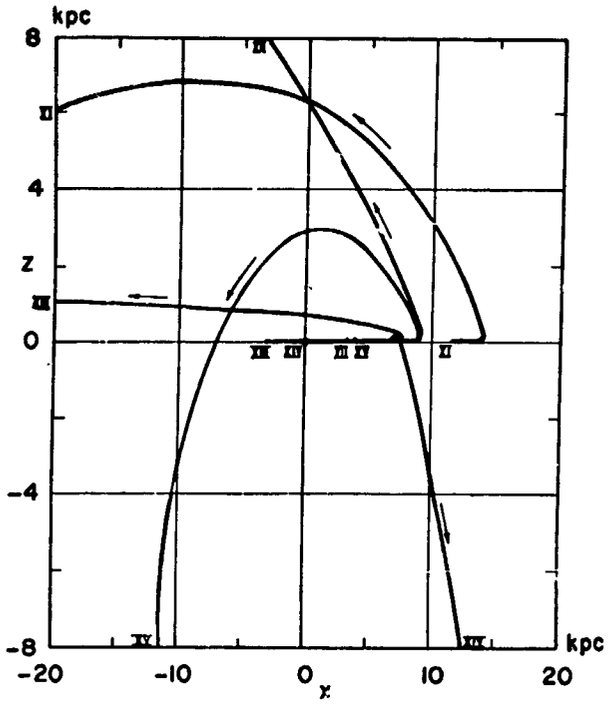

FIGURE 4.—Characteristic cases of orbits during a collision through O_1 ($\alpha=8$ kpc, $\beta=0$) with $e=45°$; XI ($r=14$ kpc, $g=0°$; escaping); XII ($r=9$ kps, $g=0°$; escaping); XIII ($r=8$ kpc, $g=-25°$; escaping); XIV ($r=7$ kpc, $g=0°$; escaping); XV ($r=9$ kpc, $g=+10°$; non-escaping). Only the projections on the xz-plane are given.

If r is near 8 kpc but $r>8$, and $g\simeq 0°$ the upward motions are so fast that the stars eventually escape upward and to the left (case XII, $r=9$, $g=0°$). If r is near 8 kpc but g not near 0° the upward motions are small (case XIII, $r=8$, $g=-25°$), and if $r<8$ kpc the stars go downward, showing only a small upward kink, as in case V. The downward motions in this case can be explained easily, because as the approaching galaxy comes from the right, it does not influence appreciably the stars to the left of O_1 until it goes beyond the point O_1 and comes rather close to them.

ii) The stars with $r<8$ but close to 8 and g near 0° show an abrupt motion downward (case XIV, $r=7$, $g=0°$).

iii) The orbits of stars with $g>0°$ show all the peculiarities mentioned in case A. The z motions are of the form of case XV ($r=9$, $g=+10°$) if $r>8$, and of the form of case XIV, if $r<8$, but with less steep descent.

We conclude that if a galaxy goes through the plane of symmetry of another galaxy at an angle different from 90° it causes the stars to acquire appreciable z velocities. The escaping stars move usually downward, but they do not follow the colliding galaxy in its course.

The final conclusion of this paper is that, during a collision of two galaxies with rather large relative velocity, only a small fraction of matter escapes and this does not form any bridge or link between the galaxies. Therefore the observed bridges between pairs of galaxies probably are not due to collisions with relative velocities of the order of 2000 km/sec. It is possible, however, that much slower collisions, not considered in this paper, may cause much larger changes in the colliding galaxies and eventually explain the formation of bridges between them.

We want to thank Dr. R. Jastrow and the NASA Institute for Space Studies, where most of the numerical work has been done. Some preliminary calculations were made by Dr. C. Goudas in Manchester, and at the Yale Computing Center, by kind permission of Dr. M. Davis; we express our thanks to both of them. The theoretical work has been done at the Astronomical Department of the University of Thessaloniki, Greece, and was supported by the Royal Hellenic Research Foundation.

DYNAMICS AND EVOLUTION OF CLOSE BINARY SYSTEMS

SU-SHU HUANG*

N66 37947

1. INTRODUCTION

Since the discovery of the periodicity of the change in light of Algol (β Persei) in 1782 by John Goodricke in England and his correct interpretation for the variability of light of this star as due to the "interpositions of a large body revolving around Algol," the study of light variation together with the accompanying variation in radial velocity, known respectively as the light curve and the (radial) velocity curve, has provided us with the sole means for the empirical study of close binary system. On the other hand, the close binary system can also be understood theoretically from Newtonian mechanics. Thus, our function is to reconcile the observational results in the form and light and velocity curve with the prediction based on the dynamical principles and thereby to derive a consistent picture of the close binary system. Indeed, the history of our study of close binaries shows clearly that, like any field in science where theories and experiments mutually help to make progress, observations of light and velocity curves and calculations based on dynamics act as two facets of a single process of successive approximations that lead finally to the present understanding of the nature of close binaries. Thus, the general form of the light and velocity curve suggests as a first approximation that dynamically the two components behave like two mass points and geometrically look like two spheres. Any analysis of light curves and velocity curves that is based on this assumption which we call the gross, analysis will be discussed in §2 and is included here for those who are not closely associated with observational astronomy.

*Goddard Space Flight Center and Catholic University, Washington, D.C.

Obviously this assumption is far from being true. Indeed, the prediction based on this assumption fails to agree completely with the observed light curve. Hence, the deviation of the observed results from the predicted ones opens up a way to improve the dynamical model of close binaries. Thus, the component stars may not be regarded as point masses and their shape not spherical. Also, other body or bodies than the two components themselves may be present in the system. Such refined treatments are given in the later sections.

Whether these complications can all be determined unambiguously from the photometric and spectroscopic observation with the aide of dynamical principles is not known at present. Is the empirical information—when conditioned by Newtonian mechanics and other laws of physics—comprehensive enough so that a unique determination of the geometrical configuration and physical state of the system can be performed at least in principle? This fundamental question has, to my knowledge, never been asked before, let alone answered. Undeniably this is a question of high mathematical complexity. Whatever the answer may be to this question, we are safe in predicting that such a unique determination is unlikely in practice because it is too difficult to disentangle one effect from many others in a single light and velocity curve, which has a limited accuracy imposed by measuring means. Such a situation which is common to all branches of observational science in general is particularly evident in astrophysics.

If we cannot treat the various deviations from the binary problem in an overall manner, we may nevertheless study them individually and compare

the results of each individual effect with observation. In this way, we can still test the consistency between observation and theory but the uniqueness of interpretation is not warranted by this kind of approach. By necessity it is this kind of approach which astrophysicists heretofore have cultivated in their study of close-binary systems and which we will follow in our treatment.

Next we consider the Roche model and the related problem of mass overflow from the stellar surface. The mass motion resulting from the overflow is then discussed according to different approaches. In the last two sections the origin and evolution of close binary stars are examined in the light of what we have learned from this article as well as from the present understanding of evolution of single stars.

Finally, we would like to add that the main purpose of the present article is to help understand the physical nature of close binary systems. It is intended to serve as an introduction to the basic physics of close binaries. Consequently, theoretical studies of a pure mathematical nature which cannot be matched in the foreseeable future with observation will not be discussed here. Similarly observational results of individual close binaries are mentioned only when they have some bearing either on general principles or on the common nature of the binary star. Because of a limitation of space we shall not be able to review here many physical problems such as models of peculiar systems, physical processes in the gaseous streams, atmospheric eclipses, etc. as well as many technical problems such as the distortions of velocity and light curves due to various causes and the methods of correction, accurate determination of the absolute dimension of eclipsing systems.

For surveys and observations the reader is referred to Kukarkin and Parenago's (1963) article.

While close binaries are not necessarily undergoing eclipse as seen by us, we are interested in only those that do, because the light variation caused by eclipse reveals much information about the nature of the system. It is true that the mere fact of undergoing eclipse does not necessarily warrant a close binary, but its chance of being one is very high. For this reason a theoretical study of close binaries is intimately associated with the observational investigation of eclipsing variables.

For definiteness we shall regard rather arbitrarily all binaries with separations less than 10 times the mean radius of the two component stars as close. Thus, the close binaries can be further classified into three categories: (1) detached systems, (2) semi-contact systems and (3) contact systems as we shall see in §5.

2. OBSERVATIONAL BACKGROUND

In this section we assume that the binary motion may be treated as a two-body problem, i.e. each component acts as a mass point and that the circular disk of each star follows a given law of limb-darkening. Under these simplifying assumptions, the physical state of the two component stars is specified by their masses (M_1, M_2), their radii (R_1, R_2) and their luminosities (L_1, L_2). Altogether there are six independent parameters to be determined for component stars themselves. In accordance with convention, we have denoted here by subscript 1 the quantity that is related to the primary component and by subscript 2 that related to the secondary component. Needless to say, the principal component is the brighter one of the two but is not necessarily the more massive one, although in most cases the brighter one is also the more massive one. From the radii and luminosities, the effective temperatures (T_1, T_2) or equivalently the surface brightness (J_1, J_2) can be readily computed.

The state of a binary can be specified under the assumption just made by the period, P, the eccentricity, e, the semi-major axis, a, of the relative orbit, the inclination i of the orbital plane, and the longitude of the periastron ω as defined by the angular distance of the periastron from the ascending node measured in the direction of orbital motion, and T the time of periastron passage. Altogether there are also six independent parameters to be determined for the binary itself. All these parameters are often called the orbital elements.

In the course of analysis of the velocity curve, it happens that we can also determine the radial velocity—called the γ velocity—of the entire binary system. Although the γ velocity is not connected with the internal properties of a binary system, it is nevertheless regarded also as an orbital element by convention.

In most cases of close binaries the two components move around each other in circular orbits. This gives $e=o$ which is sometimes assumed in the analysis of light curves of eclipsing binaries. Since the periastron loses its meaning when $e=o$, the binary motion is then fixed by the time of the deeper minimum of the light curve instead of the time of periastron passage.

The determination of the orbital elements from the light curve—a process perfected by H. N. Russell, J. E. Merrill, etc.—has been discussed in detail elsewhere in this series (Irwin 1962). While the procedure itself is a very tedious one, the underlying principle and what can be derived from it can be simply stated. First the law of limb-darkening is assumed to be a priori given for each component and is usually written as

$$J=J_c(1-x+x\cos\theta) \qquad (2.1)$$

where J_c is the surface brightness at the center of the disk, x is the coefficient of limb-darkening, and θ is the angle between the line of sight and the stellar radius vector to the point in question. Needless to say, both J_c and x vary with the wavelengths in which the light curve is obtained.

The period of the binary can be obtained very accurately from the long observation of the times of light minimum of the eclipsing binary. Then the shape of the light curve, obtained by observations and all reduced to one single cycle, depends upon the following elements, e, ω, R_1/a, R_2/a, i, $L_1/(L_1+L_2)$, x_1 and x_2. Conversely the observed light curve determines these orbital elements. If the binary satisfies the simplifying assumptions we have made and the light curve is determined in all phases, such a determination is unique in most cases and can be performed in practice, although it is quite complicated when e deviates appreciably from zero and i from $\pi/2$. Usually only the value of $e\cos\omega$ is determined with a high accuracy from the intervals of the minima in such cases. Also, under some circumstances, considerable ranges of various orbital elements lead, within the accuracy of observation, to the identical light curve.

For example, sometimes one cannot even tell from the light curve whether the eclipse is total or annular, consequently we cannot decide which one of the two component stars has a larger radius than the other. The intrinsic difficulty of determination of orbital elements however, arises in the first place from the various effects which are not included in our simplifying assumptions, and in the second place from the imperfection of the observed light curve.

As has been emphasized by Irwin (1962), only in the most favorable cases and with the best observations can we determine x_1 and x_2 from the analysis of the light curve. In general, these two parameters can be assigned beforehand in accordance with the prediction by theory of stellar atmospheres (e.g. Chandrasekhar 1950).

In any case the light curve which gives only the sizes of the stars in terms of their separation does not reveal the complete information about the nature of the binary system. In order to derive the dimension of the system in an absolute measure we depend upon the velocity curve. References to the analysis of velocity curves may be found for example in articles by Struve and Huang (1958), by Petrie (1962) and by others.

For some binaries spectra of both components may be seen on a spectrogram but for others only one is visible, depending upon the relative magnitude between the components and their colors (Hynek 1951). If both components are visible, two velocity curves —one from each component star—give $M_1\sin^3 i$, $M_2\sin^3 i$, $a_1\sin i$, $a_2\sin i$, where a_1 and a_2 are the semi-major axes of the orbit of the two components in the rest frame of reference, i.e.,

$$a=a_1+a_2 \qquad (2.2)$$

The velocity curve also gives $e\cos\omega$, $e\sin\omega$, time of periastron passage, T, and the γ velocity. Since the factor, $\sin i$, is persistently associated with the measured radial velocity, we cannot get rid of it from the spectroscopic results as we have seen. Here i determined from the light curve supplies the missing information. Hence, the spectroscopic results combined with the photometric data determine the properties of the binary system completely, if the two component stars obey our simplified assumption.

If the spectrum of only one component is visible, we can determine $e\cos\omega$, $e\sin\omega$, T, and γ without difficulty just as in the double-lined spectroscopic binary. However, concerning the mass and dimension of the system, we can now obtain

from the velocity curve (of the primary component alone) only the quantity,

$$f_1(M)=\frac{M_2^3 \sin^3 i}{(M_1+M_2)^2}, \tag{2.3}$$

known as the mass function and $a_1 \sin i$. When the results of analysis of both the light curve and the velocity curve are combined, $M_2^3/(M_1+M_2)^2$ and a_1 are obtained. In such a case we cannot determine M_1 and M_2 separately. The missing link is the mass ratio expressed by either

$$\alpha=\frac{M_2}{M_1} \quad \text{or} \quad \mu=\frac{M_2}{M_1+M_2}. \tag{2.4}$$

Thus for an eclipsing binary showing only the spectrum of one component, other means must be sought in order to determine the mass ratio. The means, if available, varies from one case to another and has no general rule. Basically it consists of an estimate from various physical arguments any one of the following parameters, m_1, m_2, α, a, R_1, and R_2 since only one additional parameter is needed to specify completely a single-spectrum eclipsing binary. The fact that a knowledge of either R_1 or R_2 can determine the masses of two components and their mean separation may be seen if we remember that R_1/a and R_2/a can be empirically obtained from the light curve. This gives a from which we can calculate M_1+M_2 from the following well-known relation

$$\left(\frac{P}{2\pi}\right)^2=\frac{a^3}{G(M_1+M_2)}, \tag{2.5}$$

where G is the gravitional constant. Consequently M_1 and M_2 may be separately determined.

In this way the physical and dynamical state of many an eclipsing binary has been painstakingly derived by investigators in the past few decades. Those binaries with apparent photographic magnitudes brighter than 8.5 at maximum have been compiled and studied by Plaut (1950, 1953). Other catalogues of the elements of eclipsing binary systems have been provided recently by Kopal and Shapley (1956) and Wood (1963).

3. DYNAMICAL CONSIDERATIONS OF THE DEVIATION FROM THE TWO-BODY PROBLEM

There are several reasons for which the motion of component stars cannot be regarded as a problem of two bodies. The component stars in a close pair obviously cannot have a spherical symmetry in density distribution. The mass of each star may not be constant. A third body or bodies in the form of stars, planets or resisting medium composed of gases, dust, and larger particles may be present in the binary system. All these effects disturb the orbit of the binary star from what would be expected from Kepler's law of binary motion.

If we regard Kepler's law as the zeroth order approximation to the orbital motion of close binaries, each of those effects mentioned above produces a corresponding perturbation which may be computed in principle to high order of approximation. It is self-evident that starting at the second order approximation, cross terms each arising from two effects will appear in the final result. While it is interesting to investigate the effect of each cause to a high degree of approximation, it is only the result of the first order approximation that the astrophysicist has actually sought in most cases because his main purpose is to identify among various perturbing factors the one that is dominant in any given binary. Needless to say, the result of higher order approximation for a single effect is often useful but we have to be very careful in applying its result quantitatively to the interpretation of observed phenomena because of the presence both of the cross terms just mentioned and of the first-order term due to some effect which has not been considered.

In what follows we shall discuss each of these perturbing factors separately, emphasizing physical significance at the expense of mathematical completeness.

3.1. Departure of Component Stars from the Spherical Symmetry

Because of the rotational and tidal distortions the component star in a close binary system can never be treated as having a spherical symmetry in its density distribution. Thus, the mutual attractive force between the two stars can be resolved into two components: one is the dominant force resulting from the mutual attraction

of two point masses M_1 and M_2 and the other is the perturbing force arising from the deviations from the spherical symmetry. Since the perturbing force is very small compared with the dominant force, the orbital motion should follow closely, with only a slight deviation, to what is predicted in the two-body problem. In other words, the component star may be approximated, in each short time interval, as exercising Keplerian motion. Because of the small perturbing force it is obvious that the orbits defined by two short time-intervals which are themselves separated by a long time-interval, cannot be identical. Thus, we may describe the motion as elliptical but the orbital ellipse changes with time. Obviously the rate of change for each of the orbital elements depends upon the perturbing force and indeed can be expressed in terms of it. The mathematical procedure underlying this physical conception is the method of variation of parameters which is often used to study the motion of a planet under the dominant force of the sun and the perturbing force of other planets. Its application to the study of close binaries was due to Russell (1928) whose calculation was later improved by Sterne (1939 a,b,c). Also, Cowling (1938) studied this problem by an entirely different approach. The presentation adopted in the following discussion follows that given by Sterne (1939 a).

The calculation consists of three steps: (1) to find the disturbing potential field, at the location of the primary due to the undistorted secondary component and due to the primary's own axial rotation, (2) to find both the deformation of the primary due to the disturbing potential obtained in the first step and the potential field at the location of the secondary due to the deformed primary and (3) to find the change of orbital elements because of the potential field obtained in the second step. Since the potential field derived in the first step distorts the primary and the distorted primary in turn produces in the second step a disturbing potential to effect the binary motion, the first two steps may be regarded as a process of successive approximation.

Let S_1 and S_2 be respectively the centers of mass of the primary and the secondary which are at a distance, r, apart. If r_1 and r_2 are respectively the distances of any point from S_1 and S_2, the undistorted secondary gives rise to a potential field (negative values throughout) equal to GM_2/r_2. At point P in the neighborhood of S_1, $1/r_2$ can be expanded in a series. Thus,

$$\frac{GM_2}{r_2}=\frac{GM_2}{r}\sum_{n=0}^{\infty}\left(\frac{r_1}{r}\right)^n P_n(\cos\theta) \qquad (3.1)$$

where P_n is the Legendre coefficient of order n and θ represents the angle PS_1S_2. If the separation between S_1 and S_2 be fixed, the first term is a constant of no consequence while the second term produces an acceleration GM_2/r^2 equal in magnitude for all elements of the primary along S_1S_2. This acceleration is simply the orbital acceleration of the primary as a whole. The remaining terms

$$V_t=\frac{GM_2}{r}\sum_{n=2}^{\infty}\left(\frac{r_1}{r}\right)^n P_n(\cos\theta) \qquad (3.2)$$

constitute the tidal potential and produce tidal distortion in the primary.

In an elliptical orbit, r is actually a function of the time. Thus, a rigorous treatment would be very complicated. The complications have been described by Sterne (1939a). However, as Cowling (1938) pointed out, the time of adjustment of a star to an external gravitational field is of the order of the period of free adiabatic oscillations of the star, which is much smaller than the orbital period of its companion around it. Therefore, it appears probable that the form of the star at any time would approach a state very close to equilibrium form in which the distortion is instantaneously adjusted to the external gravitational field given by equation (3.2). (Thus the longest axis of both component stars is always along the line joining the centers of the two components.)

Now the stars will be assumed to rotate with uniform angular velocities ω_1 and ω_2 about axes normal to the orbital plane. Such an assumption appears to be consistent with observations in general. Rotation of star introduces a disturbing potential which arises from the centrifugal force. Apart from a term which is symmetric with respect to the center of mass of the primary and consequently does not distort the star from a spherical configuration, the disturbing potential, V_r,

$$V_r=-\tfrac{1}{3}r_1^2\omega_1^2 P_2(\cos\theta') \qquad (3.3)$$

where θ' is the co-latitude.

Therefore, the total disturbing potential, V_d imposed on the primary is

$$V_d = V_t + V_r \tag{3.4}$$

and can be expanded in a series of terms of the form

$$c_{n,m} r_1^n P_n^m(\theta,\varphi) \tag{3.5}$$

where (θ,φ) are polar coordinates taken with respect to S_1, P_n^m is a tesseral surface function of (θ, φ) and $c_{n,m}$ is a constant of expansion. This completes the first step of calculation.

The problem of deformation of a sphere which cannot maintain a shearing stress, and consequently of the potential arising from the deformed body, as the result of an imposed disturbing function V_d has been studied by Clairaut, Legendre, Laplace and others. A summary of their works can be found in Tisserand (1891). Here, we shall only outline the general idea of the approach to the problem, omitting detailed calculations.

The equation of the surface of equal density in the distorted primary can be written as

$$r_1 = \xi(1 + \sum_{n,m} Y_n^m), \tag{3.6}$$

where ξ is a parameter (the mean radius) characterizing the surface in question. Thus, the density ρ of the primary is a function of ξ alone—a fact that makes ξ well suited to replace r_1 as the independent variable in the present problem. Thus, the value of the independent variable ξ at the stellar surface is R_1, the mean radius of the primary itself. The Y_n^m's in equation (3.6) are tesseral surface functions with respect to θ and φ and are also functions of ξ. Thus the deformation of the primary will be completely determined if we can find the ξ-dependence of Y_n^m and know the ρ-dependence of ξ.

The total gravitational potential Ψ at any point in the primary is the sum of the gravitational potential, U, due to the deformed primary itself and the imposed disturbing potential, v_d, i.e.,

$$\Psi = U + V_d \tag{3.7}$$

It can be shown that the condition of hydrostatic equilibrium leads to a total differential equation

$$dp = \rho d\Psi \tag{3.8}$$

where p is the pressure. It follows from equation (3.8) that both p and ρ must be functions of Ψ alone. In other words Ψ = constant over any surface of equal density and equal pressure in the primary. Furthermore, since ρ is a function of ξ alone, Ψ must be also a function ξ alone, i.e., independent of θ and φ.

Now U at any point p inside the primary consists of two parts, arising respectively from the mass (1) inside the spherical surface passing through p. (exterior potential) and (2) outside the spherical surface (interior potential). Since the equal-density surfaces are given by equation (3.6), both parts can be expressed in terms of Y_n^m. Actually when we carry out the lengthy calculation, we will find that each part of U can be expressed as a summation of terms involving Y_{nm} and other factors (like ρ, ξ) which do not contain the indices n and m (i.e., independent of θ and φ), if we assume that the distortion given by Y_n^m's is small so that only first order terms of them are retained in the calculation. We have already mentioned that V_d can be expressed as a series whose typical term is given by (3.5). Hence, we can write down Ψ as a sum of three series, two involving Y_n^m and the other involving P_n^m. All terms are indexed by n and m (i.e., indicating their θ and φ dependence). The condition that Ψ is independent of θ and φ makes it necessary that in the expression of Ψ the terms associated with each pair of indices n and m must vanish identically. In this way we derive a differential equation for each Y_n^m. (It is a differential equation because of the transformation from r, to ξ as given by equation (3.6).) If we define

$$\eta_n = \left(\frac{\xi}{Y_n^m}\right)\frac{\partial Y_n^m}{\partial \xi} \tag{3.9}$$

and

$$\rho_m = \frac{3}{\xi^3}\int_0^{\xi} \rho \xi^2 d\xi. \tag{3.10}$$

which is simply the mean density interior to ξ, we can transform the differential equation of Y_n^m into the following form:

$$\xi\frac{d\eta_n}{d\xi} + \eta_n(\eta_n - 1) - n(n+1) + \frac{\partial \rho}{\rho_m}(\eta_n + 1) = 0. \tag{3.11}$$

One reason that we introduce η_n instead of dealing directly with Y_n^m is to eliminate the (θ, φ)

dependence of Y_n^m which is simply p_n^m. Hence equation (3.11) together with p_n^m determines completely the deformation of the primary if we know the values of Y_n^m and η_n at any one point inside the star. This can be easily obtained for the point $\zeta=0$. There is no distortion at the central point. Hence $Y_n^m(0)=0$. In order to derive $\eta_n(0)$ we assume that $\rho(0)$ has a finite value. Setting $\zeta=0$ in equation (3.11) we obtain

$$\eta_n(0)=\eta-2. \tag{3.12}$$

This completes the determination of deformation of the primary.

In the process of determining the deformation we have already derived the potential U that the deformed primary produces at the external points as a series of Y_n^m. Corresponding to the (n, m) component of the distorting potential given by (3.5), the deformed primary produces a component $U_{n,}^m$ to the potential

$$U_{n,m}=c_{n,m}\frac{n+1\eta_n(\mathrm{R}_1)}{n+\eta_n(R_1)}\frac{R_1^{2n+1}}{r_1^{n+1}}P_n^m(\theta,\varphi) \tag{3.13}$$

at external points. Here $\eta_n(R_1)$ is the value of η_n at $\xi=R_1$ (i.e., at the surface). Since $\eta_n(R_1)$ is obtained by integrating equation (3.11) which involves p/ρ_m, the (n,m) component of the exterior potential depends upon the structure of the star.

The result contained in equation (3.13) can now be applied to the present case of tidal and rotational disturbance. The terms of the indices $n=2(m=o)$ in the disturbing potential $v_d-v_r+v_t$ given by equations (3.2) and (3.3) are

$$V_d=\frac{GM_2}{r^3}r_1^2p_2(\cos\theta)-\frac{1}{3}r_1^2\omega_1^2p_2(\cos\theta'). \tag{3.14}$$

Since the result given by (3.13) is independent of the choice of coordinate systems, the primary deformed by Vf of equation (3.14) produces an external gravitational potential field

$$U_2=2\frac{R_1^5}{r_1^3}k_{2,1}\left[\frac{GM_2}{r^3}p_2(\cos\theta)-\frac{\omega_1^2}{3}p_2(\cos\theta')\right], \tag{3.15}$$

where

$$k_{2,\,1}=\frac{3-\eta_2(R_1)}{2[2+\eta_2(R_1)]} \tag{3.16}$$

computed for the primary to which the second subscript is κ is referred to.

The acceleration of the secondary due to U_2 *directed towards* S_1 can be obtained by setting $r_1=r$, $\theta=$ o and $\theta'=\pi/2$ *in* $-\alpha U_2/\delta,r$, and is given by

$$\frac{R_1^5}{r^4}k_{2,\,1}\left(\frac{6GM_2}{r^3}+\omega_1^2\right). \tag{3.17}$$

If we now regard r as the independent variable, the acceleration given by equation (3.17) corresponds to a potential function,

$$\Phi_2=R_1^5k_{2,\,1}\left(\frac{GM_2}{r^6}+\frac{\omega_1^2}{3r^3}\right) \tag{3.18}$$

If the relative orbit is considered, $(1+m_2/m_1))\Phi_2$ will be identical to the disturbing function R of perturbation theory in celestial mechanics. Since the perturbing force is confined to the orbital plane which coincides with the equatorial planes of both components, the change in ω (e.g., Brower and Clemence 1961) is given by

$$\frac{d\omega}{dt}=\left[\frac{1-e^2}{G(M_1+M_2)a}\right]^{\frac{1}{2}}\frac{1}{e}\frac{\partial R}{\partial e} \tag{3.19}$$

In order to derive $\partial R/\partial e$ we have to expand R in terms of e. Since we are interested in the secular motion of the apsides, only non-periodic terms are needed in the evaluation. A detailed calculation by Sterne (1939a) thus derives the secular motion arising from the distortion of order $n=2$ of the primary as

$$k_{2,\,1}\frac{R_1^5}{M_1}\left(\frac{M_1+M_2}{Ga}\right)^{\frac{1}{2}}\left[15\frac{GM_2}{a^4}f_2(e)+\frac{\omega_1^2}{a^3}g_2(e)\right] \tag{3.20}$$

where $f_2(e)$ and $g_2(e)$ are series, convergent for any value of e less than inity,

$$f_2(e)=1+\frac{13}{2}e^2+\ldots, \qquad g_2(e)=1+2e+\ldots$$

Both $f_2(e)$ and $g_2(e)$ can also be expressed in closed expressions (Sterne 1939a) and have been computed by Plavec (1960).

Similarly, the secondary will be distorted by its own rotation and by the attraction of the primary. The perturbation produced by the distorted secondary on the primary can be easily obtained, because of symmetry, by interchanging M_1 and M_2

as well as replacing respectively R_1 and $k_{2,1}$, by R_2 and $k_{2,2}$, in (3.20). Thus the resultant motion of the apsides as compared with the mean orbital motion is

$$\frac{p}{p'}=k_{2,1}\left(\frac{R_1}{a}\right)^5\left[15\frac{M_2}{M_1}f_2(e)+\frac{a^3\omega_1^2}{GM_1}g_2(e)\right]$$
$$+k_{2,2}\left(\frac{R_2}{a}\right)^5\left[15\frac{M_1}{M_2}f_2(e)+\frac{a^3\omega_2^2}{GM_2}g_2(e)\right], \quad (3.21)$$

where p and p' are the orbital and apsidal periods respectively.

If the orbital motion and axial rotation of both components in a close binary are synchronized (Swings 1936), equation (3.21) reduces to

$$\frac{p}{p_1}=k_{2,1}\left(\frac{R_1}{a}\right)^5\left\{\frac{M_2}{M_1}[15f_2(e)+g_2(e)]+g_2(e)\right\}$$
$$+k_{2,2}\left(\frac{R_2}{a}\right)^5\left\{\frac{M_1}{M_2}[15f_2(e)+g_2(e)]+g_2(e)\right\}. \quad (3.22)$$

The contributions arising from the third and fourth order harmonic (tidal) distortion can be similarly obtained. The results can be expressed in terms of $k_{3,i}$ and $k_{4,i}$ $(i=1,2)$ which are functions of $\eta_3(R_i)$ and $\eta_4(R_i)$ respectively in a similar way as $k_{2,i}$ being a function of $\eta_2(R_i)$.

The values of k's can be readily found for any model by integrating (3.11). Thus, values of k_2 have been tabulated for a series of models by Russell (1928). For homogeneous stars, k_2 has a value 3/4; for completely concentrated stars all the k's are zero. In the case of certain polytropic models, the k_n's have been obtained by Chandrasekhar (1933) and later more extensively by Brooker and Olle (1955) for $\eta=2$ to $\eta=7$. The k's for other stellar models have been obtained by Kellar (1948), by Motz (1941, 1950, 1953), by Pike (1955), by Härm and Rogenson (1955), and by Kushwaha (1957).

Table 1 gives the k_2 values for some polytropic gaseous spheres from Brooker and Olle's paper. It illustrates its relation to two other parameters that also depend upon the density distribution in the sphere. The two parameters are the ratio of the central density ρ_c to the mean density $\bar{\rho}$ and the radius of gyration of the sphere. The values $\rho_c/\bar{\rho}$ given in Table 1 are taken from Chandrasekhar's (1939) book. The radius of gyration given in the form of I/MR^2) in the table where I denotes the moment of inertia follows Motz's (1952) calculation. According to the latter. H. N. Russell has suggested that the apsidal motion constant k_2 might depend in a simple way on the radius of gyration of a star. Indeed, in the case of polytropic gaseous spheres and main sequence stellar models, Motz (1952) has found if $\log k_2$ is plotted against $\log[I/(MR^2)]$, all points do fall on a straight line. However, he has also pointed out that the giant models do not follow this linear relationship.

TABLE 1.—*Relation between the Apsidal Motion Constant and other Parameters that Relate to the Density Distribution in the Polytropic Gaseous Sphere*

The secular variation of e and a can be similarly investigated. But it is hardly necessary to follow the calculation through. The variation must vanish because the interaction we are considering does not change the total dynamical energy and the total angular momentum of the orbital motion.

The assumption that the axes of rotation of both component stars are perpendicular to the orbital plane is likely true in most close binaries. However, if either or both axes of rotation make a considerable angle with the normal of the orbital plane, the motion of stars in a close binary would be greatly complicated, because we then would have to consider, apart from the motion in the orbital plane, the motion of the orbital plane itself and the motion of the equatorial planes of both components. Brouwer (1946) studied the problem by examining the motion of two rigid spheroids. His treatment was followed by Kopal

(1959) who has included the revolution of the tidal bulge in his considerations.

Thus, if two components have similar distributions of density so as to make corresponding k's for the two components equal, we may express in general the ratio of periods in the following form (Sterne 1939b).

$$\frac{p}{p'}=\alpha_2k_2+\alpha_3k_3+\alpha_4k_4+\ldots \qquad (3.23)$$

where α's can be computed from the orbital elements alone, while k's depend upon the stellar model. For each one-parameter family of stellar models, such as the polytropic family, the observed value of p/p' determines uniquely the parameter, such as the polytropic index. Therefore, it is frequent practice to express the observed motion of apsides in terms of the equivalent index of polytrope for the component stars. If, however, there are many plausible families of stellar models, the apsidal motion does not give any information as to which is the physically correct family. Hence, what the apsidal motion can provide for the astrophysicist is only a consistency check of the computed model.

A large number of papers have been published on the observed motion of apsides of various close binaries. The reader may find the references to these papers in several I.A.U. reports on eclipsing binaries by Kopal (1954, 1957), by O'Connell (1960, 1962) and by Merrill (1964). Also, the catalogues of orbital elements of binaries provided by Kopal and Shapley (1956) and by Wood (1963) give the observed apsidal motion where ever available. The observed results of apsidal motion of some binaries have been analyzed by Luyten, Struve, and Morgan (1939), by Sterne (1939b) and by Schwarzschild (1958).

3.2 The Perturbation Caused by a Third Body

In order to study the perturbation of the orbital elements of a close binary, caused by the presence of a third body, we have to assume that all three bodies behave like point masses. If the three bodies should move at distances of the same order of magnitude from one another, no orbital elements could be defined. Intuitively, such a state of motion is perhaps not stable. Indeed, few such systems have been found observationally What we have actually observed of triple systems usually consists of a close pair accompanied by a third companion which is at a relatively large distance from the close pair. In these cases, the orbit of the close pair and that of the distant companion are well defined and perturbation theories developed for the motion of the moon can be applied directly because the perturbation of the earth-moon system by the sun is, in many respects, similar to the perturbation of the close pair by the distant companion in a triple system. Thus, Slavenas (1927), Lyttleton (1934), Brown (1936, 1937) and Martynov (1948) have respectively applied different lunar theories to the stellar case. In principle, they all derive the change of orbital elements from the disturbing function, but their detailed calculations are so involved that it is impractical to be given in this short article. It will suffice to say that the elements of the close orbits that show secular changes are the line of apsides, the line of nodes and the mean longitude. If the p and p' are respectively the period of close binary and the orbital motion of the third body respectively, the periods of revolution of the apsidal and nodal lines p'' are given by

$$\frac{p''}{p}\sim\left(\frac{p'}{p}\right)^2 \qquad (3.24)$$

in order of magnitude.

Actually, the discovery of triple systems does not depend upon the results of these calculations. Observationally it is the change in the γ velocity obtained from spectroscopic data as well as the change in the period obtained mainly from photometric data that leads to the identification of the third body.

Since the semi-major axis of the relative orbit of the close pair suffers neither secular nor long-periodic perturbations by the third body, its period will remain constant. However, the apparent period as observed between two successive light minima will not be strictly constant because of the motion of apsides and nodes. The variation arising from these causes is small however, since the periods of revolution of the apsidal and nodal lines are very long, as one can see from equation (3.24). The actual observed variation in the apparent period is due to the continuous change in distance of the close pair from the observer. Since the velocity of light is finite, the

change in distance means also a variation in the time-interval between two successive minima.

Consider a rectangular coordinate system with its origin, 0, at the center of mass of the triple system and with its Z-axis coinciding with the line of sight. The distance of the center of mass S^{12} of the eclipsing pair from the XY plane is evidently

$$r \sin i \sin (v+\omega),$$

where r represents the radius vector from 0 to any point on the orbit of S_{12}, i, the angle of inclination of this orbit to the celestial sphere, v the true anomaly of S_{12}, and ω the longitude of the periastron as defined before. If the space motion of the entire triple system produces a γ velocity—denoted by γ_o—in the z-direction, the distance z between the eclipsing system and the observer at any time becomes

$$z=z_o+\gamma_o(t-t_o)+r \sin i \sin(v+\omega), \quad (3.25)$$

where z_o denotes the initial value of z at time t_o of a light minimum of the eclipsing system. Thus, a term $(z-z_o)/c$, where c is the velocity of light, will be introduced into the ephemeris of the light minima.

Any apparent difference in time, arising purely from the light propagation, of some cosmic event is known in astronomy as the time equation or light-time. For example, there is the light-time for converting observed time on the earth to the heliocentric time, because the light carrying the news of the event does not reach the earth and the sun at the same time as the result of a difference in distance. This converting factor can be computed from our knowledge of the earth's position with respect to the sun's. In the present case, the light-time results from the orbital motion of the eclipsing pair around a third body or bodies. Thus, the light-time in this case is the difference (0–C) between the time of observed light minimum and the computed time based on the constancy of the period of the eclipsing pair. A light-time curve can therefore be plotted which, like the velocity curve, yields information as regards the nature of orbit on which the center of mass, S_{12}, of the eclipsing pair move.

The light-time curve—a plot of 0–C against the number of eclipsing cycles—of the Algol system has been extensively studied by many investigators because its records can be traced back nearly two hundred years. Eggen (1948) has shown that the system is composed of four stars, namely the eclipsing pair themselves, a third component causing wriggles in the light-time curve with an orbital period of 1.873 years and a fourth component causing the slow but dominant variations in 0–C with an orbital period of 188.4 years. This interesting system is continuously being studied with the purpose to make a better determination of the periods.

The determination of the (light-time) orbit from the light-time curve, which has been discussed by Woltjer (1922), Martynov (1948), Irwin (1952, 1959) and Kopal (1959) is very similar to one of determining orbital elements from the velocity curve. Indeed, the two problems are basically identical because if we differentiate (3.25) with respect to t, we obtain the radial velocity of S_{12} in its course of orbital revolution around 0. Thus, the light-time curve of an eclipsing pair in a triple system is equivalent in principle to a velocity curve of the motion of the center of mass, S_{12}, of the eclipsing pair around the center of mass, 0, of the entire system.

Actually the velocity curve of S_{12} can be directly determined from observation. Since the motion of S_{12} may be regarded as constant during a few cycles of the orbital motion of the close pair, the γ-velocity determined from the velocity curve during these few cycles of one or both components of the close pair represents the radial motion of S_{12}. Thus, a velocity curve of S_{12} may be obtained by plotting the γ-velocity of the close pair in different epochs. Therefore, we can derive all those orbital elements that are derivable in any single-lined spectroscopic binary. For example, the component, with a period of 1.873 years in the Algol system, mentioned previously, was first detected in this way by McLaughlin (1934).

Both the presence of a third body and the tidal and rotational distortions of component stars produce the effect of apsidal motion. It would be difficult to separate the causes of the observed motion, if there were no other observable criteria. Fortunately, because the presence of the third body in a binary system can be independently detected by the change in γ-velocity or by the light equation, there will be little ambiguity in interpreting the motion of apsides in a close binary. Thus, if the central condensation of the

star is to be studied, we can always choose those close binaries in which no third component is detectable.

3.3 Perturbation by Galactic Objects

A binary system is continually perturbed by the encounters with other objects in the galaxy. As a result the energy is fed into the binary system, thereby increasing the separation of its two components. Ambarzumian (1937) has estimated the effectiveness of the tidal forces, due to the neighboring stars, in modifying the orbital elements of a binary. He has used the two-body approximation of stellar encounters to evaluate the tidal effects of the nearby stars. As Chandrasekhar (1944b) has pointed out, "the essentially characteristic features of the problem are ignored if an attempt is made to evaluate the differential effects of the neighboring stars on the components of a binary along the conventional lines of treating stellar encounters as a series of independent two-body problems."

In view of some recent investigations it becomes apparent that encounters with interstellar clouds play an important role in modifying the peculiar velocities of single stars (Spitzer and Schwarzschild 1951) and in feeding energy into a cluster (Spitzer 1958). On the same ground we may expect that encounters of a binary with interstellar clouds would increase the separation of the binary system. A rigorous treatment of the encounter of a binary with another object belongs to the well-known problem of three bodies in celestial mechanics and a complete solution is still lacking. A brief review of some recent investigations along this line, however, may be found in the book by Leimanis and Minorsky (1958).

In the meantime, a general statistical method has been proposed by Chandrasekhar (1943, 1944a and b) for solving many problems in stellar dynamics. The method first analyzes the nature of the force acting on a star by the rest of the stellar system and then by Markoff's process derives the probability distribution of the force field.

In the case of a binary system it is apparent that the forces exerted by the neighboring stars on the two components differ by a certain amount because of their different positions in space. For any given separation between the components there exists a definite distribution function, $(W(\vec{F}_1, \vec{F}_2)$, which governs the probability that forces of intensities $\vec{F}_1$ and $\vec{F}_2$ respectively, will act simultaneously on the two components of the binary and which can be obtained by Markoff's method (Chandrasekhar 1944a). Thus, the difference,

$$\Delta\vec{F}=\vec{F}_1-\vec{F}_2, \tag{3.26}$$

represents the differential force which tends to accelerate the star "1" relative to the star "2." The differential force may be resolved into two components, a parallel component given by where

$$\Delta F_{\parallel}=(\vec{F}_1-\vec{F}_2)\cdot\vec{k}_1, \tag{3.27}$$

$\vec{k}_1$ is a unit vector parallel to the direction of $\vec{F}_1$ and a perpendicular component. Since the perpendicular component is of a random character, it produces no net effect during a time scale, τ, long compared to the periods of the elementary fluctuations in $\vec{F}$. Therefore, the average net increase in the velocity of the star "1" relative to the star "2" during τ is given by

$$\overline{\Delta v_{1,2}}=\Delta F_{\parallel}\tau. \tag{3.28}$$

If the orbit is circular, it follows from the definition of $W(\vec{F}_1, \vec{F}_2)$ that

$$\Delta v_{1,2}=\tau\int_{-\infty}^{\infty}\int^{\infty}(\vec{F}_1-\vec{F}_2)\cdot\vec{k}_1 W(\vec{F}_1, \vec{F}_2)d\vec{F}_1 d\vec{F}_2. \tag{3.29}$$

The evaluation of this integral is very involved and we can only refer the reader to the original paper by Chandrasekhar (1944a and b). When the separation between the two components, i.e., a, is small compared with the average distance between stars, the result may be approximately written in a simple form as follows:

$$\overline{\Delta v_{1,2}}=4\pi GNMa\tau, \tag{3.30}$$

where M denotes a certain average mass for the field stars and N the number of stars per unit volume.

Instead of the time of dissociation of a wide binary system that Chandrasekhar is interested, we set ourselves to calculate the slow increase in

separation of a close binary due to galactic perturbation.

Since $\overline{\Delta v_{1,2}}$ is the increase in the relative velocity of one component with respect to the other, $\overline{\Delta v_{1,2}}^2/2$ represents the increase in the dynamical energy per unit reduced mass E of the binary, namely

$$\Delta E = \tfrac{1}{2}\overline{\Delta v_{1,2}}^2 \tag{3.31}$$

while E itself is given by

$$E = -\frac{G(M_1+M_2)}{2a}. \tag{3.32}$$

It follows from equations (3.30)--(3.32) that the new separation, denoted by a', after a time τ is given by

$$G(M_1+M_2)\left(\frac{1}{a}-\frac{1}{a'}\right) = (4\pi GNMa\tau)^2. \tag{3.33}$$

This equation reduces to Chandrasekhar's equation for determining the time scale of dissociation, τ_d, when we set $a' \to \infty$.

$$\tau d = \frac{(M_1+M_2)^{1/2}}{4\pi G^{1/2}NMa^{3/2}}. \tag{3.34}$$

Assuming, in the neighborhood of the sun, $N = 0.1$ star/(parsec)^3 and setting $M = 0.5M_\odot$, $M_1+M_2 = 1M_\odot$, Chandrasekhar has obtained from equation (3.34) the following numerical results

$$\tau_d = 2.22\times 10^{15} a^{-3/2} \text{ years} \tag{3.35}$$

if the separation, a, is expressed in astronomical units.

It becomes obvious from equation (3.35) that dissociation of close binaries does not take place in the galactic time scale, say 2×10^{10} years. What we would like to calculate is the small increase in separation during this time. For this purpose let us write

$$a' = a + \Delta a \tag{3.36}$$

Since Δa is small, it can be shown as a first approximation that

$$\frac{\Delta a}{a} = \left(\frac{\tau}{\tau_d}\right)^2 \tag{3.37}$$

which gives numerically

$$\frac{\Delta a}{a} = 2.03\times 10^{-14} \text{ in } 10^{10} \text{ years} \tag{3.38}$$

if a is 1/10 A.U. Therefore, we may conclude that close binaries are not effected by the perturbation due to neighboring stars in any time scale relevant in astronomical disscussions.

Chandrasekhar's investigation of dissolution of binaries forced by the fluctuating field of stars has been followed by Takase (1953) who considers the effect of the interstellar matter instead of stars. He assumes that the interstellar medium may be regarded as a continuous mass distribution with strong density fluctuations in space (Chandrasekhar and Münch 1952). The density fluctuation may be measured by the mean square deviation of density in the medium, denoted by $\overline{(\delta\rho)^2}$. It may be assumed that the scale of fluctuations (i.e., the size of density irregularities) is much larger than the distance between two components of a binary. Then using the relation derived by Osterbrock (1952) between the fluctuating force field and the fluctuating density field and following Chandrasekhar's reasoning, Takase obtains a formula for the time of dissociation of the binary system due to interstellar matter. His formula can be written down by simply replacing $N^2 m^2$ in equation (3.34) by $\overline{(\delta\rho)^2}/\beta$. Since $\overline{(\delta\rho)^2}$ is about the same order of magnitude as $N^2 m^2$, Takase's result does not change our previous conclusion obtained from Chandrasekhar's analysis.

3.4 Resisting Medium

The effect of the resisting medium is to reduce the dynamical energy and angular momentum of a binary system that is embedded in it. Historically, this problem has created interest among astronomers mainly through the study of the origin of our planetary system. As is evident, the matter in the solar nebula in the early phase of the solar system cannot all have condensed into planets, whatever the mechanism of their formation is. A certain amount of gas and dust must have remained in the space around the sun (especially near the fundamental plane). This remnant formed a resisting medium that the new-born planets were submerged. More recently the resisting medium has again been discussed in con-

nection with the problem of accretion of matter by stars (McCrea 1953). But the discussion has been limited only to single stars.

As an illustration of the effect of a resisting medium on the binary motion, let us assume that the medium exerts simply a retarding couple on the binary system. For simplicity, we shall denote by ℓ the retarding couple that acts on unit reduced mass of the system. Hence, the couple acting on the entire system is $M_1M_2\ell/(M_1+M_2)$. We further denote by h and E respectively the angular momentum and dynamical energy per unit reduced mass of the binary system, thus

$$h=r^2\frac{d\theta}{dt} \tag{3.39}$$

while E has already been given in equation (3.32). We obtain

$$\frac{dh}{dt}=\ell \tag{3.40}$$

and

$$\frac{dE}{dt}=\ell\frac{d\theta}{dt}. \tag{3.41}$$

from our assumption. Needless to say, the polar coordinates (r,θ), represent the position of one component star with respect to the other, θ being measured from the periastron.

Since it can be shown from the two-body problem that

$$h^2=G(M_1+M_2)a(1-e^2) \tag{3.42}$$

we find from equations (3.32) and (3.41) that

$$\frac{1}{a^2}\frac{da}{dt}=\frac{2\ell}{G(M_1+M_2)}\frac{d\theta}{dt} \tag{3.43}$$

and from equations (3.39), (3.40) and (3.42) that

$$\frac{de}{dt}=\frac{\ell}{h}[2\cos\theta+e(1+\cos^2\theta)]. \tag{3.44}$$

As the retarding couple acts against the orbital motion, ℓ is negative. Therefore, the semi-major axis, and consequently the period of the orbit decrease in the resisting medium according to equation (3.43) as would be expected. If the resistance to the motion should increase with the speed of stars, their orbital motion would encounter the strongest resistance near the periastron (i.e., $\theta=o$) and the least resistance near the apastron (i.e., $\theta=\pi$). Then de/dt integrated over a complete cycle would be negative, and the eccentricity decreases in the medium. Or if the resistance is independent of the speed, the same result follows because of the second term in the bracket in equation (3.44), the first term in the bracket being zero on the average. However, if the resistance should decrease with increasing speed, the eccentricity could either increase or decrease depending upon the exact law of resistance.

Jeffreys (1918, see also Jeans 1928) who advocated the collisional theory for the formation of the planetary system used this result to explain why planets formed from the matter ejected from the sun by the tidal action of the colliding star should finally settle into nearly circular orbits. According to the current view, the planets were formed in a medium that was already revolving around the sun. Hence, the planet would be rotating with about the same velocity as its surrounding medium from which it had emerged and the medium was no longer a resisting one.

The previous example concerning the motion of new-born planets illustrates very clearly the difficulty of treating the problem of binary motion in a gaseous medium. It shows that the effect of the medium on the binary motion depends critically upon the dynamical state of the medium itself.

Recently, two papers (Fesenkov 1956; Kiang 1963) have appeared which deal with the motion of planets in a medium that is not static (with respect to the sun). Actually, Kiang has considered three plausible cases for the state of the resisting medium: (1) static, (2) rotating freely and (3) rotating uniformly and calculated the effect in a great detail for each case. However, the basic idea in his calculations is identical to what we have described here.

The effect of a resisting medium on the eccentricity of a binary has been recently rediscussed by Varsavsky (1962) who has followed the treatment of Poincaré (1911) and has been able to explain why binaries of shorter and shorter periods have in general, smaller and smaller eccentricities

for their orbits. However it should be noted that Poincaré has assumed that the resistance increases with an increase of relative velocity of two components and with a decrease of separation between them. Obviously this law of resistance has no physical ground. Consequently, Varsavsky's quantitative analysis may not be regarded as realistic although the general idea may be valid.

The most difficult factor in treating the binary motion in a resisting medium is the variation of masses of stars themselves. As we shall see later, the medium may have been created as a result of mass ejected from the component stars. Or the stars may accret mass from the medium in which they are embedded, and which could exercise infinite varieties of laminar or turbulent motion that we can conceive of. All these factors only indicate that a medium surrounding the binary system can give widely divergent results. Indeed if the medium is rotating faster than the binary motion, the orbit will expand instead of shrinking. Therefore, mathematically it may be interesting to study the effect on the binary motion by assuming a particular state of motion for the medium (with or without an accompanying change in stellar masses), the result will represent only one of a large number of possible cases that may or may not actually confront us. What is important astrophysically is to find out the actual circumstance under which a particular binary is found: Is the binary system embedded in a medium of its own creation? Is the medium resisting or accelerating? Does either of the component stars lose or gain mass? While we cannot answer all these questions from the scanty data we have accumulated for any binary system, these are astrophysically interesting questions. It follows that it is not urgent to make any elaborate calculation for a few possible cases. Rather we should consider the problem in a general way with the aid of some simple model. For only in this way can we expect to obtain some physical insight to the problem by combining theoretical studies with observational ones. Otherwise, theoretical calculations can never meet the challenge of observations.

Since the resisting (or accelerating) medium is intimately related to the change in mass of component stars, we shall come back to this problem in the following section.

3.5 Change in Mass of the Component Stars

The effect of mass loss of component stars on the orbital elements has been discussed by Krat (1950) and Wood (1950). The following discussions, however, will be based on Huang's (1963) presentation.

Because the orbital elements—period, P, semi-major axis, a, and eccentricity, e, — are related to the masses of the two components, angular momentum, h, and dynamical energy, E, per unit reduced mass of the system by the well-known formulae in the two-body problem, it can be easily shown that

$$\frac{1}{a}\frac{da}{dt}=\frac{1}{M_1+M_2}\frac{d(M_1+M_2)}{dt}-\frac{1}{E}\frac{dE}{dt}, \tag{3.45}$$

$$\frac{1}{p}\frac{dp}{dt}=\frac{1}{M_1+M_2}\frac{d(M_1+M_2)}{dt}-\frac{3}{2}\frac{1}{E}\frac{dE}{dt}, \tag{3.46}$$

$$\frac{e}{1-e^2}\frac{de}{dt}=\frac{1}{M_1+M_2}\frac{d(M_1+M_2)}{dt}-\frac{1}{2}\frac{1}{E}\frac{dE}{dt}-\frac{1}{h}\frac{dh}{dt}, \tag{3.47}$$

where E and h are given respectively by equations (3.32) and (3.39) or (3.42). Thus, the changes in orbital elements are not uniquely determined by the rate of mass variation but are dependent also upon dE/dt and dh/dt. This illustrates clearly the importance of the mode with which the variation of mass takes place because both dE/dt and dh/dt depend critically upon the mode of mass variation. Since the mass of the component star can lose or gain in an infinite variety of ways, this makes the problem somewhat uncertain.

The quantity, h, is related to the angular momentum per unit mass, h_0 by

$$h_0=\frac{M_1M_2}{(M_1+M_2)^2}h \tag{3.48}$$

and a similar relation exists between E and E_0 the latter being dynamical energy per unit mass Eliminating dE/dt from equations (3.46) and (3.47) and combining the resulting equation with

equation (3.48) we obtain

$$\frac{1}{p}\frac{dp}{dt}=\frac{4}{M_1+M_2}\frac{d(M_1+M_2)}{dt}$$
$$-3\left(\frac{1}{M_1}\frac{dM_1}{dt}+\frac{1}{M_2}\frac{dM_2}{dt}\right)$$
$$+3\frac{1}{h_o}\frac{dh_o}{dt}+\frac{3e}{1-e^2}\frac{de}{dt} \qquad (3.49)$$

This is a very useful relation because dE/dt (or equivalently dE_o/dt) which is unknown in most cases do not appear in it.

As in any problem that has multitudinous choices of possibilities we may idealize a few simple modes of mass variation that have a physical significance and then examine their effect on the orbital elements. In this way three modes of mass loss from the component stars have been isolated: (1) slow mode, (2) intermediate mode and (3) fast (or Jean's) mode. We shall discuss these three modes here under the simplified assumption that there is no interchange of angular momentum between axial rotation and orbital revolution of the component stars. A treatment of coupling between these two kinds of motion can be found in Huang's (1963b) paper.

1. Slow Mode

This represents an extreme case of losing mass. When the ejection velocities from the stars are low, the ejected matter will not be expected to escape from the binary system. Consequently, the total angular momentum of the system will be conserved but the total dynamical energy of the binary can vary in either way.

We may subdivide this mode into two cases: (a) the particles ejected fall back either to the original star or to its companion and (b) the particles ejected from the less massive component form, after many collisions among themselves, a rotating ring around the more massive component. The second case is proposed in accordance with observational results (Joy 1942, 1947; also Sahade 1960a). Formation of a rotating ring around the less massive component from matter ejected from the more massive component does not seem common because not a single case has been observationally established without dispute. Theoretically it is difficult to form and maintain such a ring (Huang and Struve 1953; Huang 1957a) but it is by no means prohibitive.

For a long time scale, the gaseous rings are expected to dissipate since they are continuously perturbed by the less massive component of the system. Hence, case (b) represents only a transient stage of mass loss. In either case we may set as a first approximation

$$\frac{d(M_1+M_2)}{dt}=0 \qquad (3.50)$$

In adopting this approximation we may regard the rings in case (b) as a part of the more massive component.

In case (a) we have

$$\frac{dh_o}{dt}=0 \qquad (3.51)$$

which yields, after its combining with equations (3.49) and (3.50),

$$\frac{1}{p}\frac{dp}{dt}=-3\left(\frac{M_2-M_1}{M_1M_2}\right)\frac{dM_1}{dt}+\frac{3e}{1-e^2}\frac{de}{dt}. \qquad (3.52)$$

For binaries of small eccentricities, the second term on the right-hand side of equation (3.52) may be neglected. Thus, we arrive at the conclusion that a transfer of mass from the more massive component to the less massive component (i.e., $M_1>M_2$, $dM_1/dt<0$) makes the period decrease with time and a transfer of mass in the reverse direction (i.e., $M_2>M_1$, $dM_1/dt<0$) results in an increasing period. Woolf has privately pointed out that the increase in period of β Lyrae may be precisely due to this mechanism, supporting the proposition (Huang 1962, Woolf 1962) that the primary component of this system is less massive than the secondary component.

More elaborate calculation of the variations of orbital elements with mass exchange has been recently carried out by Piotrowski (1964). He has considered separately the effect on the orbital elements of ejection, of flight and of landing of each mass element. While the calculations are mathematically interesting, it is hard to evaluate their significance in connection with observed data because of the infinite varieties of ways that an individual mass element can be transferred from one component to another. Also the results will

be seriously upset by collisions of particles during the flight (Cf., §6).

In case (b) h_o is no longer constant because a part of angular momentum is absorbed in the rotating rings. If we approximate the ring (formed out of matter ejected by M_2) as rotating *directly* in a circular orbit of radius, a_t, around, and under the gravitational attraction of the more massive component, M_1, alone, we obtain

$$\frac{1}{p}\frac{dp}{dt}=\alpha\frac{1}{M_2}\frac{dM_2}{dt}+\frac{3e}{1-e^2}\frac{de}{dt} \qquad (3.53)$$

where

$$\alpha=3\left(\delta_1-1+\frac{M_2}{M_1}\right) \text{ and } \gamma_1^2=\frac{(M_1+M_2)a_t}{M_1a(1-e^2)} \qquad (3.54)$$

Numerical values of α for a few cases of a_t/a and M_2/M_1 have been given in Huang's (1963b) paper.

Finally, it is to be noted that (a) and (b) represent two physically different cases of idealized circumstances. When we mentioned that (a) represents the ultimate situation of the slow mode, we do not mean that case (b) will reduce to case (a) if the ring coalesces with the stellar surface, because that would result a transfer of angular momentum from orbital revolution to axial rotation—a situation precluded to the present discussion. In such cases we must include the coupling between orbital motion and axial rotation into our considerations.

2. Intermediate Mode

By the intermediate mode we mean that the ejection velocities are large enough to overcome the attraction of both components so that the ejected particles can penetrate the inner contact surface (Cf 5) of the system but not large enough to justify the neglect altogether of interaction between the ejected particles and the binary system. Actually the change of orbital elements under this mode of mass loss is most uncertain because we have no way to estimate the angular momentum carried away by escaped mass.

This mode may also be divided into two cases: (a) ejected particles escape to infinity directly and (b) particles form an envelope around the entire binary system, such as found in β Lyrae (Struve 1941, 1958). If the envelope is a quasi-stable rotating ring (or disk) around; and in the plane of, the binary system, the change in period may be evaluated in terms of the size of the ring (Huang 1963b). However, observationally there is no clear-cut evidence to conclude that such is actually the case.

Finally, we should again point out that case (b) represents only a transient stage of this mode since eventually the envelope will be dissipated.

3. Fast (or Jeans's) Mode

This is an extreme case, for it is assumed that there is no net reaction of the escaped mass on the binary itself. We call it Jeans's mode because Jeans (1924, 1925) was the first to treat this case when he examined the effect of radiation loss (which is equivalent to mass loss) on the binary system. Since then it has been applied to cases involving direct loss of mass (Huang 1956, Boersma 1961). The physical circumstance of actual mass ejection that may be approximated by Jeans's mode must satisfy two conditions: (1) the ejection of mass has a statistically spherical symmetry and (2) the velocities of ejection must be very high to insure a negligible interaction with the binary system. According to these conditions the loss of mass resulting from a supernova explosion (Blaauw 1961) and from ordinary nova outburst (Ahnert 1959) would closely approximate this mode. Mass loss due to corpuscular radiation may also fall into this mode if emission of particles is spherically symmetric. That corpuscular radiation may be important has been pointed out by Fesenkov (1949) and Masevich (1949) in their theory of stellar evolution. Tidman (1958) has proposed on the other hand a theory that suprathermal particles may be produced in the binary system if the expanding coronas collide each other, thus creating a region of violent motion favorable for accelerating charged particles. In any case, corpuscular radiation from component stars may be the reason, according to Huang (1958), why a luminosity anomaly exists in many binary stars.

It can be shown (Huang 1956) that Jeans's mode of ejection leads to

$$\frac{dh}{dt}=0 \text{ and } \frac{1}{E}\frac{dE}{dt}=\frac{2}{M_1+M_2}\frac{d(M_1+M_2)}{dt} \qquad (3.55)$$

which, when combined with equations (3.45)--(3.47), yield the following results due originally to Jeans:

$$\frac{1}{a}\frac{da}{dt}=-\frac{1}{M_1+M_2}\frac{d(M_1+M_2)}{dt},$$
$$\frac{1}{p}\frac{dp}{dt}=\frac{2}{M_1+M_2}\frac{d(M_1+M_2)}{dt} \tag{3.56}$$
$$-\frac{e}{1-e^2}\frac{de}{dt}=0$$

It follows from equation (3.48) and a similar equation between E and E_o, we may write equations (3.55) in the following form:

$$\left.\begin{aligned}\frac{1}{h_o}\frac{dh_o}{dt}&=\frac{1}{M_1}\frac{dM_1}{dt}+\frac{1}{M_2}\frac{dM_2}{dt}\\&\quad-\frac{2}{M_1+M_2}\frac{d(M_1+M_2)}{dt},\\\frac{1}{E_o}\frac{dE_o}{dt}&=\frac{1}{M_1}\frac{dM_1}{dt}+\frac{1}{M_2}\frac{dM_2}{dt}.\end{aligned}\right\} \tag{3.57}$$

Thus, in Jeans's mode the angular momentum per unit mass changes, although h maintains constant. Also, the dynamical energy per unit mass of the system has increased as a result of this mode of ejection.

An extreme case of Jeans's mode of ejecting matter is the sudden explosion either with a spherical symmetry or with an axial symmetry as found by Weaver (1958) in his study of Nova Aquilae (1918). If the mass ejected during the explosion exceeds a critical amount of $r(M_1+M_2)/(2a)$ where r represents the separation of the two stars at the instant when the instantaneous mass ejection takes place, it would result in a complete separation of the two component stars, as was pointed out by Blaauw (1961). Indeed he proposed that this is how the high-velocity O and B type stars sometimes observed in the galaxy had acquired their velocities from orbital motion.

So far we have discussed only the case of mass loss of component stars. It first appears that we may treat the problem of mass gain in a similar manner. Actually, the problem is much more complicated than the case of mass loss because first of all, we have to assign the state of motion of the medium from which stars may accret mass. In general, the problem of changes in orbital elements depends upon the following factors: (1) the relative motion of the center of mass of the binary system with respect to the medium, (2) the state of internal motion of the medium, such as rotation, turbulence, etc. and (3) the binary motion itself. From these factors we are supposed to evaluate the rate of accretion as well as the force (resisting or accelerating depending upon cases) that each component experiences. That this is a difficult task may be seen from a simple case that the medium possesses no net angular momentum with respect to any point inside. In such a case the total rate of accretion by both components may be roughly estimated by treating the system at large distances as a single body and thereby deriving the accretion column (McCrea 1953) of the entire system. However, how can we estimate the proportion at which the two components divide their loot in the accretion column? Since they move in the same region, the more massive component which is gravitationally stronger is expected to accret matter more effectively than the less massive one. On the other hand if we consider the size and location of the orbits we may expect the reversed situation, namely the less massive component is more effective. Here we see the intrinsic difficulty of the problem.

Observationally, we can determine only the period of a binary with any accuracy that justifies the theoretical investigations. Indeed, we have found variations in orbital period in many eclipsing binaries, although it should be remembered that the variations in period can be due to many causes other than the mass variations. For example, any perturbation due to the departure from the idealized binary composed of two mass points could produce complicated variation in observed period which is the time-interval between two consecutive principal (or secondary) eclipses. Actually, we have indeed found that periods of many binaries change in irregular ways, the same binary may have its period increasing and decreasing at different epochs in a seemingly unpredicted manner. This leads Wood (1950 see also Schneller 1962) to suggest that the changes may be due to ejection of gas jet by the component star sometime in the direction of its motion and at other times in the opposite direction. Wood's view has been criticized by Kopal (1959). The present writer inclines to regard

Wood's view to have its merit. We have found that the changes in period depend upon the modes of ejection as well as the rate of mass loss. Since there is a continuous range of possible modes and rates of ejection, it is apparent that there will be statistical fluctuations with respect to time, producing thereby corresponding fluctuations in period variations. Especially we should point out that if the velocities of ejection are high, mass could be thrown out of the star in any direction, not necessarily limited to the channel through the Lagrangian points L_1 and L_2. However, the cause of variations in period observed in eclipsing binaries is not uniquely determined. Most likely many factors are involved in producing the observed variations.

Extensive collections and analyses of observed period variations of eclipsing binaries have been given by Tung and Chang (1957), by Kwee (1958), by Prikhod'ko (1961), by Wood (1953) and by others (See references given by Kopal 1954, 1957; O'Connell 1960, 1962; and Merrill 1964).

4. RELATIVISTIC EFFECT

The advance of perihelion of the orbit of a planet around the sun resulting from the relativistic considerations provides one of the crucial tests of Einstein's theory of gravitation. Gravitation in the general theory of relativity is closely interwoven with the four dimensional space-time continuum. Using the language of geometry, we may state that the absence of gravitational field corresponds to a four-dimensional Euclidean (flat) space and the presence of any permanent gravitational field distorts the space-time continuum into a curved one. Indeed, the principles of relativistic mechanics are mainly contained in what is known as the field equation of Einstein (e.g. Eddington 1923), which connects the physical situation (i.e., the energy-momentum tensor which describes the distribution of matter and energy) with the geometry of space-time and which may be regarded as the relativistic analogue of Poisson's equation. Also, according to the theory, the space-time trajectory of a free particle is given by the geodesic, which, as is well known in geometry, directly depends upon the property of the space-time continuum and consequently on the gravitational field which shapes it. Since the property of space-time continuum corresponding to an empty space surrounding a gravitational point mass is known, the equations for a geodesic can be written down immediately and provides the basis for the treatment of the motion of planets around the sun. When these equations are reduced to an ordinary polar coordinate (r, φ) they yield the equation (e.g. Eddington 1923)

$$\frac{d^2u}{d\varphi^2}+u=\frac{GM}{(ch)^2}(1+3h^2u^2) \tag{4.1}$$

as compared with the equation of a Newtonian orbit

$$\frac{d^2u}{d\varphi^2}+\mu=\frac{GM}{(ch)^2} \tag{4.2}$$

where $u-1/r$, M is the mass of the central body, ch is a constant of integration, and c is the velocity of light in empty space.

The ratio, $3\,h^2u^2$, of the second term to the first term on the right hand side of equation (4.1) can be shown to be practically equal to three times the square of the transverse velocity of the planet measured in unit of the velocity of light. For example, the ratio for the earth is 0.000,000,03. Thus, the difference between the relativistic and Newtonian orbits must be slight. It can be shown (e.g. Eddington 1923) that the perturbation caused by the presence of this small term produces an advance of the perihelion equal to

$$\Delta\omega=\frac{6\pi GM}{c^2a(1-e^2)} \tag{4.3}$$

radians per orbital revolution.

The previous result is derived from the assumption that the planet has a negligible mass. The case of two bodies of comparable masses has been studied by Levi-Civita (1937) who shows that as a first approximation the same formula for the advance of periastron holds true in the case of binary stars as in the case of an infinitesimal planet moving around a central mass having the total mass of the binary system. Thus, except by replacing M by M_1+M_2 we have equation (4.3) for the advance of periastron in a binary system. If we write p' as the period that the periastron advances a complete cycle of 2π, equation

(4.3) can be written as

$$\frac{p'}{p}=\frac{c^2p^2(1-e^2)}{12\pi^2a^2} \tag{4.4}$$

If we now write $K=K_1+K_2$ where K_1 and K_2 are respectively the semi-amplitude of the velocity curves of the two components the previous equation can be expressed in terms of directly observable quantities, thus:

$$\frac{p'}{p}=\frac{1}{3}\left(\frac{c\sin i}{K}\right)^2. \tag{4.5}$$

Since K rarely exceeds 300 km/sec while c = 300,000 km/sec, p'/p is of the order of 3×10^5. Hence, the advance of periastron as a result of relativistic correction must be very small. Luyten, Struve and Morgan (1939) have computed the motion of apsides according to equation (4.5) and found that the computed values are less than the uncertainty in the observed values for all the seven binaries whose apsidal motion they have studied.

It is evident from (4.3) that apsidal motion due to relativistic correction should be most pronounced in massive binaries with short separations. After calculations based on various assumptions as to the dimensions and internal structure of the components, Rudkjbing (1959) has concluded that in the eclipsing binary, DI Hercules, the relativistic part of the apsidal motion may well be larger than the part due to deformation of the components. However, according to O'Connell (1962) "no indication of apsidal motion has in fact been observed as yet in this system."

Levi-Civita (1937) has furthermore pointed out that aside from the slow precession of the relative orbit, the general theory of relativity also predicts "the absolute motion in the sky of any double star system." This result comes naturally from the fact that general relativity does not include, as a rigorous law, the principle of action and reaction which plays such an important role in Newtonian mechanics. Thus, one of the most important consequences of this principle, namely, the uniform motion of the center of mass of a system in absence of external forces, becomes invalid.

According to the calculations by Levi-Civita, the secular acceleration of the center of mass of a binary is directed along the major axis towards the periastron of the more massive component, and the increase ΔV of the velocity of the center of mass in a century is given by

$$\Delta V=12.55\ \mu(1-\mu)(1-2\mu)\frac{e}{(1-e^2)^{3/2}}\frac{M_1-M_2}{M_\odot}\frac{1}{p_d^2}\ \text{km/sec}. \tag{4.6}$$

where p_d is the orbital period in days, $M_\odot$ the mass of the sun and μ is the mass ratio defined by (2.4). Because of the factor $\mu(1-\mu)(1-2\mu)$, Δv has a maximum with respect to the mass ratio at $\mu=(1-3^{-\frac{1}{2}})/2$, which roughly corresponds to two stars respectively containing $\frac{1}{4}$ and $\frac{3}{4}$ of the total mass of the system. The maximum value of $\mu(1-\mu)(1-2\mu)$ is about 0.1. Since e is usually small for close binaries, the change in velocity, even in a century, is too minute to be detected by present means of spectroscopic study. Actually, I doubt that this effect could be detected in ordinary cases even after we have observed a close binary for tens of centuries, because the apsidal motion resulting from the rotational and tidal distortion obliterates this effect completely.

As two stars revolve around each other in a binary, it is obvious that the gravitational field they produce varies with their motion. According to Newtonian theory, the effect is instantaneously felt everywhere. Consequently, the notion of gravitational waves never arises. As the relativity theory presupposes that no casual effect can travel faster than light, we might anticipate that the change in the gravitational field travels out into space with the speed of light. A moving disturbance thus propagated out may be called the gravitational wave. Such is the physical reason for the existence of gravitational waves (e.g. Eddington 1923; Synge 1960). A realistic evaluation however could be made only after empirical detection (which is now actually attempted) should be successful.

We may expect that the emission and absorption of gravitational waves carry, to be sure, very small amounts of energy. Hu (1947) has computed the very small damping forces due to the emission of these waves. Actually, the rate of energy radiated in the form of gravitational wave by a binary star (in circular motion) as given by

Landau and Lifshitz (1951) is

$$\frac{dE}{dt}=-\frac{32}{5}\frac{G^4}{c^5}\frac{(M_1+M_2)M_1^2M_2^2}{a^5} \qquad (4.7)$$

From equation (4.7) Kraft, Mathews and Greenstein (1962) have found that for the repeating nova WZ Sagittae (1913, 1946) the rate is in the range of $10^{32}-10^{35}$ ergs/sec if their mass ratio μ is between 0.1 and 0.5. However, they have pointed out that the gravitational flux reaching the earth is quite small and its detection very difficult. But they went on to suggest that the period change due to energy dissipation by gravitational wave is probably detectable. As we have seen in §3, variations in period may arise from many causes. Thus, even if the period change in this star were detected, it would remain a difficult problem to prove that the variation is indeed due to dissipation of energy through gravitational waves. This kind of uncertainty is intrinsic to observational science and strongly contrasts to the high precision of controllable investigations in experimental science, such as physics and chemistry. But nowhere in the entire field of astronomy do we encounter more frustration than in the attempt to detect relativistic effects in binary systems as we have seen in this section.

5. THE ROCHE MODEL

5.1 Stellar Surfaces According to the Roche Model

The shape of single stars without axial rotation must be a sphere since there is no one particular direction that is physically different from the other. When it rotates, the shape will no longer be spherical because of the existence of a preferred direction, namely the axis of rotation. As a result, we would expect that a rotating body, like the earth, Jupiter, etc., will be flattened to become an oblate spheroid.

In general, the component star (in the close binary) rotates in synchronism with its orbital revolution (Swings 1936, Plaut 1959). Hence, the centrifugal force does play a role in shaping the component star. However, a more serious complication arises from the force field due to its companion. What would be the shape of stars thus influenced by its close companion? We have investigated this problem in §3.1. But the result is too involved to be useful for the present purpose. Here we shall consider a simple model such that the gravitational potential due to each component star may be regarded as equivalent to a mass-point. Then the potential field of the entire system can be easily calculated and the shape of star determined. Such is the Roche model of close binary stars.

Let us assume that the two component stars in a system revolve around each other in circular orbits. Furthermore, we choose as the unit of mass the total mass of the system, i.e.,

$$M_2=\mu \qquad M_1=1-\mu \qquad (5.1)$$

Also, we choose the separation between two components as the unit of length. If we take $P/2\pi$ as the unit of time (i.e., the angular velocity of orbital motion is one), we shall have unity for the gravitational constant. This can be easily seen from equation (2.5).

We may easily write down the equations of motion of a test particle in the gravitational field of the binary system. It is equivalent to the restricted three-body problem in celestial mechanics and can be most advantageously expressed in a coordinate system rotating with the component stars (e.g., Moulton 1914, Plummer 1918). The rotating coordinate system (x, y, z) may be so chosen that its origin locates at the center of mass of the binary, that its z-axis is perpendicular to the orbital plane and that its x-axis coincides with the line joining the two component stars. If we denote by r the radius vector from the origin to the test particle (x, y, z) and by r_1 and r_2 the respective distances of the test particle from the $1-\mu$ component at $(-\mu, o, o)$ and from the μ component at $(1-\mu, o, o)$, the equation of motion becomes

$$\frac{d^2\vec{r}}{dt^2}=-2\vec{k}\times\frac{d\vec{r}}{dt}+\text{grad } U \qquad (5.2)$$

where

$$U=\frac{1}{2}(x^2+y^2)+\frac{1-\mu}{r_1}+\frac{\mu}{r_2} \qquad (5.3)$$

and $\vec{k}$ represents a unit vector in the positive z-direction. Taking the scaler product of $d\vec{r}/dt$ and equation (2) and integrating the resulting equation

over t we obtain an integral for the test particle

$$2U-\left|\frac{d\vec{r}}{dt}\right|^2=C \tag{5.4}$$

where C is a constant of integration and is therefore a characteri. tic value for the test particle of a given set of initial conditions. In celestial mechanics it is often called the Jacobian integral.

The equation (5.4) relates the kinetic energy with the coordinate of the test particle in the rotating frame of reference. Consequently negative U may be regarded as a potential function in this reference system and we may plot a series of equipotential surfaces by setting $2U=C$, namely

$$x^2+y^2+\frac{2(1-\mu)}{r_1}+\frac{2\mu}{r_2}=C \tag{5.5}$$

where C now serves as a parameter labeling the surfaces. However, it may be noted that because of the first term on the right side of equation (5.2), U does not behave exactly like a potential in an inertial system. It is for this reason that the surfaces defined by equation (5.5) are not called the equipotential surfaces in celestial mechanics.

For a given value of C, which is fixed by the initial conditions, equation (5.4) determines the speed $|dr/dt|$ of the test particle at different points in space. Therefore, we can find all the points at which the speed will vanish. The locus of these points then define the so-called zero-velocity surface in celestial mechanics. It is obvious from equation (5.4) that the zero-velocity surface thus defined is identical to the one given by equation (5.5) which we have previously called the equipotential surface.

In order to see the importance of the zero-velocity surface let us consider $|d\vec{r}/dt|^2$ of a test particle of a given value of C as a function of the coordinate according to equation (5.4). On the zero-velocity surface this function vanishes everywhere. Hence, in general, the function would be positive on one side and negative on the other. Since $|d\vec{r}/dt|^2$ cannot be negative, it only shows that the test particle cannot penetrate the zero-velocity surface into the other side. Because of this property, it is useful to know zero-velocity surfaces corresponding to different values of C (or different initial conditions). Finally, we may add that in some special cases, the values of C may be positive on both sides of a zero-velocity surface. This happens when the function i.e., $|d\vec{r}/dt|^2$ in the present case, has an extremum equal to zero at some points in space. Indeed, such an occurrence gives rise to a few interesting and critical cases of zero-velocity surface that will be discussed later.

It is to be noted that we have used C sometimes to characterize the condition of the test particle according to equation (5.4) and at other times to label the zero-velocity surfaces according to equation (5.5). Thus, a particle of a certain value of C cannot penetrate the zero-velocity surface labelled by the same value of C.

Let us now examine the general behavior of the zero-velocity surfaces defined by equation (5.5). For very large values of C, say C_l, we have three possibilities: (1) large x^2+y^2, (2) small r_1 and (3) small r_2, corresponding to three separate surfaces for a single value of C. If x^2+y^2 is large, other terms on the left side of equation (5.5) may be neglected. Consequently, the surface represents a large circular cylinder with its axis coinciding with the z-axis. Similarly, when r_1 (or r_2) is small, other terms become negligible. We then obtain a small sphere around the 1-μ component (or around the μ component). If we do not neglect small terms, we will obtain three surfaces slightly distorted from what have been described. Therefore, space around the binary can be divided into four regions, one outside the nearly cylindrical surface, two inside the two closed surfaces respectively around the two stars, and the fourth between these three surfaces. It is easy to see from equation (5.4) that the test particle whose C value is equal to C_l can be either inside the two small closed surfaces or outside the large cylindrical surface. But it is forbidden to enter space between these three surfaces. Thus, the test particle (of C_l) can move in any one of the three permitted regions but cannot jump from one to the other.

In a close system the shape of each component star that satisfies the Roche model (i.e., a highly centrally condensed star with an envelope of a negligible mass) is determined by the closed zero-velocity surface around it, since, as we have seen in equation (3.8), the equal pressure surfaces in a star must follow the equipotential surfaces as a result of the hydrostatic equilibrium under which negative U will now behave exactly like a potential function in the rotating coordinate system.

As C decreases, the two closed surfaces around the two stars increase in size and the outer cylindrical-like surface shrinks. Eventually, these surfaces will come into contact. Actually, the contact occurs first between the two closed surfaces at a certain value of C which will hereafter be denoted by C_1. This critical zero-velocity surface is often called the innermost contact surface (e.g., Kuiper 1941), or the S_1 surface as we shall call it later. The point of contact L_1 is one of the Lagrangian points (or double points), which are special solutions of the restricted three-body problem. The contact point illustrates the case we have mentioned earlier that in some special cases $|d\vec{r}/dt|^2$ can be positive on both sides of a zero-velocity surface. This is true at L_1, say along the x-axis.

In Figure 1 we have illustrated several zero-velocity surfaces including the critical ones for the case $\mu=\frac{1}{3}$. Two cross-sections for each surface have been drawn, one in the xy-plane (in the lower diagram) and the other in the xz-plane (in the upper diagram). Because of symmetry we have shown here only one half of each cross-section, namely for positive y and positive z only. The case $C=4.1$ represents the situation before surfaces come into contact. Thus, this value of C corresponds to three distinct surfaces mentioned before and all shown in the figure. The case $C=C_1=3.946$ corresponds to the innermost contact (S_1) surface. It consists of two lobes which we shall call the primary lobe (around the $1-\mu$ component) and the secondary lobe (around the μ component). A large distorted cylindrical surface associated with the same C_1 is also shown in the figure.

The importance of the contact point is the fact that it forms a channel through which a test particle with C only slightly less than C_1 may move from the permitted region around one star to that around the other. As a result of this property we can conclude that the two lobes of the S_1 surface provides respectively an upper limit to the size of individual component stars because if either of them touches the surface, the matter will leak out at the point of contact into the other lobe. We may find examples for this situation in the Algol-type eclipsing binary systems in which one star (the less massive secondary) has usually a size comparable with the corresponding lobe of the S_1 surface while the other star (the more massive primary) is invariably small compared with its lobe of the same surface.

In reality the star must be smaller than the corresponding lobe of the contact surface as the particles (atoms, ions, electrons) in the surface

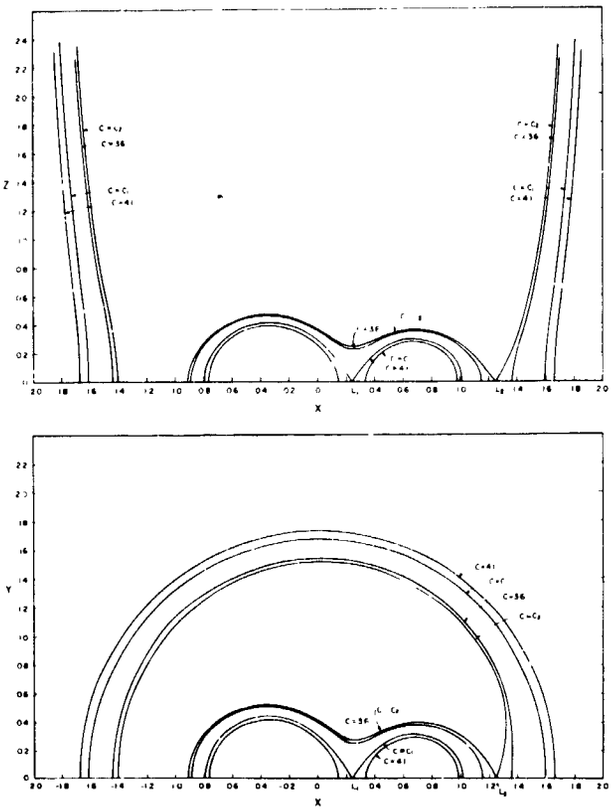

FIGURE 1.—Zero-velocity surfaces corresponding to $\mu=1/3$. The two cross-sections of several zero-velocity surfaces—one in the xy plane (below) and one in the xz plane (above) are illustrated here. The two contact surfaces are marked by C_1 (inner) and C_2 (outer) respectively with $C_1=3.95$ and $C_2=3.55$. It can be seen that for $C>C_1$ illustrated by the case $C=4.1$ each surface has three separate branches. For $C_2<C<_1$ (illustrated by the case $C=3.6$) there are two separate branches.

layer of a star are exercising all kinds of motion, thermal, turbulent or else. Therefore, they can escape the inner contact surface even before the stellar surface has reached the contact surface. However, the velocities in these motions (except of course, corpuscular radiation) may in general be regarded as small in the present consideration because the unity velocity in the present unit system is equal to $[G(M_1+M_2)/a]^{\frac{1}{2}}$ and amount to a few hundred km/sec in close binaries. Therefore, a velocity of a few tens of km/sec can be neglected

in equation (5.4), thus making the S_1 surface the actual limit of individual stars in a close system.

When C decreases from C_1, the two lobes of the innermost contact surface coalesce into one single dumb-bell like surface (corresponding to $C=3.6$ in Figure 1). They represent the appearance of two stars in actual contact such as in *W UMa* stars. Such a binary, though consisting of two stars, has a common envelope. A series of the contact configuration is possible, corresponding to different values of C. The smaller the value of C, the greater is the size of this dumb-bell like surface. On the other hand, the outer cylindrical like surface shrinks with decreasing C. Thus, C cannot decrease indefinitely without encountering another drastic change of the behavior of the zero-velocity surfaces. This time it is the contact between the dumb-bell like surface and the outer cylindrical-like surface. Kuiper has called it the outermost contact surface (or the S_2 surface) whose C value will be hereafter denoted by C_2 as is shown in Figure 1. The point of contact L_2 is another Lagrangian point. With this second contact, the inner region is connected to the outer region and the test particle with C only slightly less than C_2 can move without restriction due to energy. Thus, particles with C between C_1 and C_2 can move either inside the dumb-bell like surface or outside the distorted cylindrical surface. This leaves a forbidden region between the two surfaces. In Figure 1, this situation is illustrated by the case $C=3.6$. When $C<C_2$, there will not be any forbidden region for the particle from the consideration of the energy integral. Therefore, the S_2 surface represents the maximum size of a stable contact configuration of a close binary. For if the contact binary has reached this size, mass will continuously flow out of the system through L_2 and the binary is no longer stable.

With the aid of the S_1 surface we can now classify close binaries into three groups. If both components are well inside the S_1 surface, their system is said to be a detached one. If one component fills up the corresponding lobe of S_1 surface but the other is not, the two form a semi-contact (or semi-detached) binary. In the third group, i.e., the contact binaries, two components are in physical contact. More elaborate classification of close binaries may be found in Kopal's (1959) and Sahade's (1960 a and b) paper.

Finally, it may be noted that since the zero-velocity surfaces are defined in the rotating frame of reference, the Roche model predicts that axial rotation of stellar envelope and orbital revolution are synchronized, i.e., the two component stars revolve in their respective orbits face to face. This result appears to be valid in most close binaries (Swings 1936, Plaut 1959 Struve 1950). In a few cases, such as β Lyrae (Kopal 1959), where one or both component stars undergo secular expansion as a result of internal evolution, this synchronization could be temporarily violated.

We can now summarize the result briefly in the following way. The closed zero-velocity surfaces around two stars for $C>C_1$ represents the shape of two components that are detached from each other. The smaller the radius, the close to a sphere is the surface. What we are interested in, however, is only when the star approaches the size of the inner contact surface and is strongly distorted from a spherical shape. Thus, at $C=C_1$ each lobe of the S_1 surface represents the limiting size of the individual component. The star in a binary that is found actually in this limiting configuration is usually ejecting mass through L_1 towards its companion if the latter is still small compared with its own lobe of contact surface. For $C_1>/C>C_2$ the dumb-bell like surface of equation (5.5) represents the configuration of two component stars in physical contact. The limiting case of the contact configuration is given by the outer contact surface ($C=C_2$). Binary stars that are in this limiting configuration lose mass to outer space through the point, L_2. It can be seen from Figure 1 that the range of sizes of the contact systems (from the S_1 to S_2 surface) is quite small. Therefore, any binary that is in physical contact is usually losing mass through L_2. The problem of losing mass from a star through the points L_1 and L_2 was first extensively discussed by Kuiper (1941) (Cf. 6). Such an instability at the surface of the close binary stars gives rise to a number of observable phenomena which Martynov (1957 also Krat 1960) has summed up in a review together with examples of stars that show these various phenomena.

Because of their importance in the study of close binaries both S_1 and S_2 surfaces for different values of μ have been computed by Kuiper (1941); by Kopal, whose result was first published in 1954

and is now included in his book (1959); and by Kuiper and Johnson (1956) and more recently by Szebehely and Williams (1964). Table 2 gives C_1 and C_2 for 9 values of μ taken from Kuiper and Johnson's paper. Table 3 and 4 gives the intersection of the two contact surfaces with the xy-plane (first and second column) and with the xz-plane (first and third column) for those values of μ listed in Table 2. They are partly taken also

TABLE 2.—*Labelling Constants for the Contact Surfaces*

μ	C_1 (inner)	C_2 (outer)
.5	4	3.4567962
.4	3.9809086	3.5189346
1/3	3.9455706	3.5474582
2/7	3.9074840	3.5589342
.25	3.8706588	3.5611940
.20	3.8046532	3.5523932
.10	3.5969532	3.4666844
.05	3.4204164	3.3543942
.02	3.2523262	3.2257332

from Kuiper and Johnson's paper but partly computed especially for the use of the present occasion by Mr. C. Wade, Jr., of Goddard Space Flight Center. The case of $\mu=\frac{1}{3}$ is furthermore illustrated in Figure 1 as we have described. For diagrammatic illustrations of the contact surfaces corresponding to other values of μ we refer the reader to Kuiper's (1941) paper.

Finally, it should be noted that the basic size of a star, whether single or in a close binary, is determined by its internal structure. What we have said previously is only about the external shape of its envelope. That the envelope is all that we can observe of a star lies significance of the zero-velocity surfaces in the study of close binaries.

The Roche model of an infinitely centralized star represents only one end of a series of stellar models. At the other end there is the liquid model of a homogeneous density. Darwin (1906) and Jeans (1919) have studied the binary configurations and their stability based on the latter idealization. Darwin's and Jeans' results have recently been examined by Chandrasekhar (1964).

5.2 Departure from the Roche Model

An actual star is built neither on the infinite centralization nor on the homogeneous distribution of density. We have noted in 3.1 that the rate of apsidal motion decreases with the degree of central condensation. For component stars built on the Roche model the binary would show no apsidal motion at all. The fact that the apsidal motions in many binaries have been observed in relatively a short time of a few decades only shows how approximate the model is. However, for a prediction of the stellar surfaces the Roche model perhaps gives a good approximation. Indeed, according to a recent estimate by Plavec (1958), the departure of stars from the infinite central condensation of the Roche model does not produce a serious modification of the zero-velocity surfaces.

On the other hand, Plavec has pointed out in the same paper, that a deviation from the synchronization of axial rotation and orbital revolution would cause an important change in the shape of the contact surface. He has treated the problem of non-synchronization by simply modifying that term in U (given by equation [5.3]) which corresponds to the centrifugal force. In this way he has found that it is very simple to compute the modified contact surfaces. Unfortunately Plavec's process may not be regarded as legitimate because the centrifugal force arising from orbital motion and that arising from axial rotation do not have the same axis. This same problem has later been studied by Limber (1963) and Kruszewski (1963). The works by these two investigators are parallel and suffer the same difficulties.

In order to see the difficulties let us assume that axial rotation, say of the $1-\mu$ component, is not synchronized to the orbital motion, although its axis is still assumed to be perpendicular to the orbital plane. In considering the motion of a test particle in the envelope of the $1-\mu$ component we first translate the origin of the (xyz) coordinate system along the x-axis to the center of the $1-\mu$ component star by making the simple transformations:

$$x'=x+\mu,\ y'=y,\ z'=z, \tag{5.6}$$

and then rotate the $(x'y'z')$ system by a second transformation so that in the end it will be in

synchronization with the axial rotation of the star. Thus:

$$\begin{aligned} x' &= \xi \cos \omega t - \eta \sin \omega t, \\ y' &= \xi \sin \omega t + \eta \cos \omega t, \\ z' &= \zeta, \end{aligned} \tag{5.7}$$

where ω represents the rotational angular velocity of the star in the $(x'y'z')$ coordinate system. Therefore, the (ξ,η,ζ) coordinate system follows both the orbital revolution and axial rotation of the $1-\mu$ component. The equations of motion of the test particle in the (ξ,η,ζ) system can be easily derived by applying successively two transformations given by equations (5.6) and (5.7) to equation (5.2). If we denote by $\vec{\omega}$ the rotational angular velocity-vector, by $\vec{k}$ a unit vector in the same direction and by $\vec{r}_1$ the radius vector of the test particle from the origin o' the (ξ,η,ζ) system, the final result may be given by

$$\frac{d^2\vec{r}_1}{dt^2}+2(\vec{\omega}+\vec{k})\times\frac{d\vec{r}_1}{dt}=\text{grad } U_1+\mu\vec{s}, \tag{5.8}$$

where

$$U_1=\tfrac{1}{2}(\omega+1)^2(\xi^2+\eta^2)+\frac{1-\mu}{r_1}+\frac{\mu}{r^2}, \tag{5.9}$$

and $\vec{s}$ represents a time-dependent unit vector which has the following components·

$$-\cos \omega t, \sin \omega t, o. \tag{5.10}$$

It is now apparent that non-synchronization cannot be properly treated by simply replacing U in equation (5.2) by U_1 in equation (5.9) because equation (5.8) is not identical in form to equation (5.2). Because of the time-dependence of the

vector $\vec{s}$ and of r_2 which is now given by

$$r_2^2=(\xi-\cos\omega t)^2+(\eta+\sin\omega t)^2+\zeta^2, \quad (5.11)$$

we cannot derive a simple relation like equation (5.4) in the present coordinate system. Consequently, the potential function U_1 given by equation (5.9) predicts neither the equilibrium surfaces of the star in general nor its limiting surface in particular. A detailed discussion on this point and a proper treatment of non-synchronization will be given in a later paper.

Actually, the non-synchronization represents only one of several possibilities that will destroy the existence of zero-velocity surfaces. Indeed, under no circumstance can we define zero-velocity surface if the orbital motion of the binary is not circular or if a third star is present in the neighborhood (Huang 1964). In these cases the envelope of the component stars become unstable and stars themselves may not be expected to have stationary surfaces.

6. GASEOUS MOTION IN THE CLOSE BINARY SYSTEM

As a result of spectroscopic observations by Struve (1941, 1945 et seq. 1949a, 1950), Abhyankar (1959a, 1960) and many others, gaseous flow originating from stellar surfaces in the close binary system has been fully established. In the meantime Kuiper (1941) has examined the gaseous flow in the binary system from a theoretical point of view and introduced the idea of ejection of mass by the component stars through the Lagrangian points L_1 and L_2 discussed in the previous section. We may therefore, conclude that the components of some close binaries have touched the S_1 surface and their atmospheres become unstable such that gaseous particles are flowing out of the star either at L_1 or L_2. The conclusion is further strengthened by the photometric observations (Wood 1946, 1957; also Kopal 1959) which indicates that the relative radii of component stars in such binaries are indeed comparable to what would be expected from the two lobes of the S_1 surface for their respective mass ratios.

The establishment of gaseous flow in close binaries opened up a new field of theoretical study. Several approaches have since been advanced, namely (1) the orbital approach, (2) the hydrodynamic approach and (3) a rudimentary statistical approach. Needless to say, if the binary stars possess magnetic fields, a magnetohydrodynamic approach to the problem would be in order. However, unless we clearly know the nature of the magnetic field, we cannot proceed with our study. Consequently, no one has seriously treated the gaseous flow in the binary system as a magnetohydrodynamic problem although magnetic activities have been suggested rather quantitatively to account for the peculiar behavior of some binaries (Huang 1959). However, one of the effects of magnetic activities may be predictable and that is the braking of binary motion. Several mechanisms have been proposed for braking stellar axial rotation (e.g. Huang and Struve 1960) but the one proposed recently by Schatzman (1962) may be regarded as most effective. According to him, the angular momentum of axial rotation of a star is transferred outwards as mass is ejected out during strong magnetic activities. Similarly, we may propose that the same mechanism can dissipate the orbital angular momentum. If so, we wonder whether the many close binaries are indeed the result of braking due to magnetic activities in the early phase of their evolution.

6.1 The Orbital Approach

The motion of a particle in the binary system is computed according to equation (5.2), hence, the particle is treated as if it were a celestial body in classical mechanics. Kuiper (1941) studied the problem of gaseous motion in this way and his paper gives a simple but illuminating discussion that has often been referred to in the literature.

Kuiper first emphasizes the symmetry of the equation of motion with respect to the xy-plane. At least this symmetry will not be disturbed if an initial symmetry in the distribution of matter is assumed. Consequently the principal current should be symmetrical with respect to the plane. Furthermore, since two symmetrical currents in the z-direction would lead to a dissipation of energy not present in currents parallel to the xy-plane, Kuiper concludes that very probably the latter are the most important currents in the binary system. In what follows we shall consider only the motion in the xy-plane which incidently

is also the plane in which observations may be made in eclipsing binaries.

Kuiper next points out that because of the Coriolis force (the first term on the right side of equation (5.2)), a flow near L_1 in the positive x-direction will be deflected in the $-y$ direction. This can be seen easily from the vector product if we set the initial velocity $d\vec{r}/dt$ to be pointing in the $+x$ direction. The current will therefore go principally in the direction of $\alpha,\beta,\ldots$ as is shown in Figure 2.

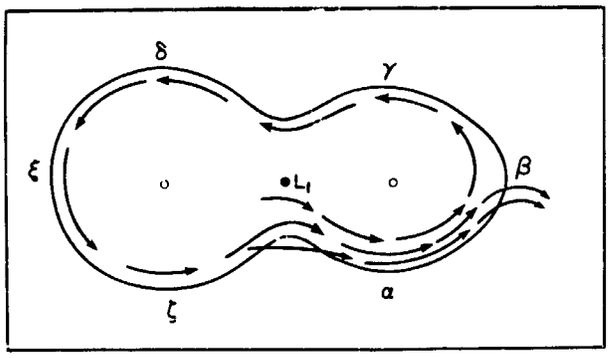

FIGURE 2.--Gaseous flow in the orbital plane expected in a close binary system (adopted from Kuiper's 1941 paper).

Numerical integrations of gaseous motion in a contact binary by Kuiper furthermore "show that if, the speed is below a certain value, the matter will go around the companion in the sense, $\alpha,\beta,\gamma\ldots$. If, however, the speed is large, the matter will fly off near β. The returning stream (in the $-x$ direction) will experience a Coriolis force in the $+y$ direction." The current would continue in the direction of δ,ξ,ζ as is shown in the figure with perhaps decreasing strength. Similarly, if the current starts in the negative x direction near L_1, the same flow pattern will result. Such a flow pattern is indeed consistent with what has been observed, say in β Lyrae.

Now if only one component of the binary is in contact with the S_1 surface, the gaseous flow pattern following the ejection of matter at L_1 will be affected by the Coriolis force in the same way as we have described for the contact binary. With frequent collisions among the ejected particles, such a tendency of motion may bring them to form a rotating ring or rings around the other component star as Kuiper has suggested. Indeed Kuiper's prediction was soon verified by Joy's (1942) discovery of a rotating gaseous ring around the primary component in the R W Tauri system —one of the Algol-type eclipsing binaries. Joy unaware of Kuiper's investigation, deduced the existence of the gaseous ring from the emission lines. This discovery induced Struve (e.g. 1950) and others to initiate an extensive study of the emission structure of many Algol type binaries. Emission rings have been since discovered in many systems. A detailed discussion of rings has been given by Struve and Huang (1957a) and a up-to-date list of such binaries may be formed in Sahade's (1960a) paper.

If the ejection velocity in the rotating system is small, the motion of particles near the point of ejection (namely L_1 and L_2) may be treated by linearized theory for the stability of orbits in the neighborhood of the Lagrangian points (Moulton 1914). Physically, we may imagine the region near the ejection point as a nozzle where the density is high and collisions are frequent. Consequently, we would not expect that any result derived from such a consideration will have any practical significance. If the ejection velocity is large, only direct numerical integration of equation (5.2) is possible. Abhyankar (1959b) has studied the motion in the neighborhood of these points in this way.

Kuiper has also investigated the motion of a particle farther away from the ejection points L_1 and L_2 by numerical integration. His pioneer work in this direction has since been followed by Kopal (1956, 1957b, 1959), Gould (1957, 1959) and many others after the introduction of the high speed digital computer. They have computed extensive series of orbits according to equation (5.2). Many orbits thus obtained are difficult to interpret because of their seemingly erratic behavior with loops, cusps, etc. which obviously will all be erased by collisions. A few, however, yield some interesting results. For example, some of the computed orbits indicate quite convincingly that particles ejected from the less massive component may indeed coalesce into a rotating ring if we properly take into account in our mental process the effect of collisions among the particles themselves.

6.2 The Hydrodynamic Approach

In spite of some success in the orbital approach, the motion of gaseous stream in a binary system

is not faithfully described by equation (5.2) since it does not include collisions and pressure. A more realistic treatment of this problem should at least take the collisions into consideration. Prendergast (1960) has examined the problem along this line. The hydrodynamic equation for the flow velocity $\vec{u}$ in space takes the following form in the rotating (x, y, z) coordinate system:

$$\frac{\partial \vec{u}}{\partial t}+\vec{u}\cdot\text{grad}\,\vec{u}+2\vec{k}\times\vec{u}=-\frac{1}{\rho}\text{grad}\,p+\text{grad}\,U \quad (6.1)$$

where U is given by equation (5.3) while p and ρ are respectively pressure and density in the gaseous medium. The unit vector $\vec{k}$ has the same meaning as in equation (5.2). The hydrodynamic equation of motion is supplemented by the equation of continuity.

$$\frac{\partial \rho}{\partial t}+d\omega(\rho\vec{u})=o \quad (6.2)$$

A comparison of equations (5.2) and (6.1) is helpful in our understanding of the difference between the two approaches. In the first place we have now introduced in equation (6.1) a new term grad p/ρ due to the pressure, which does not appear in the orbital study. Secondly, we now consider a continuous velocity field $\vec{u}(x,y,z,t)$ instead of $d\vec{r}/dt$ of individual particles. Thus, $d\vec{r}/dt$ is replaced by the first two terms in equation (6.1). We may take the continuity of the velocity field as a consequence of collisions among particles. This illustrates how by introducing the pressure and collisions we derive the hydrodynamic equation from equation (5.2). This point of view helps explain the statistical point of view of the problem that will be discussed in §6.3.

By considering a steady state ($\partial\vec{u}/\partial t=\partial\rho/\partial t=o$) and by neglecting the pressure term, Prendergast has obtained an approximate solution for the two dimensional case (in the xy-plane). He has assumed that the velocity component at right angles to the zero-velocity curve is small and to be neglected whenever convenient. Therefore, his solution is a very special one. But because of this assumption he can advantageously choose a coordinate system based on the zero-velocity curves themselves. Thus, he has found that the solution predicts circulatory currents around each of the two components inside the S_1 surface and around both components outside the S_2 surface. In this way it has been shown that the gaseous rings around the primary component of many Algol-type binaries is indeed a solution of the hydrodynamic equation.

6.3 A Statistical Point of View

In the present section we shall present a point of view from a statistical consideration. Its scope lies in the middle between the orbital approach (which neglects both pressure and collisions) and the hydrodynamic approach (which includes both). It may also be given some physical insight to the problem that cannot be seen by simply integrating equation of motion—be it equation (5.2) or (6.1). Also, it may develope into a stochastic method that treats the gaseous particles in the binary system like stars in a cluster (Chandrasekhar 1943) and eddies in turbulence (e.g., Chandrasekhar 1949). However, this is only a remote possibility.

At present, we can only give some elementary properties of gaseous particles in the binary system according to a recent paper by Huang (1965).

Let us consider n particles of mass, m_i ($i=1, 2...n$) moving in a binary system. Furthermore, the particle m_i corresponds at a given instant to a definite value of C_i for the Jacobian constant defined in equation (5.4). Because of collisions the individual C_i's of the particles change continually. However, since the particles are of atomic and subatomic sizes, the colliding particles at the instant of collision may be regarded as occupying the same point in space. If the total kinetic energy of the colliding particles is furthermore conserved during the collisions, it follows from the definition of C given by equation (5.4) that the new Jacobian constants denoted by C'_i for these particles after collisions should satisfy the following equation

$$\sum_{i=1}^{n} m_i C'_i=\sum_{i=1}^{n} m_i C_i \quad (6.3)$$

Thus, if we define an average $<C>$, we have

$$<C>=\frac{\sum_{i=1}^{n} m_i C}{\sum_{i=1}^{n} m_i}=\text{constant} \quad (6.4)$$

under the processes of elastic collisions. However, it may be noted that the dispersion of C_i's from their average value will in general change with collisions.

For inelastic collisions an equation connecting C_i's and C'_i's can always be obtained from the energy consideration if we know the detailed process of the collision. In the present consideration we shall assume that the collisions that take place among atomic particles in the binary system are statistically elastic, i.e., endoergic collisions balancing exoergic ones.

As a result of the constancy of $<C>$ during collision, the problem of gaseous flow is considerably simplified because we have now a macroscopic quantity, $<C>$, to deal with instead of following the courses of numerous particles in the system. This situation resembles the introduction of the concept of temperature and pressure which simplifies the study of the chaotic motion of molecules in gases in free space. Therefore, whatever is the nature of ejection that occurs on the stellar surface, the mean value of C_i's of ejected particles and their dispersion may serve as two of the most characteristic indices for the physical mode of ejection as regards the course of their subsequent motion.

It should be noted, however, that although the gaseous particles maintain a constant $<C>$, the mean flow does not follow the orbit derived from equation (5.2).

In this way, we can treat the problem of gaseous streams as a statistical problem of C_i's. One of the possibilities for further investigations along this line of thought is to link the statistical properties of C_i's from the theoretical consideration with the strengths of spectral lines arising from the gaseous streams observed at different phases of the binary motion.

Our immediate purpose is, however, to show that an intermediate approach between the orbital and hydrodynamic one may be obtained from a statistical consideration of C_i's as well as of the angular momentum (the z-component) per unit mass, h, of each particle in the system. Since a particle is moving in a two-centered field of force, its h, which is given by

$$h=x^2+y^2+x\frac{dy}{dt}-y\frac{dx}{dt}, \tag{6.5}$$

varies with time. However, it can be shown from equations (6.5) and (5.2) that

$$\frac{dh}{dt}=\mu(1-\mu)y\left(\frac{1}{r_1^3}-\frac{1}{r_2^3}\right), \tag{6.6}$$

which is a function of coordinates of the particle only, being independent of its velocity. What is more important is that the total angular momentum is conserved among the colliding particles if the collision may be regarded as taking place instantaneously.

We can now derive the properties of a continuous gaseous medium in the binary system from those derived from a consideration of discrete particles. Let us illustrate it by the two-dimensional case. Since the average values of C and h do not change by collision, we may write in a steady state

$$\vec{u}\cdot\nabla C=o \tag{6.7}$$

from equation (6.4) and

$$\vec{u}\cdot\nabla h=\mu(1-\mu)\left(\frac{1}{r_1^3}-\frac{1}{r_2^3}\right) \tag{6.8}$$

from equation (6.6) if we follow the streamline. While we have obtained these two equations by physical arguments, they can be easily derived from the hydrodynamic equation by first neglecting the pressure term. Naturally, equations (6.7) and (6.8) yield the same approximate solution of circulatory motions as Prendergast has obtained.

From equations (6.7) and (6.8) we can also see clearly the range of validity of the approximate solutions. As expected, the solution gives a good approximation for the circulatory motion close to each of the component stars. It has been illustrated by numerical calculation that wherever the solution represents a good approximation, the predicted motion from equations (6.7) and (6.8) approaches the periodic orbits of the restricted three-body problem (Huang 1964a). Thus, the gaseous ring observed in many binaries may be regarded equivalently either as a hydrodynamic flow or as motions of particles in a continuous series of periodic orbits that exist around each of the component stars.

Since we have emphasized the two physical parameters, h and C it is interesting to note that at some points in space certain combinations of

values for these two quantities are incompatible. In other words, with a given pair of values for h and C a particle cannot go into a certain region of space which may be called the forbidden zone (Huang 1965). Since h is not a constant of motion in the restricted three-body problem, the forbidden zone is not as important as the zero-velocity surfaces. However, it may serve some useful purposes in depicting the trend of motion in general, especially when it is applied in combination with equation (6.6).

7. THE ORIGIN OF CLOSE BINARIES

Essential difficulties encountered in various hypotheses of the formation of binary systems in general, have been discussed by Hynek (1951). Many of his arguments can be applied to the close binaries and are indeed followed in the present discussion. From a general ground we may state that the close binaries can be formed by one or more of the three possibilities. They were formed (1) as a result of the fission process in rapidly rotating single stars, (2) from distant binaries and (3) directly as close binaries in the beginning. We shall briefly discuss the plausibility of these three processes.

Jeans (1919, 1928, 1944) has spent many years in studying the fission process of rapidly rotating stars. He has found that when the rotational velocity is small, the shape of a flattened spheroid is common to all rotating bodies whether they are composed of gases, liquids or plastic material. However, if the rotational velocity is high, their shape depends greatly upon their internal constitution and especially the degree of their central condensation. According to him fission would occur in massive liquid bodies in which there is no appreciable central concentration of mass. But for a gaseous body of an extreme central condensation (i.e., the Roche model), rapid rotation only makes it flatten more and more with an accompanying loss of mass at its equator. No fission will result. Jeans further shows that all bodies having less than a certain critical degree of central condensation behave very much like those made of incompressible liquid while all bodies having more than this critical amount of central condensation behave very much like those of an infinite central condensation. Since actual stars have a central condensation much higher than the critical value, fission does not occur in them (Jeans 1944).

The fission theory encounters another difficulty in that it cannot explain the existence of binaries of large separations. Because of the conservation of angular momentum, it can be easily seen that two components of a binary resulting from the fission process must be very close together. Thus, in order to account for binaries of wider separations other mechanism of formation has to be derived. While it is not prohibitive to have two different mechanisms for the formation of one kind of objects, the smooth distribution of separations and other statistical behavior of binaries throws serious doubt, according to Kuiper (1935a and b), on any theory that cannot explain the formation of all binaries, except perhaps those really wide ones with separations of the order of interstellar distances (e.g. Van Biesbroeck 1957), by a single mechanism.

Next, let us examine the possibility of converting distant binaries into close ones. In proposing this possibility, the presence of distant binaries is assumed. Then two components are supposed to drift together due to a resisting medium such as we have seen in 3.4 or due to other energy dissipating mechanisms. In order to make the theory complete we must first of all answer the question of how these distant binaries are formed. It has often been suggested that they may be formed by star capture. However, stars are far apart in space and are moving with an average velocity of about 10–20 km/sec with respect to the local centroid. Thus, if one star by chance approaches another, each will move on an hyperbolic orbit. Consequently, the two will recede from each other to large distances unless their energy can be dissipated during the encounter. The agency which absorbs the dissipated energy can be either a third star that happens to be in the immediate neighborhood or a resisting medium. But the chance of a three-star encounter in the galaxy is vanishingly small and the interstellar medium is in general too tenuous to be effective in reducing stellar velocities (McCrea 1953; Dodd 1954).

For the same reason of low interstellar densities and high orbital velocities, it is very doubtful that the resisting force of an ordinary interstellar cloud

can greatly reduce the separation of a binary in a time scale, say of 10^{10} years. Therefore, the possibility of first forming binaries by star capture and then converting them into close ones is also ruled out.

This leaves us only the third possibility, i.e., the binaries—both close and distant—were formed as they are. It appears that we have not found any serious objection to this possibility. On the contrary many observed facts are consistent with it. For example, according to Kopal (1959) the relative frequency of close binaries found in the general galactic field is about 0.1 percent and is of about the same order of magnitude as that found in galactic clusters and stellar associations where stars are supposed to be formed. Indeed many eclipsing binaries have been identified to be members of galactic clusters (e.g., Sahade and Frieboes 1960) and of stellar associations (e.g., Kraft and Landolt 1959; Semeniuk 1962). If binaries of different separations were formed as they are, their high abundance in the galaxy strengthens the suggestion made frequently (e.g., Roberts 1957) that stars (at least Pop. I stars) are formed in groups. As a result of his statistical study Batten (1960) gives reasons to suggest that many binaries may have formed together in space. However, statistics also give us some puzzling results. Jaschek and Jaschek (1957, 1959) have found that although the frequency occurrence of spectroscopic binaries is uniform among the young stars (about 20 percent) whether they are in associations, in clusters or in the general field, the percentages of spectroscopic binaries in old groups of stars (ages from 3×10^9 to 6×10^9 years) decreases with age.

From the standpoint of star formation in general we also find the emergence of binaries quite natural. Two condensations just happened to be formed near together in the primeval medium and they will evolve to become a binary if their relative velocity is not large enough to escape from each other. Since the two adjacent condensations evolve separately on their own, they will become two stars as if they were chosen from a random sample. This prediction is again consistent with the observed result (Kuiper 1935 a and b). Here we may mention the interesting argument in favor of the simultaneous formation of two components of a close binary advanced by Krat (1952). He observed that if their formation did not occur at the same time, then the second component could never have been formed in the neighborhood of the first one because of the latter's strong tidal force and intense radiation both of which incline to disrupt the gaseous condensation that is to become the second star.

If the binary systems were formed as they are, it is inevitable to conclude that two components of a binary must have the same age. Previously this consequence was regarded as a difficulty, because one might argue, as with Jeans (1944) for example, that components of binaries like Sirius, Procyon, and others show signs of very different ages. Both Sirius and Procyon contain a white dwarf as one component together with an early-type main-sequence companion. Since the white dwarf is an old object while the early-type main-sequence star is regarded as young, it is difficult to believe that they could be coeval. However, it should be noted that whether a star is young or old refers only to its own evolutionary sequence and has nothing to do with time in the absolute measure. For example, a massive star of $10M_\odot$ or more passes through all of its evolutionary stages perhaps in a fraction of time that a star of $1M_\odot$ remains on the main sequence. Thus with a loss of mass at late stages either continuously (Deutsch 1956) or cataclysmically, there is no reason to object why one star has reached the white dwarf while the other of the same age is still at the main-sequence stage. This is a fortiori true for two components in a close binary, because, as we have seen, one component can accret mass from its companion. Since we may regard mass accretion as a rejuvenation process while mass loss as an aging process, such an exchange of mass will enhance the apparent age difference between two components in a close binary. More will be said about mass exchange and its effect on evolution of close binary stars in the next section.

Although we have concluded that binaries were formed in the way they now appear, we still do not know for sure the detailed mechanism how they actually emerged from the primeval nebula, as the study of formation of binaries, like that of single stars, is still at the speculative stage. Here we shall review briefly three suggestions regarding the physical processes that shape the binaries in general and close binaries in particular. As we

will see presently, these three suggestions are not mutually exclusive because each deals only one aspect of the many faceted problem of binary formation.

Dodd (1954) has advanced a model of binary formation after he has found that star capture in the present state of interstellar space is untenable. He takes for granted that stars are forming around various centers of condensation in the originally homogeneous medium where there are no local variations in the gravitational field. If two condensations happen to be nearby, the material in the cylindrical volume between the two condensations, according to Dodd, will collapse on the axis joining them mainly under the gravitational influence of the condensations themselves. Because the collapse on to the axis is cylindrical, energy dissipation is much more effective than would be the case of a spherical collapse. This cylindrical collapse results in a column of comparatively small cross-section extending between two condensations. When the latter moves towards each other under their gravitation, they sweep the mass between them. In acquiring mass in this way the condensations also meet resistance which dissipates the dynamical energy of the system. In the end two condensations become two component stars in a binary. It appears that Dodd has assumed the condensations to be at rest in the medium in the beginning. They form a binary instead of a single star only by a further assumption that the condensations will be deflected from the straight collision course by perturbation due to neighboring stars. Perhaps by making these two assumptions, Dodd has proposed an unrealistic model since without initial relative motions among the various condensations, one can only expect the collapse of all condensations into one big mass.

Kuiper (1935b, 1957) has studied the problem of angular momentum of binaries both observationally and theoretically. If one considers the proto-star as a single hydrodynamical unit, its Reynolds number is high and consequently motion inside it must be turbulent. Thus, its angular momentum may be computed from the random motion of large eddies as Kuiper has done. Since the motion is random, each of the three components of the total angular momenta of stars must be given by the Gaussian curve. In other words the magnitudes of the total angular momenta of proto-stars follow the Maxwellian distribution of velocity magnitudes, from which Kuiper is able to derive a theoretical distribution for the separations between two components in binaries. He has found that the theoretical distribution curve indicates a less dispersion than the observed one but has given several convincing reasons to show why this should be expected.

Parenthetically it may be noted that unaware of Kuiper's investigation, McCrea (1959 see also Struve and Zebergs 1962) has used practically the same arguments to derive the angular momenta of stars.

Finally, Huang (1957b) has suggested that solid prestellar nuclei may serve as the basis for stellar condensations. If a medium possesses a large amount of angular momentum and is composed of only gas, its contraction will lead to a rotational break-up at the equator. It will not form a binary as we have already mentioned in connection with the fission problem. However, the situation will be different if there are large solid bodies embedded in the gaseous medium. These large bodies must move very slowly in comparison with gaseous molecules for the same reason that the Brownian movement is slow compared with molecular motions. Consequently, they are gravitationally less stable than the gaseous substratum. It could therefore happen that these bodies coalesce into two revolving nuclei which serve later as two centers of condensation. As a result, a binary instead of a rapidly rotating single star is formed.

All these ideas are qualitative in nature and function no more than some vague suggestions. Much work needs to be done before any of them will develop into a complete and consistent theory. Furthermore, other ideas may come up in the future. Therefore, we cannot avoid the impression that the problem of binary formation is a wide open field for further investigations.

Let us now put aside the question of physical processes of formation and turn our attention to the phenomenological side of the problem. In his study of separations of binaries Kuiper (1935a and b) has realized that the distances of the major planets from the sun fall nearly in the mid-range of the binary separations from 10^{-2} to 10^{5} A.U. with a median value at about 20 A.U. Therefore,

Kuiper (1951) believes that the binaries and the planetary system form a single uniform group. In his way he has argued that the number of planetary systems in the galaxy must be considerable because binaries are numerous. His view is now generally accepted.

At the same time Struve (1949b, 1950; also Struve and Huang 1958) has raised some interesting points on the relation between binaries and planetary systems. Especially, he has suggested from a consideration of angular momentum that planetary systems may result from the mass dissipation of *W* Urase Majoris systems.

Whether Struve's intuition will turn out right we cannot tell at this moment. One point we are now certain is that the formation of close binaries and single stars are events with no intrinsic difference. We suggest that only a few varying parameters in the identical process of formation make all the different catagories of stars. One of the important parameters doubtless is the angular momentum. If a condensation has a low value of angular momentum, single stars neither rotating rapidly nor possessing planetary systems will be formed. If the angular momentum is high, rapidly rotating single stars, stars possessing planetary systems of close binaries will be formed. Which one of these possibilities will actually be followed depends presumably upon other parameters, among them we may mention density, total mass, turbulence, magnetic activities, and other (Huang 1965).

8. EVOLUTION OF CLOSE BINARY STARS

Concerning the evolution of close binary stars we are faced with many peculiar systems but with few tangible leads that may indicate their stages of evolution. Consequently, we have a wide choice of theories for the evolutionary scheme of close binary stars. While it is interesting to know the fascinating ideas about binary evolution advanced in the past decades, we shall follow a conservative course here in preparing this section not only because we do not have enough space but also because most of these ideas are tentative at best.

The difficulty in understanding the evolution of close binary stars can be easily seen from the fact that in spite of recent successes in the study of stellar evolution (e.g. Burbidge and Burbidge 1958; Schwarzschild 1958; Hayashi, Hōshi and Sugimoto 1962) we are still not certain about evolution of single stars after the red-giant stage. The reason for this uncertainty lies in the first place with the complications of various nuclear reactions that take place in different layers of the star. But a more serious one is the rate of loss of mass from the star at different phases at and after the red-giant stage. As a result of investigations by Deutsch (1956, 1960, 1961) there is no doubt that red giant or supergiant stars lose mass continuously but the exact amount is not certain. Coming back to the close binary stars we know even less about the rate of mass loss or gain at different stages.

Because of this uncertainty we shall discuss evolution of close binaries here only on some general ground. In the first place the component stars must follow the natural sequence of evolution of every star because of the continuous outflow of energy which is derived either from their gravitational potentials or from thermonuclear reactions. Since two components of the same binary are coeval as we have concluded in the previous section, the more massive component departs from the zero-age main sequence at a faster rate because of its higher luminosity than the less massive companion. According to Smak (1959) this is the reason why the primary components in close binaries are systematically greater than the secondaries of the same mass. However, unlike single stars we would expect that stars even at the main-sequence stage will lose mass if they are components of close binaries. This is true not only for the components in contact and semi-contact binaries but also for those in completely detached systems if prominence activities like those taking place on the solar surface are active there. Indeed the variations in period found in the detached and semi-detached systems (Kwee 1958) may well be due to this kind of mass variations.

When the star is well inside the S_1 surface, the loss of mass is slow and its internal structure will not be seriously different from that of a single star of the equivalent mass. Therefore, its structure may be derived by linear perturbation as has been performed by Morton (1960). The situation becomes quite different when one or both components reach the size of the corresponding lobe of the S_1 surface, such as in several important

categories of close binaries like β Lyrae variables, *W* Ursae Majoris variables, Algol-type variables, etc. In these cases, the rate of mass variation is presumably high and the structure of the overflowing component star at any time perhaps will find no parallel among single stars. For example, it is doubtful that the subgiant component of the Algol-type binaries has any resemblance in their internal structure to the single subgiant stars (Struve 1954). Reddish (1957) has suggested some special models for red giants in order to account for the process of mass loss.

If we cannot derive the structure of component stars of contact and semi-contact systems by applying perturbation to the normal single stars, can we calculate directly their sequence of evolution by assuming a given rate of mass loss? The prospect of doing so is not good. There are several intrinsic difficulties involved in this kind of calculations. In the first place the mass loss has an effect not only on the star itself but also on the separation and the contact surfaces which limit externally the radius of the overflowing component star. In other words, the structure of the component stars is coupled to the orbit of the binary itself. Now the contact surface is not uniquely determined by the amount of mass lost from the star. It depends critically on the mode of ejection that can vary greatly from case to case as we have already seen in 3.5. Thus, starting from one configuration of contact or semi-contact we do not know exactly what will be the configuration at the next moment even if we assume a definite rate of mass loss.

We also encounter difficulty basic to the calculation of stellar structure itself. The effect of mass loss produces not only a pressure inbalance but also a thermal inbalance in the interior. The time of adjustment to the equilibrium condition is therefore measured by the Kelvin scale of gravitational contraction instead of the much shorter time scale of pulsation (Crawford and Kraft 1957; Morton 1960; Schwarzschild 1962). In other words we no longer have the simple relation of energy loss (at the surface through radiation) balanced exactly by energy production in the interior by thermonuclear reactions. It follows that the stellar structure in the present case becomes a time-dependent problem instead of a problem of equilibrium.

Or we may put our arguments differently. According to the Vogt-Russell theorem (e.g., Chandrasekhar 1939), if the pressure, the opacity and the rate of generation of energy are functions of the local values of the density, the temperature and the chemical composition only, then the structure of a star is uniquely determined by the mass of the star and its chemical compositions. In other words, among other structural properties of a star, the radius is determined internally by the mass and the chemical composition. Now in the contact and semi-contact binaries, the radius of the overflowing component is further limited by the contact surface which is imposed externally. Therefore, in general, we cannot find a stellar model that can fulfill both internal and external condition for its radius. This is equivalent to say that no solution can be obtained from the consideration of equilibrium. This explains why we cannot derive the evolutionary sequence of models by computation for the overflowing component as we have done for the single stars.

After what has been said it becomes quite apparent that discussions on the evolution of binary stars are necessarily qualitative and highly speculative. We should always remember that these discussions represent only the preliminary probing of the possibilities but not the final verdict.

Since the secondary components of many *W* Ursae Majoris stars are over-luminous with respect to their masses by more than two magnitudes on the average, Kitamura (1959, 1960) has suggested that the extra energy radiated away is derived from the gravitational contraction of mass that is being accumulated on the secondary surface at the expense of the primary. Accordingly, he has built a series of gravitationally contracting stellar models that are accreting mass. However, he has not given any reason why the secondary captures mass from the primary instead of the reversed course, namely the primary captures mass from the secondary, for after all the gases are flowing around both components of these contact binaries. Therefore, the present writer personally inclines to regard Kuiper's (1948) interpretation of the departure from the mass-luminosity relation of *W* Ursae Majoris stars still worthy of our attention.

Because of the slowness of energy transfer in the star, the loss of mass at the surface will change

the internal structure and the luminosity only slowly (on the Kelvin time scale as we have said) Thus, we arrive as with Krat (1957) at the conclusion that the star evolves under the conditions of a constant luminosity and decreasing mass. Using a simple model Krat has shown that the process of mass ejection under these conditions will be a self-accelerating process. Hence, he went on to suggest that the ejection velocity will increase. In this way he has tried to understand the high velocities of ejected matter from the Wolf-Rayet stars. According to him "the evolution of massive stars proceeds from the stage of stable hot supergiants through the stage of Wolf-Rayet stars and red giants to the main sequence (thus approaching solar-type stars)" as a result of mass loss. It appears that Krat's view may have overstretched the idea of mass loss. However, he is not alone in putting the Wolf-Rayet stars before the main sequence (e.g., Sahade 1958).

Among the many interesting views concerning the evolution of close binary stars one that is appealing is about mass exchange between two components and the consequence as regards their evolution, proposed independently by Crawford (1955) and by Kopal (1955) for the Algol-type binaries. Consider in a detached close binary two components of different masses. Since the luminosity is proportional to about 4th power of the mass (Russell and Moore 1940), the more massive one evolves faster and consequently reaches the stage of hydrogen-exhaustion in the central core earlier than its companion. According to the current understanding of stellar evolution, once the hydrogen has been exhausted in the central core, its envelope expands. Eventually, it will reach the S_1 surface. Mass that flows out from the expanding component at near the point L_1 because of the contract condition will be collected at least partly by the other component. In this way the more massive component loses while the less massive one gains mass. According to Crawford this process can proceed until the originally more massive component becomes the less massive of the two. In this way, he explains why in the Algol-type binaries it is the less massive component that now fills up one lobe of the S_1 surface while the more massive component is small and stable.

While this is an appealing idea there remain some difficulties in applying it to the Algol-type binaries as was initially suggested by Crawford and Kopal. Let us first consider the difficulty raised by Struve and Huang (1958). If M_1 and M_2 are respectively the present masses of the primary and secondary component and if in their evolution, mass of an amount ΔM has been transferred from the secondary to the primary and mass of an amount δM has been dissipated into outer space by the secondary, the following inequality can be easily established from the condition that the initial mass of the secondary must be greater than that of the primary:

$$2\Delta M+\delta M>M_1-M_2 \qquad (8.1)$$

Now the primary of the Algol-type binaries is usually a normal main-sequence star of spectral type A and may be assigned a mass of $M_1=3M_\odot$. In some cases, M_2 has been found to be $0.2M_\odot$ or less (Sahade 1945, 1949). If we assume $M_2=0.2M_\odot$, we find from the inequality (8.1) that $\Delta M>1.4M_\odot$ if all mass dissipated by the secondary has been collected by the primary and $\Delta M=\delta M>14/15M_\odot$ if equal amounts are collected by the primary and escaped to outer space. Thus, eight-tenths to nine-tenths of the initial mass of the secondary must have been lost. If we remember that when the envelope of a star expands during its evolution after the main sequence the central core of more than one-tenth of the total mass of the star contracts, it is hard to see a star to lose eight-tenths to nine-tenths of its mass by the mechanism described above.

Indeed Kopal (1959) has finally rescinded this interpretation. In addition to the mass consideration, he has also called attention to the fact that there is a complete lack of binaries whose more massive component fills up the lobe of S_1 surface. However, the present writer does not regard this as a serious difficulty because the Kelvin time scale is short and the chance of discovery is small (Morton 1960). Kopal has further pointed out that there is not enough energy to lift the mass from the hydrogen-depleted central core of the secondary to the level of the primary surface, if more than eight-tenths of the total mass is to be transported. Therefore, his second objection arises from the difficulty of too much mass to be transferred which was discussed before. Kopal

has not provided a new explanation for the Algol-type binaries. However, he presumes on the observational ground that the less massive secondaries in these systems for some unknown reason begin to expand at a certain stage of their evolution before the more massive primaries will do so.

From these considerations this idea of mass transfer between two components does not appear promising for the interpretation of the Algol-type binaries. On the other hand, the mechanism is a plausible one because, as we have seen in 3.5, it is a necessary consequence of the slow mode of mass ejection. Indeed, we now have reasons to believe that it may be working in β Lyrae (Huang 1963a).

Thus far we have discussed only evolution of component stars in close binaries. There remains the question of evolution of the binary system itself. One can easily see that the two problems are closely related. Theoretically we cannot attack the problem of evolution of the binary system without first understanding evolution of its component stars. The difficulty encountered in the latter makes a theoretical investigation of the former impractical. Observationally, data are too scanty to lead us to any definite and plausible scheme of binary evolution. Struve (1950) once made an interesting suggestion along this line and Sahade (1960b) has recently rediscussed some of Struve's original ideas of deriving *W* Ursae Majoris stars from early-type (B or A) systems.

Another fascinating problem connected with close binaries concerns the nature of various peculiar objects in the galaxy. Struve often expressed the view that Wolf-Rayet stars, symbiotic stars, and many other peculiar objects may all be binaries and moreover derive their peculiarities from being binaries. As a result of recent investigations by Abt (1961) the metallic line stars may now be added to the list of peculiar objects which appear to exist only in binaries. Although Struve's suggestions have not been accepted by all astrophysicists, they have inspired many to look at the problem. After the discovery of the binary nature of Nova DQ Hercules (1934) by Walker (1954, 1956), the question has again been raised (Struve 1955) as to whether the novae and nova-like objects are always components of close binaries. This question has led to many interesting studies about the relationship between these exploding stars and binaries (Crawford and Kraft 1956; Huang 1956; Kraft 1962, 1964; Schatzman 1958). A review of extensive works in this field is beyond the scope of the present article.

Finally I would like to express my sincere thanks to Mr. Clarence Wade, Jr. for performing on the IBM 7094 computer some calculations used in this paper.

EFFECT OF NON-SYNCHRONOUS ROTATION* ON CLOSE BINARY STARS

N66 37948

SU-SHU HUANG†

The effect of non-synchronous rotation of the component star in close binaries on its limiting surface is analyzed and the difficulties in the previous investigations are examined. It has been shown that no potential function exists in a coordinate system following the axial (non-synchronous) rotation of the component star. Consequently, no equilibrium surfaces can be obtained in this way. It is therefore suggested that we should retain the conventional coordinate system that rotates with the binary motion. Since a simple energy integral exists in this coordinate system, we can obtain a physical picture for the problem of the non-synchronously rotating star in the binary systems. Indeed we have found that the non-synchronously rotating star will modify its rotation gradually and become eventually synchronous with its orbital revolution.

In this multifarious activities and achievements that make him one of the greatest astronomers in the modern time, Professor Otto Struve has never forsaken the binary stars. After having spent some years of successful researches in other fields of astronomy now and then he always returned to this field of his early interest. Therefore, few astronomers have observed spectroscopically as many binary stars as he has done. Fewer still have left such a distinct mark as his in the history of double stars.

In a close association and collaboration with him for a decade during which I am proud to have received his confidence and learned the process of his mental perceptions and responses as a result of our daily afternoon meetings in cafes outside the North Gate of the Berkeley Campus of the University of California, I have always been impressed by his open mindedness to new ideas, his enthusiasm for and devotions to astronomy. Because of his open mindedness he saw any problem in its multi-faceted angles, thus making him not only an outstanding scientist but also a great leader. Because of his enthusiasm, he enlisted many astronomers into the fields of his interest. Our daily contact also induced me to become a novice in the study of binary stars in the mid fifties: It is therefore befitting for me ten years later to write this article on binary stars in this memorial volume as my attribute to a great leader as well as a dear friend whom I have both respected and admired.

I. A CRITICAL REVIEW OF THE PREVIOUS INVESTIGATIONS

The shape of stellar surfaces in the close binary system has been given as a first approximation by what has been predicted by the Roche Model (e.g. Struve and Huang 1957. According to this model, the axial rotation of component stars and their orbital revolution are synchronized. While the majority of close binaries indeed obey the rule of synchronization (Swings 1936, Struve 1950, Plaut 1959) there are some exceptions to which belongs β Lyrae—a peculiar binary system that Professor Struve (1941, 1958) had a life-long interest. Therefore, in recent years attempts have been made to predict the stellar surfaces, especially the limiting surface, when the component star does not rotate in synchronization with its orbital revolution (Kopal 1956, Plavec 1958, Kruszewski 1963, and Limber 1963).

In the restricted three-body problem one can define a potential function U in a coordinate system that rotates with the binary's orbital motion

*Prepared for a Memorial Volume for Prof. Otto Struve.

†Goddard Space Flight Center and Catholic University, Washington, D. C.

(e.g., Moulton 1914). Also an energy integral can be obtained in the form that the sum of the potential energy and the kinetic energy is constant. It is the existance of the energy integral in this form that enables us to predict the stellar surfaces of close binaries because only then the density and the pressure should be constant on any equi-potential surface. Thus, we should emphasize that the mere existence of a potential function does not necessarily warrant a prediction of the equilibrium surface of a star. Indeed, this is the reason that the calculations by previous investigators have to be regarded as unsatisfactory.

Kopal (1956) first studied the limiting surface of the non-synchronously rotating star, using a potential function which Kruszewski (1963) has since pointed out to be incorrect. Later Plavec (1958), Kruszewski (1963) and Limber (1963) have all derived a potential function and obtained the limiting surface. However, even though their potential function is correct, their result is still open to debate as we may see in the following way.

Let us first choose a dimensionless system of units of measurement with the total mass of the binary as the unit of mass, with the separation between the two components as the unit of length and with $P/2\pi$ as the unit of time, where P stands for the orbital period. Thus, if we denote $1-\mu$ as the mass of one component, μ will be the mass of the other. Let us further choose a rotating (x,y,z) system such that the origin is at the center of the $1-\mu$ component, the x-axis points always towards the μ component, and the xy plane coincides with the orbital plane. We have the equations of motion for a test particle in the (x,y,z) system:

$$\frac{d^2x}{dt^2}-2\frac{dy}{dt}=\frac{\partial U_1}{\partial x},\quad \frac{d^2y}{dt^2}+2\frac{dx}{dt}=\frac{\partial U_1}{\partial y},\quad \frac{d^2z}{dt^2}=\frac{\partial U_1}{\partial z}, \tag{1}$$

where

$$U_1(x,y,z)\equiv\frac{1}{2}[(x-\mu)^2+y^2]+\frac{1-\mu}{r_1}+\frac{\mu}{r_2} \tag{2}$$

and r_1 and r_2 are respectively the distances of the test particles from the two component stars. Note that U_1 is a function of time only through the coordinates (x,y,z) of the test particle.

We now introduce a new rotating (ξ,η,ζ) system such that it is rigidly fixed to the $1-\mu$ component, sharing the latter's axial rotation. Although the axial rotation of the $1-\mu$ component is not synchronous with the orbital motion, its rotating axis (chosen as the ζ-axis) is still assumed to be perpendicular to the orbital plane. Thus, if the (ξ,η,ζ) system is rotating with an angular velocity, ω, with respect to the (x,y,z) system, it rotates with an angular velocity, $1+\omega$, with respect to the rest frame of reference. The transformation equations between (x,y,z) and (ξ,η,ζ) are as follows:

$$x=\xi\cos\omega t-\eta\sin\omega t,$$
$$y=\xi\sin\omega t+\eta\cos\omega t,\ z=\zeta \tag{3}$$

The equations of motion in the (ξ,η,ζ) system are

$$\frac{d^2\xi}{dt^2}-2(\omega+1)\frac{d\eta}{dt}=-\mu\cos\omega t+\frac{\partial U_2}{\partial\xi} \tag{4}$$

$$\frac{d^2\eta}{dt^2}+2(\omega+1)\frac{d\xi}{dt}=\mu\sin\omega t+\frac{\partial U_2}{\partial\eta} \tag{5}$$

$$\frac{d^2\zeta}{dt^2}=\frac{\partial U^2}{\partial\zeta} \tag{6}$$

where

$$U_2(\xi,\eta,\zeta)\equiv\frac{1}{2}(\omega+1)^2(\xi^2+\eta^2)+\frac{1-\mu}{r_1}+\frac{\mu}{r_2} \tag{7}$$

may be regarded as the negative value of the potential function. Acutally, it is a misleading name as we shall see presently.

$U_2(\xi,\eta,\zeta)$ as given by equation (7) does not give the limiting surface of the non-synchronous $1-\mu$ component. In the first place, we encounter the time-dependent terms $\mu\cos\omega t$ and $\mu\sin\omega t$ in equations (4) and (5). Secondly r_2, which is given by

$$r_2^2=(\xi-\cos\omega t)^2+(\eta+\sin\omega t)^2+\zeta^2, \tag{8}$$

is now an explicit function of time. Therefore $U_2(\xi,\eta,\zeta)$, unlike U_1 in the (x,y,z) system, is no longer an implicit function of time through the space coordinates alone but involves time explicitly. For brevity we write $U_2(t)$ for $U_2(\xi,\eta,\zeta)$. Because of the two complications, we can no longer derive from equations (4)–(6) the simple result that the sum of the potential energy and the kinetic energy is a constant of motion. Consequently, the surfaces defined by equation (7) do not represent equilibrium surfaces of the star. We can see this point analytically in the following way.

Multiplying equations (4)–(6) respectively by $d\xi/dt$, $d\eta/dt$ and $d\zeta/dt$ and adding the resulting equations together, we obtain after integration with respect to time that

$$\frac{1}{2}[V^2(t)-V^2(t_o)]-[U_2(t)-U_2(t_o)]$$
$$=\int_{t_o}^{t}\left[\mu\left(\frac{d\eta}{dt}\sin\omega t-\frac{d\xi}{dt}\cos\omega t\right)-\frac{\partial U_2}{\partial t}\right]dt, \qquad (9)$$

where $V(t)$ and $V(t_o)$ denote respectively the velocity of the test particle at time t and at the initial time t_o. $\partial U_2/\partial t$ may be evaluated from equations (7) and (8). When the result is substituted into equation (9), we obtain finally

$$\frac{1}{2}[V^2(t)-V^2(t_o)]-[U_2(t)-U_2(t_o)]$$
$$=\mu\int_{t_o}^{t}\left[\left(\frac{d\eta}{dt}-\frac{\omega\xi}{r_2^3}\right)\sin\omega t-\left(\frac{d\xi}{dt}+\frac{\omega\eta}{r_2^3}\right)\cos\omega t\right]dt. \qquad (10)$$

It is obvious from equation (10) that the sum of the potential and kinetic energy is no longer constant. Since the integral in equation (10) actually depends upon the path of the test particle, $-U_2$ does not behave exactly like a potential.

The previous investigators have introduced

$$U_3(\xi,\eta,\zeta)=U_2(\xi,\eta,\zeta)+\mu(\eta\sin\omega t-\xi\cos\omega t). \qquad (11)$$

In doing so, they can replace the right hand sides of equations (4)–(6) respectively by $\partial U_3/\partial\xi$, $\partial U_3/\partial\eta$, and $\partial U_3/\partial\zeta$. Because of the transformation relation (3), $U_3(\xi,\eta,\zeta)$ can now be expressed in terms of x, y and z. In this new expression for U_3, time appears only implicitly through x,y,z but does not enter explicity. Consequently, they have independently derived the limiting surface in the (x,y,z) system by considering U_3 as the potential function.

However, we should remember that it is the (ξ,η,ζ) system that is rigidly fixed to the rotating star. Any stationary surface of the non-synchronous rotating star ($1-\mu$ component) must be expressed as a function of ξ, η and ζ alone without the explicit appearance of time. It does not appear that an expression in x, y, and z can represent the stationary surfaces of the non-synchronous component because in the (x,y,z) system the component has a net rotation. Since, as we have seen before, we cannot obtain a potential function in the $(\xi\eta,\zeta)$ system, we have no means to compute the stationary surfaces of a non-synchronous rotating component star, a conclusion contrary to the previous investigators.

II. PHYSICAL INTERPRETATION

Because of the difficulties we have just observed, it is advisable to retain the (x,y,z) coordinate system that rotates with the binary motion. In this coordinate system we have for the test particle a simple energy integral

$$2U_1-V^2=C \qquad (12)$$

where $U_1(x,y,z)$ is given by equation (2).

We should now recall that the zero-velocity surfaces are labelled by C (e.g., Moulton 1914). Let the C value that is associated with the innermost contact surface S_1 (Kuiper 1941) be C_1. Therefore, all particles inside the S_1 surface with $C<C_1$ could penetrate the S_1 surface. As a result, these particles will gradually be lost from the star. Now the $1-\mu$ component is rotating with an angular velocity ω in the x,y,z coordinate system along the z-axis. Particles in the stellar surface layers have velocities

$$V=(x^2+y^2)^{\frac{1}{2}}\omega \qquad (13)$$

if thermal motion or other kinds of motion are neglected. Hence, all particles in the $1-\mu$ component star that are above the surface (called the R surface hereafter) given by

$$2U(x,y,z)-\omega^2(x^2+y^2)=C_1 \qquad (14)$$

and consequently have C values less than C_1 may be regarded as unstable and could easily escape out of the S_1 surface. Figure 1 illustrates the cross sections in both the xy plane and the xz plane of a few R surfaces for the case $\mu=0.4$ and $\omega=0$, 2, 4 and 8. The case $\omega=0$ is simply the S_1 surface for $\mu=0.4$. The elongated shape of the cross sections in the xz plane is easy to understand because those particles near the equatorial plane that have the highest linear velocities due to non-synchronous rotation are the easiest to be ejected out of the S_1 surface.

However, it should be noted that the R surfaces represent neither the limiting nor equilibrium surface. Particles below the R surface for a

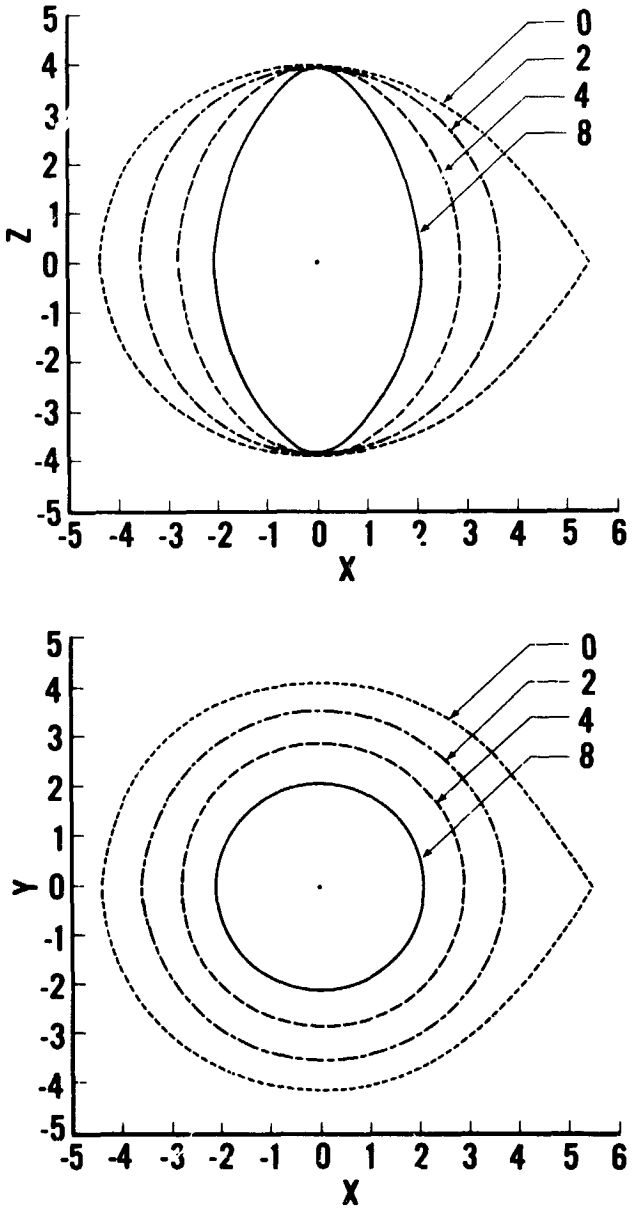

FIGURE. 1—The R surfaces for different values of ω (0, 2, 4, 8) for $\mu = 0.4$. The R surfaces are defined by equation (14). The case $\omega = o$ represents simply the innermost contact surface (denoted by S_1). When the rotation of a component star is not synchronous with its orbital motion, the gaseous particles above the R surface may escape the S_1 surface and are replaced by gaseous particles moving out from below the R surface. This process will go on until the star finally becomes synchronized to its orbital motion.

given value of ω can move up although they cannot escape through the S_1 surface without collisions. Statistically, we can state that most particles that are originally located above the R surface are lost and are replaced by particles coming from below the R surface. These new particles will naturally fill up the entire lobe of the S_1 surface. Therefore, the limiting surface of the $1-\mu$ component is still given by the S_1 surface. Since the angular momentum per unit mass due to the axial rotation of the $1-\mu$ component decreases downward in the star if it rotates as a rigid body, the new material above the R surface will rotate less rapidly (with respect to the xyz system) than the old material before the letter's escape. The simultaneous transfer of mass from below the R surface to above the R surface and from inside the S_1 surface to outside the S_1 surface will continue until the orbital revolution and the axial rotation become synchronize. Perhaps this axial rotation become synchronized. Perhaps this is one of the most effective mechanisms for synchronizing orbital revolution and axial rotation of close binary stars. Therefore, non-synchronization observed in those close binaries must be a temporary phenomenon triggered by rapid evolution of the component star itself as is suggested by Kopal (1959). But even at the time the two kinds of motion are temporarily out of step, the shape of the component is still given by the S_1 surface according to the present analysis.

Finally, one may question our argument on the ground that it has not proven that the particles are necessarily flying away from the star. If all particles on some surface of a non-synchronously rotating star should tend to move inward, this surface could be regarded as a stable surface for the star. This is however not true because when the particles move inward they collide with other particles. Since the average C value (the C value of each particle being defined by Eq. [12]) of all particles participating in a collision remains constant (Huang 1965) and since directions of the velocities will be modified after the collision, the chance of escape from the surface increases with time whatever are the directions of their initial velocities (in the xyz system). Therefore, our conclusion about the non-synchronously rotating star is valid without qualification for the Roche model.

It is my pleasure to note my thanks to Mr. Clarence Wade, Jr. who has performed the computation involved in obtaining diagrams in Figure 1.

AN INTERPRETATION OF ϵ AURIGAE*

SU-SHU HUANG†

A model of ϵ Aurigae has been proposed in order to explain the contradictory behavior of this star found in photometric and spectroscopic observations. This model which consists of a rotating gaseous disk that appears opaque when viewed edge-on resembles the one we have suggested for β Lyrae (Huang 1963). The success of this simple model to explain these two peculair stars which have defied other interpretations for so long, together with the fact that rotating gaseous rings are frequently associated with the primary component of the Algol-type binary systems (Joy 1942, also Sahade 1960) leads us to a belief that rotating gaseous rings or disks are the result of natural development of gases that are injected into the binary system by its component stars. This belief is further strengthened by our knowledge that such a rotating ring or disk is dynamically or hydro-dynamically feasible (Prendergast 1960, Huang 1964).

I. INTRODUCTION

The binary ϵ Aurigae whose period is 27.1 years—one of the longest among eclipsing systems—gives every indication in its light curve of undergoing periodically total eclipses. But the spectrum of the eclipsed component, a F2 supergiant, can be observed persistently during the totality. These two seemingly irreconcilable phenomena have puzzled astronomers since the turn of the century. A serious attempt to resolve this incompatibility in the observational results may perhaps be traced to a paper by Kuiper, Struve and Strömgren (1937). They proposed an idea of making the huge eclipsing body—referred to as the I component—so tenuous as to be optically transparent to optical light. However, they argued that the ultraviolet radiation of the F-type supergiant would ionize the crescent-like thin layer of the I component that faces the F-type primary. The scattering by free electrons produced by ionization in this layer would then cut down the light from the F-type primary when the I component is in front, producing the phenomenom of eclipse. Since electron-scattering is frequency independent, the opacity in the crescent-like layer reduces the overall flux of the F component but does not change the spectral nature of the light. In this way, they are able to explain the difficulty we have mentioned before.

While this model has indeed resolved the long-standing difficulty, it introduces several new ones of equal, if not more, serious nature. Some of them have been mentioned in a recent work by Struve and Zebergs (1962).

Although the model by Kuiper *et al.* has been criticized, the idea of electron scattering as the cause of eclipse has persisted in the latter models by Struve (1956) and more recently by Hack (1961). This same idea has also strongly influenced the directions in which spectroscopic investigations of the star has been made (Kraft 1954).

Both Struve and Hack models may be regarded as modified versions of the original one by Kuiper *et al.* Struve introduced the idea that both components are surrounded by nebulous gases that fill the respective lobe of the inner contract surface of the system. These nebulous gases are supposed to cause gas streaming from one component to another and vice versa. Struve attributed the apparent splitting of lines observed before and after total eclipse to the presence of these gaseous streams. Except for this, Struve's interpretation of this peculiar system follows the same line of thought as in their previous paper. Consequently, the basic difficulties of eclipse by electron scattering are not removed.

*Published in *The Astrophysical Journal* 141:976, April 1965.

†Goddard Space Flight Center and Catholic University, Washington, D. C.

Hack's model does introduce a new concept. She proposed a hot secondary star of an effective temperature reaching 20,000°K. According to her, it is this hot star that is responsible for the ionization of gases in the shell or ring around it. The phenomenon of eclipse is then attributed to the intervention of this shell or ring between the primary F2 component and the observer.

It is more convincing to have an O or a B star around to do the work of ionization than an F2 star. But the introduction of a hot secondary meets other difficulties as we shall see in the following ways.

The depth of the eclipse during the apparent totality is about 0.8 magnitudes, which corresponds to an optical thickness of 0.74 over the entire spectral frequencies, if we assume that the eclipse is due to obscuration of the entire F component by the shell or ring. It requires 10^{24} of electrons in the column of unit cross-section and of a length equal to the thickness of the shell or ring. Since hydrogen is the dominant constituent, there will be approximately 10^{24} atoms in each column. Now, how could one explain that these atoms in their ionized states do not impress some additional spectroscopic feature on the light that passes through them? With ionizing radiation coming from a star of 20,000°K one would expect to observe spectral lines arising from such atoms as neutral or ionized helium, ionized oxygen, nitrogen, etc. that correspond to those found in the early-type supergiant stars. None have been observed. What have been actually observed, such as doubling and strengthening of lines in certain phases during eclipse, only show that the excitation level of the absorbing medium associated with the eclipsing body is not greatly different from that of the primary F2 atmosphere. Indeed, it has been specifically pointed out in the paper by Kuiper *et al.* that the lines associated with the secondary component and observed during eclipse are approximately, though not identically, the same as the normal lines of the F2 star.

Although it may be argued that compared with the F2 supergiant component, the hot star proposed by Hack is too faint to be seen in the visible region even during eclipse, it is difficult to comprehend why it has not been detected in the ultraviolet region. All these questions impair the otherwise attractive proposal by Hack.

From what has been said before, we cannot help but conclude that in spite of various modifications and refinements made since its inception. the electron scattering theory of the eclipse of ϵ Aurigae cannot explain this binary system in an internally consistent way.

Other theories of eclipse have been suggested in the meantime, but according to Hack (1961), none of them can explain the spectroscopic behavior of the system. However, it should be noted that Kopal's (1955) theory of attributing the opacity to solid particles did introduce a new conception of a ring structure which has been followed by Hack herself.

II. A PROPOSED MODEL

The success of our interpretations of β Lyrae by the introduction of an opaque gaseous disk rotating around its secondary component (Huang 1963) has led us to examine whether the same kind of model may be used for ϵ Aurigae, because in many respects the two peculiar binary systems show a similar behavior. Their similarities are: (1) The light from the primary component can be seen during the entire duration of eclipse while the spectrum of the secondary component itself has never been observed at any phase. (2) Additional lines appear during eclipse. These lines are, in both system, displaced towards the red end before the principal mid-eclipse and towards the violet end after mid-eclipse. (3) Light shows fluctuations, especially during eclipse, and (4) both show emission features.

However, there are also differences between these two systems. In the first place, the magnitudes of wavelength shifts of those additional lines observed during eclipse are different. In the case of β Lyrae, the radial velocities corresponding to the shifts are of the order of 100–300 km/sec, while in the case of ϵ Aurigae the velocities are perhaps of the order of 30–50 km/sec. This difference actually confirms our conviction that the two systems are similar, if we remember that the period of β Lyrae is only about 13 days while that of ϵ Aurigae is about 27.1 years. Thus, for the purpose of a similarity consideration, we must compare the stream velocities in terms of the respective orbital velocities of the component stars. Then the stream velocities in the two systems are of the same order of magnitude.

Another difference between these two systems comes from the fact that β Lyrae shows a secondary eclipse but ϵ Aurigae does not. This difference can be readily explained on the basis of our model of an opaque disk, as we shall see presently.

Figure 1 shows the model we propose for ϵ Aurigae. The obscuration of the primary component by the rotating gaseous disk causes an eclipse which would look, in the light curve, like

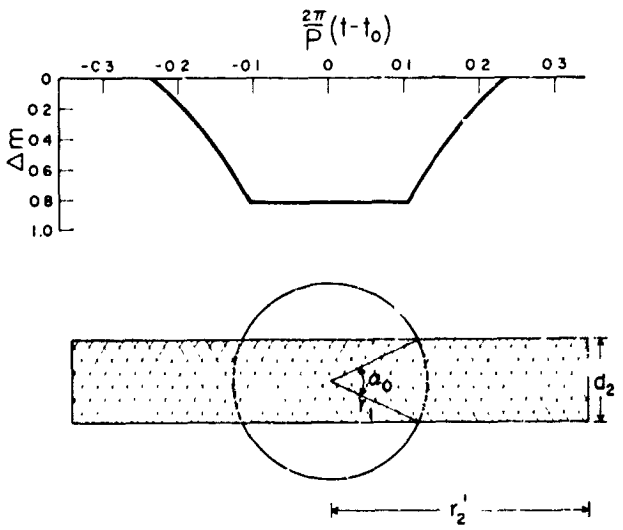

FIGURE 1.—A schematic diagram of our model for ϵ Aurigae and its resulting light curve during eclipse. It is assumed that we observe this sytem edge-on. Consequently, the rotating gaseous disk around the secondary component will appear like a dark rectangle which obscures the primary component during eclipse. The light curve at the top of the figure is derived by assuming a uniform stellar disk.

total but the light from the primary will continuously be seen even at the apparent totality. We suggest that the inclination, i, of this system is very near to 90°. Thus, we see only the edge of the disk; the secondary component itself cannot be seen because it is hidden in the disk. Because of this inclination neither do we receive any radiation from the primary reflected by the disk. As a result there will be no secondary eclipse. On the other hand, we have suggested in the previous paper that β Lyrae has an inclination which differs appreciably from 90° so that we can see the secondary star itself as well as the light reflected by the rotating gaseous disk. Consequently, we are able to observe a secondary eclipse.

Because of the difference in inclination, the shape of minimum differs in these two systems too. In the case of β Lyrae, the projected area of the disk will be an elongated ellipse, resulting in a curved minimum in the light variation. In the case of ϵ Aurigae, the projected area would be a rectangle (as shown in Figure 1), producing a flat minimum.

The sizes of the primary component and the opaque disk may be determined from the light curve. Let us, for the sake of illustration, assume that the stellar disk of the primary component is uniform in brightness and the edge of the disk we actually face is completely dark. We can now determine the radii, denoted respectively by r_1 and r_2' of both the primary component and the disk around the secondary component as well as the thickness of d_2' of the disk. All these quantities will be measured in terms of the mean separation between the two components of the system.

Different investigators gave different values for the duration of eclipse, D, and the of totality, d. We shall follow Plaut's (1950) values $D=0.0760$ and $d=0.340$, which yield after a simple calculation,

$$r_1=0.065 \text{ and } r_2'=0.171. \tag{1}$$

In order to determine d_2' we must use the observed depth of eclipse during the apparent totality. If we denote by α_0 the angle subtended at the center of the primary by the two points of intersection, all projected on the celestial sphere, between the boundary lines of the opaque disk and the primary component during eclipse (see Figure 1), the maximum light L_1 and the minimum light L_2 of the system are related by

$$\frac{L_2}{L_1}=\frac{\pi-\alpha_0-\sin\alpha_0}{\pi} \tag{2}$$

where

$$\sin\left(\frac{\alpha_0}{2}\right)=\frac{1}{2}\frac{d_2'}{r_1} \tag{3}$$

Since the observed depth of minimum is 0.81 mag., equation (2) gives $\alpha_0=0.881$ which in turns yields

$$d_2'=.055 \tag{4}$$

III. INTERPRETATION OF THE LIGHT CURVE

As an illustration that the present model can predict a light curve very much like the one actually observed, we shall consider a central eclipse ($i=90°$) of a uniformly bright stellar disk of the primary component by the dark projection of the rotating disk, shown schematically in Figure 1. If we denote by δ the apparent distance between the center of the primary and the center of the opaque disk and if we let

$$\delta_1=r_1+r_2', \qquad \delta_2=r_1\cos\tfrac{1}{2}\alpha_o+r_2', \qquad (5)$$
$$\delta_3=r_2'-r_1\cos\tfrac{1}{2}\alpha_o, \qquad \delta_4=r_2'=r_1,$$

where r_1, r_2' and α_o have been determined in the previous section, the light curve predicted on this model is given by

$$\frac{L_2}{L_1}=1-\frac{1}{2\pi}(\alpha_1-\sin\alpha_1), \quad \delta_2\leq|\delta|\leq\delta_1 \qquad (6)$$

$$\frac{L_2}{L_1}=1-\frac{1}{2\pi}(\alpha_o-\sin\alpha_o)-\frac{d_2'}{\pi r_1^2}(\delta_2-\delta),$$
$$\delta_3\leq|\delta|\leq\delta_2 \qquad (7)$$

and

$$\frac{L_2}{L_1}=1-\frac{1}{\pi}(\alpha_o+\sin\alpha_o)+\frac{1}{2\pi}(\alpha_2-\sin\alpha_2),$$
$$\delta_4\leq|\delta|\leq\delta_3 \qquad (8)$$

where

$$\cos\frac{1}{2}\alpha_1=1-\frac{\delta_1-\delta}{r_1} \text{ and } \cos\frac{1}{2}\alpha_2=1-\frac{\delta-\delta_4}{r_1}$$

For $o\leqslant|\delta|\leq\delta 4$, L_2/L_1 has already been given in equation (2).

The light curve according to these equations has been computed with the numerical values given by equations (1) and (4) and is plotted at the top of Figure 1. There is a general agreement between this predicted curve and the actually observed one (Güssow 1936).

It may be noted parenthetically that this interpretation of the light curve of ϵ Aurigae requires only that the rotating disk is opaque when viewed along the edge. Whether it is transparent or opaque in its vertical direction, does not matter in our interpretation. Indeed, we have no observational means to ascertain the optical depth in its vertical direction.

As has been pointed out by Fredrick (1960), the light curve shows a slight asymmetry. On the basis of our model, the asymmetry in the light curve reflects either a corresponding asymmetry in the thickness of the rotating disk or an additional absorption by gaseous stream above and below the rotating disk. Physically, it is difficult to envisage a permanent asymmetry in the thickness of the disk. Therefore it is most probable that the asymmetry is caused by the gaseous stream. If we assume that there is a gaseous stream flowing out from the primary component through the Lagrangian point into the secondary lobe of the innermost contact surface (Kuiper 1941), the gaseous stream will circulate around the secondary component above and below the main body of the rotating disk. As the gaseous streams circulate around the secondary component in the same sense as the rotation of the disk, which is in turn supposed to be rotating in the same sense as the binary motion, we would expect that they will gradually coalesce into the disk itself as a result of collisions. It is then not difficult to see that at any moment more gas would be found in the rear side than in the front side of the secondary component, giving rise to an asymmetry in absorption in agreement with the observed result. In this respect the behavior of the gaseous streams outside the main body of the rotating disk resembles closely what has been suggested for β Lyrae, which shows an asymmetric primary eclipse, with the decline steeper than the rise. We have attributed this asymmetry also to obscuration of gases just streaming out from the primary component, this obscuration making the eclipse last longer, and consequently show slower decline than would be the case of intervention of a simple disk. According to this interpretation, the light curves of both ϵ Aurigae and β Lyrae before mid-eclipse are perhaps less distorted by gaseous streams outside the rotating disk than those after mid-eclipse.

Other interesting facts found in this system are, according to Güssow (1936) and Fredrick (1960), that the light fluctuation far away from eclipse does not exceed 0.1 mag., that in 3–5 years before and after eclipse the variation may get as large as, but seldom 0.2 mag. and that in totality, the fluctuation may reach 0.3 mag. or even slightly larger. Such a manner of variations

in light follows also quite naturally from our model. While the intrinsic variation of light far away from eclipse is expected from the supergiant F2 primary itself, the greater fluctuation in light near and during eclipse only indicates the unsteadiness of gaseous streams on both sides of the rotating disk.

IV. INTERPRETATION OF SPECTROSCOPIC RESULTS

That ϵ Aurigae shows an H_α emission has long been known (Adams and Sanford 1930). More recently, Wright and Kushwaha (1958) have made an extensive study of the structure of this H_α line both inside and outside the last eclipse. According to them, the two emission wings are almost equal in intensity outside eclipse. Moreover, the central absorption gives the same radial velocity as the absorption lines of *Fe*II, *Ba*II, and *Y*II in all phases outside eclipse. This result suggests that the material that produces the emission feature moves with the primary.

Moreover, Wright and Kushwaha have found that just before and during ingress the emission wing towards violet is usually stronger than that towards red and during egress, the reverse is true. At the time of totality, the absorption becomes dominant.

The H_α emission is produced by gases moving with the primary component, but we still do not know how they are distributed in space around the primary component. The line profile outside eclipse appears to suggest a rotating gaseous ring like the one observed in many an Algol-type binary system (Joy 1942; also Sahade 1960). However, the behavior of this emission line found in ϵ Aurigae during eclipse differs from what has been observed in the Algol-type variables. In the latter, the emission wing toward violet decreases in strength when the system enters into eclipse, but in ϵ Aurigae, the same wing increases in strength. Similarly, in egress, the two cases show variation in the relative intensity of the two emission wings in opposite directions. Two hypotheses as regards the distribution of emitting gases may be proposed to explain the behavior of H_α emission found in ϵ Aurigae in and out of eclipse. (1) The emission indeed comes from a gaseous ring rotating around the primary but the sense of rotation is opposite to the orbital revolution of components in the system. (2) Emission is produced by expanding gases ejected from the primary component. It is interesting to note that Adams and Sanford (1930) did find that H_α showed then as an emission line with an absorption border on its violet edge, indicating outward motion of gases. Consequently, Beals (See Hack 1961) classified it as a ρ Cygui star.

According to Wright and Kushwaha the weak emission feature that occurs during totality seems to correspond to the velocity of the system and could be due to the tenuous gases enveloping the entire binary.

White the H_α emission mainly comes from gases associated in whatever way with the primary component, the complicated absorption feature of this line observed during eclipse is due to gases spilled above and below the main body of the disk around the secondary component.

It is reasonable to assume that the distribution of gases around the secondary component is not confined to the disk itself. However, for the same reason that the material density in the galactic plane falls off rapidly in the polar directions, the density around the secondary component must also decrease rapidly with the perpendicular distance. At places not too far away from the main body of the disk, the gaseous distribution would be so rare that it is no longer opaque to the continuous radiation but it may still produce line absorption. Therefore, we should expect to observe it through spectroscopic study. Indeed, according to our model, it is this gas distribution that produces the additional absorption that modifies the profile of H_α continuously with phase during eclipse. Thus, during ingress, additional absorption which occurs in the red side of the normal position makes the emission wing toward violet appear stronger than the other. A similar argument leads to the reverse conclusion at the time of egress. During totality the light from the primary passes through a large amount of gases, resulting in a dominantly absorption line as observed. In this way Wright and Kishwaha's results can be satisfactorily explained on the present model.

Because of the appearance of H_α emission in its spectrum, it has been proposed (Wright and Kishwaha 1958) that the excitation might be due

to a hot secondary, since under normal conditions, no emission at H_α appears in the spectra of a star as late as spectral type F of the primary component. As we have seen before, Hack has incorporated this suggestion in her theory in order to explain the ionization of gases in the shell or ring around the secondary. In section I, we have seen that a hot secondary introduces some new difficulties. Now we have found that the H_α emission comes from gaseous distribution associated with the primary instead of the secondary. Hence, the hypothesis of a hot secondary made in order to explain H_α emission becomes even less satisfactory than the case if the emission were associated with the secondary.

If the gases spilled over the disk give rise to absorption that cuts into H_α emission, we would expect during eclipse the appearance of lines belonging to other elements than hydrogen. Indeed, the indication of such an additional absorption long been known. According to Kuiper *et al*, the spectral lines of many elements become asymmetric during ingress by the presence of a strong core on the red side. The degree of asymmetry increases, reaches a maximum at second contact and then diminishes until mid-eclipse when each line becomes symmetric as it is outside eclipse. However, the intensities of lines at mid-eclipse are somewhat stronger than those outside eclipse. After mid-eclipse, the lines become asymmetrical again, but with a strong core on the violet side this time. This asymmetry increases rapidly until it reaches third contact. The asymmetry is obviously due to the presence of a double structure (Adams and Sanford 1930) and indicates the additional line absorption by gases spilled over from the disk. The sense of the Doppler shift of these lines agrees again with what one would expect from gaseous streams rotating in the same sense as the orbital revolution.

In the previous section we have attributed the asymmetry of the light curve also to gaseous streams which are located perhaps closer to the disk than those giving rise to absorption lines. We have suggested that the gaseous streams must be more complicated and extend a larger region in the rear side than in the front side of the secondary. Accordingly, we would expect the structure of absorption lines observed after mid-eclipse to be more complicated than that observed before mid-eclipse. Struve and Pillans' (1957) observational results appear to bear this prediction out. They have found that at the very end of totality, the absorption lines show a remarkable amount of structure not previously observed in the star. Some lines are triple, while others show a double structure, indicating gaseous streams, just coming out from the primary before collision which would have erased the velocity differences of the streams.

V. THE F2 SUPERGIANT ATMOSPHERE, ITS MASS EJECTION AND TURBULENT VELOCITIES

Finally, we may say a few words about the atmosphere of the F2 supergiant primary. Whatever is the mass ratio of the system, it is reasonably certain that the size of the primary component derived in Section II must be small compared with the innermost contact surface (e.g. Kuiper 1941), which will be referred to hereafter as the S_1 surface. Indeed, the light curve outside eclipse does not indicate any distortion due to ellipticity. On the other hand, both spectroscopic and photometric results indicate that mass is continuously flowing out of the primary lobe of the S_1 surface into the secondary lobe. It follows that at the photospheric surface, the star must steadily eject matter to keep the flow of gas from the primary lobe to the secondary lobe of the S_1 surface. Since the photosphere is well below the S_1 surface, the effect of its comparison must be small. Consequently, mass ejection at the stellar surface (i.e. photosphere) must be intrinsic to this F2 supergiant primary and should not be attributed to the interaction within a binary.

Thus, between the photosphere and the corresponding lobe of the S_1 surface, the vast volume must be filled with a tenous atmosphere. Its extension must be several times the stellar radius; through the extended atmosphere the primary is losing its mass. The picture thus derived agrees completely with what Deutsch (1956, 1960) has found in many red giant and supergiant stars and confirms the general belief that a supergiant—whatever is its spectral type—is always ejecting mass.

Violent motions have always been found in atmosphesre of supergiant stars (e.g. Huang and Struve 1960). This is especially true in the primary of ϵ Aurigae (Wright and van Dien 1949;

Hack 1959). However, the nature of the observed motion has never been clearly understood, although frequently but rather vaguely we have attributed it to some kind of prominence activities. With the conception of mass ejection by the supergiant star reasonably established, we can now understand why violent motion should always be associated with its atmosphere. Indeed, the mass ejection from the stellar surface, presumably due to convective currents below, acts as a stirring mechanism of the atmosphere over the photosphere. The ejection creates a velocity field in the atmosphere which also makes the latter very extended.

THE MOTION OF GASEOUS STREAMS IN THE BINARY SYSTEM*

SU-SHU HUANG†

We have studied several problems in connection with the gaseous flow in the close binary system. First, the statistical property of the Jacobian constants of colliding particles in the system is examined and a conversation law for their mean value established. Then the velocity-independent nature of the rate of change in angular momentum of a particle moving in the binary system is pointed out. These properties prompt us to derive for the gaseous flow a set of differential equations that provide a point of view lying in the middle between the orbital approach (which neglects both pressure and collision) and the hydrodynamic approach (which includes both) because our equations take into account the collision but not the pressure. The equations have been solved under the same approximation as Prendergast (1960) has assumed and have been found to yield a similar result as was obtained by him from the hydrodynamic equations.

Because of our emphasis on the Jacobian constant and angular momentum in the treatment of gaseous flow we have called attention to the fact that some combinations of these two physical quantities are incompatible in a certain region of space which we have called the forbidden zone.

Finally, the formation, the evolution and the significance of rotating rings observed in many Algol-type eclipsing binaries are discussed in an effort to understand the mode of ejection of matter from the secondary surface.

I. INTRODUCTION

The problem of gaseous streams observed in some binary systems has been studied theoretically either as individual bodies moving in orbits independently of each other (Kopal 1959, Gould 1959) or as an aerodynamical flow (Prendergast 1960). Both approaches encounter difficulties, though of entirely different nature. In the present paper, we shall call the attention to a few general properties of the motion of gaseous particles in the binary systems, which lead us to a theory that somewhat reconciles these two fundamentally different approaches and thereby makes the flow problem easier to comprehend.

II. STATISTICAL PROPERTY OF THE JACOBIAN CONSTANTS DURING A COLLISION OF PARTICLES

One of the differences between the two approaches mentioned in Section I concerns the collision of particles. While the neglect of this important process makes the orbital approach unrealistic, some results obtained in celestial mechanics of the motion of an infinitesimal body in a gravitational field of two revolving components has its physical significance. This is because of the statistical property of the Jacobian constants that we will discuss in this Section.

Let us assume that the two stars are revolving around each other in circular orbits. This is generally true for close binaries (Struve 1950). Thus, a motion of a particle in such a system is identical to what is treated in the restricted three-body problem in celestial mechanics (e.g., Moulton 1914; Brouwer and Clemence 1961). Following the standard treatment of the problem we shall choose as the unit of length, the separation between the two components, as the unit of mass, the total mass of the two components, and as the unit of time, the perior of the orbital motion of the two components divided by 2π. In such a unit system the gravitational constant is one. Let us now denote by μ the mass of the secondary component. Thus, the mass of the primary will be $1-\mu$. If, furthermore, a rotating coordinate system xyz is

*Published in *The Astrophysical Journal*, 141(1):201–209, January 1, 1965.

†Goddard Space Flight Center and Catholic University, Washington, D. C.

so chosen that its origin is at the center of mass of the two components, its x-axis coincides at all times with the line joining the two components and its z-axis is perpendicular to the orbital plane of the stars, then the coordinates of the primary will be $x_1=-\mu, y_1=o, z_1=o$ and those of the secondary will be $x_2=1-\mu, y_2=o, z_2=o$ in consistency with the adopted unit system.

The equations of motion of the third infinitesimal body in the restricted three-body problem admits an integral, frequently known as the Jacobian integral, as follows:

$$C=2U-(\dot{x}^2+\dot{y}^2+\dot{z}^2) \tag{1}$$

where

$$U=\frac{1}{2}(x^2+y^2)+\frac{1-\mu}{r_1}+\frac{\mu}{r_2} \tag{2}$$

Here r_1 and r_2 are respectively the distances of the infinitesimal body from the primary $(1-\mu)$ and the secondary (μ) component, while (x,y,z) the three vector components of $\vec{r}$, are the coordinates of the infinitesimal body. The dot represents as usual the time derivative. The integration constant C, is known as the Jacobian constant.

We can transform equation (1) into a stationary system. Let us now consider a collision of n particles of mass, $m_i(i=1, 2 \ldots n)$. Since we have particles of atomic sizes, the coordinates may be regarded as the same for all colliding particles at the instant of collision. Moreover, the total kinetic energy of the colliding particles conserves during an elastic collision. It follows from these considerations as well as the definition of C by equation (1) that

$$\sum_{i=1}^{n} m_i C_i' = \sum_{i=1}^{n} m_i C_i \tag{3}$$

where C_i and C_i' are respectively the Jacobian constant of the i-th particle before and after the collision. Thus, if we define an average C, such that

$$<C>\sum_{i=1}^{n} m_i = \sum_{i=1}^{n} m_i C_i, \tag{4}$$

$<C>$ will be an invariant under the physical processes of elastic collisions. However, it may be noted that the dispersion of C's from their average value will in general change after each collision.

For inelastic collisions an equation connecting various C_i and C_i' can always be obtained from the energy consideration if we know the detailed process of the collision. We shall assume in the present paper that the collisions that take place among particles in the binary system are statistically elastic, i.e., endoergic collisions balancing exoergic ones.

As a result of the constancy of $<C>$ during collision, the problem of gaseous flow is considerably simplified because we have now a macroscopic quantity, $<C>$, to deal with instead of following the courses of numerous particles in the system. Thus, the gaseous particles must maintain a constant value of $<C>$ in their stream motion. Indeed, Prendergast (1960) has shown that C is a constant along a stream line. This situation resembles the introduction of the concept of temperature and pressure which simplifies our study of the chaotic motion of molecules in gases in free space. Therefore, whatever is the nature of ejection that occurs on the stellar surface, the mean value of C's of ejected particles and their dispersion serve as two of the most characteristic indices of the mode of ejection as regards the course of their subsequent motion.

It should be noted, however, that although the gaseous particles maintain a constant $<C>$, the mean flow does not follow the orbit derived from the equations of motion of the three-body problem. It is physically obvious that all those loops, cusps, sudden reversal in the direction of motion, and other erratic behavior found in the orbits of the three-body problems must be completely erased by collisions.

III. THE RATE OF CHANGE OF ANGULAR MOMENTUM

The angular momentum (the z-component) per unit mass of the third body with respect to the center of mass of the binary system will be denoted by h. It is given by:

$$h=x^2+y^2+x\frac{dy}{dt}-y\frac{dx}{dt} \tag{5}$$

and varies with time because the third body is continuously interacting with the two revolving component stars.

Although h varies with time, there are two points which make it physically significant. First, the total angular momentum is conserved among the colliding particles if the collision takes place rapidly. Secondly, it can be easily shown from the equations of motions in the restricted three-body problem that

$$\frac{dh}{dt}=\mu(1-\mu)y\left(\frac{1}{r_1^3}-\frac{1}{r_2^3}\right). \tag{6}$$

The significance of equation (6) derives from the fact that $^{dh}/_{dt}$ is a function of coordinates of the third body only, being independent of its velocity. Moreover, it is anti-symmetric with respect to the x-axis and to the line bisecting the separation segment between the two finer bodies. Thus, it vanishes on these two lines. Here we see physically why five Lagrangian points all lie on either of these two lines. It follows that any steady flow in a closed curve must cross either one or both of these lines so that h will recover to its original value after the completion of the circuitous flow. Indeed, this is the case of rotating gaseous rings frequently observed around the primary component in many an Algol-typebinary system (Joy 1942, 1947; also Sahade 1960).

In the three dimensional case, $^{dh}/_{dt}$ vanishes in the XZ plane and in the plane bisecting the line joining the two components. Thus, if we divide space into four regions by these two planes the sign of $^{dh}/_{dt}$ is positive in the two regions and negative in the other two.

IV. GASEOUS FLOW DERIVED FROM THE C AND h CONSIDERATIONS

In the two dimensional case, a knowledge of C and h at every point defines completely the flow pattern. Therefore, a velocity vector field of gaseous motion in a binary system can be defined by two scalar fields of h and C. Since the average values of C and h do not change by collision, we may write

$$\frac{\partial C}{\partial t}+\vec{u}\cdot\nabla C=o \tag{7}$$

from the constancy of C and

$$\frac{\partial h}{\partial t}+\vec{u}\cdot\nabla h=\mu(1-\mu)\left(\frac{1}{r_1^3}-\frac{1}{r_2^3}\right) \tag{8}$$

from equation (6) when we follow the stream lines. In writing these equations where u denotes velocity at points (x, y) we have made an additional assumption that C and h are continuous over the plane. In this way, we have derived two flow equations from the results of celestial mechanics.

By imposing the continuity condition of C and h over space we are able to take advantage of the result derived from celestial mechanics but at the same time to discard as meaningless the seemingly erratic and infinitely varied forms of orbits that one may actually obtain by a straight integration of the equations of motion in the three-body problem. Thus, equations (7) and (8) are proposed here purely from physical arguments of conservation laws in collisions. A mathematical derivation from hydrodynamic equations is given in the Appendix.

Since the pressure is not included in equations (7) and (8), the present formulation of the flow problem lies between the orbital approach (which neglects both pressure and collision) and the bona fide hydrodynamic equations of flow (which include both). Thus, the present treatment is mathematically equivalent to the hydrodynamic approach when the pressure is neglected. In presenting the problem in this manner we gain a better physical insight because both C and h are physical quantities.

Actually an inclusion of pressure would make the problem very difficult. Indeed, Prendergast (1960) who started directly from hydrodynamic equations also neglected the pressure term when he came to the stage of solving the equations. Thus, the equations (7) and (8) should be equivalent to what Prendergast has used, although the basic approach is different.

What we will show in the following is that we can obtain a similar solution as obtained previously by Prendergast. Also by following the present derivation we can see very clearly the conditions under which the solution will be valid.

Following Prendergast, we shall consider the two-dimensional case, neglect the velocity component at right angles to the zero-velocity curves and choose a right-handed orthogonal curvilinear coordinate system (ξ, η, z) where ξ is the label of the zero-velocity curves, namely

$$U=\xi, \tag{9}$$

U is given by equation (2) and η is an angular measure along the zero-velocity curve. If we now denote Q_ξ and Q_η the metric coefficients corresponding to this coordinate system, we can express equations (7) and (8) in this new system as follows:

$$\frac{u_\xi}{Q_\xi}\left[1-\left(u_\xi\frac{\partial u_\xi}{\partial \xi}+u_\eta\frac{\partial u_\eta}{\partial \xi}\right)\right] -\frac{u_\eta}{Q_\eta}\left(u_\xi\frac{\partial u_\xi}{\partial \eta}+u_\eta\frac{\partial u_\eta}{\partial \eta}\right)=o \quad (10)$$

and

$$\frac{u_\xi}{Q_\xi}\left(\frac{\partial r^2}{\partial \xi}+r_\xi\frac{\partial u_\eta}{\partial \xi}+\frac{\partial u_\xi}{\partial \xi}u_\eta-r_\eta\frac{\partial u_\xi}{\partial \xi}-\frac{\partial r_\eta}{\partial \xi}u_\xi\right) +\frac{u_\eta}{Q_\eta}\left(\frac{\partial r^2}{\partial \eta}+r_\xi\frac{\partial u_\eta}{\partial \eta}+\frac{\partial r_\xi}{\partial \eta}u_\eta-r_\eta\frac{\partial u_\xi}{\partial \eta}-\frac{\partial r_\eta}{\partial \eta}u_\xi\right) =\mu(1-\mu)y\left(\frac{1}{r_1^3}-\frac{1}{r_2^3}\right) \quad (11)$$

if we assume a steady state of flow. Here the subscripts ξ and η denote respectively the components of the vector in the ξ and η direction.

If we neglect u_ξ we obtain

$$\frac{\partial u_\eta}{\partial \eta}=o \quad (12)$$

from equation (10) and

$$\frac{u_\eta}{Q_\eta}\frac{\partial r^2}{\partial \eta}+\frac{u_\eta}{Q_\eta}\left(r_\xi\frac{\partial u_\eta}{\partial \eta}+\frac{\partial r_\xi}{\partial \eta}u_\eta\right)=\mu(1-\mu)y\left(\frac{1}{r_1^3}-\frac{1}{r_2^3}\right) \quad (13)$$

from equation (11). Combining equations (12) and (13) we obtain a second degree algebraic equation for u_η

$$\frac{u_\eta}{Q_\eta}\frac{\partial r^2}{\partial \eta}+\frac{u_\eta^2}{Q_\eta}\frac{\partial r_\xi}{\partial \eta}=\mu(1-\mu)y\left(\frac{1}{r_1^3}-\frac{1}{r_2^3}\right) \quad (14)$$

By neglecting u_ξ in one of the two hydrodynamic equations of flow a u_ξ^2 in the other, Prendergast has also obtained and second degree algebraic equation for u_η. While the coefficients in the equation here (which involves $\partial r^2/\partial \eta$ and $\partial r_\xi/\partial \eta$) are completely different from those in Pendergast's equation, (which involves $\partial Q\eta/\partial_\xi$), both results are valid under the same approximation. Now it appears from equation (10) that in order to neglect u_ξ, $\partial u_\eta/\partial \eta$ must be small. This is the condition for the validity of our solution.

Physically we have started by assuming that the flow follows the zero-velocity curves, but once we have found u_η, according to equation (14) we immediately see that u_ξ does not vanish because $\partial u_\eta/\partial \eta$ does not. So the flow cannot exactly follow the zero-velocity curves. Whether we can find a converging field of velocities for this steady state by an iterating process, we do not know. Neither has Prendergast commented on this possibility.

However, near the two finite bodies, the variations of velocity with η is small, so the flow pattern obtained here represents a good approximation. This explains why gaseous rings are frequently observed around the primary component of many an Algol-type eclipsing binary.

In order to complete the analogy of the present calculation with Prendergast's, we may write equation (10) by neglecting u_ξ^2 and higher order terms, as follows

$$u_\xi=\left(\frac{Q_\xi}{Q_\eta}\right)u_\eta^2\frac{\partial u_\eta}{\partial \eta}\left(1-u_\eta\frac{\partial u_\eta}{\partial \xi}\right)^{-1}$$

We can now examine the asymptotic behavior of u_η for small values of r_1 (or similarly of r_2). In the immediate neighborhood of the $1-\mu$ component, we may take the position of this component as the origin and use the polar coordinate system (r_1, φ) where φ is the angle that the radius vector $\vec{r}_1$ makes with the x-axis, being counted, as usual, positive in the counter-clockwise direction from the positive x-axis. The zero-velocity curves in the immediate neighborhood can be approximated by circles. Thus, we have

$$\xi=U\to\frac{1-\mu}{r_1},\ Q_\eta=r_1 \quad (15)$$

and

$$\eta=-\varphi \quad (16)$$

since (ξ,η,z) is a right-handed coordinate system.

It can be easily shown that equation (14) reduces to

$$u_\eta^2-2r_1u_\eta-\frac{1-\mu}{r_1}=o, \quad (17)$$

under the approximation given by equations (15) and (16). We take the negative sign before the square root in the solution of this quadratic equation, because as Prendergast has pointed out, the velocity should vanish if the force vanishes. Retaining the dominant terms, we find the solution for small r_1

$$u_\eta = r_1 - \left(\frac{1-\mu}{r_1}\right)^{\frac{1}{2}}. \tag{18}$$

This asymptotic expression represents the Keplerian velocity in the neighborhood of the $1-\mu$ component in the rotating coordinate system.

In order to study the asymptotic behavior at large distances from both the components, we use the polar coordinates (r, θ) and expand all quantities in terms of $1/r$, θ being now the angle between the radius vector $\vec{r}$ and the x-axis. It can be shown that the angle that the normal to the zero-velocity curve makes with the radius vector $\vec{r}$ decreases as $1/r^5$. Consequently, we may take the radius vector as the normal to the curve as a first approximation for zero-velocity curves at large distances. Similarly, we can show that the radius of curvature may be set equal to r if we neglect terms of $1/r^5$ and higher orders. With these approximations we can easily derive from equation (14)

$$u_\eta = -r, \tag{19}$$

if we remember that in this asymptotic case

$$\eta = \theta. \tag{20}$$

According to equation (19) the gas remains at rest in the stationary frame of reference. Thus, the asymptotic behavior in both cases is, as it should be, identical to what Prendergast has obtained.

The numerical evaluation of u_η is not simple but it can be done. We shall illustrate it by computing values of u_η at those two points in the flow around the $1-\mu$ component where a stream line intersects with the x-axis. At these two points we can take advantage of the simplification arising from the symmetry of the zero-velocity curves with respect to the x-axis.

Let point $A(x_o, o)$ be the one of these points on the right side of the $1-\mu$ component and point $B(x_o, o)$ the one on the other side. Thus, $x_o > -\mu$ at A and $x_o < -\mu$ at B. The relation between x_o, r_1 and r_2 at both A and B can be easily obtained.

Since Q_η denotes the radius of curvature of the zero-velocity curve at A or B then we have in the immediate neighborhood of A or B

$$r^2 = Q_\eta^2 + (x_o \mp Q_\eta)^2 + 2Q_\eta(x_o \mp Q_\eta)\cos\varphi \tag{21}$$

and

$$r_\xi = -Q_\eta - (x_o \mp Q)\eta\cos\varphi, \tag{22}$$

where φ represents the angle which the normal to the zero-velocity curve at any point near A or B makes with the positive x-axis. When two signs appear together, the upper one corresponds to point A and its neighborhood and the lower one points to B and its neighborhood. Again $\eta = -\varphi$ as in the first case of asymptotic expansions. With the aid of equations (21) and (22) we may reduce equation (14) to

$$u_\eta^2 - 2Q_\eta u\eta + kQ_\eta^2 = o \tag{23}$$

where

$$k = \frac{\mu(1-\mu)}{x_o \mp Q_\eta}\left(\frac{1}{r_1^3} - \frac{1}{r_2^3}\right) \tag{24}$$

for point A and B respectively according to whether we take the upper or lower sign in equation (24). The solution of equation (23) is

$$u_\eta = Q_\eta[1 - (1-k)^{\frac{1}{2}}], \tag{25}$$

the minus sign before the parenthesis has been chosen in order to agree with the asymptotic behavior found previously in equation (18). The radius of curvature Q_η can be derived from equation (9). We shall omit its long expression here.

We have computed u_η according to equation (25) for several cases of x_o with $\mu = 0.2$. It appears evident from the results of computations that velocities thus obtained are very near to those found in the periodic orbits which we may obtain either by the numerical process of successive approximation (Huang and Wade 1963) or by the series solution (Huang 1964). In the second and third column of Table 1 we have a few velocities of a particle as it crosses the x-axis obtained by equation (25) and from the periodic solutions respectively. Needless to say, the disagreement in sign between $\dot{y}$ and u_η in one half of

the cases in Table 1 arises purely from the difference in the coordinate system. We should compare only the magnitudes between the second and third column. As would be expected, the agreement between two kinds of computations becomes better and better as we approach more and more to the star. Thus, the gaseous rings found observationally in many binary systems may be regarded equivalently either as a hydrodynamic flow or as motions of particles in a continuous series of periodic orbits that exist around the component.

V. THE FORBIDDEN ZONE

Since our approach to the problem of gaseous flow in the binary system emphasizes the two phvsical quantities C and h, it is interesting to point out that at some points in space, a certain combination of values for these two quantities is incompatible. In other words, with a given value of C and h, sometimes the particle cannot into a certain region of space which we shall call the forbidden zone. It can be easily seen as follows. We may express equations (1) and (5) simply as

$$\dot{x}^2+\dot{y}^2+\dot{z}^2 A, \tag{26}$$

and

$$x\dot{y}-y\dot{x}=B, \tag{27}$$

where A and B are functions of x, y, z, C and h and can be easily found from equations (1) and (5). Now in the (x, y, z) velocity space, equation (26) represents a sphere with the center at the origin and with a radius equal to $A^{1/2}$, while equation (27) represents a plane. It is then obvious that for any given combination of A, B, x, y, z (or equivalently C, h, x, y, z) the two surfaces may or may not intersect with each other. If they do not, no real velocity components (x, y, z) will satisfy both equations. This means that the particle with the given values of C and h cannot reach the point (x, y, z). In other words, the point (x, y, z) lies in the forbidden zone associated with the given C and h values.

The forbidden zone can be easily calculated from the condition that the distance of the origin from the plane given by equation (27) in the velocity place is greater than the radius, $A^{1/2}$ of equation (26). Explicitly, the forbidden zone is given by

$$B^2>A(x^2+y^2) \tag{28}$$

We shall illustrate the forbidden zone only in the x, y plane. It can be obtained by plotting the curve defined by the following equation

$$f(r, \theta)\equiv r^2+r\left[r^2+\frac{2(1-\mu)}{r_1}+\frac{2\mu}{r_2}-C\right]-h=0. \tag{29}$$

where θ which enters into the expression for r_1 and r_2 denotes the angle between the radius vector $\vec{r}$ of the third body and the positive x-axis.

Although h is a physical quantity, it is not a constant of motion in the restricted three-body problem. Consequently, the forbidden zone is not as important as the zero-velocity curves in depicting the motion of particles. However, combined with the property of dh/dt discussed in the previous section, the forbidden zone may serve some useful purpose of excluding certain modes of gaseous flow in the binary system.

Figure 1 illustrates three forbidden zones in the x, y plane for $C=3.5$ and for the three values of h. The areas that include the origin are forbidden to particles having the assumed C and h values. Because of the symmetry with respect to the x-axis, only one half of the zone is drawn in each case. However, the signs of dh/dt are marked in the figure in all four quadrants at the corners.

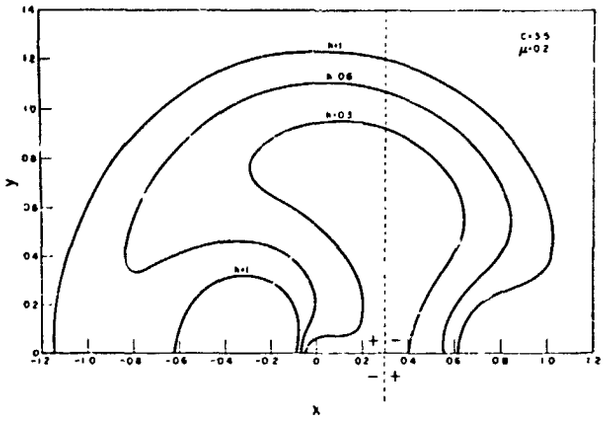

FIGURE 1.—The Forbidden Zone—Particles with given C and h at any instant cannot be found in a certain region of space, called the forbidden zone. Three forbidden zones in the xy plane are illustrated here for three pairs of (C, h). They are (3.5, 1), (3.5, 0.6) and (3.5, 0.3). Because of symmetry with respect to the x-axis, only one-half of each zone is shown here. The forbidden zone corresponding to each of the other two pairs of (C, h) lies inside a single closed curve. The sign of dh/dt is marked at each corner of the four quadrants formed by $x=o$ and $y=0.5$.

VI. SOME REMARKS CONCERNING THE ROTATING GASEOUS RINGS OBSERVED IN THE BINARY SYSTEM

1. The Chance of Ring Formation

Let us denote C_1 and C_2 as the value of C that corresponds respectively to the innermost and outermost contact surface (Kuiper, 1941). The latter will be hereafter called, for the sake of brevity, the S_1 and S_2 surface. Both C_1 and C_2 have been computed by Kopal (e.g. 1959) and Kuiper and Johnson (1956).

According to the result obtained in the restricted three-body problem, those ejected particles whose C values are greater than C_1 cannot penetrate the S_1 surface, and those whose C values are greater than C_2 cannot penetrate the S_2 surface. It follows that those particles whose C values are less than C_2 could escape from the system and those whose C values are larger than C_1 will remain inside the S_1 surface.

The quantity,

$$\Delta C = C_1 - C_2, \tag{30}$$

measures the closeness of the two critical zero-velocity surfaces S_1 and S_2 and may have an important effect on the flow of matter ejected by the secondary component into the primary lobe of the S_1 surface. We do not mean that only those particles with C values between C_1 and C_2 will penetrate into this volume, since any particle with $C<C_1$ can move into it. But the amount of accumulation of matter inside this volume at any given time perhaps increases with the increase of ΔC. It follows from this reasoning that formation of gaseous rings around the primary $(1-\mu)$ component favors large values of μ, as we can easily see, for example, from Kuiper and Johnson's Table, that ΔC increases with μ.

On the other hand, we have pointed out (Huang and Struve, 1956) that from the consideration of available space for their ring formation around primary component, gaseous rings have a better chance to exist in binaries of small μ. From the two arguments we may conclude that perhaps formation of gaseous rings has its highest chance in binaries with μ neither near the maximum end of 0.5 nor near the minimum end of approaching zero. Observationally gaseous rings have been found in binaries with μ around 0.2. While this result agrees with the prediction from the previous simple arguments, it may also be caused by the effect of observational selection, since it is extremely difficult to measure μ when it is much less than 0.1

In passing, it may be noted that following the argument of available space we have predicted a few eclipsing binaries in which gaseous ring may be expected but not yet observationally detected (Huang and Struve, 1956). Among these predicted stars is β Per. (Algol) whose emission feature was later discovered by Struve and Sahade, 1957. While they have concluded that the emission feature does not indicate a ring structure, it nevertheless reveals an accumulation of gases in the system. And the accumulation of gases is a necessary condition for the ring formation.

2. Ring Formation, Mass Dissipation and Ejection Velocities

It is evident from observations that the gaseous particles flowing in the binary system come from the component stars themselves (e.g. Wood 1950; Kopal 1959; Sahade 1960). In fact, it is usually the less massive component that is losing mass. Accordingly, we will assume the injection of particles into the system by the μ component.

Let $\vec{V}$ be the velocity of ejection with respect to that point of the stellar surface from which the

particle is ejected. If the secondary component is rotating axially as a rigid body with an angular velocity $\vec{\omega}$ with respect to a stationary frame of reference, any particle that is attached to the surface rotates with a velocity $\vec{\omega}\times\vec{R}_2$ where $\vec{R}_2$ is the radius vector of a point on the secondary surface from its center. Since the center of the secondary revolves with a unit angular velocity $\vec{k}$ in the z-direction in its orbit, the ejection velocity in the xyz coordinate system is given by

$$\frac{d\vec{r}}{dt}=\vec{V}+(\vec{\omega}-\vec{k})\times\vec{R}_2. \tag{31}$$

In order to compute the C values of ejected particles, we can take advantage of the fact that the surface of the secondary coincides with the secondary lobe of the S_1 surface. Thus, it follows from the equation (1) that

$$C-C_1-\left(\frac{d\vec{r}}{dt}\right)^2 \tag{32}$$

If axial rotation and orbital revolution of the secondary (μ) component are synchronized

$$C=C_1-V^2.$$

While the particles ejected from the secondary component has values always less than C_1 according to equation (32), the C values corresponding to those periodic orbits close to the $1-\mu$ component are greater than C_1. It becomes evident that before the ejected particles accumulate to form gaseous rings close to the primary component, they must have collided one another many times such that C's of some particles have been increased to the necessary values to make the ring formation possible. Because of the conservation law given by equation (3) we may expect that C's of other particles must have been reduced as a result of collisions. Since particles of small C correspond to high velocities, they will easily escape from the system. It can, therefore, be concluded that the formation of gaseous rings of small radii around the primary component must be accompanied by dissipation of mass from the system.

If V should be very large, it would be doubtful whether the velocities of an appreciable amount of particles can be reduced by collisions to make ring formation possible. Therefore, we would suggest that the ejection velocities from the secondary are in general, small if gaseous rings are observed around the primary component. That is why we have classified ejection leading to the ring formation as a slow mode (Huang 1963).

3. Evolution and Physical Significance of Rotating Gaseous Rings

The gaseous rings around the primary component formed by the material from the secondary component cannot be permanent. Because of the tidal friction, the rapidly rotating ring will gradually lose the angular momentum to its original source of orbital motion. As the angular momentum of rotating particles decreases, they fall into the primary. Therefore, without other disturbances, the rotating rings represent only an intermediate step in the transfer of mass from the secondary to the primary component. If the ring will be dissipated easily, its presence can only indicate an active secondary at the epoch of observation.

We know solar surface activities because they provide us with a disk to observe. In the case of stars, little can be learned about their surface conditions because they appear to us as point sources, although eclipsing binaries have revealed some of the secrets of the stellar surface. Now from the observable behavior of gaseous rings we can derive, according to the present idea of ring formation, the mode of ejection of mass from stellar surface. Thus, if the ring can maintain its existence only when matter is continually supplied to it by the secondary component, its fluctuations in intensity or even its disappearance and re-emergence, which have been actually observed (Wyse 1934; Joy 1947; McNamara 1951) can only reflect the manner in which matter from the secondary is ejected.

Rings may disappear when the secondary ceases to eject matter. In this case, their disappearance would be gradual. Rings may also disappear when the secondary suddenly ejects a large number of particles of high velocities. The latter simply sweeps all rotating particles off their orbit. In this case, the disappearance of rings would most likely occur suddenly. Perhaps the fluctuation of light intensity of gaseous rings and sometimes their total disappearance actually observed are due to the second cause.

In any case, from what has been observed of the gaseous rings the ejection of matter from the

stellar surface does not resemble a continuous steady process such as the evaporation from a liquid surface. If there is ever a steady background flow out of the secondary, it is superimposed by intermittent bursts like the prominence activities on the solar surface. Thus, by observing the variation in intensity and structure of the emission lines that are produced by the rotating rings we will be able to learn something about the manner of how a component star loses its mass when its evolutionary stage of expansion brings it to touch the S_1 surface. Since such an empirical knowledge is unlikely to be found elsewhere, the importance of observing gaseous emission in binary systems cannot be exaggerated.

There remains the question whether a rotating ring or disk can be formed around the secondary (less massive) component when the primary component is losing mass. It is obvious that the ring would be less stable around the secondary than around the primary because of a larger perturbation in the first case. Also the available volume for ring formation is smaller in the first than the second case. But there is no a priori reason to believe that rings cannot be formed around the secondary component. However, observationally we have never found a gaseous ring around the secondary component.

Actually we have found few binaries whose more massive component has filled the primary lobe of the S_1 surface while those of less massive components remain small compared with the secondary lobe of the S_1 surface. Therefore, the impending question is not why we have not found any gaseous ring around the less massive component, but rather why systems whose more massive component injects particles into the secondary lobe should be so rare. Presumably, some selection effect plays a role here, but it is unlikely that this is the sole cause.

ACKNOWLEDGMENT

It is my pleasure to note my sincere thanks to Mr. Clarence Wade, Jr. for performing on the IBM 7094 computer some numerical calculations involved in this paper.

APPENDIX

DERIVATION OF EQUATIONS (7)–(8) FROM HYDRODYNAMIC CONSIDERATIONS

Equation (7) has been derived already by Prendergast (1960), while equation (8) can be obtained as follows: if we neglect the pressure term, the hydrodynamic equations in the orbital x–y plane become:

$$\frac{\partial u_x}{\partial t}+u_x\frac{\partial u_x}{\partial x}+u_y\frac{\partial u_x}{\partial y}-2\mu_y=\frac{\partial U}{\partial x} \tag{1}$$

$$\frac{\partial u_y}{\partial t}+u_x\frac{\partial u_y}{\partial x}+u_y\frac{\partial u_y}{\partial y}+2u_x=\frac{\partial U}{\partial y} \tag{2}$$

Multiplying equation (1) by y and equation (2) by x and subtracting the two resulting equations we obtain

$$x\frac{\partial u_y}{\partial t}+x\left(u_x\frac{\partial u_y}{\partial x}+u_y\frac{\partial u_y}{\partial y}\right)+2xu_x-y\frac{\partial u_x}{\partial t}-y\left(u_x\frac{\partial u_x}{\partial x}+u_y\frac{\partial u_x}{\partial y}\right)+2yu_y=x\frac{\partial U}{\partial y}-y\frac{\partial U}{\partial x} \tag{3}$$

Since h may be written now as

$$h=x^2+y^2+xu_y-yu_x, \tag{4}$$

it can be easily shown that equation (3) becomes identical to equation (8) in the main test.

ROTATIONAL BEHAVIOR OF THE MAIN-SEQUENCE STARS AND ITS PLAUSIBLE CONSEQUENCES CONCERNING FORMATION OF PLANETARY SYSTEMS*

SU-SHU HUANG†

A phenomenological theory for the behavior of axial rotation of main-sequence stars is proposed here by considering the effect of braking. It does not specify the physical process of braking but does provide a statistical model by which histograms of observed rotational velocities of stars of different spectral types can be explained in terms of the braking strength. It shows that rotation of all stars including those of O and B type has been braked in various degrees during their course of evolution.

As a result of braking, the stellar angular momentum is transferred outwards to the surrounding nebula that may be regarded as the remnant of star formation. This leads plausibly to the formation around the star of a planetary system from the nebula. If the angular momentum is not further dissipated from the nebula, we can estimate the size of the planetary system and its probability of occurrence. It shows that the size of a planetary system around any star is critically dependent upon the mass in the nebula as compared to that of the star itself.

I. A THEORY FOR EXPLAINING THE OBSERVED DISTRIBUTION OF STELLAR ROTATIONAL VELOCITIES

Axial rotation of the main-sequence stars stops quite abruptly at about F5 (Struve 1930). It has frequently been attributed to the braking effect of various mechanisms reviewed in a previous paper (Huang and Struve 1960). A more efficient braking mechanism than those previously proposed has recently been suggested by Schatzman (1962) as due to mass loss through stellar magnetic activities.

In the present paper we do not intend to discuss the physical process of how the braking of stellar rotation is actually affected. Rather, we will show phenomenologically that the observed distribution of rotational velocities of stars belonging to different spectral types can indeed be understood in terms of braking strengths.

As the result of a statistical study (Struve 1945; Huang and Struve 1954) it has been concluded that the rotational axes show no preference in their directions in space. This indicates that the rotating stars have not acquired their angular momentum from the galactic rotation of the pre-stellar gaseous medium. Instead, their angular momenta must have been derived from a random process, such as collisions of interstellar clouds, turbulence, etc. (Huang and Struve 1954). Consequently, we may expect that the angular momenta per unit mass, h, of stars are originally distributed according to the Maxwellian law. Finally we would like to call attention here to the fact that this observational consequence has not been fully appreciated. Many theoreticians still take the rotational angular momenta of stars as due ultimately to the galactic rotation of the tenuous pre-stellar medium (e.g. Edgeworth 1946; Hoyle 1960).

For a given spectral type the geometrical radius and the radius of gyration do not vary greatly. Hence, we may take the equatorial rotational velocity, v, to be in direct proportion to h. If we set $x = v/v_m$, where v_m denotes the most probable

*Published in The Astrophysical Journal 141: 985, April 1965.

†Goddard Space Flight Center and Catholic University, Washington, D. C.

equatorial rotational velocity, the original distribution of x in a given spectral range should be given by

$$f_o(x) = \frac{4\gamma}{\sqrt{\pi}} x^2 e^{-x^2}, \quad x \leq x_c \tag{1}$$

according to our assumption. Here x_c is the upper limit of rotational velocities because of rotational instability and γ is a numerical factor to normalize the function $f_o(x)$. Now if we assume that the star rotates as a rigid body, x is obviously related to the angular momentum per unit mass, h, of the star as follows:

$$h = Rk^2 v_m x \tag{2}$$

where R is the geometrical radius and Rk the radius of gyration of the star. We may define $h = h_c$ by equation (2) when $x = x_c$. Then interstellar clouds with $h > h_c$ could very possibly lead to the formation of close binary systems. Since at present we are interested mainly in the behavior of the observed distribution at its small-velocity end which is not significantly affected by the high-velocity tail, we shall set, for simplicity of calculation, $x_c > \infty$ and consequently $\gamma = 1$.

As a simple model, we propose that the effect of braking is to reduce h of all stars in a given spectral range by a constant amount, h_1. Define $x = x_1$ when $h = h_1$ is substituted in equation (2). It is then obvious that x_1 measures the degree of braking of axial rotation of the stars within a spectral type, namely, the stronger the braking mechanism, the greater the value of x_1. In this way we are able to obtain the distribution of rotational velocities after the braking mechanism has been applied.

Needless to say, this statistical model is very idealized and represents an extreme case. Most likely h_1 is not a constant even within a spectral sub-type but increases with the original value of h. However, since the observed distribution is not well determined, we do not see any advantage at this moment to build an elaborate model which usually would involve many adjustable parameters. On the other hand, because of this over-simplified model, the quantitative results obtained in this paper represent only a very rough estimate.

If we accept this simplified model, the distribution of equatorial rotational velocities after braking has taken its toll becomes

$$f(x, x_1) = \psi_o(x_1)\delta(x-o) + \frac{4}{\sqrt{\pi}}(x+x_1)^2 e^{-(x+x_1)^2} \tag{3}$$

where

$$\psi(x) = \frac{2}{\sqrt{\pi}}\left(\int_o^x e^{-t^2} dt - x e^{-x^2}\right) \tag{4}$$

and $\delta(x-o)$ denotes the delta function.

If $\varphi(y, x_1)$ denotes the distribution of observed velocities, y, we have (Kuiper 1935; Chandrasekhar and Münch 1950)

$$\varphi(y, x_1) = y \int_y^\infty \frac{f(x, x_1)dx}{x(x^2-y^2)^{\frac{1}{2}}} \tag{5}$$

Substituting equation (3) into equation (5) we obtain

$$\varphi(y, x_1) = \psi_o(x_1).\delta(y-o) + \psi(y, x_1) \tag{6}$$

where

$$\psi(y, x_1) = \frac{4}{\sqrt{\pi}} \int_o^{\pi/2} (y \sec\theta + x_1)^2 e^{-(y \sec\theta + x_1)^2} d\theta \tag{7}$$

The observed distributions are given in the form of histograms, i.e.,

$$\Phi(y, x_1) = \int_{(n-1)\Delta y}^{n\Delta y} \varphi(y, x_1)dy, \qquad \gamma(n-1)\Delta y < y < n\Delta y. \tag{8}$$

In Figure 1 we have shown 11 computed histograms of $\Phi(y, x_1)$ according to equations (5)–(7) for / / values of x_1 (0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 1.0, 1.4, 1.8, 2.6) with $\Delta y = 0.2$. This sequence of histograms illustrates the effect of the braking strength on the distribution of observed rotational velocities of stars in a spectral type. The case $x_1 = 0$ corresponds to that of no braking, while the case $x_1 = 2.6$ leads practically to a complete stop of axial rotation by braking.

These diagrams should be compared with the observed histograms. Unfortunately, as we can see in our previous paper (Huang 1953), the two sets of observed diagrams derived from two uncombinable sets of observational data show slight differences. The two uncombinable sets of observational data are respectively from the three-prism and two-prism spectrograms that have

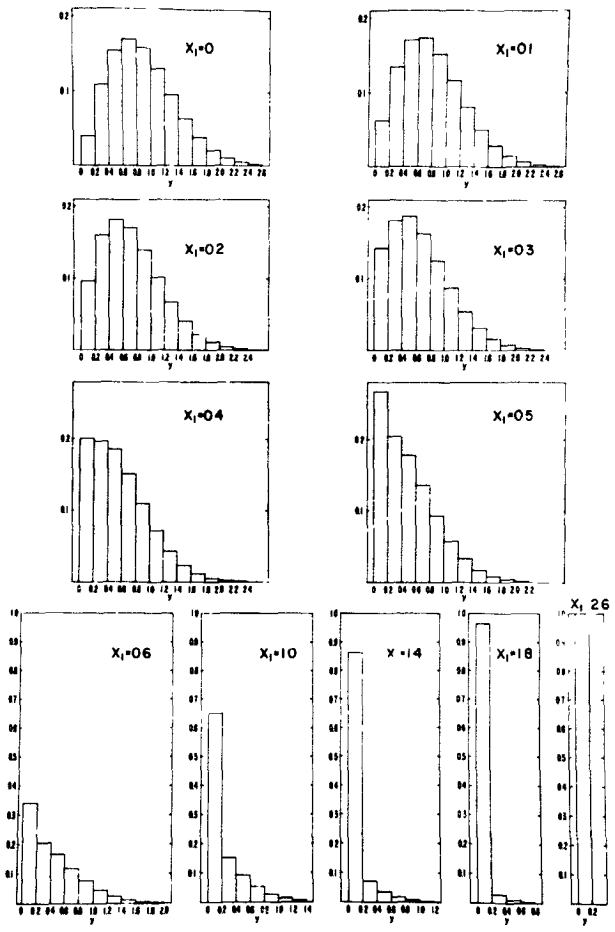

FIGURE 1.—Computed histograms of projected rotational velocities of groups of stars that have suffered different degrees of braking. We have plotted here 11 histograms for 11 values of X, which, according to our model, measures the strength of braking of stellar axial rotation.

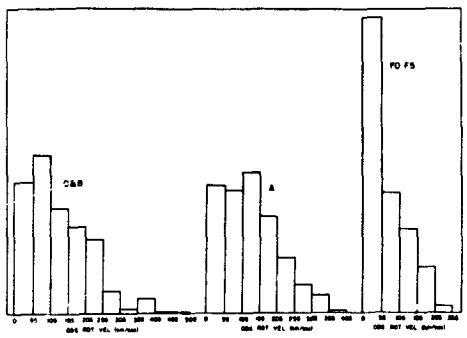

FIGURE 2—.Observed histograms of projected rotational velocities of three groups of stars, O and B, A and F0–F5, taken from a previous paper. The histogram of projected rotational velocities for later type stars will be consisted of only a single column of small velocities. These histograms should be compared with those in Figure 1. The trend of increasing braking strengths from O and B, through A and F0–F5 to later-type stars is unmistakable. From the comparison we may make a rough estimate of x_1 for each of these three groups of stars.

been taken during the years by astronomers at the Lick Observatory. There are 1103 stars for which rotational velocities were measured from three-prism spectrograms and 445 stars for which rotational velocities were measured from two-prism spectrograms. Therefore, the histograms of rotational velocities derived from the three-prism spectrograms are definitely more reliable than those from the two-prism spectrograms from a consideration of both the dispersion and the number of stars studied. For this reason we shall compare the computed histograms in Figure 1 with the observed ones obtained from three-prism histograms, the latter being reproduced here in Figure 2. Finally, it may be noted that there are available better observational data for rotational velocities (Slettebak 1949 et seq.; Cf. Huang and Struve 1960) than what was adopted here. However, our crude measurements of stellar rotational velocities provide the only uniform set of data which cover such a large number of stars that make the histograms in Figure 2 statistically significant.

In Table 1 we give the results of our determination of x_1 and v_m for each of three observed histograms after a comparison with those in Figure 1, x_1 being determined by the shape and v_m by the scales of abscissas of both observed and computed diagrams. It should once more be emphasized that these values are very tentative as both theory and observational data (especially the conversion of measured widths of the spectral line to rotational velocities) are crude. However, there is no doubt at all that x_1 is least (but definitely non-vanishing) for O and B-type stars, increases only slightly for A-type stars and becomes much larger for F0–F5 stars. Since few single stars of spectral types later than F5 are found to be rotating with a measurable velocity, we must conclude that x_1 for these late-type stars is greater than 2.6.

While we cannot determine x_1 accurately because of the uncertainty in observational data, the general behavior does indicate that our simple statistical model for the braking effect represents very well the gradual change of the distribution of observed rotational velocities from O and B through A and F0–F5, and finally to later-type

stars. Especially it explains the long puzzled fact that a large number of O, B, A stars do not rotate appreciably, although their average rotational velocities as group are high.

The previous result induces us to conclude that contrary to our previous belief, braking is not limited only to stars of spectral types later than F5 but extends to O, B, A and early F stars as well. It suggests that along the main sequence all stars show evidence of having been braked. However, the braking mechanism is weak at the upper branch of the main sequence and increases its strength rapidly after F0. It becomes so strong after F5 that rotation of all stars is practically stopped by it.

We have mentioned before that by assuming $x_c \to \infty$ we introduce an approximation. While this approximation does not seriously modify the distribution function at the lower end of observed rotational velocities, it makes an appreciable difference at the upper end. Thus, when we compare histograms (those of $x_1 = 0.3$, 0.4 and 0.8) in Figure 1 with those in Figure 2, we can immediately see a systematic difference arising from this approximation, since in all three histograms obtained from observed data, the distribution function drops much more rapidly than what have been calculated on the assumption of $x_1 \to \infty$. Thus, a cut-off of rotational velocities at their upper end is evident in all three cases in Figure 2. This shows that rotational instability has played a role not only in O- and B-type stars but also in F- and perhaps even later-type stars sometime during the course of their evolution. This result may be significant to our search of clues for star formation.

The strength of braking varies with the moment of braking force and the duration in which braking acts. If indeed the braking is due to magnetic activities which are in turn induced by convection and rotation itself in the early phase of the star's evolution as Schatzman (1962) has suggested, we would expect from the present study that magnetic activities have occurred in stars of all masses in their early phases of evolution, differing only in the strength and duration of such activities. This conclusion is in agreement with Pvoeda's (1964) interpretation of flare stars based on Hayashi's (1961) results of evolution on one hand and Fowler, Greenstein and Hoyle's (1962) theory of formation of light elements—Li, Be, B—in the early phase of the solar system on the other.

Thus far, we have followed the reasoning of both Schatzman and Poveda that the magnetic field is generated in the star as a result of convective motion and differential rotation. However, it may be noted that it would not modify our conclusion if we assume that the strong magnetic field is derived from accretion of interstellar magnetic lines of force during the period of star formation. If so, the strong magnetic activities in the early phase would represent the dissipation because of convection, of magnetic energy that is already there.

II. PROBABILITY OF FORMATION OF PLANETARY SYSTEMS AROUND STARS

It has often been suggested (e.g. Huang 1959) that the disappearance of rotation after F5 may indicate the emergence of planetary systems because it is difficult to understand how the original distribution of angular momenta of the late-type stars should be so radically different from that of early ones. This is especially true if we follow the reasoning in the previous section where the original distribution of angular momenta per unit mass of stars is assumed to follow the Maxwellian distribution (which may be truncated at the high-value end because of rotational instability). Indeed, if angular momenta that have been dissipated from the stars remain in their neighborhood, formation of planetary systems would appear inevitable. Following this line of reasoning we shall make in this section an estimate, though a very crude one, not only of the probability among single stars that will possess planetary systems but also of their general behavior with respect to the spectral type of their parent stars.

Before we shall understand why our planetary system was formed in a state as it is, we are not expected to derive, simply from a consideration of the angular momentum, the detailed structure of planetary systems around stars. In order to obtain a general behavior of any planetary system around a star without going into the detail structure we may define the concept of an "equivalent planet," which is a fictitious planet that would be moving in a circular orbit with an angular momentum per unit mass, h', equal to the average value

of the entire mass outside of, but belonging to, the star. Thus, in the case of our solar system, we have (Allen 1955) the total angular momentum of the planetary system equal to 3.15 x 10^{50} gm cm^2/sec, while its total mass is 2.68 x 10^{30} gm. Consequently, its h', denoted hereafter by h_s' is

$$h_s = 1.176 \times 10^{20} \text{ cm}^2/\text{sec}. \tag{9}$$

Then it is easy to find that the equivalent planet of our own planetary system is located at a distance

$$a_s = 1.042 \times 10^{14} \text{ cm} \tag{.10}$$

from the sun (i.e. between Jupiter and Saturn as would be expected) and revolves with a linear velocity

$$V_s = 11.3 \text{ } km/\text{sec}. \tag{11}$$

around the sun. It is obvious from our definition of the equivalent planet that it does give us a measure of the extent of any planetary system although it conveys no idea about its total mass and mass distribution in the system.

Let us now assume that the gaseous remnant around a star after its formation is m and the mass, radius and radius of gyration of the star itself are respectively M, R, and Rk. Therefore, the total angular momentum of the star is

$$\Omega(v) = MRk^2v \tag{12}$$

After braking, all of its angular momentum is transported into the surrounding medium (of mass m) according to our theory if $v \leq v_1 (= x_1 v_m)$ and a constant part (equal to $\Omega_1 = MRk^2 v_m x_1$ of it is transported out if $v > v_1$. However, we should realize that the angular momentum in the nebula that will evolve to become a planetary system could be different from what has been fed into it by the star, because some angular momentum, say $\vec{\Omega}_0$, may be originally associated with it and has never gone into the star. Since both the star and its surrounding nebula are supposed to have been formed from the same interstellar medium, we may reasonably assume that the vector, $\vec{\Omega}_0$, points to the same direction as the stellar angular momentum does. Hence, we can consider their magnitudes only and the angular momentum associated with the nebula (of mass m) after the completion of braking process has the following value:

$$\begin{aligned} \Omega(x) &= MRk^2 v_m x + \Omega_0 \text{ for stars with } x \leq x_1 \\ &= MRk^2 v_m x_1 + \Omega_0 \equiv \Omega_1 \text{ for stars with } x > x_1 \end{aligned} \tag{13}$$

For stars with slow rotation which indicates smallness of h of the pre-stellar medium, Ω_0 must be small and may be neglected. However, for stars of rapid rotation and especially for those which have passed through the stage of rotational instability in the course of their evolution, h of the prestellar medium must be large and Ω_0 large too.

If we include the possibility that a part of the angular momentum in the nebula may be dissipated away (for example through the loss of mass), Ω_0 may be even negative. Thus, Ω_0 cannot be estimated from the present consideration. However, as we shall see, this uncertainty can be formally circumvented in the following calculation.

Since

$$h' = \frac{\Omega}{m} = (GMa)^{\frac{1}{2}}, \tag{14}$$

where a is the radius of the equivalent planet's orbit around a star and

$$h_s' = a_s V_s = (GM_\odot a_s)^{\frac{1}{2}} \tag{15}$$

for the planetary system of the sun, we may introduce a new variable

$$\xi = \left(\frac{Ma}{M_\odot a_s}\right)^{\frac{1}{2}} \tag{16}$$

to measure the size of the equivalent planet's orbit around any star. It follows from equations (13)–(16) that ξ extends from

$$\xi_0 = \frac{\Omega_0}{ma_s V_s} \quad \text{to} \quad \xi_1 = \frac{\Omega_1}{ma_s V_s} \tag{17}$$

if Ω_0 is positive and zero to ξ_1, if Ω_0 is negative. Therefore, the lower and upper limit of the radius of the equivalent planet's orbit denoted respectively by a_0 and a_1 are given by

$$\xi_0 = \left(\frac{Ma_0}{M_\odot a_s}\right)^{\frac{1}{2}} \quad \text{and} \quad \xi_1 = \left(\frac{Ma_1}{M_\odot a_s}\right)^{\frac{1}{2}} \tag{18}$$

Now x and ξ are related by

$$x=\lambda\xi-\frac{\Omega_o}{MRk^2v_m} \tag{19}$$

where

$$\lambda=\frac{m}{M}\frac{a_s}{R}\frac{V_s}{v_m}\frac{1}{k^2} \tag{20}$$

It is easy to derive from equations (1) and (19) that the distribution function $\delta(\xi)$ with respect to ξ.

If we further let

$$t=\xi-\frac{\Omega_o}{ma_sV_s} \tag{21}$$

and

$$t_1=\xi_1-\frac{\Omega_o}{ma_sV_s}=\frac{x_1}{\lambda} \tag{22}$$

we obtain from $\delta(\xi)$ that

$$g\left(t+\frac{\Omega_o}{ma_sV_s}\right)=\frac{4}{\sqrt{\pi}}\lambda^3t^2e^{-\lambda^2t^2}\delta(t-t_1)[1-\psi_o(x_1)] \tag{23}$$

Since from t to ξ it involves only a horizontal translation, the shape of the distribution function does not depend upon Ω_0. If Ω_0 is positive, we simply translate the entire curve to the right, thereby increasing systematically the size of the expected orbits. If Ω_0 is negative, we translate the curve to the left and set the probability to zero everywhere that is on the left side of the origin. In this way we are able *formally* to take into account any value of Ω_0. Physically, however, we should remember that Ω_0 likely varies from case to case and moreover we do not know how it does vary (say, with respect to M, h, m, h^1, etc.). Hence, it is one of the uncertain factors that prevent us to derive the probability of occurrence of a planetary system of a given size.

Since we can obtain easily the distribution with respect to ξ from that with respect to t, we shall consider hereafter only the latter which, as we see from equation (24), depends upon two parameters, λ and t^1 or equivalently λ and x, because of equation (23). While x_1 has been determined from observed data, t, involves an unknown parameter, namely m/M.

From the values of x_1 and v_m in Table 1 we can compute t_1 (or λ) for each of the three cases given there. We shall use the mean radius $R/R_\odot=3.9$ and mean mass $M/M_\odot=5.9$ for O and B stars, $R/R_\odot=1.74$ and $M/M_\odot=2$ for A stars and $R/R_\odot=1.35$ and $M/M_\odot=1.4$ for F0–F5 stars. In all cases we adapt $k^2=0.05$. Then it follows from Table 1 and equations (20) and (23) that mt_1/M

TABLE 1.—*Values of x_1 and v_m determined from a Comparison and Observed and Calculated Histograms of Rotational Velocities*

Sp. Type	x_1	v_m(km/sec)
O and B	0.3	~200
A	0.4	~200
F0–F5	0.8	~200
later than F5	>-2.6	----------

is equal to 6.9×10^{-4} for O and B stars, equal to 4.1×10^{-4} for A stars, and equal to 6.4×10^{-4} for F0–F5 stars. It is quite evident that the error involved in the determination of x_1 and v_m is much greater than the differences we have found in these three expressions of t_1. Consequently, we may roughly set

$$t_1=6\times10^{-4}\frac{M}{m} \tag{24}$$

as representing all stars from 0 to F5. If $=0$, equation (24), when combined with equations (17), (18) and (23), gives

$$\frac{a_1}{a_s}=(6\times10^{-4})^2\frac{MM_\odot}{m^2} \tag{25}$$

which states that the maximum size of the planetary system is directly proportional to the mass of its parent star and inversely proportional to the square of its total mass. It should be noted that the numerical coefficient in equation (24) does not apply to stars later than F5 for which we do not have any observed data for making the calculation.

We have seen how critically does the size of a planetary system depend upon the mass in the

nebula. A further complication is the dissipation of mass in the nebula and accompanying dissipation of angular momentum before the formation of a planetary system of finite bodies. The difficulty of this point can be seen from the fact that even in our own planetary system there is no consensus concerning the amount of mass in the solar nebula in the beginning, as som einvestigators advocate a value of $m/M=0.1$ while others use considerably smaller values.

Since the actual size of any planetary system must be equal to or less than the upper limit, we have for our own planetary system $a_1 \geq a_s$. It then follows from equations (17) and (18) that

$$\frac{m}{M_\odot} \leq \frac{\Omega_o}{a_s V_s M_\odot} + \left(\frac{R_\odot}{a_s}\frac{v_m}{V_s}k^2\right)x_1 \qquad (26)$$

The ratio m/M for the solar system at present is equal to 1.3×10^{-3}. In the early days it must be much greater than this value. If we now take v_m to be the same as that determined in Table 1 (200 Km/sec), we have

$$\frac{R_\odot}{a_s}\frac{v_m}{V_s}k^2 = 5.9\times10^{-4} \qquad (27)$$

Therefore, it follows from equation (26) that if $\Omega_0=0$, $x_1>2.2$. Equation (1) shows that the probability of having $x>2.2$ is rather small. This would put our planetary system as an unusual case, namely its chance of occurrence is small. The other alternative is that Ω_0 is appreciable. This means that a significant portion of the angular momentum that is now found in our planetary system has never belonged to the sun. The present consideration cannot decide which alternative is the more plausible one.

Thus, we have seen many uncertainties concerning planetary systems around the stars in general. They cannot be resolved for the time being. What we can predict from the present simple theory is that the size of a planetary system increases with a decrease of its total mass and that the distribution of sizes (measured by ξ of the equivalent planet's orbit) behaves like a Maxwellian distribution of velocity magnitudes at the lower end and is truncated at the upper end. For O, B and A stars the truncation occurs at relatively small values. Therefore unless Ω_0 has a large variation among individual systems, their sizes do not vary greatly from one to the other. Most of them are crowded at the upper limit. The truncation of systems around F-type stars occurs at relatively larger values. Consequently, the spread of sizes is also larger, although there is still an appreciable number of them at the upper limit of their size. On the other hand, the sizes of planetary systems around late-type (later than F) stars are expected to be distributed like a complete Maxwellian curve with a wide spread of values. They should not show the tendency to accumulate at any particular size like systems around early-type stars do. All these consequences would be modified if Ω_0 varies greatly from one system to another; in such cases the distribution of planetary sizes can be derived only when we know the variation of Ω_0.

Finally, we would like to ask if it is possible that there is no mass left after the actual processes of star formation (i.e., $m=0$). In that case no planet would be formed. Indeed from the point of view of star formation we do not have any compelling reason to assure us that there must be some mass left behind to form planets after the star itself is formed. On the other hand, the rotational behavior of stars does suggest that there must be some mass left behind since axial rotation could not be effectively braked without the presence of such mass around the star, although we cannot at present estimate the amount of mass that is there. It is therefore the main point of this paper, if nothing else, to show the behavior of axial rotation of stars indicates the high probability of occurrence of planetary systems around stars.

The present paper perhaps represents the first serious attempt to link the problem of occurrence of planetary systems in the stellar universe with some observational facts. The uncertainties in both theory and observation force us to adapt an over-simplified model. Thus, it should be regarded as a pioneer exploration of a nebulous field of learning rather than a legitimate treatment of something that is clearly understood. As a result we emphasize only the qualitative conclusions that have been derived here.

It is my pleasure to express my thanks to Mr. Clarence Wade, Jr. for the numerical integrals in equations (7) and (8) on the IBM 7094 digital computer at Goddard.

SEQUENCE OF EVENTS IN THE EARLY PHASE OF THE SOLAR SYSTEM*

SU-SHU HUANG†

The purpose of this note is to construct a sequence of events in the early phase of the solar system by bringing together several recent theories in different fields of learning. First we show that these theories are mutually salutary. Thus, when we put them together, a reasonably clear picture of the formation of the planetary system emerges.

In a recent investigation by Fowler, Greenstein and Hoyle (1) (2), it has been assumed that there was strong magnetic activities on the surface of the primeval sun. The light elements, lithium, beryllium and boron were then produced according to them by spallation processes when high-energy particles (mainly protons), which had been accelerated by the electromagnetic force on the solar surface, bombarded the dense material in the solar nebula. Furthermore, they have concluded from observed fact that at the time of being bombarded the planetesimals in the solar nebula must be on the average of 12 meters in radius if their shape was spherical.

In the meantime Hayashi (3) (4) has shown that the premain sequence stars must be in a convective equilibrium. He and his associates have calculated evolutionary tracks in the H-R diagram for these stars of several masses including the solar mass. Their results differ from the previous model based on the radiative equilibrium (5) (6) by the high luminosities in the early phase of the evolution before the main sequence.

In a paper by Faulkner, Griffiths and Hoyle (7), a question as regards the consistency between Fowler's and Hayashi's theory has been raised, because in Fowler's theory, it is required that the temperature in the solar nebula must be low—a requirement that appears to contradict the high luminosity obtained by Hayashi. However, in a recent article (8) we have argued that the temperature in the solar nebula can be low even when the luminosity of the primeval sun is high if the solar nebula is opaque enough in the directions in the plane of disk (9) (10). Since the charged particles which follow the magnetic lines do not necessarily travel in the plane of disk, the high density in the disk does not prevent charged particles to bombard the planetesimals in the disk.

More recently, Poveda (11) has presented a theory of flare stars. The success of his theory for explaining the location of these stars in the H-R diagram indicates the sound reasoning of his arguments. Now, if we follow the same reasoning as he does in his investigation of flare stars, we can immediately conclude that not only Hayashi's theory presents no difficulty to Fowler's theory, but the two are mutually conducive. In order to see this point, we have to describe briefly Poveda's theory.

The flare stars show very rapid and non-periodic change in brightness (12). They are always dwarfs stars of late spectral types. It has long been suggested that the flare stars obtain their variations of luminosity in a similar manner as the solar flares do (13) (14). Since it is generally known that solar flares are a result of magnetic activities which are in turn caused by convective motion and differential rotation (15), Poveda argues that flares must be very active when stars are undergoing evolution where convection dominates. From the calculated results of Hayashi and his associates (4), Poveda is able to plot a

*Published in *the Astronomical Society of the Pacific* 77:42, February 1965.

†Goddard Space Flight Center and Catholic University, Washington, D.C.

curve in the H-R diagram on which convection stops to be a dominant factor. Thus the flare stars should all lie on that side of the curve where convection dominates and none on the other side. Indeed, that is just what has been observed.

Then we have Schatzman's theory (16) of braking axial rotation of stars due to magnetic activities. Schatzman also invokes convective motion in the early phase of stars as the cause for magnetic activities and thereby explains why axial rotation of the main-sequence stars stops at about F5 (17). In the case of the solar system, it is very difficult to understand the present distribution of angular momentum with its high concentration in major planets as representing the original state. Schatzman's theory provides an effective mechanism for braking the rotation of the primeval sun.

Thus, we have seen three theories (Fowler's, Poveda's and Schatzman's) which predict results in agreement with observed facts and at the same time all consistently require intensive magnetic activities in the primeval sun and one theory (Hayashi's) which satisfactorily explains the loci of new stars in the H-R diagram and, at the same time, provides the clue why there should be intense magnetic activities. All these four theories not only predict observed phenomena but also have strong theoretical base. Hence, the appearance of magnetic activities in the primeval sun may be regarded as an established fact.

It follows that we should inquire whether there are indeed magnetic activities in *T* Tauri stars and flare stars that are now evolving toward the main sequence. It appears that no such stars are on the list of magnetic stars discovered by Babcock (18). However, it should be noted that the magnetic field of a star has a good chance to be discovered only when it is systematic like that of a dipole field. When the magnetic activities in stars are chaotic as are envisaged by the previous theories, the lines of force are oriented at random. Hence, they are difficult to be discovered by polarization measurements.

Hayashi and his associates (4) have given the time at which the primeval sun stopped to be completely convective to be less than 10^6 years from the time of its initial condensation and the time at which the "hydrogen burning" began to be about 25×10^6 years. If we follow Poveda that the solar surface activities of the primeval sun became reduced to the present level when the evolutionary track based on the convective model meets that of the radiative model, the time of intensive magnetic activities proposed by Fowler and others would be confined to the first 8×10^6 years of the formation of the system. This is the time that has generally been accepted as the gravitationally contracting time of the sun (1). If the intensive magnetic activities occurred only when the sun was completely convective, the formation of planetesimals of an average radius of 12 meters must have taken place in the first 10^6 years after the sun attended hydrostatic equilibrium. It is conceivable that the magnetic activities were more intense at the very early stage when the luminosity was high and convection complete than at later stages. If so, we may indeed expect that the formation of the planetesimals occurred in the first few 10^6 years.

Another supporting fact for the shorter time scale for the formation of planetesimals comes from a recent study by Hunger (19), who claims that contrary to the previous understanding (20) (21), T Tauri stars do not rotate rapidly because he has found many sharp stellar lines in three of these stars. He attributes the broad features previously believed to be due to axial rotation now to the blending of lines. It follows from his conclusion that axial rotation has already been reduced by magnetic braking before the evolving star becomes a T Tauri star.

We can now reconstruct the sequence of events in the early phase of the solar system from the previous and other theories. The early phase of evolution of the sun (or for that matter, any star) has often been divided into two stages: (1) the condensing or collapsing stage characterized by hydrodynamic inflow of matter and (2) the stellar stage characterized by hydrostatic equilibrium. According to recent studies (22) (23), the first stage is catastrophic if we neglect the effect of angular momentum and magnetic field. Gaustad (23) gives a time scale of 5×10^5 years for complete free-fall from interstellar densities to stellar conditions. The presence of a net angular momentum in the cloud prolongs somewhat the time of collapse. But from a consideration of the average angular momentum of the entire solar system observed at present we find that the effect of angular momentum on the time scale is small. Hence,

we may take one half to one million years as the time that the sun underwent the first stage. The time scale of the second stage follows results given by Hayashi and his associates (4).

The early phase of evolution of the planetary system can be divided into two corresponding stages. The transition occurred when the evolution of the sun itself was at its second stage.

As masses were falling into the protosun, accumulation of mass by direct capture of non-volatile matter (24) (25) (26) to form small local condensations far away from the primeval sun took place in what may be regarded as the primeval solar nebula which was then distributed in a spherical symmetry with respect to the sun. We may regard it as the outermost layers of infalling material at low temperatures.

According to a recent investigation by Donn and Sears (27), the particles first formed in the solar nebula are expected to be filaments and thin platelets which they call whiskers. When the whiskers are collected together they form loosely compacted instead of solidly packed condensations. Thus, the condensations in the solar nebula would have a structure resembling the lint-balls under beds or balls made of tumbleweeds that roll in the wind over the prairie under the fall sky.

Regarding the mass of these local condensations we may take the clue from Fowler's planetesimals which may be estimated from their radii to be 10^{10} gm on the average. For various reasons, a density of 10^{-9} gm/cm^3 has often been assumed for the flattened solar nebula. With this density the rate of growth of condensations by direct accumulation of mass can be calculated (24) (25). It grows about 1 cm in radius in ⅓ to 30 years, independent of the size of the body itself (25). In the spherical distribution before flattening, the density must be less than 10^{-9} (say 10^{-11} to 10^{-13}) and the rate of growth would be correspondingly slower. However, it may be noted that the previous rate was obtained (25) by assuming that the accumulating body is solidly packed. For the porus body the rate of growth in radius is faster by a factor inversely proportional to the ratio of the over-all density to the mass density of the porus body. Thus, we estimate the time of formation of condensations of mass comparable to Fowler's planetesimals to be about 10^6 years. The formation took place when the solar nebula was spherical distributed. This time scale is consistent with the time scale of solar evolution. It also agrees with the fact that the orbits of comets now observed are randomly oriented, indicating that the local condensations took place when the solar nebula was still spherical.

When strong magnetic activities appeared in the sun in its second stage of evolution before reaching the main sequence, the transfer of angular momentum from the sun to the solar nebula induced inevitably the collapse of the solar nebula from a spherical distribution to a disk one. This marks the transition of the evolution of the solar nebula from the first to the second stage. Therefore, the transition from the first stage to the second stage for the sun and that for the solar nebula are not supposed to occur at the same time but differ by an interval which covers the time for developing strong magnetic fields in the sun from hydrodynamic motion and for transporting angular momentum outward.

The local condensations might be temporarily heated up and perhaps melt during the collapse, or a rapid accumulation of matter in the process might fill their porus matrix. In any case the local condensations must have lost their porus nature and became planetesimals that Fowler envisaged when they were settled down in the rotating disk to be bombarded by high-energy particles from the sun. The collapse of the solar nebula from a spherical to a disk distribution being about 100 years if the nebula extended not far beyond Pluto's orbit, we may regard that these planetesimals received all their dosage of bombardment when they were already in the rotating disk.

The solar nebula has a life time of 2×10^8 years (25). Therefore, the formation of planets from the planetesimals must have taken place in a time scale less than this value. By considering first direct capture and then gravitational accretion, Kuiper (25) has found that this time scale is only barely enough to form planets. However, we are inclined to suggest that the formation of planets from planetesimals may take a much shorter time than this. Our reasoning rests on the fact that the planetesimals are gravitationally unstable. One can easily visualize this instability by imagining a large number of planetesimals floating in

space. A slight increase in density at one point (due to statistical fluctuations) will easily cause a rapid inflow of these bodies to that point, thereby producing a condensation of the planet size. If so, the time of formation is simply the free-falling time. Since the free falling started from a density of 10^{-9} which is more than 10^{10} times the interstellar density, the free-falling condensation of proto-planets would take only a few years.

Two points should be noted here however. First, this kind of gravitational instability is not what is known as Jeans instability which applies to a gaseous medium (28). Secondly, the present instability would be damped when gas and dust are present together with planetesimals. Therefore, it might take a longer time to form major planets. In any case, it is very likely that when the sun reached the main sequence stage (i.e., when energy dissipated is completely balanced by energy produced by thermonuclear reactions of converting hydrogen into helium), the solar system was practically in the same state as it is now found.

We now propose that because of the difficulty of transporting angular momentum to great distances, the collapse of the solar nebula into a disk occurred only in the solar neighborhood, perhaps not far beyond the orbit of Pluto. Local condensations within this limit must all have fallen into the disk. For even if they survived the initial collapse, their later crossings of the disk, which reduce their vertical velocity component, would force them to follow the general motion of gas and dust in the disk.

The local condensations contained in that part of the spherical distribution that did not undergo the collapse continued their accretion of matter by direct capture until the remnant of the solar nebula was completely dissipated. We have mentioned that at the time of formation of the disk, the local condensations had an average mass of about 10^{10} gm each. Further accretions made these condensations to reach the comet masses of $10^{15}-10^{17}$ gm each. Since these condensations have not suffered catastrophic collapse and have remained far away from the sun all the time, they maintain the porous nature till today as comet nuclei (29).

It follows from the above considerations that comets must have been much more numerous in the early days of the solar system, because there was a large volume (corresponding to the uncollapsed portion of the solar nebula) which contained these cometary nuclei. Gradually, however, the cometary nuclei were perturbed by planets either to the vicinity of the sun and were then disintegrated or to large distances from the sun and were thereby survived. The latter forms the reservoir of comets at large distances from the sun from which the present observable comets come as a result of stellar perturbation. Except by putting the original formation beyond the orbit of Jupiter, the present picture follows what has been proposed by Oort (30).

We have seen that events in the early phase of the solar system formed a natural sequence one necessarily leading to the next. Consequently, we have now good reasons to expect that the existence of planetary systems around main-sequence stars, especially of spectral type later than F5 where axial rotation stops, must be common in the universe as has been heuristically suggested before (31).

It is a pleasure to acknowledge my sincere thanks to Dr. A. Poveda for letting me read his paper before publication. It is his paper that induced me to prepare this note.

PLASMA NEUTRINO EMISSION FROM A HOT, DENSE ELECTRON GAS*

CULLEN L. INMAN† AND MALVIN A. RUDERMAN‡

Neutrino pair emission from coherent electrone excitations (transverse plasmons) in a hot, dense stellar plasma is calculated for a regime of temperatures and densities relevant to stellar evolution. Detailed numerical results are presented for temperatures in the range 4×10^7–5×10^8 °K and densities in the range 10^4–10^8 gm/cm³.

I. INTRODUCTION

A coupling of electron and neutrino pairs is implied by almost all models which describe the weak Fermi interactions of elementary particles. Although there has not yet been any direct experimental detection of such an electron-neutrino coupling, it is a necessary consequence of the apparent existence (Brookhaven 1963) of an intermediate heavy charged boson in β-decay. Moreover the form and magnitude of the resulting electron-neutrino interaction are unambiguously determined. The strength of the coupling is characterized by the small Fermi constant

$$g\sim3.08\sim10^{-12}\frac{\hbar^3}{m_e{}^2c},$$

where m_e is the electron mass; its form is analogous to the interaction of electromagnetic radiation with the electron current. An accelerated electron can then radiate a neutrino (ν)–antineutrino ($\bar{\nu}$) pair with the same matrix element as that for electromagnetic radiation but with greatly reduced probability. For example in an atomic transition of energy E the probability $R_{\nu\bar{\nu}}$ for radiation of $\nu\bar{\nu}$, relative to R_γ, that for radiating a photon, is only

$$\frac{R_{\nu\bar{\nu}}}{R_\gamma}\sim\frac{g^2E^4}{e^2\hbar^5c^5}\sim10^{-21}\left(\frac{E}{m_ec^2}\right)^4. \tag{1}$$

The probability for emitting a $\nu\nu$ pair rises rapidly with energy (in this case, like E^7) but even an electron-positron pair will annihilate into $\nu\nu$ rather than a pair of gamma rays only about once in 10^{22} times.

An extremely strong energy dependence is characteristic of all mechanisms for radiating $\nu\nu$ pairs: an electron moving with frequency ω in a classical circular orbit of radius R radiates electromagnetic waves, gravitational waves, and neutrino pairs with powers, P, that follow from simple dimensional considerations:

$$P_\gamma\sim\frac{e^2}{c^3}R^2\omega^4, \tag{2}$$

$$P_{\text{Grav}}\sim\frac{Gm_e{}^2R^4\omega^6}{c^5}\quad\text{(quadrupole)}, \tag{3}$$

and

$$P_{\nu\nu}\sim\frac{g^2R^2\omega^8}{hc^8}. \tag{4}$$

At low frequencies neutrino pair processes are entirely negligible. For a double star in which each member has a different electron molecular weight, the center of electron charge rotates about the fixed center of mass, but the neutrino pair radiation is smaller by perhaps eighty orders of

†Goddard Space Flight Center and New York University.

‡New York University, on leave from the University of California, Berkeley, California.

magnitude than the small quadrupole radiation of gravitational waves. High frequencies ($\omega \gtrsim 10^{18}$ ~1 keV), sufficient for significant $\nu\nu$ radiation by electrons, are available only on the microscopic scale where electrons are strongly accelerated by photons or intimate collisions.

Mechanisms for the radiation of $\nu\nu$ pairs by electrons within a star include the following:

(a) $\gamma+e\rightarrow e+\nu+\nu$, (photoneutrinos) (Ritus 1962; Ida and Vahara; Chiu and Stabler 1961)

(b) $e^-+e^+\rightarrow\nu+\nu$, (pair annihilation neutrinos) (Chiu and Morrison 1960; Chiu 1961)

(c) e+Coulomb field$\rightarrow e+\nu+\nu$, (neutrino bremsstrahlung) (Gandel'man and Pineau 1960)

(d) γ+Coulomb field$\rightarrow\nu+\nu$, (photonuclear neutrinos) (Rosenberg 1963; Matinyan and Tsilosani 1962)

(e) $\gamma+\gamma\rightarrow\gamma+\nu+\nu$, (van Hieu and Shabalin 1963)

(f) plasma excitation$\rightarrow\nu+\nu$. (plasma neutrinos) (Adams, Ruderman, and Woo 1963).

Processes (a), (b), and (f) are the dominant ones in those regimes of density and temperature typical of stellar interiors (Reeves 1963). Photo and pair annihilation neutrino emissions have exact analogues in Compton scattering and the two-photon annihilation of an electron-positron pair. The main contribution to process (d) arises from the electron current associated with a transverse (E perpendicular to k) electromagnetic wave moving through the plasma.

II. PLASMA NEUTRINOS

Plasma neutrino emission has been calculated by Adams, Ruderman, and Woo (1963) for any medium whose dielectric constants are known functions of frequency and wave-number. The relevant dielectric constants have also been evaluated for an electron gas which may be relativistic and degenerate. For a plasma frequency ω_o such that $(\hbar\omega_o)^2 \ll 4(m_e c^2)^2$ the relevant transverse dielectric constant is well approximated by

$$\epsilon^t = 1-\frac{\omega_o^2}{\omega^2}, \tag{5}$$

with

$$\omega_o^2=\frac{4\pi e^2}{m_e}\int dp f(p)\left(1-\frac{p^2c^2}{3E_p^2}\right)\frac{m_e c^2}{E_p}. \tag{6}$$

Here $f(p)$ is the momentum distribution function for the electrons and

$$E_p=(p^2c^2+m_e^2c^4)^{1/2}. \tag{7}$$

The dielectric constant of equation (5) leads to a greatly simplified neutrino pair emissivity Q_t(erg/sec/cm^3):

$$Q_t=\frac{g^2\omega_o^6}{12\pi^4c^2\hbar^5}\int_0^\infty k^2dk(e^{\omega\beta}-1)^{-1}, \tag{8}$$

with $\omega=(\omega_o^2+k^2c^2)^{1/2}$ and $\beta=(k_BT)^{-1}$. The function Q_t computed from equations (6) and (8) is given as a function of density and temperature in Section III.

The form of equation (8) can be inferred in a rather straightforward way from equation (5). For a transverse electromagnetic wave in a plasma with the dielectric constant the dispersion relation is

$$\omega^2=k^2c^2+(1-\epsilon)\omega^2=k^2c^2+\omega_o^2. \tag{9}$$

Therefore such waves, when quantized, behave as if they were relativistic particles of mass $\hbar\omega_o/c^2$, and they are energetically unstable against the decay into a neutrino pair. If r is the decay rate for such a particle at rest, its decay rate when moving is decreased by the usual relativistic time dilatation to $(r\omega_o/\omega)$ and its rate of production of $\nu\nu$ becomes $(r\omega_o/\omega)\hbar\omega=r\hbar\omega_o$. Thus the total neutrino emissivity per unit volume is

$$Q_t\sim r\hbar\omega_o 8\pi\int\frac{k^2dk}{(2\pi)^3}(e^{\beta\omega}-1)^{-1}. \tag{10}$$

The integral is just the total number of "photons" of mass per unit volume in a canonical Einstein-Bose distribution. We need only calculate the $\nu\nu$ emission $r\hbar\omega_o$ caused by the oscillating electric field with $\omega=\omega_o$ and infinite wavelength ($k=0$). When $k=0$ this mode is identical to the usual plasma oscillation; the accelerated electrons oscillating in phase with frequency ω_o, amplitude x, and acceleration ω_o^2x coherently radiate neutrino pairs. But because of the finite neutrino wavelength $\lambda_\nu\sim c/\omega_o$ all of the electrons in a large volume Ω can not radiate as if they constituted a

single highly charged particle. Rather only those electrons in a cube of volume $\sim(\lambda_\nu)^3$ effectively radiate coherently. Then from a large volume Ω with electron density n, the total rate of neutrino energy emission P can be estimated from equation (4):

$$P\sim\frac{g^2\omega_o{}^8x^2}{hc^8}(n\lambda_\mu{}^3)^2\frac{\Omega}{(\lambda_\nu)^3}, \tag{11}$$

with

$$\lambda_\nu=\frac{c}{\omega_o}. \tag{12}$$

The additional kinetic energy of the oscillating electrons is $\frac{1}{2}m\omega_o{}^2x^2n\Omega$. This energy together with an equivalent average potential energy must total $h\omega_o$ when the oscillation amplitude is quantized to correspond to a single quantum of excitation (plasmon). Thus

$$m\omega_o{}^2x^2n\Omega=h\omega_o. \tag{13}$$

The combination of equations (11), (12), and (13) yields P for a single plasmon at rest, i.e., $rh\omega_o$:

$$h\omega_o r\sim\frac{g^2}{c^5}\omega_o{}^4\frac{n}{m}. \tag{14}$$

But

$$\omega_o{}^2\sim4\pi ne^2/m, \tag{15}$$

so that

$$h\omega_o r\sim\frac{g^2}{c^2}\frac{\omega_o{}^6}{c^5}. \tag{16}$$

Equations (16) and (10) yield equation (8).

III. EXACT CALCULATION OF THE TRANSVERSE EMISSIVITY

(a) Introduction

In Section II it was shown that the rate of loss of energy in neutrino pairs due to decay of transverse plasmons is

$$Q_t=2g^2(3\pi e^2)^{-1}(2\pi)^{-3}\omega_o{}^6\sum_1^\infty\int^\infty \exp(-n\beta\omega)k^2dk. \tag{17}$$

The units are $h=m_e=c=1$. Here $g=3.08\times10^{-12}$ is the weak coupling constant; ω is given by the dispersion relation for the transverse plasmons, $\omega^2=\omega_o{}^2+k^2$; and

$$\omega_o{}^2=4e^2p_F{}^3/3\pi E_F) \tag{18}$$

is the plasma frequency. Of course $\beta=1/k_BT$). We take $\mu_e=2$.

We define a function $\mathfrak{F}(x)$ of x alone by

$$\mathfrak{F}(x)=\sum_1^\infty\int_0^\infty \exp[-nx\cosh\xi]\sinh^2\xi\cosh\xi d\xi. \tag{19}$$

By considering the dispersion relation and equation (17) one sees that

$$Q_t=2g^2(3\pi e^2)^{-1}(2\pi)^{-3}\omega_o{}^9\mathfrak{F}(\beta\omega_o), \tag{20}$$

and we may note that the expression for the number density of a gas of bosons at zero chemical potential is

$$\frac{N}{V}=\frac{1}{\pi^2}\left(\frac{mc}{\hbar}\right)^3\mathfrak{F}(\beta mc^2). \tag{21}$$

Apart from care in handling the conversion of units we need then only discuss the calculation of $\mathfrak{F}(x)$.

(b) The Function $\mathfrak{F}$ (x)

1. *Small ($x\leq0.5$) values of the argument.*—It is shown in the Appendix that for $x<2\pi$ there exists an expansion of $x^3\mathfrak{F}(x)$; note

$$\zeta(3)=\sum_{n=1}^\infty(1/n^3).$$

Truncating it,

$$\mathfrak{F}(x)\doteq\frac{1}{x^3}\left[\left[2\zeta(3)+\frac{1}{2}x^2\ln x-\frac{1}{4}(2\ln2+1)x^2+\frac{1}{96}x^4\ln x-\frac{1}{96}\left\{\ln2-\frac{1}{4}+\ln2\pi+\left[-\frac{\zeta'(2)}{\zeta(2)}\right]\right\}x^4\right]\right]. \tag{22}$$

For $x=0.5$ this gives a result which differs from that obtained by summing the Hankel series (see subsection 2 below) by one part in 10^6. It will also be seen that by taking only the constant term in the square brackets, and using equation (20), we get just the equation preceding equation (28) in Adams *et al.* (1963).

2. *Intermediate and large values of the argument ($x\geq0.5$).*—Chandrasekhar (1957) gives a result (p. 398, eq.[252] and [248] that, omitting the

minus signs and Λ, since we have bosons at zero chemical potential, reads

$$\mathfrak{F}(x)=\sum_{n=1}^{\infty}\frac{K_2(nx)}{nx}\doteq\sum_{n=1}^{M}\frac{K_2(nx)}{nx}, \qquad (23)$$

where $K_2(z)$ is the modified Bessel function of the second kind, of order 2. The criterion for the choice of M is discussed in subsection 3. The series equation (23) is a Hankel series, similar to a Dirichlet series, and converges for all x, albeit very slowly for small x: (see Greenwood [1941]). Note that for small ξ, $K_2(\xi)\approx 2/\xi^3$, so that substituting this expression in equation (23) we get again

$$\mathfrak{F}(x)\approx\frac{2}{x^3}\sum_{n=1}^{\infty}\left(\frac{1}{n^3}\right)=\frac{2\zeta(3)}{x^3},$$

for small x, just what one obtains by taking only the *zero*th-order term in braces in equation (22).

For large ξ, on the other hand, $K_2(\xi)\approx(\pi/2\xi)^{1/2}e^{-\xi}$, and if we take only the first term of equation (23), using this expression as an approximation for it, we get $\mathfrak{F}(x)\approx(\pi/2)^{1/2}x^{-3/2}e^{-x}$, for large x.

If one uses this last plus equation (20) one gets just the equation preceding equation (29) in Adams *et al.* (1963).

3. *Error terms.*—For equation (22), the small argument form, it is shown in the Appendix that the lowest order neglected term is $O(x^6\ln x)$. The coefficient multiplying this term will be quite small.

For equation (23), the intermediate and large form, we break off the sum when

$$\frac{K_2(Mx)}{Mx}<10^{-6}\frac{K_2(x)}{x}.$$

By approximating, for large M, the remainder term by

$$\sum_{n=M+1}^{\infty}\frac{K_2(nx)}{nx}\approx\frac{1}{x}\int_{M+1/2}^{\infty}\frac{K_2(nx)}{n}dn$$

$$=\frac{1}{x}\frac{K_1[(M+\tfrac{1}{2})x]}{(M+\tfrac{1}{2})x}<\frac{1}{x}\frac{K_2(Mx)}{Mx},$$

we find that the error is less than $(1/x)\times10^{-6}$ times the first term. This is for the range 0.5–5, since for larger values we have no need of many terms.

(c) Conversion of Units

The dimensions of Q_t are erg/cm^3/sec. In the units in which equation (20) is given, units of energy, length, and time are m_ec^2, $\hbar/m_ec$, and $\hbar/m_ec^2$, respectively. Thus Q_t in c.g.s. units is

$$Q_t=\frac{m_ec^2}{(\hbar/m_ec)^3}\frac{1}{\hbar/(m_ec^2)}\left[\frac{2}{3\pi}\times137.04\times(3.08\times10^{-12})^2\frac{1}{(2\pi)^3}\right]+\left(\frac{\hbar\omega_o}{m_ec^2}\right)^9\mathfrak{F}(\beta\hbar\omega_o)=$$

$$=1.228\times10^{22}\left(\frac{\hbar\omega_o}{m_ec^2}\right)^9\mathfrak{F}(\beta\hbar\omega_o), \qquad (24)$$

where now all dimensioned quantities are in c.g.s. units. In c.g.s. units

$$p_F{}^3=3\pi^2N_{\mathrm{AVO}}\frac{1}{\mu_e}\rho=\frac{3}{2}\pi^2N_{\mathrm{AVO}}\,\rho.$$

Thus in c.g.s. units

$$\hbar^2\omega_o{}^2=2\pi(\hbar c)^2\left[1+\left(\frac{\hbar}{m_ec}\right)^2\left(\frac{3}{2}\pi^2N_{\mathrm{AVO}}\,\rho\right)^{2/3}\right]^{-1/2}N_{\mathrm{AVO}}\frac{e^2}{m_ec^2}\rho$$

or

$$\hbar\omega_o=3.265\times10^{-11}(1+6.413\times10^{-5}\rho^{2/3})^{-1/4}\rho^{1/2}, \qquad (25)$$

where now all dimensioned quantities are in c.g.s. units.

In c.g.s. units

$$\beta=\frac{7.244\times10^8}{T_7}, \qquad (26)$$

where T_7 is the temperature in units of 10^7 °K.

Using equations (25) and (26) in equation (24) we can compute Q_t for given values of ρ and T. Of course

$$q_t=\frac{Q_t}{\rho}.$$

Table 1 gives q_t as a function of ρ and T.

APPENDIX

CALCULATION OF $x^3\mathfrak{F}(x)$ FOR SMALL x

Put $\eta = x\cosh\xi$ in equation (19); then

$$x^3\mathfrak{F}(x) = \int_x^\infty \frac{1}{e^\eta - 1}\left(1-\frac{x^2}{\eta^2}\right)^{1/2}\eta^2 d\eta. \tag{27}$$

By splitting the integral

$$x^3\mathfrak{F}(x) = \int_0^\infty \frac{1}{e^\eta-1}\eta^2 d\eta - \int_0^x \frac{\eta}{e^\eta-1}\eta d\eta - \frac{1}{2}x^2\int_x^\infty \frac{1}{e^\eta-1}d\eta + \int_x^\infty \frac{1}{e^\eta-1}\left[\left(1-\frac{x^2}{\eta^2}\right)^{1/2} - 1 + \frac{1}{2}\frac{x^2}{\eta^2}\right]\eta^2 d\eta,$$

or

$$x^3\mathfrak{F}(x) = 2\zeta(3) - a_1(x) + \tfrac{1}{2}x^2\ln(1-e^{-x}) + a_2(x). \tag{28}$$

Now

$$a_1(x) = \int_0^x\left[1-\frac{1}{2}\eta+\frac{1}{12}\eta^2-\frac{B_2}{4!}\eta^4+O(\eta^6)\right]\eta d\eta = \frac{1}{2}x^2-\frac{1}{6}x^3+\frac{1}{48}x^4-O(x^6) \tag{29}$$

for $x < 2\pi$.

An elementary calculation gives

$$\tfrac{1}{2}x^2\ln(1-e^{-x}) = \tfrac{1}{2}x^2\ln x - \tfrac{1}{4}x^3 + \tfrac{1}{48}x^4 - O(x^6). \tag{30}$$

The calculation of $a_2(x)$ is quite lengthy; we begin by splitting the integral again:

$$a_2(x) = -\frac{1}{8}x^4\int_A^\infty \frac{1}{e^\eta-1}\frac{d\eta}{\eta^2} + O(x^6) + \int_x^A \frac{1}{e^\eta-1}\left[\left(1-\frac{x^2}{\eta^2}\right)^{1/2} - 1 + \frac{1}{2}\frac{x^2}{\eta^2}\right]\eta^2 d\eta$$

$$= -\frac{1}{8}\left(\int_A^\infty \frac{1}{e^\eta-1}\frac{d\eta}{\eta^2}\right)x^4 + a_3(x) + O(x^6). \tag{31}$$

Put $n\xi = x$; then

$$(e^{\eta}-1)^{-1}\eta^2 d\eta = x^2\frac{x}{\xi}(e^{x/\xi}-1)^{-1}\frac{d\xi}{\xi^3}$$

and

$$a_3(x) = x^2\int_{x/A}^{1}\frac{x/\xi}{e^{x/\xi}-1}[(1-\xi^2)^{1/2}-1+\frac{1}{2}\xi^2]\frac{d\xi}{\xi^3} = x^2\int_{x/A}^{1}\left[1-\frac{1}{2}\frac{x}{\xi}+\frac{1}{12}\frac{x^2}{\xi^2}-\frac{B_2}{4!}\frac{x^4}{\xi^4}+\ldots+(-)^{n+1}\frac{B_n}{(2n)!}\frac{x^{2n}}{\xi^{2n}}\right.$$

$$\left.+\ldots\right]\cdot[(1-\xi^2)^{1/2}-1+\frac{1}{2}\xi^2]\frac{d\xi}{\xi^3},$$

where we require

$$\frac{x}{\xi}<2\pi \quad \text{or} \quad A<2\pi.$$

Integrating term by term, we get

$$a_3(x) = x^2 b_o(x)-\frac{1}{2}x^3 b_1(x)+\frac{1}{12}x^4 b_2(x)-\frac{B_2}{4!}x^6 b_4(x)+\ldots+(-)^{n+1}\frac{Bn}{(2n)!}x^{2n+2}b_{2n}(x)+\ldots, \tag{32}$$

where

$$b_m(x) = \int_{x/A}^{1}\left[(1-\xi^2)^{1/2}-1+\frac{1}{2}\xi^2\right]\frac{d\xi}{\xi^{3+m}}$$

These integrals are elementary; in particular

$$b_o(x) = \frac{1}{4}-\frac{1}{2}\ln 2+\frac{1}{16}(x/A)^2+O(x^4), \tag{33}$$

$$b_1(x) = -\frac{1}{6}+\frac{1}{8}\frac{x}{A}+O(x^3), \tag{34}$$

$$b_2(x) = \frac{1}{8}\ln\frac{x}{A}+\frac{1}{32}-\frac{1}{8}\ln 2+O(x^2), \tag{35}$$

$$b_4(x) = -\frac{1}{16}(x/A)^{-2}+O(\ln x); \tag{36}$$

and for $n>2$

$$b_{2n}(x) = -\frac{1}{8(2n-2)}\left(\frac{x}{A}\right)^{2-2n}+O(x^{4-2n}). \tag{37}$$

Substituting equations (33)–(37) into equation (32), we get

$$a_3(x) = \left(\frac{1}{4}-\frac{1}{2}\ln 2\right)x^2+\frac{1}{12}x^3+\frac{1}{96}x^4\ln x+\left[\frac{1}{16}\frac{1}{A^2}-\frac{1}{16}\frac{1}{A}-\frac{}{96}\ln A+\frac{1}{12}\left(\frac{1}{32}-\frac{1}{8}\ln 2\right)\right.$$

$$\left.+\frac{B_2}{4!\,16}A^2+\ldots+(-)^n\frac{B_n}{(2n)!\,8(2n-2)}A^{2n-2}+\ldots\right]x^4+O(x^6\ln x). \tag{38}$$

Substituting equations (29), (30), and (31) into equation (27), and using equation (38), we get

$$x^3\mathfrak{F}(x) = 2\zeta(3)+\frac{1}{2}x^2\ln x-\frac{1}{4}(2\ln 2+1)x^2+\frac{1}{96}x^4\ln x-\frac{1}{8}q(A)x^4+O(x^6\ln x), \tag{39}$$

re

$$q(A)=\int_A^\infty \frac{1}{e^\eta-1}\frac{d\eta}{\eta^2}-\frac{1}{2}\frac{1}{A^2}+\frac{1}{2}\frac{1}{A}+\frac{1}{12}\ln A+\frac{1}{12}\left(\ln 2-\frac{1}{4}\right)$$
$$-\frac{B_2}{4!\,2}A^2+\cdots+(-)^{n+1}\frac{B_n}{(2n)!\,(2n-2)}A^{2n-2}+\cdots, \tag{40}$$

$q(A)$ is, of course, a constant; it is, however, a bit difficult to evaluate. We will use the relations

$$\frac{1}{t}\frac{1}{e^t-1}+\frac{1}{2}\frac{1}{t}=\frac{1}{2t}\coth\frac{t}{2}=\sum_{n=1}^\infty\frac{2}{4n^2\pi^2+t^2}+\frac{1}{t^2}. \tag{41}$$

Using the first of equations (41) we find on integrating by parts

$$-\int_A^\infty \ln t\left[\frac{d}{dt}\left(\frac{1}{2t}\coth\frac{t}{2}-\frac{1}{t^2}\right)\right]dt=\int_A^\infty\frac{1}{e^t-1}\frac{dt}{t^2}-\frac{1}{2}\frac{1}{A^2}+1/(2A)+(1/12)\ln A+O(A^2\ln A)$$
$$\therefore\ q(A)=q(0)=-\int_0^\infty \ln t\left[\frac{d}{dt}\left(\frac{1}{2t}\coth\frac{t}{2}-\frac{1}{t^2}\right)\right]dt+\frac{\ln 2-\frac{1}{4}}{12}. \tag{42}$$

Substituting the second of equations (41) into equation (42), and using the absolute and uniform convergence of the series (Knopp 1963) we obtain

$$q(0)-\frac{1}{12}\left(\ln 2-\frac{1}{4}\right)=4\int_0^\infty t\ln t\left(\sum_{n=1}^\infty\frac{1}{(4n^2\pi^2+t^2)^2}\right)dt=4\sum_{n=1}^\infty B(2n\pi), \tag{43}$$

where

$$B(\xi)\equiv\int_0^\infty\frac{x\ln x}{(x^2+\xi^2)^2}dx.$$

Putting $x^2=y$, we get (deHaan 1963)

$$B(\xi)=\frac{1}{4}\int_0^\infty\frac{\ln y}{(\xi^2+\nu)^2}d\nu=\frac{1}{4}\frac{1}{\xi^2}\ln(\xi^2)=\frac{1}{2\xi^2}\ln\xi.$$

By using this in equation (43),

$$q(0)-\frac{1}{12}\left(\ln 2-\frac{1}{4}\right)=2\sum_{n=1}^\infty\frac{1}{(2n\pi)^2}\ln(2n\pi)=\frac{1}{2\pi^2}\left(\ln 2\pi\sum_{n=1}^\infty\frac{1}{n^2}+\sum_{n=1}^\infty\frac{\ln n}{n^2}\right). \tag{44}$$

But

$$\sum_{n=1}^\infty\left(\frac{1}{n^2}\right)=\zeta(2)=\frac{\pi^2}{6},$$

and

$$\sum_{n=1}^\infty\frac{\ln n}{n^2}=\left[-\frac{d}{dz}\sum_{n=1}^\infty e^{-z\ln n}\right]_{z=2}=-\zeta'(2).$$

So

$$q(0)=\frac{1}{12}\left(\ln 2-\frac{1}{4}+\ln 2\pi-\frac{\zeta'(2)}{\zeta(2)}\right). \tag{45}$$

Using this in equation (39)

$$x^3\mathfrak{F}(x)=2\zeta(3)+\frac{1}{2}x^2\ln x-\frac{1}{4}(2\ln 2+1)x^2+\frac{1}{96}x^4\ln x$$
$$-\frac{1}{96}\left(\ln 2-\frac{1}{4}+\ln 2\pi-\frac{\zeta'(2)}{\zeta(2)}\right)x^4+O(x^6\ln x). \tag{46}$$

MAGNETOGRAVITATIONAL INSTABILITY OF ANISOTROPIC PLASMA WITH HALL EFFECT*

G. L. KALRA† AND S. P. TALWAR

1. INTRODUCTION

The problem of the magnetogravitational instability of interstellar matter is of considerable importance in connection with protostar and star formation in magnetic dust clouds. The initial analysis of gravitational instability in an infinite homogenous medium is due to Jeans (1929) who derived the expression for the maximum size of a uniform gravitating mass which is stable to small fluctuations in density. This analysis has been extended in recent years to include a variety of other effects, e.g., isotropic turbulence (Chandrasekhar, 1951), rotation (Chandrasekhar, 1954; Bel and Schatzman, 1958) and uniform magnetic field (Chandrasekhar and Fermi, 1953). It has been shown that a uniform magnetic field and rotation (or even both together) leave the Jeans' criterion for fragmentation unchanged. Furthermore, it is also found that the transport processes like finite electrical conductivity and viscosity do not modify Jeans' formula (Pacholczyk and Stadolkiewicz, 1960).

In all investigations on magnetogravitational stability reported so far (Pacholczyk, 1963), the scalar pressure approximation has been used. The interstellar medium, is, however, very dilute and the interparticle collisions are too infrequent so that in the presence of the interstellar magnetic field, the plasma pressure is likely to assume a tensorial character, with unequal magnitudes parallel and perpendicular to the magnetic field. If this anisotropy becomes large enough, it may lead to instability in an otherwise stable system. Further Ware (1961) pointed out that an important factor which has hitherto been ignored in various stability investigations is the Hall effect. He suggested, without, however, solving any definite problem that when the Hall effect is included, a growing wave instability (overstability) should replace the pure instability as predicted by the ideal magnetohydrodynamic equations. It is felt that the Hall effect assumed importance in a low density plasma such as interstellar space.

With this viewpoint, we investigate, in the present note, the problem of the magnetogravitational instability of a static, unbounded, inviscid, homogenous, gravitating plasma including finite conductivity and Hall effect. We assume the plasma to be carrying a uniform magnetic field so that the physical conditions prevalent in the medium require the gas pressure to be anisotropic. We shall be making use of the "Double-Adiabatic" hydromagnetic equations (Chew, Goldberger and Low, 1956).

2. PERTURBATION EQUATIONS AND DISPERSION RELATION

Neglecting heat flow tensor, we may write the linearized equations for the problem under considerations as,

$$\zeta_0 \frac{\partial v}{\partial t} = -\nabla \cdot \delta p + \rho_0 \nabla \delta U + \frac{L}{4\pi}(\nabla \times h) \times H. \tag{1}$$

$$\frac{\partial}{\partial t}\delta\rho = -\rho_0 \nabla \cdot v \tag{2}$$

*Goddard Space Flight Center Document X-640-64-40, January 1964.
†Delhi University, India.

$$\nabla^2\delta U = -4\pi G\delta\rho \tag{3}$$

$$\frac{\partial L}{\partial t} = \nabla\times(v\times H_o)+\eta\nabla^2 h-\frac{c}{4\pi ne}\nabla\times[(\nabla\times h)\times H_o]+\frac{c^2}{4\pi\omega\rho^2}\frac{\partial}{\partial t}\nabla^2 h \tag{4}$$

$$\nabla\cdot h = o \tag{5}$$

$$\frac{\delta p_\parallel}{p_\parallel} = 3\frac{\delta\rho}{\rho_o}-2\frac{h_z}{H_o} \tag{6}$$

$$\frac{\delta p_\parallel}{p_\parallel} = \frac{\delta\rho}{\rho_o}+\frac{h_z}{H_o} \tag{7}$$

Here $\eta = c^2/4\pi\sigma$ (σ being the electrical conductivity) and $\omega\rho = \sqrt{\frac{4\pi ne^2}{m}}$ (plasma frequency). Further V, $\delta\rho$, δU, h, $\delta p_\parallel$, $\delta p_\perp$ denote respectively the velocity vector, perturbations in density, gravitational potential, magnetic field vector, plasma pressure parallel and perpendicular to the initial magnetic field H_0. $p_\parallel$ and $p_\perp$ represent the constant components of pressure (along and perpendicular to the magnetic field respectively) of the pressure tensor $\underset{\leftrightarrow}{p}$ given by,

$$\underset{\leftrightarrow}{p} = p_\parallel n\cdot n+p_\perp(\underset{\leftrightarrow}{i}-n\cdot n) \tag{8}$$

where n is a nuit vector along the magnetic field and l is lunit dyadic.

Choosing the orientation of the coordinate axes such that $H_0 = (0,0H_0)$ and seeking solutions which are independent of y and whose dependence on x, z, and t is of the form exp. $(ik_x x+ik_z z+\omega t)$, we rewrite the equations (1) to (5) as,

$$\rho_0\omega v_x = -ik_x\delta p_\perp-ik_z(p_\parallel-p_\perp)\frac{h_x}{H_0}+ik_x\rho_0\delta U+\frac{H_0}{4\pi}(ik_x h_x-ik_x h_z) \tag{9}$$

$$\rho_0 u v_y = -ik_z(p_\Delta-p_\perp)\frac{hy}{H_0}+ik_z\frac{H_0}{4\pi}h_y \tag{10}$$

$$\rho_0\omega v_z = -ik_z\delta p_\parallel+ik_z(p_\parallel-p_\perp)\frac{h_z}{H_0}+ik_z\rho_0\delta U \tag{11}$$

$$\omega\delta\rho = -\rho_0\nabla\cdot v \tag{12}$$

$$\delta U = -\frac{4\pi G\rho_0}{k^2}\nabla\cdot v \tag{13}$$

$$\left\{\omega\left(1+\frac{c^2}{4\pi\omega\rho^2}k^2\right)+\eta k^2\right\}h_x = ik_z H_0 v_x-\frac{c}{4\pi ne}k_z^2 H_0 hy \tag{14}$$

$$\left\{\omega\left(1+\frac{c^2k^2}{4\pi\omega\rho^2}\right)+\eta k^2\right\}h_y = ik_z H_0 v_y-\frac{c}{4\pi ne}ik_z H_0(ik_z h_x-ik_x h_z) \tag{15}$$

$$\left\{\omega\left(1+\frac{c^2k^2}{4\pi\omega\rho^2}\right)+\eta k^2\right\}h_z = -H_0(\nabla\cdot v-ik_z v_z)-\frac{c}{4\pi ne}H_0 ik_x k_z h_y \tag{16}$$

$$ik_x h_x-ik_z h_z = o \tag{17}$$

Taking divergence of equation (1), and using equation (3), we get

$$\rho_0\omega\nabla\cdot v = -\nabla\cdot(\nabla\cdot\delta\underset{\leftrightarrow}{p})-4\pi G\rho_0\delta\rho+\frac{H_0}{4\pi}k^2 h_z \tag{18}$$

where

$$k^2 = k_x^2 + k_z^2.$$

The first term on the right hand side of equation (18) is written with the help of equations (6) and (7) as,

$$-\nabla\cdot(\nabla\cdot\delta\underset{\leftrightarrow}{p}) = -\frac{\mu_z}{H_0}\left[2k_z^2(2p_\parallel - p_\perp) - k_x^2 p_\perp\right] - \frac{\nabla\cdot v}{\omega}\left[k_x^2 p_\perp + 3k_z^2 p_\parallel\right] \tag{19}$$

Through a process of elimination wherein we use the equations (9), (11), (14), (15) and (17) we obtain,

$$h_z\left[A + \left(\frac{c}{4\pi ne}\right)^2 \frac{H_0^2 k_x^2 k_z^2}{\Lambda + \frac{k_z^2}{\rho_0\omega}\left(\frac{H_0^2}{4\pi} - p_\parallel + p_\perp\right)}\right] = -H_0(\nabla\cdot v - ik_z v_z) \tag{20}$$

where

$$\Lambda = \omega\left(1 + \frac{c^2k^2}{4\pi\omega\rho^2}\right) + \eta k^2 \tag{21}$$

Substituting equations (12), (19) and (20) in equation (18), we get

$$\frac{\nabla\cdot v}{\omega}\left[\rho_0\omega^2 + \frac{\omega\left\{\frac{k^2H_0^2}{4\pi} - 2k_z^2(2p_\parallel - p_\perp) + k_z^2 p_\perp\right\}}{A + \left(\frac{c}{4\pi ne}\right)^2 \frac{H_0^2 k^2 k_z^2}{A + \frac{p_z^2}{\rho_0\omega}\left(\frac{H_0^2}{4\pi} - p_\parallel + p_\perp\right)}} + (3p_\parallel k_z^2 + k_x^2 p_\perp - 4\pi G\rho_0^2)\right]$$

$$= ik_z v_z\left\{\frac{k^2H_0^2}{4\pi} - 2k_z^2(2p_\parallel - p_\tau) + k_z^2 p_\perp\right\}\left\{A + \left(\frac{c}{4\pi ne}\right)^2 \frac{H_0^2 k^2 k_z^2}{A + \frac{k_z^2}{\rho_0\omega}\left(\frac{H_0^2}{4\pi} - p_\parallel + p_\perp\right)}\right\}^{-1} \tag{22}$$

The expression for $\nabla\cdot v$ in terms of v_z is now obtained from equation (11), using equations (6), (7) and (20). We get

$$\nabla\cdot v = v_z \frac{\left[\rho_0\omega + \frac{k_z^2(3p_\parallel - p_\perp)}{A + \left(\frac{c}{4\pi ne}\right)^2 \frac{H_0^2 k^2 k_z^2}{A + (H_0^2/4\pi - p_\parallel + p_\tau)k_z^2/\rho_0\omega}}\right]}{ik_z\left[\frac{3p_\parallel - 4\pi G\rho_0^2/k^2}{\omega} \frac{(3p_\parallel - p_\perp)}{A + \left(\frac{c}{4\pi ne}\right)^2 \frac{H_0^2 k^2 k_z^2}{A + \frac{k_z^2}{\rho_0\omega}\left(\frac{H_0^2}{4\pi} - p_\parallel + p_\perp\right)}}\right]} \tag{23}$$

From equations (22) and (23) we finally obtain the dispersion relation as,

$$\left[\rho_0\omega^2 + 3p_\parallel k_z^2 + k_x^2 p_\perp - 4\pi G\rho_0^2\right]\left[\omega\rho_0\left\{A + \left(\frac{c}{4\pi ne}\right)^2 \frac{H_0^2 k^2 k_z^2}{A + \frac{k_z^2}{\rho_0\omega}\left(\frac{H_0^2}{4\pi} - p_\parallel + p_\perp\right)}\right\} + k_z^2(3p_\parallel - p_\perp)\right]$$

$$+ \left[\frac{k^2H_0^2}{4\pi} - 2k_z(2p_\parallel - p_\perp) + k_z^2 p_\perp\right]\left[\omega\rho_0 - k_z^2\left(3p_\parallel - \frac{4\pi G\rho_0^2}{k^2}\right)\right] = 0 \tag{24}$$

The equation (24) reduces without the Hall effect to the one obtained in an earlier paper (Tandon and Talwar, 1963) with $\Omega=0$.

3. DISCUSSION OF THE DISPERSION RELATION

The dispersion relation (24) is a sixth order equation in ω, the parameter to decide the question of the stability of the configuration. We shall, however, simplify our discussion by considering the following special cases.

Case (i) Transverse Propagation

In the case of transverse propagation ($k_x=k$, $k_z=0$), the dispersion relation assumes the simple form,

$$\omega^2+\frac{\omega}{A}[V^2+S_\perp{}^2]k^2+(k^2S_\perp-4\pi G\rho_0)-0 \tag{25}$$

where $V^2=H_0^2/4\pi P_0$, $S_\perp{}^2=p_\perp/P_0$ and the parameter A is given by equation (21).

The equation (25) is rewritten as,

$$\omega^3\left(1+\frac{c^2k^2}{4\pi\omega\rho^2}\right)+\eta\omega^2k^2+k^2\omega\left[V^2+S_\perp{}^2+\left(1+\frac{c^2k^2}{4\pi\omega\rho^2}\right)\left(S_\perp{}^2-\frac{4\pi G\rho_0}{R^2}\right)\right]+\eta k^2(k^2S_\perp{}^2-4\pi G\rho_0)=0 \tag{26}$$

For plasma with infinite electrical conductivity ($\eta=0$) and $\omega\rho\to\infty$, we conclude that the configuration is unstable for transverse propagation vector less than a certain critical value k^* given by

$$k_*^2=\frac{4\pi G\rho_0}{V^2+2S_\perp{}^2} \tag{27}$$

On the other hand if the conductivity were finite the equation (27) gives,

$$k_*=\sqrt{\frac{4\pi G\rho_0}{S_\perp{}^2}} \tag{28}$$

as the critical wave number below which any perturbation increases its amplitude monotonically till the linear theory breaks down. Further the equation (26) admits two complex conjugate roots with positive real part. It therefore follows that irrespective of the fact that the system is self-gravitating or not, there are present, for transverse propagation in a finitely conducting medium alone, growing wave instability (overstability).

Case (ii) Parallel Propagation

With $k_x=k$, $k_z=0$ and restricting ourselves to infinitely conducting configuration but retaining the Hall current term, we obtain the dispersion relation as,

$$[\omega^2+3k^2S_\parallel{}^2-4\pi G\rho_0]\left[\{\omega^2+k^2(V^2+S_\perp{}^2-S_\parallel{}^2)\}^2+\left(\frac{c}{4\pi ne}\right)^2H_0^2k^4\omega^2\right]=0 \tag{29}$$

This gives a gravitational mode uncoupled with the other two modes which involve the Hall effect term. The gravitational mode leads to instability provided $k<k^*$ where k^* is given by,

$$k^*=\sqrt{\frac{4\pi G\rho_0}{3S_\parallel{}^2}} \tag{30}$$

For a non-gravitating plasma, the instability could result from the second factor in equation (29). The non-gravitating configuration shall be stable if $(S_\parallel{}^2-S_\perp{}^2-V^2)\leqslant 0$. On the other hand if

$(S_\parallel^2 - S_\perp^2 - V^2) > 0$, the configuration without Hall term is unstable for all modes of disturbance (Lüst, 1960). In our present context there is no instability for wave numbers greater than a certain critical value k_c given by,

$$k_c^2 = \frac{2(S_\parallel^2 - S_\perp^2 - V^2}{(c/4\pi ne)^2 H_0^2} \tag{31}$$

We, therefore, conclude that the mode of disturbance (in range k_c to ∞) which leads to instability in a configuration devoid of Hall effect, is stabilized by the Hall effect, athough the Hall effect is unable to suppress instability for all wavelengths.

THE DETECTION OF SOLAR NEUTRINOS*

HUBERT REEVES†

An old dream of nuclear physicists has now entered the realm of possibility. Raymond Davis of Brookhaven National Laboratory has the plans for an apparatus capable of detecting the flux of neutrinos from the sun. The Brookhaven Solar Neutrino Observatory, as this equipment is called, will be built in future years and buried thousands of feet underground. Then, for the first time a direct "view" into the center of the sun will be possible.

Neutrino astronomy is quite new, but physicists have in recent years become increasingly involved with these elementary particles. The story of neutrinos goes back to the early days of nuclear physics (about 1935), when a number of disturbing facts came to light.

For instance, the beta disintegration (emission of a negative electron) of certain nuclei showed no sign of conserving energy and momentum. An important case (discovered later) was the observed decay of a neutron into a proton and an electron. Analysis of this process showed that the sum of the energies of the proton and electron (including the rest mass) was *smaller* than the total energy of the neutron. Further, this sum was not constant but varied according to the particular neutron observed. It was also discovered that the two emerging particles did not move in opposite directions (as would be expected from a neutron at rest), but were directed in many possible ways, as in Fig. 1.

To overcome these difficulties, W. Pauli postulated the existence of a third, unobserved particle emitted during beta decay. This particle—neutral and massless, like a photon of light—carried off the balance of the energy and momentum; it was later named *neutrino*. According to the principles of quantum mechanics, it could be detected by a reaction inverse to the one responsible for its birth. For example, a neutron could absorb a neutrino and give rise to a proton and an electron. But calculations showed that the probability of capture was extremely small, far below the detection power of existing equipment. This explains why the presence of neutrinos had not been felt before in physics.

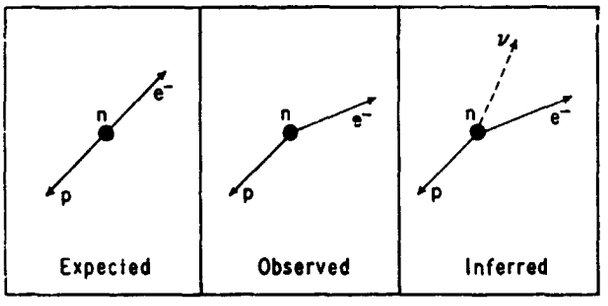

FIGURE 1.—The dynamics of neutron decay, in which the lack of symmetry gave rise to the prediction that an unknown particle was present. In the third section this particle, a neutrino, is symbolized by the Greek letter nu (ν).

Later it was shown that this particle existed in two brands: neutrinos and antineutrinos. The only difference between them that is important to us concerns their origins. Neutrino births accompany the beta decay of protons (in complex nuclei for energy considerations), and antineutrinos are born when neutrons undergo beta decay. Inversely, a neutrino can be captured only by a neutron, an antineutrino only by a proton.

As physicists developed beta-decay theory, close agreement between its predictions and the experiments gave abundant indirect evidence for the existence of neutrinos. It soon became clear that they had reality and were not mere artifices of thought; they became accepted in physics on the same footing as other elementary particles.

Experimental detection of neutrinos had to wait many years. But World War II gave tremendous

*Published in *Sky and Telescope*, 27(5), May 1964.

†Goddard Space Flight Center and University of Montreal.

impetus to nuclear physics technology, and created huge antineutrino sources in the form of nuclear reactors. Their production of neutron-rich isotopes roused hopes that finally materialized in 1958, when F. Reines and C. L. Cowan, Jr., succeeded in detecting antineutrinos coming from the Savannah River reactor. Although their detection apparatus was exposed to a flux of about 10^{13} antineutrinos per square centimeter per second, the counted number was, at best, a few per hour. The antineutrino capture probability was thus very small indeed, but it agreed with the prediction made in the early days of neutrino theory. Elusive as the neutrino is, belief in its existence has an excellent foundation both in experiment and theory.

Recently it has been shown that two other types of neutrinos exist, related to the decay of muon particles.

NEUTRINOS AND ASTRONOMY

Nuclear physics has brought an answer to a very old problem: Where does the sun find the energy that it has been radiating for so many eons? Around 1938, Hans Bethe showed convincingly that the centers of the sun and other stars are seats of intense thermonuclear reactions. Both the liberation of energy and the formation of new isotopes occur in these stellar nuclear furnaces. Analysis of the network of reactions taking place showed that interspersed among some purely nuclear reactions were a certain number of beta-decay processes—hence, neutrino-emitting reactions.

But even a star is not thick enough to absorb traveling neutrinos appreciably. Proper shielding would require a few billion stars lined up one after another! The sun is essentially transparent to neutrinos, which escape, carrying away their energy. Any proper study of stellar interiors has to take this escape into account: the solar furnace must be hotter to make up for the loss.

In the sun this effect is only a few percent. But its immediate consequence is that an appreciable neutrino flux reaches the earth, about 6.5×10^{10} neutrinos per square centimeter per second. The flux of antineutrinos from the sun is negligibly small, since most solar nuclear reactions are of the proton-capture type, forming proton-rich neutrino-emitting isotopes.

SOLAR NEUTRINOS

Basically, the source of the sun's energy is the conversion of four hydrogen atoms into one helium atom. Under stellar conditions, the transformation is accomplished through four main channels, the so-called PP branches illustrated in Fig. 2. Notice that each of these branches includes neutrino emission.

In each process, the numbers of neutrinos having different energies follow a specific pattern. As illustrated in Fig. 3 for neutrinos from hydrogen, most emitted particles belong to a broad hump, but there is also a sizable peak of particles all with about the same energy—some one million electron volts greater than the maximum energy in the hump. For certain nuclei, such as beryllium-7, *two* peaks of monoenergetic neutrinos are emitted, since the beta decay sometimes goes to an excited state of lithium-7.

The PP Chain

$$H^1 + H^1 \rightarrow D^2 + \beta^+ + \nu$$
$$D^2 + H^1 \rightarrow He^3 + \gamma \qquad \text{PP I}$$
$$He^3 + He^3 \rightarrow He^4 + 2\,H^1$$

or

$$He^3 + He^4 \rightarrow Be^7 + \gamma$$
$$Be^7 + e^- \rightarrow Li^7 + \nu + \gamma \qquad \text{PP II}$$
$$Li^7 + H^1 \rightarrow 2\,He^4$$

or

$$Be^7 + H^1 \rightarrow B^8 + \gamma$$
$$B^8 \rightarrow Be^8 + \beta^+ + \nu \qquad \text{PP III}$$
$$Be^8 \rightarrow 2\,He^4$$

The CNO Cycle

$$C^{12} + H^1 \rightarrow N^{13} + \gamma$$
$$N^{13} \rightarrow C^{13} + \beta^+ + \nu$$
$$C^{13} + H^1 \rightarrow N^{14} + \nu \qquad \text{PP IV}$$
$$N^{14} + H^1 \rightarrow O^{15} + \gamma$$
$$O^{15} \rightarrow N^{15} + \beta^+ + \nu$$
$$N^{15} + H^1 \rightarrow C^{12} + He^4$$

FIGURE 2.—Nuclear reactions responsible for energy generation in the sun. In some of the proton-proton series, later reactions depend on earlier ones. Greek letter symbols are $\beta+$ (positron), γ (gamma ray), and ν (neutrino).

Before we can evaluate the neutrino energy spectrum from the sun, and compute the mean energy, we must specify the conditions in the solar interior. Indeed, a first step is to find the contribution of each PP branch to the sun's total energy output.

Using the most recent data about nuclear energy generation rates and stellar opacities, we have computed a solar model whose evolution during the past 4½ billion years is described in Table I. For completeness, we include the changing luminosity, adius, surface and central temperatures, and ther

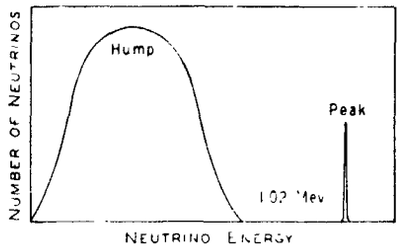

FIGURE 3.—The energy spectrum of neutrinos coming from hydrogen nuclei. The hump is the result of processes involving creation of an electron during the decay, while the peak indicates processes involving the capture of an orbital or a free electron by the decaying nucleus.

TABLE I.—*Evolution of the Sun*

Billions of years ago	4.5	3.6	2.7	1.8	0.9	Now
Luminosity	0.73	0.77	0.83	0.87	0.92	1.00
Radius	0.95	0.95	0.97	0.98	0.99	1.00
Surface temperature (degrees Kelvin)	5,400	5,500	5,500	5,600	5,600	5,800
Central temperature (millions of degrees)	14	15	15	15	16	16
Central density	89	98	110	120	140	170
Percent hydrogen	68	61	53	46	38	31
% PP I	86	82	79	71	64	56
% PP II	13	17	22	28	34	40
% PP III	0.004	0.008	0.01	0.02	0.03	0.05
% PP IV	0.4	0.06	0.9	1.3	2.0	3.2

Luminosity and radius are in terms of the present value for the sun, central density in grams per cubic centimeter. The percentage of hydrogen is in terms of the sun's mass. The last four lines give the percentage of the total energy provided by the four different reactions.

central density and central hydrogen abundance. But note particularly the last four lines of the table, which give the fractional contribution of each PP branch. We see that more than half the sun's energy has come from PP I during the past 4½ billion years. The PP II branch has been slowly increasing in importance until it now provides 40 percent of the sun's energy. On the other hand, the remaining two branches appear to be relatively unimportant.

Our computations have included a detailed calculation of how temperature, pressure, and other properties change from the center out to the surface of the present sun. This permitted a further computation that gave the relative contributions of the four PP branches at different levels in the solar interior. Finally, we could predict the neutrino energy spectrum of the sun, illustrated in Fig. 4.

From this chart we see the relative importance of different neutrino sources over the whole energy range. For instance, the hump marked H represents the reaction where two protons unite to form a deuteron, positron, and neutrino (see the first line of PPI in Fig. 2). At an energy of 0.3 million electron volts, it rises to a flux of about three neutrinos per square centimeter each second per million electron volts. Almost the same flux comes from the peak H′, for the combination of two protons and an electron to yield a deuteron and neutrino (not included in Fig. 2).

The most prominent features are the two peaks of beryllium-7, which rise to 47 and 344 but are very narrow. Although the neutrinos from boron-8 are very rare, they turn out to be the most important, because their high energies mean very large capture cross sections and hence easier detection. Since this chart has been normalized to

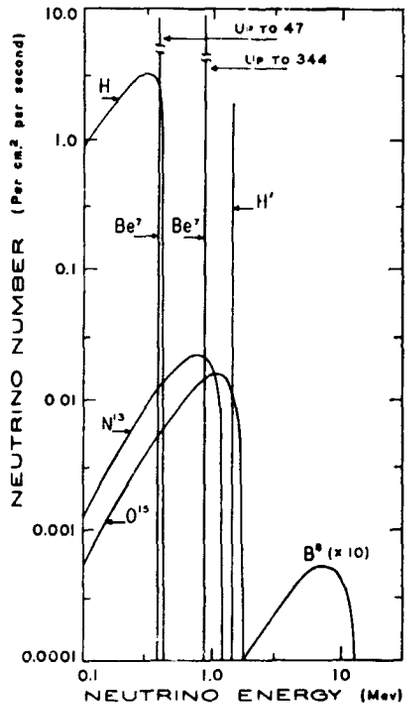

FIGURE 4.—The neutrino energy spectrum of the sun, normalized to one particle in the entire flux. The horizontal scale is in millions of electron volts. Capture of free electrons by beryllium-7 nuclei and by protons (H') results in very narrow, high peaks. Their heights depend on density and temperature in the sun's interior.

one neutrino over the whole energy range, to obtain the flux at the earth multiply ordinate values by 6.5×10^{10}.

DETECTING SOLAR NEUTRINOS

A neutrino, as we have seen, can be captured by a neutron (either free or in a complex nucleus). Since free neutrons are not readily available, a detection system must utilize some suitable isotope. A very good choice is chlorine-37, which can react with a neutrino to yield argon-37 and an electron.

For capture by chlorine-37 to take place, an incident neutrino must have an energy of at least 0.814 million electron volts. And above this limit, high-energy neutrinos have a much better chance of inducing the reaction, since the collision cross section is proportional to the square of the energy of the out-coming electron.

Looking back at Fig. 4 with these facts in mind, we see at once that most of the solar neutrinos are not capable of inducing this reaction. Indeed, we lose all the neutrinos from the hump of the proton-proton reaction, and all the neutrinos from the first beryllium-7 peak.

In fact, a recent calculation by J. N. Bahcall shows that of every 100 solar neutrinos captured by a chlorine-37 detector, about eight will come from the higher beryllium-7 peak and about 92 from the boron hump. Negligible contributions come from the other neutrino-producing processes. The total probability of a capture per target nucleus of chlorine-37 will be as low as 4×10^{-35} per second.

This means that any feasible detection apparatus must be enormous! Indeed, multiplying this rate by the number of chlorine atoms will give the probability of an event per second in the detector. Since practical considerations require a counting rate not much smaller than one a day, the detector must contain about 10^{30} chlorine atoms. At the present time, Dr. Davis considers the experiment perfectly feasible.

THE DETECTING EQUIPMENT AND ITS OPERATION

In his first attempt, Dr. Davis has worked with a 1,000-gallon and later a 3,000-gallon tank of carbon tetrachloride (CCl_4). Now he uses perchlorethylene (C_2Cl_4) as it is less toxic and has a lower vapor pressure. The estimate noted in this article has required him to consider a detecting tank holding 100,000 gallons of material (2.2×10^{30} atoms of chlorine-37). This amount of liquid would fill 40 tank trucks of the usual size one sees on the highway!

Before use, the filled tank has to be cleansed of all argon atoms already there from atmospheric contamination or other sources. The procedure is to sweep helium bubbles through the liquid. Then the tank is left to rest, exposed as always to the effect of solar neutrinos. Gradually, at a rate of about one per day, chlorine-37 atoms are transformed into argon-37 by the reactions. However, the argon-37 is naturally radioactive, and through beta decay changes back to chlorine-37 in about 35 days, so it does not pay to wait too long. In fact, after a few months, the concentration of argon-37 saturates and remains at the same level indefinitely.

Therefore, after about 100 days the tank will again be swept clear of argon. Then the helium

will be removed from the argon by another chemical process, and the argon atoms will be gathered in small containers. Among various other isotopes, the argon contains argon-37 produced by neutrino reactions. Through their beta disintegration, these atoms will produce a signal measurable by standard nuclear physics techniques, thus making their presence known.

As can well be imagined, the major problem is background. A large number of other processes may give exactly the same final result, and the experimentalist must make absolutely sure that the counts he registers in his counter are really from argon-37 generated by solar neutrinos. The tank is close to the impossible, and requires the utmost skill of the experimental nuclear chemist. For instance, to avoid competition by cosmic rays in producing this reaction, the tank and all the chemical equipment will have to be buried far beneath the surface of the earth. Present indications are that the tank is to be located in a mine at a depth of several thousand feet, in a room specially excavated to hold all the apparatus. So far, the whole experiment is on paper, except for the detection apparatus, which is partly set up at Brookhaven, New York. We hope that construction will start soon, and that there will be some results within a few years.

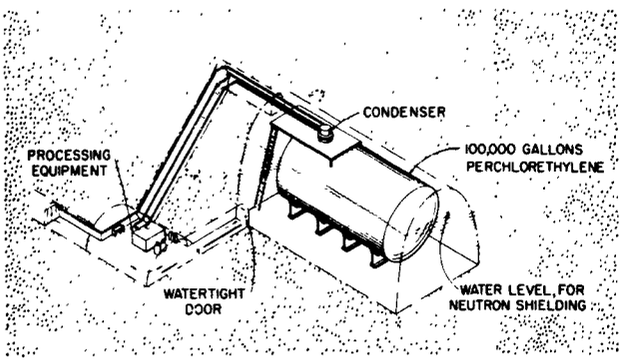

FIGURE 5.—A plan for the Brookhaven observatory that may detect neutrino emission from the sun. In this enormous tank, roughly 20 feet in diameter and 40 feet long, the nuclear chemist will have to fish for perhaps 100 atoms of radioactive argon–37 generated by chlorine-neutrino interactions. Illustration courtesy Raymond Davis.

WHAT CAN WE LEARN FROM SOLAR NEUTRINOS?

If the experiment is successfully carried through, one possibility is that we will find just what has been predicted. This in itself would be a major feat. All that we know directly about the sun has come from observations of its surface layers. We have been able to explore the interior only by applying point by point the differential equations of theoretical physics. Thus, we have only highly indirect evidence of conditions deep inside the sun, from which the nuclear reactions taking place there must be analyzed. The weight of indirect evidence should not be underestimated, but it would be very desirable to obtain *direct* information on the center of the sun, and to verify that our understanding of the processes there is correct. In particular, the rate of neutrino emission would provide a sensitive test of the adopted central temperature. There is also a rather remote possibility that some important physical factors, as yet unknown, are operating inside the sun. The history of science teaches us about many such upsets.

Is it possible that the neutrino flux from the sun varies with time, for instance with the solar cycle? Most solar experts consulted believe this unlikely. But we really cannot tell beforehand what will come from this and some other suggested problems for the solar neutrino observatory. In any event, it is a new channel of information for solar physics, and should be thoroughly explored. We are all waiting for the first clicks in Dr. Davis' immense tank.

ACCRETION OF INTERSTELLAR MATTER BY MASSIVE OBJECTS*

E. E. SALPETER†

N66 37950

Observations of quasi-stellar radio sources have indicated the existence in the Universe of extremely massive objects of relatively small size. The present note discusses the possible further growth in mass of a relatively massive object, by means of accretion of interstellar gas onto it, and the accompanying energy release. Although there is no evidence for (and possibly some evidence *against*) quasi-stellar radio sources occurring inside ordinary galaxies, for the sake of concreteness we consider the fate of an object of mass $M>10^6$ (masses in solar units throughout) in an ordinary spiral galaxy somewhat like ours.

We first re-examine the hypothetical problem of an object of mass M moving with velocity U (in km/sec) relative to a completely uniform gas medium of density n (expressed as H-atoms per cm^3) and thermal speed $U_{\rm th}$. We define (Hoyle and Lyttleton 1939) a characteristic length s_0 and express the rate of accretion in terms of a dimensionless parameter α to be determined,

$$s_0=GM/U^2=(M/U^2)\times 4.3\times 10^{-3}\ \text{pc},$$
$$dM/dt=2\pi\alpha s_0^2\, nU=\alpha M/t_0, \qquad (1)$$
$$t_0=(U^3/Mn)\times 3.3\times 10^{11}\ \text{years}.$$

We assume that the size of the object, as well as the collision mean free path in the gas, is very much smaller than s_0. For cases with large Mach number, $U\gg U_{\rm th}$, a standing (relative to the object) shock front develops behind the object, with a large pressure increase across the front. The shape of the shock front is conical about the accretion axis, as shown schematically in Figure 1, but the cone angles depend on the specific heat ratio γ of (and on any irreversible energy loss from) the gas. If $\gamma-1\ll 1$ (almost isothermal compression) then the density increases greatly across the shock front, the cone angles are everywhere small, and pressure gradients parallel to the accretion axis are small compared with gravitational forces. For such cases Bondi and Hoyle (1944) found that $1<\alpha<2$, no matter what the degree of mixing in the shocked region is. For the special case of purely laminar flow, the results are as though molecules moved without collisions except for giving up their transverse momentum when they reach the accretion axis. In this case all the gas with impact parameters less than $\sqrt{(2)}\ s_0$ is accreted and $\alpha=2$.

If $\gamma-1$ is appreciable, then the cone angles of the shock front are not very small, and the gas molecules lose less of their transverse momentum when crossing the shock front and also regain some longitudinal momentum during the re-expansion in the shocked region (see Ruderman and Spiegel [1964]). These effects result in α decreasing with

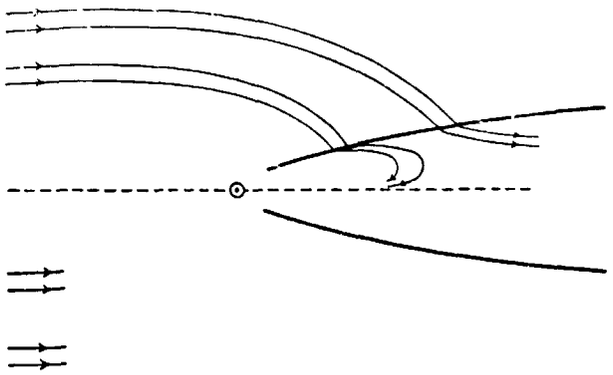

FIGURE 1.—A schematic view of the flow. The dotted line is the axis of accretion. The heavy line is the standing shock front; the thin lines are (laminar) flow lines.

increasing γ. Explicit calculations for $\alpha(\gamma)$ have not yet been carried out but plausibility arguments lead to the conjecture that α is non-zero for $\gamma<\frac{5}{3}$ and not much less than unity for $\gamma<\frac{4}{3}$. The α is also reduced slightly if U is only slightly larger than U_{th} (see Bondi [1952] for cases with $U<nU_{th}$).

McCrea (1953) has discussed the slowing down of an object during its passage through a gas cloud with velocity $U\ll U_{th}$. This retardation, analogous to that experienced by a charge moving through a plasma, can be expressed as

$$dU/dt=-\beta U/t_0, \qquad \beta\approx 1+\ln(b_{max}/s_0), \qquad (2)$$

where t_0 and s_0 are defined in equation (1). For a uniform medium of infinite extent the limiting impact parameter would be $b_{max}\sim U/\sqrt{(4\pi\rho G)}$ as in the plasma problem. In practice the limit in the gravitational problem is the extent of the uniform medium (e.g., thickness of the galactic disk). Consider a massive object in the "halo population" with $U\sim 100$ or 200 (relative to the galactic disk) which spends a fraction of about $(10/U)$ of its time in the disk. According to equations (1) and (2) the time required for slowing down is $(U10)\ t_0/4\beta$ (if mass increase is neglected and β assumed constant). Unlike accretion of mass, the retardation involves only distant gravitational encounters and does not require collisions by the "gas molecules," so that the stars in the disk also contribute to the retardation. We assume an average gas density $n\sim 1$ in the disk and $n_{tot}\sim 10n$ (including stars) and $\beta\approx 5$. A halo object with initial velocity U (relative to the disk) will slow down in a time less than 10^{10} years, roughly the age of our Galaxy, if its mass M exceeds a critical value of

$$M_{cr,\,sl.}\approx (U/100)^4\times 1.5\times 10^6. \qquad (3)$$

For a highly supersonic object retardation is more rapid than accretion ($4\beta n_{tot}\gg\alpha n$), an we need to consider accretion only after the object has slowed down to a velocity U not much bigger than U_{th}. For our large mass M the characteristic impact parameter s_0 exceeds the "spacing between interstellar gas clouds" (or "turbulence scale length") d, and we have to include the random cloud velocities in the thermal velocity. We assume $U_{th}\sim 10$ or 15, $U\sim 25$, $n\sim 1$. We thus cannot make use of the much lower thermal velocity and higher density available in individual H I region, as attempted in previous work for smaller masses. On the other hand, the difficulties encountered previously (Schatzman 1955) due to the heating and expansion of H I regions are absent wher $s_0>d$. The energies released by the compression at distances near s_0 can easily be radiated away at typical H II temperatures, so the compression is almost isothermal ($\gamma-1$ small). The presence of turbulent magnetic fields in the gas makes the compression more adiabatic and raises the effective γ toward $\frac{4}{3}$. The accretion time (t_0/α) is less than 10^{10} years if the mass M exceeds

$$M_{cr,\,acc.}\approx (U/25)^3\ (0.25/\alpha n)\times 2\times 10^6, \qquad (4)$$

and α probably lies between 0.1 and 1. The characteristic impact parameter is $s=\sqrt{(\alpha)}s_0$ (with $s\approx 7$ pc for $M=M_{cr,\,acc.}$) and the size of the object must be less than s. The mass of typical halo globular clusters in our own Galaxy is too small for retardation and accretion to become catastrophic by one order of magnitude or so (and their diameter would be sufficiently small).

So far we have only discussed the gravitational capture of gas atoms from the stream at radial distances r from the central object with $r\sim s$, where the energy released per H atom ($\sim GMH/S\sim\frac{1}{2}HU^2$) is only a few eV. If the original gas stream possessed no angular momentum about the accretion axis at all (and $\gamma<\frac{5}{3}$) the captured gas would immediately collapse toward the center, somewhat as in star formation but with a continuously increasing mass in the condensation. The evolution of massive stars takes less than 10^7 years and no zero-temperature spherical equilibrium models exist exceeding two or three solar masses. After a relatively short time, then, most of the accreted matter would have collapsed to the "Schwarzschild singularity" ($r=2GMc^2$). Although the gravitational redshift for radiation from "collapsed matter" is large, note that its "active gravitational" (as well as "passive inertial") mass is essentially undiminished. If the original star cluster (or other non-condensed object) exceeded both critical masses in equations (3) and (4), then the accreted collapsed matter eventually dominates as the cause for further accretion.

Theories for quasi-stellar (or other condensed) objects which invoke the gravitational collapse of an *isolated* mass or cluster usually encounter some difficulties in shedding original angular momentum. In our problem the incident "turbulent" gas stream will also carry some small angular momentum at any instant of time, and a captured gas "turbule" will not be able to penetrate to very small radial distances by itself. For our continuous gas stream, however, the angular momentum is only a statistical quantity, provided that the accretion impact parameter s is much smaller than characteristic dimensions of the galaxy. The angular momentum then changes sign over times of the order of s/U and in about that time a gas "turbule" can shed its angular momentum by collisions with other turbules and spiral in toward the Schwarzschild radius. In this turbulent manner gravitational energy is continually converted into bulk kinetic energy, compressional heating, and compression of turbulent magnetic fields. Densities $n(r)$ at radial distance $r \ll s$ must lie in the range between $(s/r)^{1.5}n$ and $(s/r)^3 n$ and radiating away energy (bremsstrahlung or synchrotron radiation via energetic electrons) at these high densities presents no great problems.

Each accreted gas atom eventually approaches the Schwarzschild radius $r=2r_0$ (with $r_0=GM/c^2 = (M/10^8)\times 4.7\ 10^{-6}$ pc), and we have to estimate the fraction $f_{\rm tot}$ of its rest-mass energy which is radiated away altogether. As a simplified model for the spiraling in via many collisions, consider a particle in circular orbits with diminishing radii caused by a slow drain of angular momentum and energy. Due to general relativistic effects (see the Appendix) the orbits become unstable to *spontaneous* spiraling in at $r=6r_0$. By this time a fraction $f=0.057$ of the rest-mass energy has escaped to infinity. If, at $r=6r_0$, the particle could be brought to rest (by the unlikely collision with a matched particle of opposite momentum) an additional fraction $\Delta f=0.126$ could in principle escape. After free fall to $r=3r_0$ the additional fraction is 0.22, and so on. However, the chances of arresting the free fall with appreciable efficiency seem small. In addition, even in the absence of any optical absorption, 50 per cent of all radiation (or highly relativistic particles) emitted isotropically at $r=3r_0$ would be prevented from escaping by general relativistic effects (but only 14.5 per cent at $r=6r_0$). We estimate $f_{\rm tot}$ (net energy escaping to infinity in all forms) to lie in the range of 0.05–0.20. Note that the gravitational mass of the collapsed source is increased by a fraction $1-f>0.8$ of the accreted mass, and we omit a corresponding correction factor which should be applied to equation (1).

The optical luminosity $L_{\rm opt}$ can be written in the form

$$L_{\rm opt}=\left(\frac{25}{U}\right)^3 n\frac{\alpha}{0.25}\,\frac{f_{\rm opt}}{0.03}\left(\frac{M}{10^7}\right)^2\times 2\times 10^9 L_\odot \quad (5)$$

If α (and n) remained constant, then M (and L) would increase to infinity after a finite time (t_0/α), according to equation (1). However, the effects of radiation pressure decrease the effective value of the gravitational constant appreciably as $(L_{\rm opt}/M)$ approaches a limiting value which depends on the average opacity coefficient. $(L_{\rm opt}/M)_{\rm lim}$ can be as low as 100 (in solar units) in H II-regions in our Galaxy, due to the presence of dust grains (van de Hulst 1955) and as large as 3×10^4 in pure ionized hydrogen if only Thomson scattering is important. Once the mass M has grown sufficiently for equation (5) to give a value of $(L_{\rm opt}/M)$ close to this limit, radiation pressure automatically lowers α in such a way as to keep $L_{\rm opt}/M$ almost constant. Subsequently, M (and hence $L_{\rm opt}$) increases with time only exponentially as $e^{t/\tau}$, where

$$\tau=(f_{\rm opt}/0.03)(10^3\, M/L_{\rm opt})\times 4\times 10^8 \text{ years}, \quad (6)$$

and the characteristic accretion impact parameter $s=\sqrt{(\alpha)}s_0$ increases only as $\sqrt{M}$. For instance, under typical conditions for our galactic disk with $(L_{\rm opt}/M)_{\rm lim}\sim 200$, the exponential growth would start at $M\sim 10^7$ and s would reach about 350 pc when $M\sim 10^9$ and $L_{\rm opt}\sim 2\times 10^{11}$.

To summarize the situation for a highly evolved spiral galaxy like ours (with only a few per cent of the mass remaining in the form of gas): Objects of the order of $10^6\ M_\odot$, more than typical globular cluster masses, are required to initiate a catastrophic accretion process. Unlike theories involving the gravitational collapse of *isolated* objects, the time scale of our process never becomes very short due to the self-limiting effects of radiation pressure. In our Galaxy, in fact, dust grains would keep the time scale well above 10^8 years,

which is much longer than required for quasi-stellar objects, and the luminosity too low ($<10^{12}\ L_\odot$). The situation is likely to be more favorable in systems less evolved than our Galaxy where (*a*) a larger fraction of the mass is still in the form of gas and (*b*) the relative abundance of heavier elements, and hence of dust grains, is lower. This leads to a shorter time scale and a larger limiting value for the luminosity-mass ratio for the accreting condensation.

I am indebted to Drs. R. P. Feynman, M. Ruderman, M. Schwarzschild, E. Spiegel, L. Spitzer, and L. Woltjer for helpful criticism and suggestions. In fact, they have contributed most of the positive ideas in this note without being responsible for any of the unwarranted conjectures. I am also grateful to the National Academy of Sciences for a senior postdoctoral fellowship.

APPENDIX

We use the usual Schwarzschild metric outside of a mass M (and put $c=1$),

$$ds^2\,(1-2u)dt^2-(1-2u)^{-1}dr^2-r^2d\theta^2, \qquad \text{(A1)}$$

where $u=GM/_r$, and we consider the motion of a single test particle of unit mass in this field. As discussed by Feynman in unpublished lecture notes, the following quantities are constants of the motion

$$k\equiv(1-2u)t^{(1)}, \qquad l\equiv r^2\theta^{(1)}, \qquad \text{(A2)}$$

where a superscript (1) denotes differentiation with respect to proper time. The terms l and k are generalizations of angular momentum and energy, respectively, and are also conserved in any *local* collision processes (any number of particles at the same u). The radial distance r satisfies the equation

$$[r^{(1)}]^2=k^2-1+2u-(1-2u)l^2u^2. \qquad \text{(A3)}$$

The circular orbit with the smallest radius which is stable is then at $u=\frac{1}{6}$ with $l=2\sqrt{3}$ and $k=\sqrt{\frac{8}{9}}$. A photon (or an extremely relativistic particle) can have an unstable circular orbit at $u=\frac{1}{3}$. A particle at rest at distance $r(r[1]=l=0)$ has $k=\sqrt{(1-2u)}$. Consider a particle which started at rest far away ($k=1$, $u=0$) and ends up at some finite distance from the source with some value of k. If the energy released during the change all escapes "to infinity" then the escaped energy (*after* all redshift corrections) is simply $(1-k)c^2$.

C_2 SWAN BANDS IN COMETS*

N66 37951

RALPH E. STOCKHAUSEN AND DONALD E. OSTERBROCK†

The relative populations of the vibrational levels of the X $^3\Pi$ and A $^3\Pi$ electronic levels are calculated assuming the fluorescence mechanism. Pure vibrational transitions are taken into account by making a rough estimate of the magnetic-dipole transition probabilities. Both the approximate method, Rosseland's theory of cycles applied to a three-level molecule, and the accurate solution of the equations of statistical equilibrium for a 10-level molecule, give similar results. The excitation temperatures derived from these relative populations agree satisfactorily with the observations of the Swan bands by McKellar and Climenhaga (1953) for various sun-comet distances. Finally, an estimate is made of the infrared radiation, due to pure vibrational transitions, expected from a bright comet. The expected amount of radiation is small and will be difficult to detect.

It is well known that the C_2 Swan bands observed in comets are excited by the mechanism of resonance fluorescence (Stawikowski and Swings 1960). Observations give excitation temperatures (defined by a Boltzmann distribution of the relative populations of vibrational levels of the X $^3\Pi$ ground electronic term) in the range $T_{ex} \approx 2000$–$3000°$ at sun-comet distances of 0.48 to 1.40 a.u. (McKellar and Climenhaga 1953). Other cometary molecules such as CN, CH, NH and OH are observed to have much lower excitation temperatures, and this is understood qualitatively to be a consequence of spontaneous downward radiative transitions (vibrational and pure rotational) within the ground electronic terms of these molecules (Wurm 1936). In fact, quantitative calculations using estimated transition probabilities approximately match the observed excitation temperature (Hunaerts 1953, 1957). However C_2 has no permanent electric dipole moment, and the downward radiative transitions within the ground term are therefore forbidden, so that large populations occur in highly excited vibrational levels (Wurm 1936).

Houziaux (1960) has calculated the expected populations of successive vibrational levels in C_2, taking account only of resonance fluorescence in the Swan bands, and assuming all transition probabilities within the ground X $^3\Pi$ term to be identically zero. However the calculations do not agree very well with observation in that the calculated excitation temperatures are higher than the observed excitation temperatures and furthermore vary considerably from one level to the next.

In fact, however, magnetic dipole transitions of the type $\Delta\Sigma = \pm 1$ can occur within the ground X $^3\Pi$ term of C_2, since all the selection rules for this type of transition are fulfilled (Van Vleck 1934). We can see the approximate effect of these transitions by applying Rosseland's theory of cycles to a simplified 3 level molecule, taking the lowest levels 1 and 2 as successive vibrational levels of X $^3\Pi$, and the high level 3 as any vibrational level of the upper A $^3\Pi$ term that is connected by strong radiative transitions with both levels 1 and 2. Then the population ratio is (Ambartsumyan 1958).

$$\frac{n_2}{n_1} = We^{-h\nu 21/kT} \frac{A_{31}e^{-h\nu_{32}/kT} + \frac{A_{21}}{A_{32}}(A_{31}+A_{32})}{WA_{31}e^{-h\nu_{32}/kT} + \frac{A_{21}}{A_{32}}(A_{31}+A_{32})} \equiv e^{-h\nu 21/kT_{ex}} \quad (1)$$

where W is the dilution factor, T is the radiation temperature and T_{ex} is the observed temperature as defined above.

*Published as *Goddard Space Flight Center document X-614-64-252*, August 1964.

†Washburn Observatory, Madison, Wisconsin.

In a crude first approximation $A_{31} \approx A_{32} \gg A_{21}$ so if $WA_{31} \exp(-h\nu_{32}/kT) \gg A_{21}$, that is if the transition 2→1 is strongly forbidden, then $T_{ex} \approx T \approx 5730°$. Alternatively, if $A_{31} \exp(-h\nu_{32}/kT) \gg A_{21}$, that is 2→1 can occur, then $[W] \exp(-h\nu_{21}/kT) \approx \exp(-h\nu_{21}/kT_{ex})$. For a comet at 1 a.u. distance from the sun the geometrical dilution factor is $W \approx 5 \times 10^{-6}$, $(h\nu_{21}/kT) \approx 0.4$, and this limit gives $T_{ex} \approx 180°$. The magnetic dipole transition probability is (Condon and Shortley 1951)

$$A_{vib} = \frac{64\pi^4 \sigma^3}{3h} (aMb)^2, \qquad (2)$$

where $\sigma = 1618$ cm^{-1} is the wave number between successive vibrational levels, and (aMb) is the matrix element of the magnetic dipole moment, which we can crudely estimate to be 1 Bohr magneton. We thus roughly estimate $A_{21}(=A_{vib}) = 10^{-1}$ sec^{-1}, which is of the same order of magnitude as $WA_{31}\exp(-h\nu_{32}/kT)$, but smaller than $A_{31}\exp(-h\nu_{32}/kT)$, since for the strongest transitions in the Swan bands $A_{31} \approx 5 \times 10^6$sec^{-1}. Accordingly, we expect the calculated excitation temperature to be between the two limits above but closer to the first, that is, to be of the order of a few thousand degrees.

Therefore accurate calculations of the statistical equilibrium of cometary C_2 were made, taking into account the lowest 5 vibrational levels of the ground X $^3\Pi$ term and also the lowest 5 vibrational levels of the upper A $^3\Pi$ term.

The relative populations were obtained by solving the equations of statistical equilibrium. Equations similar to those of Houziaux (1960) were used, with the addition of pure vibrational transitions within the electronic terms. Only those pure vibrational transitions with $\Delta v = \pm 1$ were considered. For compieteness, pure vibrational absorptions of solar infrared radiation were included, although they had negligible influence on the results. Following are the equations of statistical equilibrium, lower electronic term, i = 1, 5:

$$n_{i-1} B_{i-1\ i} \rho_{i-1\ i} - n_i(B_{i\ i-1} \rho_{i\ i-1} + A_{i\ i-1} + B_{i\ i+1} \rho_{i\ i+1} + \sum_{k=6}^{10} B_{ik} \rho_{ik}) + n_{i+1} (B_{i\ i+1} \rho_{i\ i+1} + A_{i+1\ i}) + \sum_{k=6}^{10} n_k (B_{ki} \rho_{ki} + A_{ki}) = 0 \qquad (3)$$

upper electronic term, j = 6, 10:

$$n_{j-1} B_{j-1\ j} \rho_{j-1\ j} - n_j[B_{j\ j-1} \rho_{j\ j-1} + A_{j\ j-1} + B_{j\ j+1} \rho_{j\ j+1} + \sum_{=1}^{5} (B_j \rho_j + A_j)] + n_{j+1} (B_{j+1\ j} \rho_{j+1\ j} + A_{j+1\ j}) + \sum_{=1}^{5} n B_j \rho_j = 0 \qquad (4)$$

The notation is essentially the same as used by Houziaux (1960).

The same values of A_{vib} were used for all vibrational transitions of both upper and lower electronic terms. For the pure vibrational absorptions, all upper levels were assumed to absorb at $\lambda = 5.70\mu$ while the lower absorbed at 6.18μ (these are wavelengths of the $v=0$ to $v=1$ transitions). The solar radiation at these wavelengths was obtained from Allen (1963). Values of the other parameters used in equations (3) and (4) are listed in Table 1. The columns headed m and n refer to the subscripts used in equations (3) and (4). The transition probabilities were computed from the overlap integrals and the oscillator strength using the same values of these quantities as Houziaux (1960). The radiation densities were derived from the "mean monochromatic intensities" in Table 1 of Minnaert (1953). The transition probabilities and radiation densities computed here are slightly different from those of Houziaux, but either set of values gives essentially the same results.

The equations of statistical equilibrium were solved with the aid of an electronic computer. For comparison, we show in Table 2 the results of our work for the case with $A_{vib} = 0$ and a sun-comet distance of 0.72 a.u. (which is probably the distance used by Houziaux) and Houziaux's results for the same case. We believe that there is some error in the latter. Table 3 shows the results for various values of A_{vib} and the sun-comet distance. In order to allow for uncertainties in the value of A_{vib}, calculations were made with the assumed values $A_{vib} = 1.0$, 0.1 and 0.01 sec^{-1}.

It can be seen that the results of Table 3 have the same behavior as the three-level case, i.e., decreasing vibrational temperature with increasing vibrational transition probability. It is also seen that transition probabilities between $A_{vib} = 0.1$ and 1.0 sec^{-1} give excitation temperatures in the 2000–3000° range observed by McKellar and Climenhaga.

From the relative populations given in Table 3 it is also possible to estimate the expected infrared radiation of cometary C_2. We will make this calculation for the (1,0) band of the lower electronic term, which occurs at 6.18μ. Both the earth-comet and sun-comet distances are taken as 1 a.u.

According to Wurm (1963), the number of C_2 molecules in the ground state of a typical bright comet is

$$N(C) \approx 6\times 10^{32} \text{ molecules}$$

The luminosity in the (1,0) band is then given by the expression

$$L \approx \frac{N(v''=1)}{N(v''=0)} \cdot N(C_2) A_{vib}\, h\nu_{vib}$$

where $N(v''=1)/N(v''=0)$ is a relative population given in Table 3. With the assumption $A_{vib}=0.1$ $\sec^{-1}$ we obtain $L \approx 9\times 10^{18}$ ergs/sec, or a flux received at the earth, assuming the whole comet is in the field of the telescope, of about 3×10^{-9} ergs/cm^2 sec.

Rough calculations can be made as to the possibility of detecting this band. Assuming that the minimum power (i.e. Noise Equivalent Power) detectable by an infrared detector is about 10^{-11} watts; and that 0.1 of the power incident on the telescope reaches the detector, then it would require a telescope diameter of several hundred inches to observe this band (even above the atmosphere). Clearly, detection of the infrared lines of C_2 are not to be expected.

In summary, then, with the estimated pure vibrational transition probabilities and the assumption of the fluorescence mechanism, we have been able to derive relative populations of a 10-level C_2 molecule. These results are in agreement with those suggested by a simplified 3-level molecule and with published observations of comets.

It has also been possible to predict the infrared emission expected from a bright comet. This emission seems too weak to be observed. Similar calculations need to be performed on other cometary molecules to predict their infrared spectra.

EVOLUTION OF O STARS. II. HYDROGEN EXHAUSTION AND GRAVITATIONAL CONTRACTION*

RICHARD STOTHERS

The evolution of a star of 30 $M_\odot$ is considered from the end of the stable phase of hydrogen burning to the onset of helium burning. Ten models are constructed for the hydrogen-exhaustion (E) phase, and six models for the gravitational contraction (G) phase.

The time scale of the E-phase is so short (8.8×10^4 years) that the shell source remains peaked at $q=0.34$ and undergoes little hydrogen depletion. Because radiation pressure remains strong in the core, convection does not vanish when the hydrogen content at the center falls to zero. Gravitational contraction of the core contributes more to the luminosity than shell burning, but since the total luminosity changes little, the structure of the envelope is hardly affected. On the H–R diagram, the evolutionary track turns back toward the main sequence when $X_c=0.03$, and does not turn away again until the shell source becomes important.

The G-phase begins when $L_{H,\,core}/L<0.001$, and lasts 9×10^3 years. Although the temperature in the shell increases, hydrogen depletion remains negligible because of the short time scale. However, the shell narrows considerably and its peak moves slightly inward for a while. The steep temperature gradient outside the shell causes the semiconvective zone to move inward to $q=0.48$; the hydrogen discontinuity attains a value $\Delta X=0.1$. As the luminosity and radiation pressure in the shell simultaneously increase, the envelope expands. The shell then behaves like a node, since the core continues to contract. The convective region near the center shrinks asymptotically to a value $q=0.06$, but at no time does the core approach an isothermal condition. The gravitational energy release is nearly uniform throughout the core in all phases. At the onset of helium burning, $T_c=1.5\times10^8$ °K and $\rho_c=270$ gm/cm³. Because of the brightening shell source, the stellar radius increases rapidly, bringing the evolutionary track to completion of the typical S-shaped curve on the H–R diagram.

When helium starts to burn, the spectral type is B3, and the star is expected never to return to the region of O stars during its active life.

I. INTRODUCTION

In massive stars when the central hydrogen content falls to a value of 0.03, the whole structure undergoes a drastic reorganization. Kushwaha (1957) first considered the subsequent early phase of hydrogen burning in a shell outside the convective core for a star of 10 $M_\odot$. Reiz (1963) has reconsidered and extended this work, but Hayashi and Cameron (1962) and Hayashi, Hoshi, and Sugimoto (1962) have pursued the study of a star of $15.6M_\odot$ into the entire hydrogen-exhaustion phase and then into the gravitational contraction phase preceding helium burning. These phases have also been considered for stars of intermediate mass, as follows: $3.89M_\odot$ (Hoyle 1960), $4M_\odot$ (Hayashi, Nishida, and Sugimoto 1962; Hayashi, Hoshi, and Sugimoto 1962), $5M_\odot$ (Polak 1962), and $7M_\odot$ (Hofmeister, Kippenhahn, and Weigert 1963). It is the purpose of the present paper to follow the evolution of a star of $30M_\odot$ during these phases to the onset of helium burning at the center. The previous hydrogen-burning stage has been computed in Paper I (Stothers 1963).

II. ASSUMPTION AND DEFINITIONS

a) Assumptions

The same general assumptions as in Paper I are made, except that nuclear-energy generation also occurs in a radiative shell around the core and the

*Published in *The Astrophysical Journal*, 140(2): 510–523, August 15, 1964. This paper and "Evolution of O Stars. I Hydrogen Burning" were based on the author's doctoral dissertation, Harvard University, 1963.

time rate of change of the physical variables must be taken into account during these fast evolutionary phases.

The opacity of stellar material is again assumed to be due only to electron scattering, and the equation of state is represented by the sum of the perfect gas pressure and radiation pressure.

b) Notation

In general, we apply the same notations for stellar zones as in Paper I, except here we divide the radiative intermediate zone into outer (Zone IIIa) and inner (Zone IIIb) subzones, separated by the radiative, hydrogen-burning shell (denoted by a subscript s).

To designate the successive evolutionary phases we introduce H (hydrogen burning), E (hydrogen exhaustion), and G (gravitational contraction) followed by a number indicating the particular model in the phase.

c) Chemical Composition

The outer radiative envelope retains the initial age-zero composition assumed in Paper I:

$$X_e=0.70,\ Y_e=0.27,\ Z_e=0.03,\ X_{\rm CNO}=Z_e/2. \quad (1)$$

The semiconvective zone constantly adjusts its composition to maintain convective neutrality. A discontinuity in X marks its interface with the inner radiative zone, which retains a constant gradient in X, left behind by the retreating, homogeneous convective core. The distribution of X for the last model of the hydrogen-burning phase is given by Figures 3 and 4 of Paper I. In the core of that model $X_c=0.07$.

The change of hydrogen content as an explicit function of time, τ, and mass fraction, q, is given by

$$\frac{\partial X}{\partial \tau}=-\frac{\epsilon_{\rm H}}{E_{\rm H}} \text{(radiative region)} \quad (2)$$

and

$$\frac{\partial X}{\partial \tau}=-\frac{1}{q_4 E_{\rm H}}\int_0^{q_4}\epsilon_{\rm H}dq \text{ (convective core)}, \quad (3)$$

where $\epsilon_{\rm H}$ is the energy generation due to hydrogen burning and $E_{\rm H}=6.0\times10^{18}$ erg/gm is the energy released per CNO cycle.

d) Nuclear Energy

The accurate expression for the rate of energy release due to the conversion of hydrogen into helium via the full CNO cycle has been given by Reeves (1962) in terms of the $N^{14}+H^1$ rate:

$$\epsilon_{\rm H}=7.94\times10^{27}f_{14,1}g_{14,1}\left(\frac{X_{14}}{X_{\rm CNO}}\right)X_{\rm CNO}X\rho T_6^{-2/3} \exp\left(-152.3T_6^{-1/3}\right) \text{ erg/gm sec} \quad (4)$$

where

$$f_{14,1}=1+1.75\,\rho^{1/2}T_6^{-2/3}, \quad (5)$$

$$g_{14,1}=1+0.0027\,T_6^{1/3}-0.0037\,T_6^{1/6}-0.00007T_6, \quad (6)$$

$$X_{14}/X_{\rm CNO}=0.99-0.00067\,T_6. \quad (7)$$

Here $f_{14,1}$ is the weak electron-screening factor, $g_{14,1}$ is the correction term to the zero-energy S factor, and $X_{14}/X_{\rm CNO}$ has been estimated from tables given by Reeves (1962) for temperatures in excess of 2.5×10^7 °K. We are assuming everywhere the full equilibrium abundance of oxygen, which, strictly speaking, is not attained in the cooler shell source because of the short time scale involved.

e) Gravitational Energy

The amount of energy involved during a gravitational contraction or expansion is expressed as the difference between the work done by the pressure and the change in thermal energy of the gas and radiation:

$$\epsilon_g=-P\frac{\partial v}{\partial s}-\frac{\partial u}{\partial \tau}=\frac{3kT}{2\mu H}\left[\frac{\partial}{\partial \tau}\ln\left(Ty^{-2/3}e^{-8y/3}\right)+\frac{5+8y}{3}\frac{\partial}{\partial \tau}\ln\mu\right], \quad (8)$$

where

$$v=\frac{1}{\rho},\qquad \frac{u}{v}=\frac{3}{2}\frac{k}{\mu H}\rho T-aT^4,\qquad y=\frac{1-\beta}{\beta}, \quad (9)$$

and the time derivative applies to a given mass fraction. As Hayashi and Cameron (1962) have noted, the logarithmic arguments in equation (8) are independent of position in convective regions of the star.

III. BASIC EQUATIONS

The basic equilibrium equations are given in Paper I. For Zones I–IIIa the equations were transformed and integrated, and the zones fitted to each other in the same way as before. Henceforth we shall call this region simply the *envelope*. It is specified only by the luminosity L (through the parameter C) since, down to the chosen termination point $q_f=0.500$, the composition in the radiative region has been fixed by the previous models.

In the *core* (Zones IIIb and IV) we employ q as the independent variable and logarithms of $r, L(r)$, P, and T as dependent variables. The core solutions are specified by β_c and T_c and are integrated from the center out through the shell to q_f, beyond which any energy sources are negligible. The customary series expansions near the center (Schwarzschild (1958), p. 114) have been modified to include radiation pressure and applied at $q=0\,002$. The step value was taken to be $\Delta q=0.001$.

Fitting of the envelope and core is made at q_f in U, V, and $L(r)=L$. Since L was expected to change little during the present evolutionary phases, it was sufficient to integrate a short series of envelopes at equally spaced intervals of L and then to interpolate values of U_f and V_f at finer intervals of L.

The change in $X(q)$ as a function of time has been given by equations (2) and (3). These may be approximated by difference equations, with the known run of (ϵ_H/X) as a function of q from the previous model. Letting ι refer to quantities of the previous model, we write in an obvious notation

$$\frac{\Delta \ln X}{\Delta \tau}=-\frac{1}{2E_H}\left[\left(\frac{\epsilon_H}{X}\right)^{\iota}+\left(\frac{\epsilon_H}{X}\right)\right]=-\Xi_r(q), \qquad (q\geq q_4^{\iota}) \quad (10)$$

$$\frac{\Delta \ln X}{\Delta \tau}=-\frac{1}{(q_4{}^{\iota}+q_4)E_H}\int_0^{q_4}\left[\left(\frac{\epsilon_H}{X}\right)^{\iota}+\left(\frac{\epsilon_H}{X}\right)\right]dq=-\Xi_c(q_4), \qquad (q_4\geq q>0) \quad (11)$$

$$\frac{\Delta \ln X}{\Delta \tau}=\Xi_r(q)+[\Xi_c(q_4)-\Xi_r(q_4)]\frac{q_4{}^{\iota}-q}{q_4{}^{\iota}-q_4}, \qquad (q_4{}^{\iota}\geq q\geq q_4) \quad (12)$$

for $q_4{}^{\iota}-q_4$ small. These approximations are slightly more accurate than those used by Haselgrove and Hoyle (1956) and by Hayashi and Cameron (1962). Outside the convective core, in which X_c is known (constant), an iterative procedure must be used to calculate X from equation (10) or equation (12), since (ϵ_H/X) depends implicitly on X through ρ. Using X from the previous model, we calculate a preliminary value of ρ and hence (ϵ_H/X). Insertion of (ϵ_H/X) into equations (10) or (12) yields a projected value of X. Repetition of this procedure yields a definitive value of X correct to the second order.

The method of producing an evolutionary step was varied according to the magnitude of the ratio of luminosity supplied by gravitational contraction to total luminosity, as follows.

a) $L_g/L<0.1$

The method of Hayashi and Cameron (1962) was adopted for this case only, although they seem to have used it up to $L_g/L\approx 0.6$. Here the part of the gravitational energy release inclosed in brackets in equation (8) is expressed as a quadratic function of q, with coefficients extrapolated from the previous models:

$$\epsilon_g=\frac{3}{2}\frac{kT}{\mu H}(a_0+a_1q+a_2q^2). \qquad (13)$$

The basic equations, where now $\epsilon=\epsilon_H+\epsilon_g$, are integrated from the center with input values of X_c, β_c, T_c, a_0, a_1, a_2, $q_4{}^{\iota}$, and the run of X^{ι} and $(\epsilon_H/X)^{\iota}$ as a function of q. At q_4, $\Delta\tau$ is determined by equation (11). When a self-consistent model is obtained, the quantity in brackets in equation (8) is computed exactly and improved values of a_0, a_1, and a_2 are obtained by least squares. Another model is integrated with the new values, but this second model is always sufficiently accurate for $L_g/L<0.1$.

b) $0.1<L_g/L<0.5$

In this case we specify X_c and estimate $\Delta\tau$ by extrapolation from the previous models. Hence ϵ_g can be computed exactly from equation (8) with the given $\Delta\tau$. In the course of integrations to find the correct β_c and T_c it is possible continually to improve $\Delta\tau$ by use of equation (11).

c) $L_g/L>0.5$

As L_g/L increases, L becomes more sensitive to ϵ_g and hence to $\Delta\tau$. To cope with the increasing difficulty of making $\Delta\tau$ converge, we choose a parameter that loses importance with increasing L_g/L, namely, X_c. In this case, we take the time step by specifying $\Delta\tau$ explicitly. With a value of X_c extrapolated from the previous models, it is possible to obtain a definitive value for X_c in the same way as for $\Delta\tau$ in Section III*b*. Eventually, when hydrogen burning ceases entirely in the shrinking convective core, we need only specify $\Delta\tau$.

IV. HYDROGEN-EXHAUSTION PHASE

The results of the computations for this phase are presented in Table 1. It is curious that the stellar radius starts to decrease, causing the star to turn back toward the main sequence in the H–R diagram, as soon as $X_c \approx 0.03$ for a broad range of stellar masses ($10 < M/M_\odot < 60$), even though the mass fractions contained in the convective core are very different (see Table 2). It is clear, however, why the radius will shrink when X_c becomes small. To maintain the luminosity, the central temperature must correspondingly increase; but since μ_c changes little, $R \sim T_c^{-1}$ from equation (10) of Paper I.

For a while hydrogen burning in the core is able, alone, to maintain the energy balance (Schwarzschild and Härm 1958). However, eventually an accelerated contraction of the core is necessary to supplement the deficient $L_{H,core}$ with a growing L_g. When the temperature becomes high enough, hydrogen burning in a shell outside the core also becomes important. It is interesting to note that in the above range of masses the peak of this shell source always coincides with the mass fraction of the convective core when $X_c \approx 0.07$, i.e., just *before* the radius starts to decrease. Table 2 shows that q_s, the peak of the shell source, is roughly half of q_0, the mass fraction of the core of the initial main-sequence model. Furthermore, q_0 itself increases by about 0.15 every time the stellar mass is doubled; this is a consequence of the increasing importance of radiation pressure (diminishing β), which extends the convective regions outward.

It is for this reason, the very distance of the hydrogen-rich regions, that the temperature at $X \approx 0.07$ is low and shell burning is consequently delayed. (In massive stars, β is low not so much by virtue of high temperature as of low density.) In stars of lower mass the point at which $X_c \approx 0.07$ lies closer to the center, and shell burning begins to contribute significantly to the luminosity before the core contraction does. The critical mass for this to happen is about $20M_\odot$. If q_s is small enough that the core mass lies below the Schönberg-Chandrasekhar limit ($q \approx 0.1$), thus becoming isothermal or even degenerate, then L_ϱ may always be small. The approach to isothermality may be seen in a plot of log T against q for $5M_\odot$ (Polak 1962, Fig. 3), where $q_s = 0.11$. It may be inferred for $15.6M_\odot$ (Hayashi and Cameron 1962), where $q_s = 0.17$, since $L_{H,\,shell} > L_\varrho$ until $X_c < 0.001$. In stars with mass $\sim 1M_\odot$ (Schwarzschild and Selberg 1962), the shell source supplies practically all the luminosity outside a very large degenerate core. The critical stellar mass for the occurrence of degeneracy in the core prior to helium burning is $\sim 4M_\odot$ (Hayashi, Nishida, and Sugimoto 1962).

At $30M_\odot, q_s \gg 0.1$ and the core never even approaches an isothermal condition. Thus gravitational contraction proceeds unchecked to increase T_c in accordance with the virial theorem. The subsequent increase in ϵ_H reduces X_c to less than 1 percent. Thereafter the drop in X_c outruns the increase in T_c, and ϵ_H decreases, being supplanted by $\epsilon_\varrho \sim \partial T_c / \partial \tau$. However, hydrogen burning in the core still supplies over half the total luminosity even when X_c is as low as 10^{-4}.

The distribution of hydrogen in the central regions may be seen in Figure 1. It is clear that,

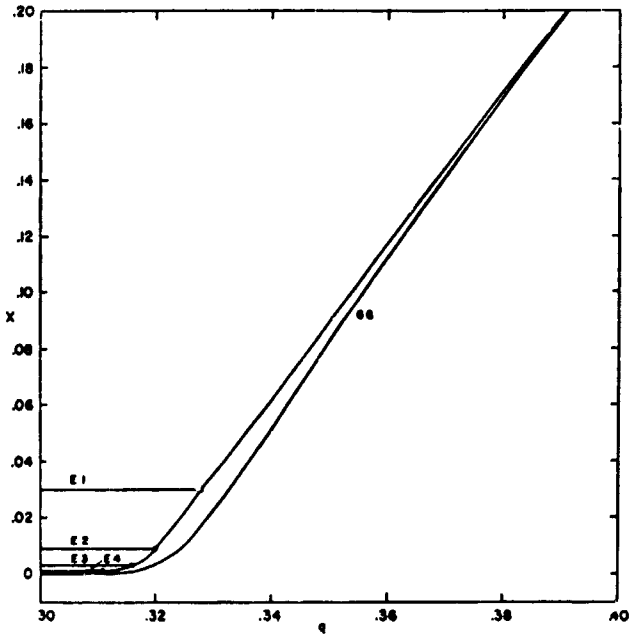

FIGURE 1.—Depletion of hydrogen as a function of mass fraction during the hydrogen-exhaustion (E) and gravitational-contraction (G) phases. Filled circles represent the boundary of the convective core in the E models.

because of the high central temperature and the luminosity requirements, X_c begins to decrease more and more rapidly with q_4. This has the effect of necessitating an even sharper increase of temperature, which consequently exhausts the central hydrogen and ignites a region which is still relatively hydrogen-rich but close enough to the center to feel the temperature rise. Thus Figure 1 shows why a shell source develops near $q = 0.34$ for $30M_\odot$. We expect this shell to be initially broader in massive stars than in stars of lower mass because the mean gradient of hydrogen throughout this region is gentler (larger $q_0 - q_s$; see

Table 2). The subsequent growth of the shell source is shown in Figure 2.

In Figure 3 the relative contributions to the energy generation may be compared. The magnitude of ϵ_ϱ is very nearly constant throughout the core for all stages.

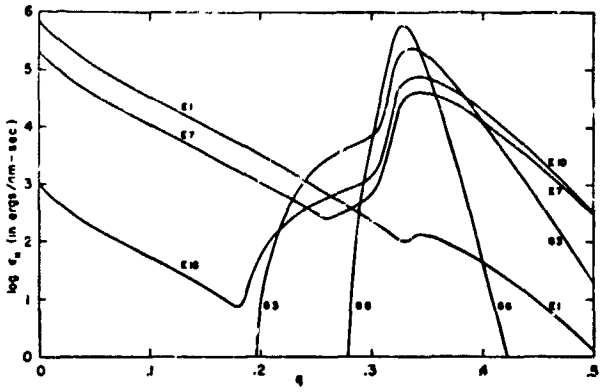

FIGURE 2.—Logarithm of the energy generation due to hydrogen burning as a function of mass fraction. Curves are labeled with the model numbers.

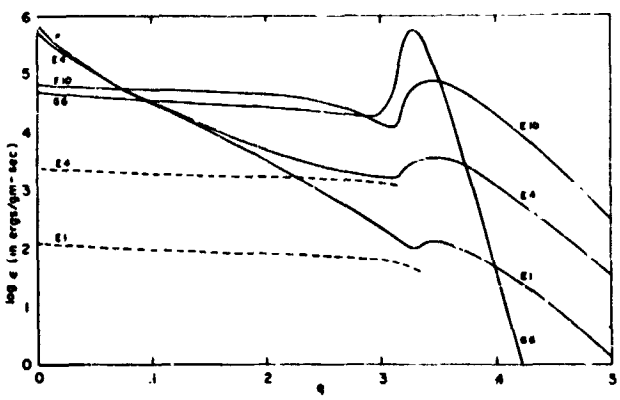

FIGURE 3.—Logarithm of the energy generation as a function of mass fraction. Solid curves refer to the contributions from both hydrogen burning and gravitational contraction. The dashed curve refers only to gravitational contraction. Curves are labeled with the model numbers.

Shrinkage of the convective core is at first slow because β_c remains almost constant. Hence the evolution of the center approximates Lane's law, $\rho_c \sim T_c^3$. When the shell source becomes important for $X_c < 10^{-4}$, ρ_c increases at a slightly greater rate than T_c^3, the only concession to isothermality that the core makes. At this point (Model E7), $L_\varrho/L \approx 0.5$ and $L_{H,\,shell}/L \approx 0.1$. It seems that as soon as L_ϱ/L grows much larger, contraction of the core begins to be offset by an expansion of the envelope (cf. Hayashi and Cameron 1962). This expansion is due to an increase of $L_{H,\,shell}$, compensating for the reduction of $L_{H,\,core}$. Exactly why the envelope expands as $L_{H,\,shell}$ increases will be made evident in the next section. The result on the H—R diagram is that the star takes another turn away from the main sequence.

When the hydrogen content at the center of the star vanishes after Model E10, the convective core does not disappear. This contrasts with the results on stars of lower mass (Hoyle 1960; Polak 1962; Hayashi and Cameron 1962), where apparently it is just the nuclear-energy generation that maintains the steep temperature gradient. However, in the case of $30M_\odot$, β is still so low that convection persists near the center.

The time scale of this phase is short enough (8.8×10^4 years) that the shell source, which remains peaked at $q_s = 0.342$, undergoes very little hydrogen depletion. Because of the struggle of the various energy sources to maintain the luminosity, L increases but slightly. Thus the structure of the envelope remains nearly constant.

V. GRAVITATIONAL CONTRACTION PHASE

This phase is taken to start when $L_{H,\,core}/L < 0.001$. The hydrogen content of the convective core is negligible, and the sole nuclear-energy source is the hydrogen-burning shell. In Model E9 the rise of the shell source had terminated the upward growth of L_ϱ/L, which reached a maximum value of 0.75. This fraction becomes all the more impressive when we compare it with 0.56 for a star of $15.6M_\odot$ (Hayashi and Cameron 1962). Table 5 shows that even at the onset of helium burning (Model G6) the contribution of gravitational contraction to the luminosity is still a sizable fraction. This suggests that for stars more massive than $30M_\odot$ hydrogen burning in a shell may not become dominant.

During the shell-burning phase, the computational difficulty of fitting models increases. The reason lies in the shift of the $U-V$ curve to the left, as seen in Figure 4. This is caused by the developing chemical inhomogeneity, which began after the initial main-sequence state, and by the shell source, which produces the leftward loop on the $U-V$ plane. Because of the short time scale, the amount of hydrogen depletion is very small

and the shell source remains peaked at roughly the same mass fraction. Since the shell provides the driving mechanism for the expanding envelope while the core is contracting, r at the outer boundary of the shell remains roughly constant. Thus it is here that the change of log r with q is greatest (see Fig. 5), that is, U is a minimum, isolating the energy-producing regions from the envelope. Unless small increments in q are taken in the numerical integrations through the shell, the solutions diverge. Since the region behaves like an outer boundary ($U_s \to 0$), V tends to blow up for small changes of the input parameters, β_c and T_c.

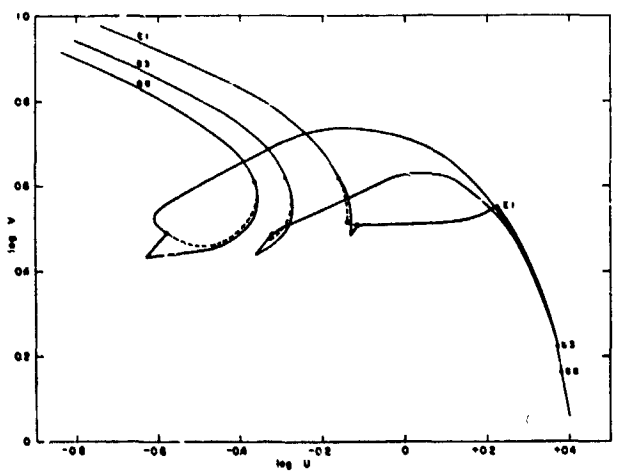

FIGURE 4.—Evolution of a star of 30 M⊙ in the U–V plane during the hydrogen-exhaustion (E) and gravitational-contraction (G) phases. Curves are labeled with the model numbers. Dots and jumps represent fitting points. The dashed lines in the solutions represent the assumed radiative zone (see Paper I).

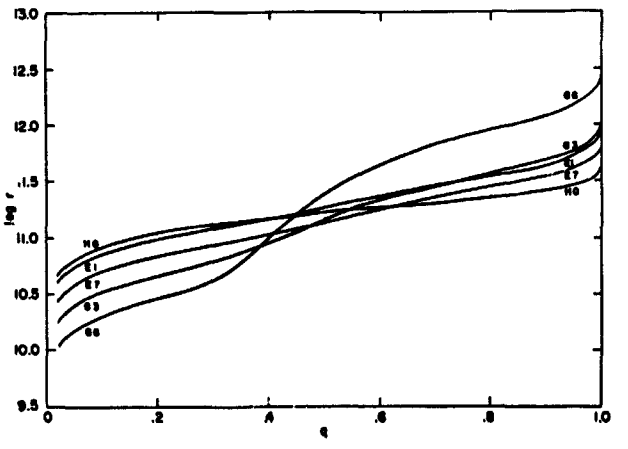

FIGURE 5.—Logarithm of the radius as a function of mass fraction. Curves are labeled with the model numbers.

Hayashi, Hoshi, and Sugimoto (1962) have interpreted the envelope expansion in terms of the $U-V$ plane. For values of the polytropic index $3 \leq N > 1$, where $P=K\rho^{1+1/N}$ and K and N are constants, the centrally condensed solutions of a polytropic envelope form a leftward loop on the $U-V$ plane and converge to a point $U=0$ and $V=N+1$ as $r \to 0$. For an electron-scattering envelope, N is 3 near the surface, decreases inside, and then approaches 3 again as $r \to 0$. Hence such an envelope approximates the polytropic case $N=3$, where $V \to 4$ as $U \to 0$ (see Fig. 4). Interior to q_s, $L(r) \ll L_{\mathrm{H,\ shell}}$ so that the radiative index becomes large, since $(n+1)_{\mathrm{rad}} \sim (1-\beta)/\kappa L(r)$. Hence the core approximates roughly the isothermal case $N=\infty$, which loops outward in the $U-V$ plane much as in Figure 4.

It remains to see how the shell source actually expands the envelope. We have already noted that, in order to tap additional nuclear fuel, the temperature in the core rises and starts shell burning. Consequent to hydrogen exhaustion in the core, the temperature in the shell must continue to rise so that $L_{\mathrm{H,\ shell}}$ can assume more of the total luminosity burden. As $L_{\mathrm{H,\ shell}}$ increases during the evolution, $(n+1)_{\mathrm{rad}}$ decreases, steepening the temperature gradient beyond q_s (see Fig. 6). But actually $n+1$ can only decrease until the adiabatic value is reached. Therefore, to compensate for the increasing luminosity, β decreases (see Fig. 7). This relative increase in radiation pressure expands the envelope.

To make this point more definite, we look at the structure of the envelope, which may be considered a polytrope of some characteristic index.

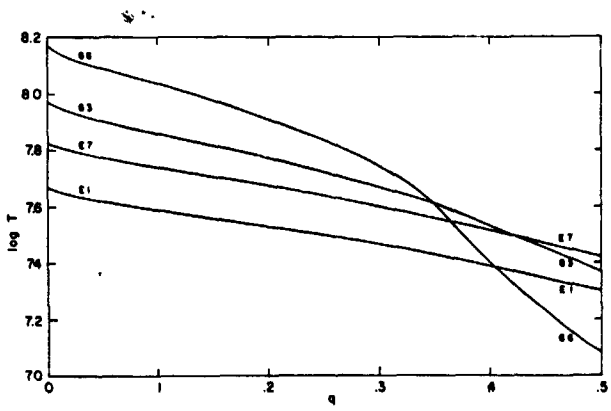

FIGURE 6.—Logarithm of the temperature as a function of mass fraction. Curves are labeled with the model numbers.

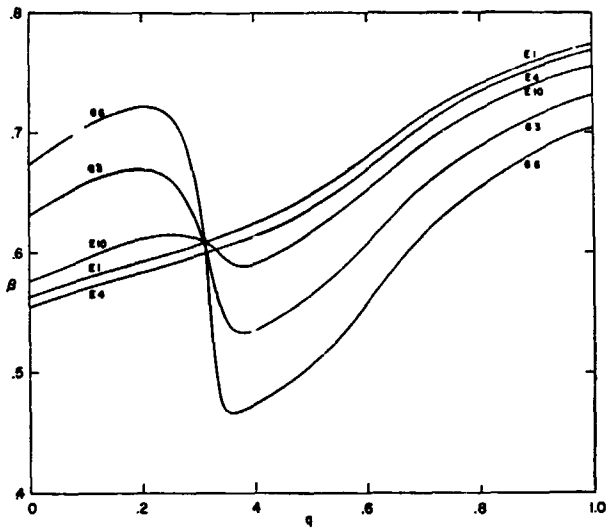

FIGURE 7.—Ratio of gas pressure to total pressure as a function of mass fraction. Curves are labeled with the model numbers.

The effective termination point of the envelope must be taken just outside the shell peak, where U is a minimum on the $U-V$ plane. Now it may be shown generally for a polytrope of any index and constant $\beta=\beta_c$ that $R \sim (T_c/\beta_c\rho_c)^{1/2}$. Eliminating ρ, we have $R \sim (1-\beta_c)^{1/2}/\beta_c T_c$. Thus the expansion may be considered as fundamentally due to the relative increase in radiation pressure, as stated above. Further, the same result can be obtained by examining equation (8). A decrease in β causes expansion by making ϵ_g negative, and an increase causes contraction by making ϵ_g positive. The consequences may be seen by comparing Figures 5–7. During phases of roughly constant β, the change of T will determine the change in R.

If we take the stellar core to be a polytrope, then we may similarly explain the changes of shell radius, r_s (see Tables 1 and 3). By extension, a star with m shell sources may be subdivided into $m+1$ zones whose structure is assumed to be polytropic. Then, approximately, the changes of β and T at a given shell should determine the changes of r at the next outer shell, unless the mass fraction of the shell changes by a drastic amount. Qualitative agreement is found between this picture of evolution and the accurate published results on the evolution of stars of $4M_\odot$ and $15.6M_\odot$ from the initial main sequence through carbon burning (Hayashi, Nishida, and

Sugimoto 1962; Hayashi and Cameron 1962; Hayashi, Hoshi, and Sugimoto 1962).

In this regard we note that the last model before helium burning in a star of $1.3M_\odot$ considered by Schwarzschild and Selberg (1962) had $\beta_s = 0.87$. Since they neglected radiation pressure and used $\beta = 1$ throughout, it might be expected that the radii they derive are too small. Indeed the track of their theoretical models on the H–R diagram deviates leftward of the observed red-giant branch in globular clusters. One reason may be the neglect of varying β in their models; apart from other factors, for a closer agreement with observations β should be explicitly included.

Since the envelope evolves independently of the core (each with a fixed mass), the expansion of the envelope must lower the local density. Since β is also decreasing in the envelope, the temperature near q_s actually does not change very much (see Fig. 6). Beyond the shell, however, it [illegible] considerably, because the temperature gradient is approaching the adiabatic value. This increase of the temperature gradient has two major effects: (1) The semiconvective zone moves steadily inward; by Model G6 it has reached $q = 0.48$. The hydrogen discontinuity grows to $X_2 - X_3 = 0.10$, although $\mu_2/\mu_3 = 0.91$ because the actual hydrogen content is lower at small q. (2). The shell source becomes narrower, on account of the decreasing temperature outside (and the decreasing hydrogen content inside). A curious result, not occurring in stars of lower mass, is that q_s moves slightly inward at first because of the rising temperature inside and the rather broad shell distribution of hydrogen, but thereafter remains stationary as it encounters less and less hydrogen. The total amount of hydrogen depletion (in the shell) is 0.0004, and the maximum local change in X is 0.011 at $q = 0.329$.

In the core, although β_c steadily rises, the central convection persists and recedes only to a roughly constant $q_4 = 0.06$ at the onset of helium burning. Hence convection probably never disappears completely from the center of very massive stars.

Model G6 corresponds to the onset of helium burning. At this point, $L_{He}/L \approx 0.004$ and T_c is 150 million degrees. This value of T_c is almost the same as the corresponding value for a star of $15.6M_\odot$ because of the steep temperature dependence of the energy-generation formula. However, ρ_c is only 270 gm/cm^3, lower by a factor of 10 than in the star of $15.6M_\odot$. But in the heavier star the core mass is four times as large.

The gravitational contraction phase is very short (9×10^3 years), although large changes in the stellar radius take place.

VI. FINAL REMARKS

Although the computed values of the *fractional* luminosities should not be considered exact (since we have neglected in the computations to take account of the radiative flux that is absorbed in the expansion of the envelope), nevertheless Figure 8 shows up a brief peak in the luminosity due to gravitational contraction, whereas the nuclear-energy sources are spread over longer time intervals. Since the total energy available to the star as a result of gravitational contraction is small compared with the nuclear-energy store, it is expected that the time scale of contraction phases will be very short. Indeed, the post–main-sequence age at the onset of helium burning is 4.9 million years, of which 4.8 million are spent burning almost half of the initial hydrogen content.

During this time the interior structure of the star undergoes drastic changes, especially in the

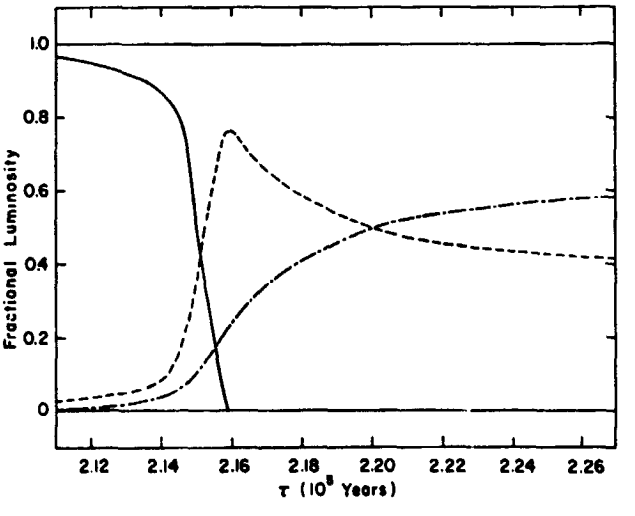

FIGURE 8.—The fraction of the total luminosity contributed by hydrogen burning in the core *(solid curve)*, gravitational contraction in the core *(dashed curve)*, and hydrogen burning in the shell *(dash-dot-curve)* is plotted against the time elapsed since the last model of the hydrogen-burning phase (Model H4 of Paper I).

short (0.1×10^6 years) contraction phase, as shown in Figure 9. One complication not occurring in stars of lower mass may arise from the existence of the semiconvective zone. That is, the inward-moving semiconvection brings hydrogen-enriched material toward the shell source, which is simultaneously moving outward. A hydrogen flare-up might be expected to occur. However, the results of Table 3 show that ΔX is only about 0.1 at the radiative-semiconvective interface. Moreover, from the results on a star of $15.6 M_\odot$ (Hayashi and Cameron 1962; Hayashi, Hoshi, and Sugimoto 1962), the total luminosity is expected to increase little during helium burning, so that the structure of the envelope (and hence of the semiconvective zone) will change very slowly; the outward motion of q_s is also rather slow. Thus the star could probably accommodate quietly the sharp increase in X, despite the narrowness of the shell source. However, it seems unlikely that the inner edge of the semiconvective zone will ever penetrate the shell before the whole envelope becomes convective during the rightward swing of the evolutionary track in the H–R diagram toward red carbon-burning models. We need only worry about possible hydrogen flaring in stars of mass greater than $30 M_\odot$.

The evolution on the theoretical H–R diagram is shown in Figure 10 for the phases considered in this paper. The ages are given in units of 10^4 years. At $\tau = 9.07$ the spectral class becomes B0, and at $\tau = 9.67$ it is B3. The star is expected never to return to the region of O stars during its active life.

THE RV TAURI POPULATION*

RICHARD STOTHERS

Our understanding of the RV Tauri stars has come mainly from photometric and spectrographic studies based on several tabulations of these stars since 1921.[1–9] Although members of this group are too distant for accurate parallax derterminations, their absolute magnitudes are known through the discovery and identification of some in globular clusters.[5,10] It is the purpose of this paper to analyze the spatial distribution of the RV Tauri stars in the field and to compare properties of these stars with properties of similar stars found in globular clusters.

The data are taken mainly from the *General Catalogue of Variable Stars*[8] (*GCVS*), which lists 92 stars of this class based on criteria that are essentially those of Payne-Gaposchkin, Brenton, and Gaposchkin.[4] RV Tauri stars are supergiants with (1) comparatively stable periodicity of light variation, whose amplitude may reach 3 magnitudes, (2) alternating shallow and deep minima, which occasionally interchange, (3) double-period of 30–150 days, and (4) F to K spectral class, which is earliest near maximum light. From the *GCVS* list we disregard those variables designated RV? and include only stars with periods in the range 39–110 days, since this is roughly the range of RV Tauri stars in globular clusters. Although some types of red variables in the same period range have light curves resembling those of RV Tauri stars, we assume that those variables without known spectra are yellow. In some cases photographic magnitudes were obtained from other sources.[4,6] Since the magnitude of CN Centauri is uncertain at minimum, it has been omitted from the distance determinations. Preston, Krzeminski, Smak, and Williams have shown that UU Herculis and V453 Ophiuchi are RV Tauri stars.[9] Apart from these two variables, their list of RV Tauri stars does not otherwise conflict with assignments given by the *GCVS*, in the period range 39-110 days. We have used their magnitudes and period for V 453 Ophiuchi. The total number of variables whose distances we may determine is 45, of which 25 have known spectra.

Preston *et al.*[9] have defined three groups of RV Tauri stars on spectroscopic criteria: A.—All spectral features indicate type G or K, except that TiO bands may occur during deep light minima. B.—The type based on the Ca II lines differs from that based on the hydrogen lines; strong CN bands occur at and around light minima. C.—The spectrum resembles that group B, except that CN bands never appear. Moreover, the stars in group A are redder than those in groups B and C (which cannot be distinguished photometrically). The RV Tauri stars may be distinguished from the yellow semiregulars on the basis of U,B,V colors and strength of hydrogen emission. At the end of this paper we shall comment on these subdivisions.

The distribution of RV Tauri stars in longitude is far from scraggly, contrary to the results indicated by the smaller numer of stars used in earlier investigations.[7] Indeed, Figure 1 shows a strong concentration of stars in the direction of the galactic center. Their spatial concentration depends on a knowledge of distances, which we may obtain from globular clusters.

In general, RV Tauri stars in globular clusters are specified by the same criteria as those in the field. Small deviations from these criteria have been discussed by Rosino[5] and Joy.[6] Other differences will be pointed out below. Using the mean photographic magnitudes of the nine certain RV Tauri stars in clusters (from the writer's previous paper,[10] hereafter called Paper I), we

*Published in the *Publications of the Astronomical Society of the Pacific*, 76 (449): 98–105, April 1964.

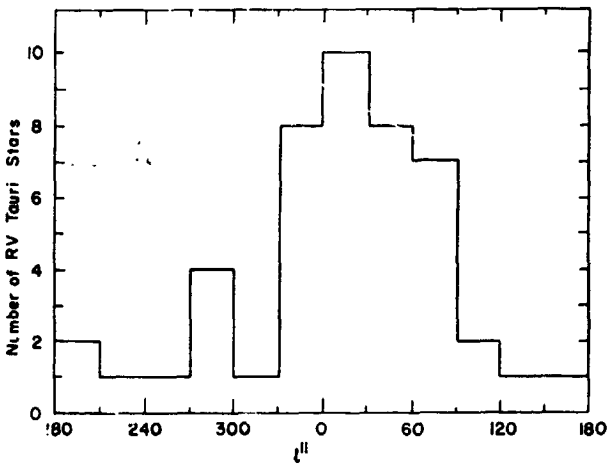

FIGURE 1.—Frequency distribution of the field RV Tauri stars in longitude.

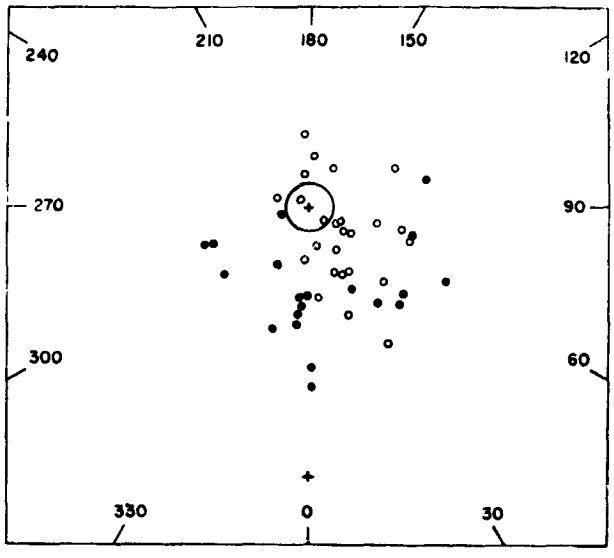

FIGURE 2.—Field RV Tauri stars with known spectra (open circles) and unknown spectra (filled circles) are projected on the galactic plane. The positions of the sun and galactic center are denoted by + signs. The circle around the sun has a radius of 1 kpc.

may obtain a period-luminosity relation, if the distance moduli of the clusters are known. We take the moduli from Hogg's list,[11] where she assumed that $M_{pg}=0.0$ for the RR Lyrae stars. For M 2, M 5, and M 13, we have used the values of M_v of the RR Lyrae stars corrected for reddening listed by Arp[12] and have added C.I. $=+0.1$. For M 22, which closely resembles M 13,[13,14] and for ω Centauri, which has a main sequence turnoff at the same magnitude as M 3[15] (also listed by Arp), we assume analogous values of M_{pg}. For M 56 and NGC 6712 we adopt the mean of all the known values, $M_{pg}=+0.3$. Applying these corrections to Hogg's distance moduli, we obtain absolute magnitudes of the cluster RV Tauri stars. The period-luminosity relation is then $<M_{pg}>=-4.0+0.026P\pm0.36$, where P is in days, in reasonable agreement with previous determinations which depended on indirect or statistical methods.[5,6,7,17,18,19,20,21]

To calculate the distance of the RV Tauri stars in the field, we use

$$<M_{pg}>=<m_{pg}>-10-5\log r-a$$

where r is in kpc and $a=0.7r$ if $|b^{II}|<20°$ or $0.25\csc|b^{II}|$ if $|b^{II}|>20°$. The first formula for extinction is used by Payne-Gaposchkin[16] and also happens to be the mean of extinctions derived for five RV Tauri stars by Kameny.[7]

Figure 2 shows the RV Tauri stars projected on the galactic plane. Variables with known spectra are indicated by open circles, those with unknown spectra by filled circles; the crosses denote the positions of the sun and the galactic center. It is difficult to corroborate the previously suspected[7] groupings near Ophiuchus (30°), Aquila (40°), and Gemini (180°), on the meager data available and the uncertain extinction. Other clumpings at 60° and 75° are also suspect, although the Sagittarius group (0°) is probably real. There is no apparent correlation of period with position in the Galaxy.

Figure 3 shows a vertical cross-section of the Galaxy, where the sun is assumed to lie at 10 kpc from the galactic center. As indicated also by Figures 1 and 2, the number of variables increases in the direction of the galactic center. Their apparent absence at low galactic heights is due to interstellar extinction. The distribution strongly resembles that of the long-period variables with $P<250$ days, that is, intermediate between the distribution of long-period variables with $P>250$ days (Population I) and the distribution of the halo RR Lyrae stars (Population II).[18] The vertical density gradient y, where $\log N=x-y$ (r sin b) and N is the relative number of stars, is 1.1, and the median height $\overline{r \sin b}$ is 0.45 kpc. Both these quantities are similar to those for the long-period variables with $P<250$ days.

Perepelkina suspected that the RV Tauri stars form an intermediate subsystem.[17] Their relatively low radial velocities and latitudes indicate

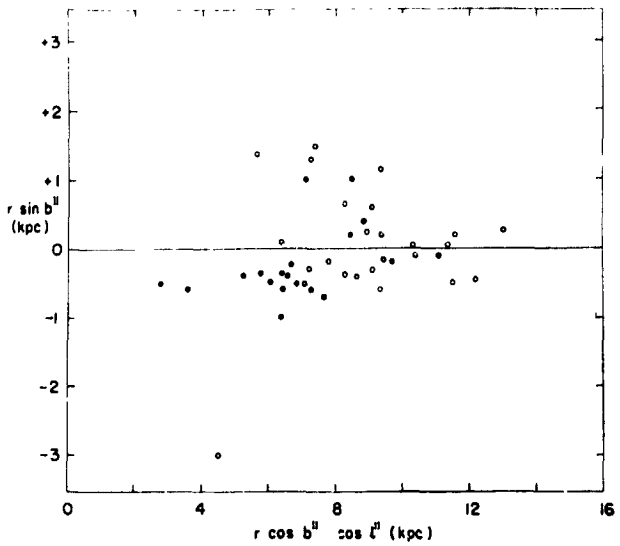

FIGURE 3.—Vertical cross-section of the Galaxy, showing the distribution of field RV Tauri stars on the assumption that the sun lies at 10 kpc from the galactic center. Same symbols as in Figure 2.

a weak Population I, but their excessive blueness (like the W Virginis stars) and discontinuous velocity curves indicate Population II.[7] The yellow semiregulars, however, seem to be real Population II objects.

The general similarity of the RV Tauri stars in globular clusters to those in the field and the approximately equal ratios of number of RV Tauri stars to number of RR Lyrae stars[7] indicate that field and cluster RV Tauri stars belong to the same family. At maximum light the RV Tauri stars are usually the brightest cluster members and are found close to the cluster center (compared with the long-period variables).[10] Therefore, because of the long relaxation times of globular clusters, it seems unlikely that the RV Tauri stars in the field have evaporated from clusters, even apart from the observation that they do not form a halo population.

Besides their spatial distribution, some other differences between the field and cluster variables should be mentioned. While Rosino found no period-spectrum relation for the variables in the field,[8] Paper I showed such a relation for the cluster variables, although the stars seem to be separated chiefly into a 60- and a 90-day group. Kameny[7] found that the short-period RV Tauri stars in the clusters were slightly bluer than those in the field. No very long-period RV Tauri stars have yet been identified in globular clusters. Moreover, in the clusters there is a marked absence of RV Tauri stari stars in the period range 68–87 days. We note in Table I an actual anticorrelation of period frequency with the corresponding field variables. Lastly, we mention that

TABLE I.—*Period Frequencies of the RV Tauri Stars*

P (days)	Globular Clusters		Field	
	RV	All Variables	RV (with Sp.)	RV (all)
28–47	0	1	3	5
48–67	5	7	6	15
68–87	0	2	15	23
88–107	4	13	3	5
>107	0	16	5	24

no RV Tauri stars in globular clusters have light amplitudes exceeding 2 magnitudes, whereas about one-third of the field stars in the same period range have greater amplitudes. All these differences may be due to different ages and chemical compositions.

The results of work by Preston *et al.*[9] indicate that, at least spectroscopically, the RV Tauri stars do not comprise a homogeneous class. Their group A of these stars shows TiO at minimum and resembles kinematically an intermediate (disk) population.[6] Group B is probably also related kinematically to the disk, and we note that it, too, shows the presence of metals in the strong CN bands. The radial velocities of group C stars are very high and suggest a halo population; the absence of CN is also suggestive. We note that the two variables from globular clusters that Preston *et al.* studied probably belong to the "halo" group C; it is interesting that, whereas groups A and B show a wide range in period, the three field variables from group C have periods lying in the "forbidden" range of the clusters.

If the RV Tauri stars plotted on the vertical cross-section of the Galaxy (Fig. 3) are distinguished according to groups, then it appears that groups B and C adhere very well to the above galactic assignments, whereas group A populates

both the disk and the halo. However, it is clear that RV Tauri stars do not really range far enough to separate groups into halo and disk populations. Therefore the suggestion by Preston *et al.* that groups B and C belong to a larger family raises the further speculation that all the groups form really one family. At least this has been indicated by previous work.

In this connection, we note that there is no apparent relation between spectroscopic criteria and shape of light curve or period. Moreover, the colors appear to form a continuous sequence, despite the spectroscopic differences. Although Preston *et al.* could not obtain reliable luminosity classes at the dispersion they used, Rosino's data[5] suggest that the luminosity class falls with increasing period, in agreement with the results on variables in globular clusters.[10] Comparison of the general period-luminosity relations for the variables in globular clusters and those in the field suggests that any difference in the luminosity between the cluster and field RV Tauri stars does not exceed 1 mag. (Paper I, Fig. 11). We believe that the statistical identification of luminosities in the clusters and in the field is sufficient to outline the general spatial distribution of RV Tauri stars, as considered in this paper.

In conclusion, the RV Tauri stars seems to form an intermediate subsystem between Population I and II. Except for the underabundance of metals and the period-frequency anomaly, the RV Tauri stars in globular clusters resemble their counterparts in the field. Perhaps long-period variables in clusters with late integrated spectra should be investigated for RV Tauri behavior; in this connection we note the 105-day variable in NGC 6712 (GA). Certainly the known semiregular and irregular variables with undetermined periods should be checked for periods in the range 68–87 days.

II. CELESTIAL MECHANICS AND GEODESY

LONG-PERIOD CONTRIBUTIONS TO THE DISTURBING FUNCTIONS OF THE EARTH FROM THE SEVENTH, NINTH, AND ELEVENTH ZONAL HARMONICS*

T. L. FELSENTREGER AND W. J. WICKLESS

INTRODUCTION

It is the purpose of this paper to present explicit formulas for the long-period terms due to the seventh, ninth, and eleventh zonal harmonics in the disturbing function of the earth in the case of an artificial earth satellite. The formulas are given for terms of the satellite's orbital elements and the Delaunay variables. G. Giacaglia (1) has given general expressions for the long-period terms due to any of the zonal harmonics, which can be expressed in terms of the orbital elements. The apparent differences between the results of this paper and those in Giacaglia's have been verified as due to the errors in the latter as it appears in the A.J.

The contributions of the long-period terms to the mean motion of the argument of perigee are also given.

THE DISTURBING FUNCTION

The earth's gravitational potential at a distance r from the center of the earth is

$$U=\frac{\mu}{r}\left[1-\sum_{n=2}^{\infty}\left(\frac{R}{r}\right)^{n}J_nP_n\ (\sin\phi)\right],$$

where

$\mu = GM$

G = gravitational constant

M = mass of the earth

R = radius of the earth

J_n = zonal harmonic coefficients ($n+2$, 3,...)

P_n = Legendre polynomials ($n=2$, 3,...)

ϕ = geocentric latitude.

Here, the earth's radius is adopted as the unit of length. The seventh, ninth, and eleventh Legendre polynomials are

$$P_7\ (\sin\phi)=\frac{1}{16}(429\sin^7\phi-693\sin^5\phi+315\sin^3\phi-35\sin\phi)$$

$$P_9\ (\sin\phi)=\frac{1}{128}(12155\sin^9\phi-25740\sin^7\phi+18018\sin^5\phi-4620\sin^3\phi+315\sin\phi)$$

$$P_{11}\ (\sin\phi)=\frac{1}{256}(88179\sin^{11}\phi-230945\sin^9\phi+218790\sin^7\phi-90090\sin^5\phi+15015\sin^3\phi-693\sin\phi).$$

*Published as *Goddard Space Flight Center Document X-547-64-333*, August 1964.

Let

a = semi-major axis of satellite's orbit

e = eccentricity of orbit

i = inclination of orbital plane to equatorial plane

ℓ = mean anomaly

f = true anomaly

g = argument of perigee.

The Delaunay variables L, G, and H are

$$L=\sqrt{\mu a}$$

$$G=L\sqrt{1-e^2}$$

$$H=G\cos i.$$

Use is also made of the relations

$$\sin\phi=\sin i\sin(f+g)$$

$$\frac{a}{r}=\frac{L^2}{G^2}(1+e\cos f).$$

The long-period terms in the expansion of U as a Fourier series in ℓ and g are given by

$$\frac{1}{2\pi}\int_0^{2\pi} U\,d\ell, \qquad \text{(see reference 2)}$$

making use of the relation

$$d\ell=\frac{L}{G}\,\frac{r^2}{a^2}df.$$

Denoting the long-period parts of U_7, U_9, and U_{11} by Δ_7F_{2p}, Δ_9F_{2p}, and $\Delta_{11}F_{2p}$, respectively, we have

$$\Delta_7F_{2p}=-\frac{21\mu^9J_7e\sin i}{16384L^3G^{13}}\left[10\left(5-135\frac{H^2}{G^2}+495\frac{H^4}{G^4}-429\frac{H^6}{G^6}\right)\left(33-30\frac{G^2}{L^2}+5\frac{G^4}{L^4}\right)\sin g\right.$$

$$-15\left(3-69\frac{H^2}{G^2}+209\frac{H^4}{G^4}-143\frac{H^6}{G^6}\right)\left(11-14\frac{G^2}{L^2}+3\frac{G^4}{L^4}\right)\sin 3g$$

$$\left.+33\left(1-15\frac{H^2}{G^2}+27\frac{H^4}{G^4}-13\frac{H^6}{G^6}\right)\left(1-2\frac{G^2}{L^2}+\frac{G^4}{L^4}\right)\sin 5g\right]$$

$$\Delta_9F_{2p}=-\frac{3\mu^{11}J_9e\sin i}{524288L^3G^{17}}\left[210\left(7-308\frac{H^2}{G^2}+2002\frac{H^4}{G^4}-4004\frac{H^6}{G^6}+2431\frac{H^8}{G^8}\right)\times\right.$$

$$\times\left(7-1001\frac{G^2}{L^2}+385\frac{G^4}{L^4}-35\frac{G^6}{L^6}\right)\sin g-10780\left(1-40\frac{H^2}{G^2}+234\frac{H^4}{G^4}-416\frac{H^6}{G^6}+221\frac{H^8}{G^8}\right)\times$$

$$\times\left(39-65\frac{G^2}{L^2}+29\frac{G^4}{L^4}-3\frac{G^6}{L^6}\right)\sin 3g+12012\left(1-32\frac{H^2}{G^2}+146\frac{H^4}{G^4}-200\frac{H^6}{G^6}+85\frac{H^8}{G^8}\right)\times$$

$$-49725\Big(1-41\frac{H^2}{G^2}+250\frac{H^4}{G^4}-514\frac{H^6}{G^6}+437\frac{H^8}{G^8}-133\frac{H^{10}}{G^{10}}\Big)\times\Big(19+60\frac{G^2}{L^2}+66\frac{G^4}{L^4}-28\frac{G^6}{L^6}-3\frac{G^8}{L^8}\Big)\sin 7g$$

$$+20995\Big(1-25\frac{H^2}{G^2}+90\frac{H^4}{G^4}-130\frac{H^6}{G^6}+85\frac{H^8}{G^8}-21\frac{H^{10}}{G^{10}}\Big)\times\Big(1-4\frac{G^2}{L^2}+6\frac{G^4}{L^4}-4\frac{G^6}{L^6}+\frac{G^8}{L^8}\Big)\sin 9g\Big]$$

CONTRIBUTIONS TO dg/dt

Since the Delaunay set of variables is canonical with respect to the Hamiltonian F, which includes Δ_7F_{2p}, Δ_9F_{2p}, and $\Delta_{11}F_{2p}$, we have

$$\frac{dg}{dt}=-\frac{\partial F}{\partial G}\quad\text{(see reference 2).}$$

Therefore, a computation of $\partial(\Delta_iF_{2p})/\partial g(i=7,9,11)$ provides the long-period terms in dg/dt due to the seventh, ninth, and eleventh zonal harmonics.
The results are

$$\frac{\partial(\Delta_7F_{2p})}{\partial G}=\frac{21\mu^9J_7}{16384L^3G^{14}e\sin i}\Big\{10\Big[(\sin^2 i-e^2)\Big(5-135\frac{H^2}{G^2}+495\frac{H^4}{G^4}-429\frac{H^6}{G^6}\Big)\Big(33-30\frac{G^2}{L^2}+5\frac{G^4}{L^4}\Big)$$

$$+e^2\sin^2 i\Big(65-2025\frac{H^2}{G^2}+8415\frac{H^4}{G^4}-8151\frac{H^6}{G^6}\Big)\Big(33-30\frac{G^2}{L^2}+5\frac{G^4}{L^4}\Big)$$

$$+20e^2\sin^2 i\Big(5-135\frac{H^2}{G^2}+495\frac{H^4}{G^4}-429\frac{H^6}{G^6}\Big)\frac{G^2}{L^2}\Big(3-\frac{G^2}{L^2}\Big)\Big]\sin g$$

NOTES ON VON ZEIPEL'S METHOD*

GIORGIO E. O. GIACAGLIA

1. INTRODUCTION

Since the rediscovery of von Zeipel's method by D. Brouwer (1959) and its successful application to the problem of artificial satellites, many other problems have been solved by that same method, thus proving its great applicability. It is the purpose of these notes to present the general equations of von Zeipel's method and discuss briefly their applicability.

The reduction of the order of a differential canonical system can, in theory, be performed by obtaining, one way or another, integrals of the system. One of them is the Hamiltonian itself when it is time independent. Actually, this integral of the system (physically its "energy"), can describe completely the geometry of the solutions in a phase space of $2n$ dimensions where $2n$ is the order of the system. When this order is 2, then the solution is completely specified and the use of the Hamiltonian reduces it to a first order differential equation which can be integrated by quadrature. The introduction of p integrals in a system of n degrees of freedom ($2n^{th}$ order), reduces it to one of $n-p$ degrees of freedom which can be integrated immediately when $n-p\leq 1$ (where, of course, p cannot be greater than n).

A few comments can be made with respect to the more famous methods of reduction to show their eventual connection with von Zeipel's method.

2. FROM HAMILTON TO VON ZEIPEL

In the discussion that follows only methods that have been used in connection with differential systems describing the motion of a physical system are considered. The presentation does not necessarily follow a chronological order.

Consider then a system of n degrees of freedom given by $2n$ first order canonical equation

$$\dot{x}_j=\frac{\partial H}{\partial y_j} \qquad (j=1, 2, \cdots, n) \qquad (1)$$
$$\dot{y}_j=-\frac{\partial H}{\partial x_j}$$

where the Hamiltonian $H=H(x_1,\ldots,x_n,y_2,\ldots y_n)$ is presumed to be time independent. If this is not the case, the introduction of time as a new canonical coordinate x_{n+1} (the associated momentum being $-H$) always reduces the latter to the former case. The degree of freedom will however increase by one.

A canonical transformation of the variables (x,y) to new variables (x',y') will be, *in this exposition*, equivalent to the problem of finding a generating function $S=S(x',y,t)$ such that

$$y'_j=\frac{\partial S}{\partial x'_j} \qquad (j=1, 2, \cdots, n) \qquad (2)$$
$$x_j=\frac{\partial S}{\partial y_j}.$$

It is easily seen that this is a sufficient condition to satisfy the Jacobi-Poincare relation

$$\sum_{j=1}^{n}(x_j\,dy_j-x'_j\,dy'_j)=dW. \qquad (3)$$

which is valid whether or not S is an explicit function of time. The Hamiltonian of the new system will be equal to that of the old one inasmuch as one is obtained from the other by introducing the transformation of variables expressed by Equations (2) when $\partial S/\partial t=0$.

a. *HAMILTON-JACOBI*—The method introduced by Hamilton and Jacobi consists in obtaining a canonical transformation such that the new

*Published as *Goddard Space Flight Center Document X-547-64-161*, June 1964.

Hamiltonian is identically zero. In such a case, the new variables are all constants.

b. *LINDSTEDT'S METHOD*—Lindstedt's method is a particular application of the Hamilton-Jacobi method for cases where the Hamiltonian is expanded in terms of small parameters. In this particular case the solution gives the coordinates as linear functions of time and the momenta as constants (usually called action angle variables). The comparison with the Hamilton-Jacobi method is purely formal since the method devised by Lindstedt is quite original. Actually, the real difference between von Zeipel's and this method is that Lindstedt does not make use of a generating function.

c. *WHITTAKER'S METHOD* (solution by series). This method obtains n integrals of the system by reducing the Hamiltonian to a function of the products $p_j=x_jy_j(j=1,2,\ldots,n)$. In this case, since

$$\dot{x}_j=\frac{\partial H}{\partial y_j}=\frac{\partial H}{\partial p_j}x_j$$

$$\dot{y}_j=-\frac{\partial H}{\partial x_j}=-\frac{\partial H}{\partial p_j}y_j,$$

it follows that

$$\dot{x}_j\dot{y}_j+x_jy_j=0 \text{ or } p_j=\text{const } (j+1,2,\ldots,n).$$

d. *DELAUNAY'S METHOD*—This method, as Lindstedt's, can be applied only when the Hamiltonian consists of a "zero order" part (the corresponding system having a known solution) and a "disturbing function" that has a small numerical factor. The basic approach of the von Zeipel's method is the same as that of Delaunay's method; however, the latter one makes no use of a generating function and breaks the disturbing function into parts which are treated separately. The Hamiltonian must be constructed after the transformation is performed for each particular part.

A few more techniques could be mentioned but one deserves more attention than all the others. The concept of adiabatic invariants in Quantum Mechanics is quite analogous to the concept of "mean variables" in von Zeipel's method, or to a certain extent to what Whittaker calls Adelphic Integrals.

3. THE VON ZEIPEL'S METHOD (1916)

It has been quite common, after Delaunay, to use the negative of the Hamiltonian. Thus, if $F=-H$ and if $\ell_j(j=1,2,\ldots,n)$ and $L_j(j=1,2,\ldots,n)$ are the coordinates and momenta respectively, then

$$\dot{\ell}_j=-\frac{\partial F}{\partial L_j}$$

$$(j=1, 2, \cdots, n) \qquad (4)$$

$$\dot{L}_j=\frac{\partial F}{\partial \ell_j}.$$

Suppose

$$F=F(\ell,L;\epsilon) \qquad (5)$$

where ϵ is a "small parameter" and ℓ and L indicate the sets $(\ell_1,\ldots,\ell n)$ and $(L_1,\ldots,L_n)$. A canonical transformation involving the parameter ϵ will be given by a generating function

$$S=S(\ell,L^*;\epsilon)$$

such that

$$L_j=\frac{\partial S}{\partial \ell_j}$$

$$(j=1, 2, \cdots, n)$$

$$\ell_j^*=\frac{\partial S}{\partial L_j^*} \qquad (6)$$

where (ℓ^*,L^*) are the new coordinates and momenta. If F^* is the negative of the new Hamiltonian, then we assume

$$F^*(\ell^*,L^*;\epsilon)=F(\ell(\ell^*,L^*;\epsilon),L(\ell^*,L^*;\epsilon);\epsilon) \qquad (7)$$

or, from Equations (6),

$$F^*\left(\frac{\partial S}{\partial L^*},\ L^*;\ \epsilon\right)=F\left(\ell,\frac{\partial S}{\partial L};\ \epsilon\right). \qquad (8)$$

In a more restrictive sense it is assumed that the series

$$\bar{F}=\sum_{k=0}^{N}\epsilon^kF_k(\ell,\ L) \qquad (9)$$

represents the negative of the Hamiltonian to the required degree of precision and converges to $F(\ell,L;\epsilon)$ as $N\to\infty$. From this point $\bar{F}$ is written

as F without danger of confusion. Furthermore, it is assumed that

$$S(\ell, L^*; \epsilon)$$

$$F_k(\ell, L)$$

$$F^*(\ell^*, L^*; \epsilon)$$

are developable in Taylor's series in the neighborhood of $\epsilon=0$, so that the series

$$S=\sum_{k=0}^{\infty}\epsilon^k S_k(\ell, L^*)_{\epsilon=0}$$

$$F_p\left(\ell, \frac{\partial S}{\partial \ell}\right)=\sum_{k=0}^{\infty}\frac{\epsilon^k}{k!}\left(\frac{d^k F_p}{d\epsilon^k}\right)_{\epsilon=0} \tag{10}$$

are convergent for sufficiently small ϵ.

By the conservation property

$$\sum_{k=0}^{\infty}\epsilon^k F_k\left(\ell, \frac{\partial S}{\partial \ell}\right)=\sum_{k=0}^{\infty}\frac{\epsilon^k}{k!}\left(\frac{d^k F^*}{d\epsilon^k}\right)_{\epsilon=0} \tag{11}$$

where it is important to note that $\partial S/\partial \ell$ contains ϵ through Equation (6). Equating the coefficients of like powers in ϵ in both sides of Equation (11) gives a system of partial differential equations in S and F^*. The next step is obtaining this system.

4. DIFFERENTIAL EQUATIONS OF THE VON ZEIPEL'S METHOD

The m^{th} derivative of F_k with respect to ϵ at the point $\epsilon=0$ is obtained as follows.

Consider

$$\frac{dF_k}{d\epsilon}=\sum_{i=1}^{n}\frac{\partial F_k}{\partial L_i}\frac{dL_i}{d\epsilon}=\sum_{i=1}^{n}\frac{\partial F_k}{\partial L_i}\frac{d}{d\epsilon}\left(\frac{\partial S}{\partial \ell_i}\right).$$

Using Equation (10) it follows that

$$\left(\frac{dF_k}{d\epsilon}\right)=\sum_{i=1}^{n}\frac{\partial F_k}{\partial L_i}\frac{d}{d\epsilon}\left\{\sum_{j=0}^{\infty}\epsilon^j\frac{\partial S_j(\ell, L^*)}{\partial \ell_i}\right\}=\sum_{i=1}^{n}\sum_{j=1}^{\infty}j\,\epsilon^{j-1}\frac{\partial F_k}{\partial L_i}\left(\frac{\partial S_j}{\partial \ell_i}\right)_{\epsilon=0}. \tag{12}$$

Let us now compute

$$\frac{d^{m-1}}{d\epsilon^{m-1}}\left(\epsilon^{j-1}\frac{\partial F_k}{\partial L_i}\right)$$

where

$$F_k=F_k\left(\ell, \frac{\partial S}{\partial \ell}\right).$$

Applying Leibniz' formula, this becomes

$$\frac{d^{m-1}}{d\epsilon^{m-1}}\left(\epsilon^{j-1}\frac{\partial F_k}{\partial L_i}\right)=\sum_{\nu=0}^{\min(m-1,\, j-1)}\binom{m-1}{\nu}\frac{d^\nu \epsilon^{j-1}}{d\epsilon^\nu}\frac{d^{m-1-\nu}}{d\epsilon^{m-1-\nu}}\left(\frac{\partial F_k}{\partial L_i}\right).$$

For $\epsilon=0$ the only possible choice is $j<m$. Then

$$\left\{\frac{d^{m-1}}{d\epsilon^{m-1}}\left(\epsilon^{j-1}\frac{\partial F_k}{\partial L_i}\right)\right\}_{\epsilon=0}=\binom{m-1}{j-1}(j-1)!\left\{\frac{d^{m-j}}{d\epsilon^{m-j}}\left(\frac{\partial F_k}{\partial L_i}\right)\right\}_{\epsilon=0}.$$

Now using Equation (12)

$$\left(\frac{d^m F_k}{d\epsilon^m}\right)_{\epsilon=0}=\sum_{i=1}^{n}\sum_{j=1}^{\infty}j\binom{m-1}{j-1}(j-1)!\left\{\frac{d^{m-j}}{d\epsilon^{m-j}}\left(\frac{\partial F_k}{\partial L_i}\right)\right\}_{\epsilon=0}\left(\frac{\partial S_j}{\partial \ell_i}\right)_{\epsilon=0}.$$

It is now desirable to rewrite the above equation as

$$\left(\frac{d^m F_k}{d\epsilon^m}\right)_{\epsilon=0}=\sum_{i_1=1}^{n}\sum_{j_1=1}^{\infty}j_1\frac{(m-1)!}{(m-j_1)!}\left(\frac{\partial S_{j_1}}{\partial \ell_{i_1}}\right)_{\epsilon=0}\left[\frac{d^{m-j_1}}{d\epsilon^{m-j}}\left(\frac{\partial^1 F_k}{\partial L_{i_1}}\right)\right]_{\epsilon=0}. \tag{13}$$

Equation (13) is now applied to find

$$\left[\frac{d^{m-j_1}}{d\epsilon^{m-j_1}}\left(\frac{\partial^1 F_k}{\partial L_{i_1}}\right)\right]_{\epsilon=0}^{\cdot}.$$

The result is

$$\left[\frac{d^{m-j_1}}{d\epsilon^{m-j_1}}\left(\frac{\partial^1 F_k}{\partial L_{i_1}}\right)\right]_{\epsilon=0}^{\cdot}=\sum_{i_2=1}^{n}\sum_{j_2=1}^{\infty}j_2\frac{(m-j_1-1)!}{(m-j_1-j_2)!}\left(\frac{\partial S_{j_2}}{\partial \ell_{i_2}}\right)_{\epsilon=0}\times\left[\frac{d^{m-j_1-j_2}}{d\epsilon^{m-j_1-j_2}}\left(\frac{\partial^2 F_k}{\partial L_{i_1}\partial L_{i_2}}\right)\right]_{\epsilon=0}^{\cdot}$$

The process is repeated up to the point where

$$m-j_1-j_2-\cdots-j_N=0, \tag{14}$$

so that

$$\left[\frac{d^{m-j_1-j_2-\cdots-j_N}}{d\epsilon^{m-j_1-j_2-\cdots-j_N}}\left(\frac{\partial^N F_k}{\partial L_{i_1}\partial L_{i_2}\cdots\partial L_{i_N}}\right)\right]_{\epsilon=0}^{\cdot}=\left(\frac{\partial^N F_k}{\partial L_{i_1}\cdots\partial L_{i_N}}\right)_{\epsilon=0}^{\cdot}.$$

Substituting these successive derivatives into Equation (13), it follows that

$$\left(\frac{d^m F_k}{d\epsilon^m}\right)_{\epsilon=0}^{\cdot}=\sum_{i_1=1}^{n}\sum_{j_1=1}^{\infty}j_1\frac{(m-1)!}{(m-j_1)!}\left(\frac{\partial S_{j_1}}{\partial \ell_{i_1}}\right)_{\epsilon=0}\times\sum_{i_2=1}^{n}\sum_{j_2=1}^{\infty}j_2\frac{(m-j_1-1)!}{(m-j_1-j_2)!}\left(\frac{\partial S_{j_2}}{\partial \ell_{i_2}}\right)_{\epsilon=0}$$

$$\times\sum_{i_3=1}^{n}\sum_{j_3=1}^{\infty}j_3\frac{(m-j_1-j_2-1)!}{(m-j_1-j_2-j_3)!}\left(\frac{\partial S_{j_3}}{\partial \ell_{i_3}}\right)_{\epsilon=0}\times\cdots\times\sum_{i_N=1}^{n}\sum_{j_N=1}^{\infty}j_N\frac{(m-j_1-j_2-\cdots-j_{N-1}-1)!}{(m-j_1-j_2-\cdots-j_N)!}\left(\frac{\partial S_{j_N}}{\partial \ell_{i_N}}\right)_{\epsilon=0}$$

$$\times\left(\frac{\partial^N F_k}{\partial L_{i_1}\partial L_{i_2}\cdots\partial L_{i_N}}\right)_{\epsilon=0}^{\cdot}.$$

The numerical factors are reduced to

$$j_1 j_2\cdots j_N\frac{m!}{m(m-j_1)(m-j_1-j_2)\cdots(m-j_1-j_2-\cdots-j_{N-1})}\equiv m!\,C(m;j_1,j_2,\cdots,j_N)$$

and the second summation does not run in general up to infinity but to a limit given by condition (14). Thus the above relation becomes

$$\left(\frac{d^m F_k}{d\epsilon^m}\right)_{\epsilon=0}^{\cdot}=\sum_{(m)}\prod_{p=1}^{N}\left(\sum_{i_p=1}^{n}\right)m!\,C(m;j_1,\cdots,j_N)\prod_{p=1}^{N}\left(\frac{\partial S_{j_p}}{\partial \ell_{i_p}}\right)_{\epsilon=0}\left(\frac{\partial^N F_k}{\partial L_{i_1}\cdots\partial L_{i_N}}\right)_{\epsilon=0}^{\cdot} \tag{15}$$

where $\sum_{(m)}$ stands for summation over all possible positive integers j_p whose sum is m (according to Equation (14)), and the first product $\prod_{p=1}^{N}$ refers to the summation signs $\sum_{i_p=1}^{n}$. There are n of these integers. Equation (15) will be valid even for $m=0$ with the definitions

$$\frac{d^0 F_k}{d\epsilon^0}\equiv F_k$$

and

$$C(0;-)\equiv 1.$$

From Equations (10) and (11) it follows that

$$F=\sum_{k=0}^{\infty}\epsilon^k F_k(\ell, L)=\sum_{k=0}^{\infty}\epsilon^k\sum_{m=0}^{\infty}\frac{\epsilon^m}{m!}\left(\frac{d^m F_k}{d\epsilon^m}\right)_{\epsilon=0}=\sum_{k=0}^{\infty}\sum_{m=0}^{\infty}\frac{\epsilon^{m+k}}{m!}\left(\frac{d^m F_k}{d\epsilon^m}\right)_{\epsilon=0}=\sum_{\nu=0}^{\infty}\sum_{m=0}^{\nu}\frac{\epsilon_\nu}{m!}\left(\frac{d^m F_{\nu-m}}{d\epsilon^m}\right)_{\epsilon=0}.$$

The substitution of these results into Equation (14) leads to

$$F=\sum_{\nu=0}^{\infty}\sum_{m=0}^{\nu}\sum_{(m)}\prod_{p=1}^{N}\left(\sum_{i_p=1}^{n}\right)C(m; j_1, \cdots, j_N)\prod_{p=1}^{N}\left(\frac{\partial S_{j_p}}{\partial \ell_{i_p}}\right)_{\epsilon=0}\left(\frac{\partial^N F_{\nu-m}}{\partial L_{i_1}\cdots\partial L_{i_N}}\right)_{\epsilon=0}\epsilon^\nu. \tag{16}$$

In a complete similar way, if

$$F^*=\sum_{k=0}^{\infty}\epsilon^k F_k^*\left(\frac{\partial S}{\partial L^*}, L^*\right),$$

then

$$F^*=\sum_{\nu=0}^{\infty}\sum_{m=0}^{\nu}\sum_{(m)}\prod_{p=1}^{N}\left(\sum_{i_p=1}^{n}\right)C(m; j_1, \cdots, j_N)\prod_{p=1}^{N}\left(\frac{\partial S_{i_p}}{\partial L_{i_p}^*}\right)_{\epsilon=0}\left(\frac{\partial^N F_{\nu-m}^*}{\partial \ell_{i_1}^*\cdots\partial \ell_{i_N}^*}\right)_{\epsilon=0}\epsilon^\nu. \tag{17}$$

It is important to note that in Equation (16), $\epsilon=0$ is equivalent to $L_r=\partial S_0/\partial \ell_r (r=1,2,\cdots,n)$, and in Equation (17) $\epsilon=0$ is equivalent to $\ell_r^*=\partial S_0/\partial L_r^* (r=1,2,\cdots,n)$, according to Equation (10). The equality of factors of the same power of ϵ in Equations (16) and (17) gives the partial differential equations for the von Zeipel's method

$$\sum_{m=0}^{\nu}\sum_{(m)}\prod_{p=1}^{N}\left(\sum_{i_p=1}^{n}\right)C(m; j_1, \cdots, j_N)\prod_{p=1}^{N}\left\{\frac{\partial S_{j_p}}{\partial \ell_{i_p}}\left(\frac{\partial^N F_{\nu-m}}{\partial L_{i_p}\cdots\partial L_{i_N}}\right)+-\frac{S\partial_{j_p}}{\partial L_{i_p}^*}\left(\frac{\partial^N F_{\nu-m}}{\partial \ell_{i_1}^*\cdots\partial \ell_{i_N}^*}\right)\right\}_{\epsilon=0}=0 \tag{18}$$

for $\nu=0, 1, 2, \cdots$.

For instance, Equation (18) gives:

$\underline{\nu=0}$

$$F_0\left(\ell, \frac{\partial S_0}{\partial \ell}\right)=F_0^*\left(\frac{\partial S_0}{\partial L^*}, L^*\right) \tag{19}$$

$\underline{\nu=1}$

$$F_1\left(\ell, \frac{\partial S_0}{\partial \ell}\right)+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\frac{\partial F_0}{\partial L_i}\right)_{L_i=\frac{\partial S_0}{\partial \ell_i}}=F_1^*\left(\frac{\partial S_0}{\partial L^*}, L^*\right)+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\frac{\partial F_0^*}{\partial \ell_i^*}\right)_{\ell_i^*=\frac{\partial S_0^*}{\partial L_i^*}} \tag{20}$$

$\underline{\nu=2}$

$$F_2\left(\ell, \frac{\partial S_0}{\partial \ell}\right)+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\frac{\partial F_1}{\partial L_i}\right)_{L_1=\frac{\partial S_0}{\partial \ell_i}}+\sum_{i=1}^{n}\left(\frac{\partial S_2}{\partial \ell_i}\frac{\partial F_0}{\partial L_i}\right)_{L_i=\frac{\partial S_0}{\partial \ell_i}}+\frac{1}{2}\sum_{i,\,j=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\frac{\partial S_1}{\partial \ell_j}\frac{\partial^2 F_0}{\partial L_i \partial L_j}\right)_{L_k=\frac{\partial S_0}{\partial \ell_k}}$$

$$=F_2^*\left(\frac{\partial S_0}{\partial L^*}, L^*\right)+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\frac{\partial F_1^*}{\partial \ell_i^*}\right)_{\ell_i^*=\frac{\partial S_0}{\partial L_i^*}}+\sum_{i=1}^{n}\left(\frac{\partial S_2}{\partial L_i^*}\frac{\partial F_0^*}{\partial \ell_i^*}\right)_{\ell_i^*=\frac{\partial S_0}{\partial L_i^*}}+\frac{1}{2}\sum_{i,\,j=1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\frac{\partial S_1}{\partial L_j^*}\frac{\partial^2 F_0^*}{\partial \ell_i^* \partial \ell_j^*}\right)_{\ell_k^*=\frac{\partial S_0}{\partial L_k^*}} \tag{21}$$

$\nu=3$

$$F_3\left(\ell,\frac{\partial S_0}{\partial \ell}\right)+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\frac{\partial F_2}{\partial L_i}\right)_{L_i=\frac{\partial S_0}{\partial \ell_i}}+\sum_{i=1}^{n}\left(\frac{\partial S_2}{\partial \ell_i}\frac{\partial F_1}{\partial L_i}\right)_{L_i=\frac{\partial S_0}{\partial \ell_i}}+\sum_{i,\,j=1}^{n}\frac{1}{2}\left(\frac{\partial S_1}{\partial \ell_i}\frac{\partial S_1}{\partial \ell_j}\frac{\partial^2 F_1}{\partial L_i \partial L_j}\right)_{L_k=\frac{\partial S_0}{\partial \ell_k}}+$$

$$+\sum_{i,\,j,\,k=1}^{n}\frac{1}{6}\left(\frac{\partial S_1}{\partial \ell_i}\frac{\partial S_1}{\partial \ell_j}\frac{\partial S_1}{\partial \ell_k}\frac{\partial^3 F_0}{\partial L_i \partial L_j \partial L_k}\right)_{L_p=\frac{\partial S_0}{\partial \ell_p}}+\sum_{i,\,j=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\frac{\partial S_2}{\partial \ell_j}\frac{\partial^2 F_0}{\partial L_i \partial L_j}\right)_{L_k=\frac{\partial S_0}{\partial \ell_k}}+\sum_{i=1}^{n}\left(\frac{\partial S_3}{\partial \ell_i}\frac{\partial F_0}{\partial L_i}\right)_{L_i=\frac{\partial S_0}{\partial \ell_i}}$$

$$=F_3^*\left(\frac{\partial S_0}{\partial L^*},L^*\right)+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\frac{\partial F_2^*}{\partial \ell_i^*}\right)_{\ell_i^*=\frac{\partial S_0}{\partial L_i^*}}+\sum_{i=1}^{n}\left(\frac{\partial S_2}{\partial L_i^*}\frac{\partial F_1^*}{\partial \ell_i^*}\right)_{\ell_i^*=\frac{\partial S_0}{\partial L_i^*}}+\sum_{i,\,j=1}^{n}\frac{1}{2}\left(\frac{\partial S_1}{\partial L_i^*}\frac{\partial S_1}{\partial L_j^*}\frac{\partial^2 F_1^*}{\partial \ell_i^* \partial \ell_j^*}\right)_{\ell_k^*=\frac{\partial S_0}{\partial L_k^*}}$$

$$+\sum_{i,\,j,\,k=1}^{n}\frac{1}{6}\left(\frac{\partial S_1}{\partial L_i^*}\frac{\partial S_1}{\partial L_j^*}\frac{\partial S_1}{\partial L_k^*}\frac{\partial^3 F_0^*}{\partial \ell_i^* \partial \ell_j^* \partial \ell_k^*}\right)_{\ell_p^*=\frac{\partial S_0}{\partial L_p^*}}+\sum_{i,\,j=1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\frac{\partial S_2}{\partial L_j^*}\frac{\partial F_0^*}{\partial \ell_i^* \partial \ell_j^*}\right)_{\ell_k^*=\frac{\partial S_0}{\partial L_k^*}}$$

$$+\sum_{i=1}^{n}\left(\frac{\partial S_2}{\partial L_i^*}\frac{\partial F_0^*}{\partial \ell_i^*}\right)_{\ell_i^*=\frac{\partial S_0}{\partial L_i^*}} \tag{22}$$

where use has been made of the coefficients

$C(1;\,1)=1$
$C(2;\,2)=1 \quad C(2;\,1,\,1)=\frac{1}{2}$
$C(3;\,3)=1 \quad C(3;\,2,\,1)=\frac{2}{3} \quad C(3;\,1,\,2)=\frac{1}{3} \quad C(3;\,1,\,1,\,1)=\frac{1}{6}.$

5. ELIMINATION OF VARIABLES

Since the solution of the system is known where F is reduced to F_0, the problem is to eliminate variables which are not present in F_0. Suppose a canonical transformation is found in such a way that p of the n coordinates ($p\leq n$) have been eliminated from the Hamiltonian, that is

$$F^*=F^*(\ell_{p+1}^*,\cdots,\ell_n,L_1^*,L_2^*,\cdots,L_n^*). \tag{23}$$

The equations of motion then yield

$$L_k^*=C_k(\text{const.}) \qquad (k=1,2,\cdots,p). \tag{24}$$

If these constants are replaced in F^*, then

$$F^*=F^*(\ell_{p+1}^*,\cdots,\ell_n^*,C_1,C_2,\cdots,C_p,L_{p+1}^*,\cdots,L_n^*)$$

and the problem is reduced to one of $n-p$ degrees of freedom.

a. If $p=n$, the problem is completely solved, since

$$L_k^*=C_k \qquad (k=1,2,\cdots,n)$$

and

$$\ell_k^*=\omega_k(C_1,\cdots,C_n)t+\ell_k^*(0). \qquad (k=1,2,\cdots,n)$$

b. If $p=n-1$, the problem is integrable by quadrature. In fact,

$$L_k^* = C_k \qquad (k=1,2,\cdots,n-1)$$

$$\dot{L}_n^* = \frac{\partial F^*}{\partial \ell_n^*} = \Lambda(C_1, C_2, \cdots, C_{n-1}; L_n^*, \ell_n^*)$$

$$\dot{\ell}_n^* = -\frac{\partial F^*}{\partial L_n^*} = \lambda_n'(C_1, C_2, \cdots, C_{n-1}; L_n^*, \ell_n^*).$$

Since

$$F^*(C_1,\cdots,C_{n-1}; \ell_n^*, L_n^*) = C = \text{const.},$$

then

$$L_n^* = L_n^*(C, C_1, \cdots, C_{n-1}; \ell_n^*)$$

and therefore

$$\dot{\ell}_n^* = \lambda_n(C, C_1, \cdots, C_{n-1}; \ell_n^*)$$

and

$$t - t_0 = \int_{\ell_{n(0)}^*}^{\ell_n^*} \frac{d\zeta}{\lambda_n(C, C_1, \cdots, C_{n-1}; \zeta)}$$

The coordinate ℓ_n^* becomes a known function of time as well as L_n^*.

Therefore, the equations

$$\dot{\ell}_k^* = -\frac{\partial F^*}{\partial L_k^*} = \lambda_k\Big(C_1, C_2, \cdots, C_{n-1}; L_n^*(t), \ell_n^*(t)\Big) (k=1, 2, \cdots, n-1)$$

can be integrated by quadrature.

The von Zeipel's method consists in the elimination of some of the coordinates (angular variables) and the reduction of the problem to case (b) and possibly (a). The adaptability of this method is based on a set of hypotheses which are listed below in Roman numerals.

(I) The new and old corresponding variables differ by a quantity at least of the first order, i.e.

$$\ell_i' - \ell_i = 0(\epsilon)$$

$$(i=1, 2, \cdots, n)$$

$$L_i^* - L_i = 0(\epsilon).$$

This automatically fixes S_0 to correspond to the identity transformation since for $\epsilon=0$, the above conditions give

$$\ell_i^* \equiv \ell_i$$

$$(i=1, 2, \cdots, n)$$

$$L_i^* \equiv L_i.$$

Therefore

$$S_0 = \sum_{i=1}^{n} \ell_i L_i^*. \tag{25}$$

If expression (25) is substituted into Equations (19), (20), (21) and (22), then

$\nu=0$

$$F_0(\ell, L^*)=F_0^*(\ell, L^*) \tag{26}$$

$\nu=1$

$$F_1(\ell, L^*)+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\right)_{L_i=L_i^*}\frac{\partial F_0}{\partial L_i^*}=F_1^*(\ell, L^*)+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\right)_{\ell_i^*=\ell_i}\frac{\partial F_0^*}{\partial \ell_i} \tag{27}$$

$\nu=2$

$$F_2(\ell, L^*)+\sum_{i=1}^{n}\left(\frac{\partial S_i}{\partial \ell_i}\right)_{L_i=L_i^*}\frac{\partial F_i}{\partial L_i^*}+\sum_{i=1}^{n}\left(\frac{\partial S_2}{\partial \ell_i}\right)_{L_i=L_i^*}\frac{\partial F_0}{\partial L_i^*}+\frac{1}{2}\sum_{i,\,j=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\frac{\partial S_1}{\partial \ell_j}\right)_{L_k=L_k^*}\frac{\partial^2 F_0}{\partial L_i^*\partial L_j^*}=F_2^*(\ell, L^*)$$

$$+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\right)_{\ell_i^*=\ell_i}\frac{\partial F_1^*}{\partial \ell_i^*}+\sum_{i=1}^{n}\left(\frac{\partial S_2}{\partial L_i^*}\right)_{\ell_i^*=\ell_i}\frac{\partial F_0^*}{\partial \ell_i}+\frac{1}{2}\sum_{i,\,j=1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\frac{\partial S_1}{\partial L_j^*}\right)_{\ell_k^*=\ell_k}\frac{\partial^2 F_0^*}{\partial \ell_i\,\partial \ell_j}. \tag{28}$$

and similarly for Equation (22).

It is seen that $S_k(L^*, \ell)$ and $F_k^*(L^*, \ell)$ are unknown functions. In order to perform a particular solution toward the elimination of certain angular variables in F^* we impose conditions (which are usually suitable in Celestial Mechanics) on the functions S_k and F_k^*. They are

II) $F_k^*(L^*, \ell)$ does not depend on $\ell_i(i=1, 2,\cdots,p\leq n)$ for any $k\geq 0$.

III) $S_k(L^*, \ell)$ only depends on the $\ell_i(i=1,2,\cdots,n)$ through trigonometric functions, for any $k>0$. This avoids "secular perturbations" in the momenta L_j, or in other words differences

$$L_j-L_j^*=\frac{\partial(S-S_0)}{\partial \ell_j}$$

are periodic functions of the $\ell_k(k=1, 2,\cdots,n)$.

The application of these conditions, together with the obvious fact that F_0 does not depend on angular variables $\ell_i(i=1,2,\cdots,p\leq n)$ which are to be eliminated, yields the relations

$$F_0(\ell_{p+1},\cdots, \ell_n, L_1^*,\cdots,L_n^*)=F_0^*(\ell_{p+1},\cdots\ell_n,L_1^*\cdots,L_n^*) \tag{29}$$

$$F_{1s}=F_1^*$$

$$F_{1p}+\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\right)_{L_i=L_i^*}\frac{\partial F_0}{\partial L_i}=\sum_{i=p+1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\right)_{\ell_i^*=\ell_i}\frac{\partial F_0^*}{\partial \ell_i} \tag{30}$$

$$F_{2s}+P_{2s}=F_2^*+P_{2s}^*$$

$$F_{2p}+P_{2p}+\sum_{i=1}^{n}\left(\frac{\partial S_2}{\partial \ell_i}\right)_{L_i=L_i^*}\frac{\partial F_0}{\partial L_i^*}=P_{2p}^*+\sum_{i=p+1}^{n}\left(\frac{\partial S_2}{\partial L_i}\right)_{\ell_i^*=\ell_i}\frac{\partial F_0^*}{\partial \ell_i} \tag{31}$$

and so forth. The functions F_{1s} and F_{1p}, F_{2s} and F_{2p}, P_{2s} and P_{2p}, P_{2s}^* and P_{2p}^* are the portions of F_1, F_2, P_2 and P_2^* which are respectively independent of and dependent on the $\ell_i(i=1,2,\cdots,p)$, and where

$$P_2=\sum_{i=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\right)_{L_i=L_i^*}\frac{\partial F_1}{\partial L^*}+\frac{1}{2}\sum_{i,\,j=1}^{n}\left(\frac{\partial S_1}{\partial \ell_i}\frac{\partial S_1}{\partial \ell_j}\right)_{L_k=L_k^*}\frac{\partial^2 F_0}{\partial L_i^*\partial L_j^*}$$

$$P_2^*=\sum_{i=p+1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\right)_{\ell_i^*=\ell_i}\frac{\partial F_1^*}{\partial \ell_i^*}+\frac{1}{2}\sum_{i,\,j=p+1}^{n}\left(\frac{\partial S_1}{\partial L_i^*}\frac{\partial S_1}{\partial L_j^*}\right)_{\ell_k^*=\ell_k}\frac{\partial^2 F_0^*}{\partial \ell_i\partial \ell_j}. \tag{32}$$

In the usual problems of Celestial Mechanics F_0 does not depend on any angular variable so that the Equations (30), (31), (32) and the corresponding equations for higher order are much simplified. Thus, the additional hypotheses will be considered.

IV) F_0 and thus F_0^* depend only on the momenta L_i^*

V) The angular variables ℓ_i $(i=1,2,\cdots,m)$ corresponding to momenta $L_i(i=1,2,\cdots,m)$ that are present in F_0 have been eliminated to the k^{th} order.

The next problem is the possibility of elimination of angular variables whose conjugate momenta are not present in F_0. At this stage the Hamiltonian of the system is

$$F^*=F_0^*(L_1^*,\cdots,L_m^*)+F_1^*(\ell_{m+1},\cdots,\ell_n,L_1^*,\cdots,L_n^*)+\cdots+F_k^*(\ell_{m+1},\cdots,\ell_n,\cdots,L_n^*) \tag{33}$$

where

$$L_j^*=C_j=\text{const}(j=1,2,\cdots,m),$$

and the old and new variables are related by

$$\begin{aligned} L_j-L_j^*&=\frac{\partial S_1}{\partial \ell_j}+\frac{\partial S_2}{\partial \ell_j}+\cdots+\frac{\partial S_K}{\partial \ell_j} \\ \ell_j^*-\ell_j&=\frac{\partial S_1}{\partial L_j^*}+\frac{\partial S_2}{\partial L_j^*}+\cdots+\frac{\partial S_K}{\partial L_j^*}. \end{aligned} \qquad (j=1,2,\cdots,n) \tag{34}$$

Assume a new canonical transformation from the variables $(\ell_{m+1}^*,\cdots,\ell_n^*,L_{m+1}^*,\cdots,L_n^*)$ to the variables $(\ell_{m+1}^{**},\cdots,\ell_n^{**},L_{m+1}^{**},\cdots,L_n^{**})$ and let

$$S^*=S^*(\ell_{m+1}^*,\cdots,\ell_n^*,L_{m+1}^{**},\cdots,L_n^{**}) \tag{35}$$

be its generating function. Then, since $L_j^*=C_j=\text{const}$ $(j=1,2,\cdots,m)$,

$$F_0^*(L_1^{**},\cdots,L_m^{**})=F_0^{**}(L_1^{**},\cdots,L_m^{**})=\text{const } L_k^{**}=L_k^*=C_k=\text{const } (k=1,2,\cdots,m) \tag{36}$$

$$F_1^*(\ell_{m+1}^*,\cdots,\ell_n^*;C_1,C_2,\cdots,C_m,L_{m+1}^{**},\cdots,L_n^{**})=F_1^{**}(\ell_{m+1}^*,\cdots,\ell_n^*;L_{m+1}^{**},\ldots,L_n^{**}). \tag{37}$$

The last equation implies that the elimination of further variables is possible if and only if F_1^* does not depend on them. For in this case

$$F_1^*(\ell_{m+p+1}^*,\cdots,\ell_n^*,C_1,C_2,\cdots,C_n,L_{m+1}^{**},\cdots,L_n^{**})=F_1^{**}(\ell_{m+p+1}^*,\cdots,\ell_n^*;L_{m+1}^{**},\cdots,L_n^{**})$$

and

$$\begin{aligned} F_2^*(\ell_{m+1}^*,\cdots,\ell_n^*;L_{m+1}^{**},\cdots,L_n^{**})+\sum_{i=m+1}^{n}\frac{\partial S_1^*}{\partial \ell_i^*}\frac{\partial F_1^*}{\partial L_i^{**}} \\ =F_2^{**}(\ell_{m+p+1}^*,\cdots,\ell_n^*;L_{m+1}^{**},\cdots,L_n^{**})+\sum_{i=m+p+1}^{n}\frac{\partial S_1^*}{\partial L_i^{**}}\frac{\partial F_1^{**}}{\partial \ell_i^*}. \end{aligned} \tag{38}$$

which defines S_1^*. It is important to note that in such a case S_1^* will be defined by an equation involving *2nd order* terms; these terms are therefore necessary to obtain *first order* "perturbations." This fact is exactly what happens in Brouwer's theory on artificial satellites (1959), where

a) The elimination of g^* is possible because F_1^* is independent of this variable.

b) The development for long period perturbations (those of argument g^*) needs the evaluation of 2nd order terms.

This type of reasoning can be carried on up to any order in exactly the same way. It may then happen that the elimination of a certain angular variable by obtaining S_1^* requires the evaluation of terms of the kth order.

However if F_1^* depends on the angular variables to be eliminated the problem cannot be solved unless it happens that the remaining system has one degree of freedom. For example, this is the case of the perturbations on the motion of an artificial satellite by the moon.

6. SMALL DIVISORS

The case of critical inclination for the theory of artificial satellites of an oblate planet for which P_2 is the dominant zonal harmonic and $J_4 \neq -J_2^2$, is a well known example of the problem of small divisors. Here, only a particular aspect of the question is dealt with. Consider the solution of Equation (30) in the usual case where F_0^* does not depend on the ℓ_i. The characteristic associated system is

$$\frac{d\ell_1}{\dfrac{\partial F_0}{\partial L_1^*}} = \frac{d\ell_2}{\dfrac{\partial F_0}{\partial L_2^*}} = \cdots \equiv \frac{d\ell_p}{\dfrac{\partial F_0}{\partial L_p^*}} = \frac{dS_1}{F_{1p}}. \tag{39}$$

Should one of the partials $\partial F_0/\partial L_i^*$ happen to be zero, the general solution would certainly be discontinuous since a "small divisor" is present. However this divisor is not exactly zero because the quantity $\partial F_0/\partial L_i^*$ is evaluated to first order only.

In the case of critical inclination it is necessary to take

$$S = S_0 + \epsilon^{1/2} S_{1/2} + \epsilon S_1 + \epsilon^{3/2} S_{3/2} + \cdots.$$

However, in doing so the separation of "long periodic" and "secular" perturbations is lost. The integration leads, in most cases, to elliptic integrals (Hori, 1960).

The question of small divisors usually arises whenever the problem presents cases of libration as particular solutions.

Another case to be mentioned is the resonance for an artificial satellite whose period is commensurable with the period of rotation of the Earth when tesseral harmonics are included. Again, expansion in powers of $\epsilon^{1/2}$ can be used to solve the problem (Morando, 1962).

Finally it is important to note that singularities in the Equations (39) reflect singular points in the hypersurface defined by the Hamiltonian of the system in a phase-space of $2(n-p)$ dimensions if p variables have already been eliminated.

7. SUMMARY

The general differential equations of the von Zeipel's method have been given to any order. It is hoped that this will avoid tedious Taylor expansions if one needs to go to order higher than the second.

At the same time, the brief discussion on the applicability and a few pathological cases of the method, may give some guidance toward the solution of new problems.

A SERIES SOLUTION FOR SOME PERIODIC ORBITS IN THE RESTRICTED THREE-BODY PROBLEM ACCORDING TO THE PERTURBATION METHOD*

N66 37952

SU-SHU HUANG†

A series is obtained for those periodic orbits surrounding the more massive of the two finite bodies in the restricted three-body problem. The expansion is in terms of the mass of the less massive finite body. The initial conditions predicted by the series for several periodic orbits are compared with those obtained by purely numerical processes. They are in good agreement for the case corresponding to the earth-moon system. Also, a simple theory of nearly periodic orbits in the neighborhood of a periodic orbit is developed and numerically verified by examples. Finally, it is suggested that, if asteroids avoid places where their orbits would be commeasurable with the period of Jupiter, then artificial satellites and dust particles may avoid certain areas around the earth as a result of the presence of the moon.

INTRODUCTION

A periodic solution may be regarded as a solution of the differential equations of motion that satisfies, in addition to the initial conditions, the condition that after a lapse of one period, P, both coordinates and velocities return to their initial values. Thus, the problem of finding a periodic orbit in celestial mechanics resembles the problem of finding the eigen function for an eigen value in quantum mechanics, since the eigen value is determined by boundary conditions. Indeed, it is this basic concept that led to the derivation of a series solution for those periodic orbits in the restricted three-body problem that are revolving around the more massive of the two finite mass points. The recent papers by Szebehely give a detailed discussion of the restricted three-body problem (References 1 and 2).

The mathematical method used here follows the standard technique employed in classical mechanics under these circumstances. Indeed, it is very similar to the method Hill used in his lunar theory (References 3 and 4; also see Reference 5). Actually, the present analysis is somewhat parallel to the analysis that led Hill to his variation orbit, for both his and the present method depend upon some series expansions. However, in his lunar theory Hill expanded the solution in terms of the ratio of the mean motion of the sun to that of the moon in the rotating coordinate system. In this present theory for artificial satellites orbiting the earth in the earth-moon system the solution is expanded in terms of the mass of the moon. The mathematical simplicity in terms of the lunar mass is obvious; however, the result cannot be applied to the study of the motion of the moon because the moon is revolving around a relatively much less massive body (i.e., the earth) in the earth-sun system; consequently, it is senseless to expand the solution in terms of the solar mass.

EQUATIONS OF MOTION

The total mass of the two finite bodies is considered the unit of mass, and their separation the unit of length. The unit of time is such that the gravitational constant is unity. If we adopt the line joining the two finite mass points as the x-axis and the location of the greater of these masses as the origin, the equations of motion of the third,

*Published as *NASA Technical Note* D-2488, September 1964.

†*Goddard Space Flight Center* and Catholic University, Washington, D.C.

infinitesimal body in this rotating system of reference become:

$$\frac{d^2x}{dt^2} - 2\frac{dy}{dt} = x - \mu - (1-\mu)\frac{x}{(r_1')^3} - \mu\frac{x-1}{(r_2')^3}, \quad (1)$$

$$\frac{d^2y}{dt^2} + 2\frac{dx}{dt} = y - (1-\mu)\frac{y}{(r_1')^3} - \mu\frac{y}{(r_2')^3}, \quad (2)$$

where it is assumed that the mass $1-\mu$ is at the origin. Consequently the mass μ is at point (1, 0). Also, r_1' and r_2' are the distances of the third body from the $1-\mu$ and μ components, respectively. It is obvious that r_1' is also the distance of the third body from the origin; so

$$r_1' = r. \quad (3)$$

We are interested in the periodic orbits revolving around the $1-\mu$ component. Therefore, we make the transformations

$$x = r\cos\theta, \quad (4)$$

$$y = r\sin\theta. \quad (5)$$

This brings Equations 1 and 2 into the forms

$$\frac{d^2r}{dt^2} - r\left(\frac{d\theta}{dt}\right)^2 - 2r\frac{d\theta}{dt} = r - (1-\mu)\frac{1}{r^2} - \mu\frac{r}{(r_2')^3} + \mu\left[\frac{1}{(r_2')^3} - 1\right]\cos\theta, \quad (6)$$

$$r\frac{d^2\theta}{dt^2} + 2\frac{dr}{dt}\frac{d\theta}{dt} + 2\frac{dr}{dt} = -\mu\left[\frac{1}{(r_2')^3} - 1\right]\sin\theta. \quad (7)$$

EQUATIONS OF PERTURBATION

When μ equals zero all circles with their center at the origin are the periodic solutions of the problem. We can now argue that if μ is small, the periodic orbit deviates only slightly from a circular one. The deviation obviously depends upon μ. Therefore, the periodic solutions may be written as

$$r = r_0 + \mu r_1(t) + \mu^2 r_2(t) + \cdots, \quad (8)$$

$$\theta = \lambda t + \mu\theta_1(t) + \mu^2\theta_2(t) + \cdots, \quad (9)$$

where r_0 and λ are to be determined and are independent of time. Substituting Equations 8 and 9 into Equations 6 and 7 gives equations of different orders of approximation after a series of long but straightforward calculations.

The zeroth order (μ^0) approximation gives

$$(\lambda+1)^2 = \frac{1-\mu}{r_0^3}, \quad (10)$$

which is simply Kepler's third law in the problem of two bodies, the $1-\mu$ component and the third, infinitesimal body. The term is $\lambda+1$ instead of λ because the equations are expressed in the rotating coordinate system. Also, λ may have positive or negative values, corresponding respectively to the direct and retrograde motion of the third body.

The first order (μ^1) approximation yields

$$\frac{d^2r_1}{dt^2} - 2(\lambda+1)r_0\frac{d\theta_1}{dt} - 3(\lambda+1)^2 r_1 = \frac{1}{2}r_0 + \frac{3}{2}r_0\cos 2\lambda t + \frac{1}{8}r_0^2(9\cos\lambda t + 15\cos 3\lambda t), \quad (11)$$

$$r_0\frac{d^2\theta_1}{dt^2} + 2(\lambda+1)\frac{dr_1}{dt} = -\frac{3}{2}r_0\sin 2\lambda t - \frac{3}{8}r_0^2(\sin\lambda t + 5\sin 3\lambda t), \quad (12)$$

if the terms involving third and higher orders of r_0 are neglected.

With the same degree of approximation in regard to the series in r_0, the second order (μ^2)

equations are:

$$\frac{d^2 r_2}{dt^2} - 2(\lambda+1) r_0 \frac{d\theta_2}{dt} - 3(\lambda+1)^2 r_2 = r_0 \left(\frac{d\theta_1}{dt}\right)^2 + 2(\lambda+1) r_1 \frac{d\theta_1}{dt} - 3(\lambda+1)^2 \frac{r_1^2}{r_0}$$

$$+ \frac{1}{2} r_1 (1 + 3\cos 2\lambda t) + \frac{1}{4} r_0 r_1 (9\cos \lambda t + 15 \cos 3\lambda t)$$

$$- 3 r_0 \theta_1 \sin 2\lambda t - \frac{r_0^2 \theta_1}{8} (45 \sin 3\lambda t + 9 \sin \lambda t) , \qquad (13)$$

and

$$r_0 \frac{d^2 \theta_2}{dt^2} + 2(\lambda+1) \frac{dr_2}{dt}$$

$$= - 2 \frac{dr_1}{dt} \frac{d\theta_1}{dt} - r_1 \frac{d^2 \theta_1}{dt^2} - \frac{3}{2} r_1 \sin 2\lambda t - 3 r_0 \theta_1 \cos 2\lambda t$$

$$- \frac{1}{4} r_0 r_1 (3 \sin \lambda t + 15 \sin 3\lambda t) - \frac{1}{8} r_0^2 \theta_1 (3 \cos \lambda t + 45 \cos 3\lambda t) . \qquad (14)$$

In a similar way equations of higher orders can be derived in terms of the solutions of the equations of lower orders.

THE FIRST ORDER EQUATIONS

The solutions of Equations 11 and 12 can be easily found:

$$r_1 = - \frac{r_0}{6(\lambda+1)^2} + A_1' \cos(\lambda+1)t + A_2' \sin(\lambda+1)t - \frac{2B_1'}{3(\lambda+1)} + k_1 \cos \lambda t + k_2 \cos 2\lambda t + k_3 \cos 3\lambda t , \qquad (15)$$

$$r_0 \theta_1 = l_1 \sin \lambda t + l_2 \sin 2\lambda t + l_3 \sin 3\lambda t + B_1' t + B_2' - 2A_1' \sin(\lambda+1)t + 2A_2' \cos(\lambda+1)t . \qquad (16)$$

A_1', A_2', B_1', and B_2' are arbitrary constants which make Equations 15 and 16 the most general solution, k_n and l_n are defined by

$$k_1 = \frac{15+6}{8\lambda(2\lambda+1)} r_0^2 , \qquad (17)$$

$$k_2 = - \frac{3(2\lambda+1)}{2\lambda(3\lambda^2 - 2\lambda - 1)} r_0 , \qquad (18)$$

$$k_3 = - \frac{5(5\lambda+2)}{8\lambda(8\lambda^2 - 2\lambda - 1)} r_0^2 , \qquad (19)$$

$$l_1 = - \frac{3(10\lambda^2 + 12\lambda + 3)}{8\lambda^2(2\lambda+1)} r_0^2 , \qquad (20)$$

$$l_2 = \frac{3(11\lambda^2 + 10\lambda + 3)}{8\lambda^2(3\lambda^2 - 2\lambda - 1)} r_0 , \qquad (21)$$

$$l_3 = \frac{5(6\lambda^2 + 4\lambda + 1)}{8\lambda^2(8\lambda^2 - 2\lambda - 1)} r_0^2 . \qquad (22)$$

It should be observed that λ (or, equivalently, r_0), which appears in Equation 10, is not an integration constant in the perturbed case, although it is in the unperturbed case. Indeed, in the unperturbed case λ is the only integration constant that does not vanish under the assumed initial conditions. The integration constants in the perturbed case are A_1', A_2', B_1', and B_2'. In general, if higher orders of μ are considered, A_1, A_2, B_1, and B_2 are defined by

$$A_1 = A_1' \mu + A_1'' \mu^2 + \cdots , \quad \text{etc.},$$

because, as we shall see later, the complementary

functions in different orders of approximation are of the same form. Consequently, the integration constants in different orders of μ can be combined into four arbitrary constants A_1, A_2, B_1, and B_2 to agree with the expected number of four that occur in the solution of two second order differential equations (Equations 6 and 7).

The integration constants A_1, A_2, and B_2 are not particularly relevant, but it is important to note the dynamical meaning of B_1. If λ' is the mean angular velocity in the perturbed case, we have, from Equations 9 and 16,

$$\lambda' = \lambda + \frac{B_1' \mu}{r_0}$$

or in general

$$\lambda' = \lambda + \frac{B_1}{r_0} .$$

Therefore, $B_1'\mu/r_0$ (or B_1/r_0) is the change in the mean angular velocity from the unperturbed case to the perturbed case. Hence the four integration constants for the perturbed case may be taken as A_1, A_2, λ', and B_2 (or A_1', A_2', λ', and B_2' in the first approximation), and λ, or equivalently r_0, acts in the perturbed case as a standard for comparison with the perturbed orbits and is consequently a parameter.

We can set $\lambda' = \lambda$ for the sake of simplicity because both the perturbed and unperturbed periodic orbits form a continuous family. This leaves $B_1' = 0$.

Even with $B_1' = 0$, the general solution does not give the periodic orbits because there are two fundamental periods $2\pi/(\lambda+1)$ and $2\pi/\lambda$, with several harmonics of the latter. However, since the existence of some periodic solutions has been proved (see for example Reference 1), these periodic orbits must correspond to the particular integral obtained from Equations 15 and 16 by setting $A_1' = A_2' = B_1' = 0$. Then the solutions contain only terms with period $2\pi/\lambda$ of the fundamental oscillation, and shorter periods corresponding to its harmonics. Thus the periodic orbits around the $1-\mu$ component may be given, to the first order of μ and the second order of r_0, by

$$r = r_0 + \mu r_1 , \tag{23}$$

$$\theta = \lambda t + \mu \theta_1 , \tag{24}$$

where

$$r_1 = -\frac{r_0}{6(\lambda+1)^2} + k_1 \cos \lambda t + k_2 \cos 2\lambda t + k_3 \cos 3\lambda t , \tag{25}$$

$$r_0 \theta_1 = l_1 \sin \lambda t + l_2 \sin 2\lambda t + l_3 \sin 3\lambda t . \tag{26}$$

It follows from the solution given by Equations 15 and 16 that, in general, a periodic solution can be obtained for any given value of λ only by setting A_1, A_2, B_1, and B_2 equal to zero. Thus, one periodic orbit is associated with one value of the period. However, if λ is a ratio of two integers, periodic orbits may exist for arbitrary (small) values of these constants. If they do, a large number of periodic orbits would be found for some particular values of the period.

THE SECOND ORDER EQUATIONS

When the solutions of r_1 and $r_0\theta_1$ given by Equations 25 and 26 are substituted into the second order equations (13 and 14) and the resulting equations are simplified, we obtain:

$$\frac{d^2 r_2}{dt^2} - 2(\lambda+1) r_0 \frac{d\theta_2}{dt} - 3(\lambda+1)^2 r_2 = \beta_0 + \sum_{n=1} \beta_n \cos n\lambda t , \tag{27}$$

$$r_0 \frac{d^2 \theta_2}{dt^2} + 2(\lambda+1) \frac{dr_2}{dt} = \sum_{n=1} \rho_n \sin n\lambda t . \tag{28}$$

These equations have the same form as Equations 11 and 12, except for more terms on the right-hand side. Therefore, the solution can be derived in the same manner as in the case of the first order equations, although finding the explicit expressions of the solutions is much more tedious because of the lengthy equations that define β_n and ρ_n. The author has evaluated only β_0. From this the average radius of the periodic orbit may be derived:

$$\langle r \rangle = r_0 \left\{ 1 - \frac{\mu}{6(\lambda+1)^2} + \mu^2 \left[\frac{1}{18(\lambda+1)^4} + \frac{3(19\lambda^2+14\lambda+3)}{32\lambda^2(\lambda+1)^2(3\lambda^2-2\lambda-1)} + \frac{9(2\lambda+1)^2}{8\lambda^2(3\lambda^2-2\lambda-1)^2} \right] \right\}, \quad (29)$$

correct to the second order both in μ and r_0.

It follows from Equation 29 that for a given value of λ the average radius of the periodic orbit around the earth in the presence of the moon is slightly less than that given by Equation 10, which is for the case of the absence of the moon. This fact may be easily understood because the overall long-range effect of the moon on a satellite that is revolving around the earth is to reduce the central attractive force of the earth on the satellite. The argument becomes physically apparent if we imagine the moon and its orbit to be replaced by an annular ring of the same mass as the moon, with this mass uniformly distributed. From this reasoning the presence of the sun may be expected to further reduce, by a small amount, the average value of the radius of the satellite's orbit. The prediction has been verified by actual calculations.

The similarity between the present calculation and the perturbation theory in quantum mechanics is apparent. In neither case is the convergence of the series solution proven. But, it will be shown in the following sections that the periodic orbits derived in this way agree perfectly with those obtained by the trial and error method, just as the effectiveness of the perturbation method in quantum mechanics is based on its ability to predict empirical results.

On the other hand, the present perturbation method differs in many ways from that in quantum mechanics. For example, the main purpose of the perturbation theory in quantum mechanics is to find the new eigen value as a result of perturbation, whereas here we are interested in the variation in the orbital nature for a given value of λ.

Although the approach parallels Hill's determination of the variation orbit, differences do exist. In the first place, Hill started with a set of differential equations already approximated by the neglecting of terms involving the ratio of the mean distance of the moon to that of the sun. The present investigation uses the equations in the restricted three-body problem. Secondly, Hill was concerned only in obtaining a particular solution but we are interested in the general solution that involves four aribtrary constants, A_1, A_2, B_1, and B_2, which determine, as shall be seen later, those nearly periodic orbits in the neighborhood of the exact periodic solution. Consequently, the present solution gives an entire family of orbits in the neighborhood of any periodic solution that we can determine. Needless to say, for orbits that depart greatly from the periodic one, the approximation employed in this analysis breaks down. Consequently, those orbits can no longer be represented by the equations derived.

The differences between Hill's analysis and the present one clearly reflect divergent problems faced in different times. Indeed, the present solution of periodic and nearly periodic orbits around a more massive component, expanded in terms of the mass of the less massive component, would have had little practical significance in Hill's time.

NUMERICAL APPLICATIONS

In a previous paper (Reference 6), by a numerical method (Reference 7) a synchronous orbit around the earth was derived, under the idealization of the restricted three-body problem with $\mu = 0.012149$. Now we are able to derive it from Equations 23–26.

In the XY coordinate system with the origin at the mass point $1-\mu$, the initial conditions of

the synchronous orbit, derived by successive approximations, are

$$\left.\begin{aligned} x_0 &= 0.1095908\upsilon\ , \\ y_0 &= 0\ , \\ \dot{x}_0 &= 0\ , \\ \dot{y}_0 &= 2.8927303\ , \end{aligned}\right\} \qquad (30)$$

which yield

$$P=0.23802754 \qquad (31)$$

for the period.

We can now calculate for this case the values of k_n and l_n from Equations 17–22, with

$$\lambda=\frac{2\pi}{P}=26.396884, \qquad (32)$$

which gives $r_0=0.10958800$ from Equation 10.

Table 1

Values of k_n and l_n for $\mu = 0.012149$ and $\lambda = 26.396884$.

n	k_n	l_n
1	4.249394×10^{-4}	8.756117×10^{-4}
2	-1.644862×10^{-4}	2.296898×10^{-4}
3	-6.901187×10^{-6}	8.365787×10^{-6}

The computed values are listed in Table 1. Substituting these values of k_n and l_n in the solution given by Equations 23–26 and transforming variables from r and θ to x and y, in accordance with Equations 4 and 5, shows that the values $x(t)$,$y(t)$,$\dot{x}(t)$, and $\dot{y}(t)$ derived from the present formulas agree to seven significant figures with those obtained from direct integration under the initial conditions given by Equations 30. In particular, at $t=0$ our formulas predict the initial conditions

$$\left.\begin{aligned} x_0 &= 0.10959080\ , \\ y_0 &= 0\ , \\ \dot{x}_0 &= 0\ , \\ \dot{y}_0 &= 2.8927300\ , \end{aligned}\right\} \qquad (33)$$

for the periodic orbit with P given by Equation 31. The agreement between Equations 30 and 33 must be regarded as satisfactory.

As would be expected, the prediction of periodic orbits by Equations 23 and 24 becomes less and less accurate as the period increases. A few cases are given in Table 2 to show the progressive worsening of the prediction. However, it should be noted that even at $P=1.6$, the two sets of calculations—one from the numerical approach and the other from the present formulas—still give results that agree to the fourth significant figure.

ORBITS IN THE NEIGHBORHOODS OF THE PERIODIC ONES

It is obvious that for orbits which are not exactly periodic, the general solution given by

Table 2

Initial Conditions Derived by the Series Solution Compared with those Obtained by the Method of Successive Approximation ($\mu = 0.012149$, $y_0 = \dot{x}_0 = 0$).

1.6000716	0.34385494	1.3522620	0.34384680	1.3524439	4.0638285

Equations 23 and 24 together with Equations 15 and 16 should be applied instead of the particular integral given by Equations 23–26. Let us now consider the behavior of these orbits when we make the initial values of x_0 and $\dot{y}_0$ only slightly different from those corresponding to the periodic orbit, while maintaining $y_0 = x_0 = 0$.

The initial values of r, θ, $\dot{r}$, $\dot{\theta}$ will be denoted by r_i, θ_i, $\dot{r}_i$, $\dot{\theta}_i$. Thus, by setting $t=0$ in Equations 15 and 23

$$r_i = r_0 + \mu\left[-\frac{r_0}{6(\lambda+1)^2} - \frac{2B_1}{3(\lambda+1)} + k_1 + k_2 + k_3 + A_1\right]. \tag{34}$$

By assuming $\theta_i = 0$ as usual

$$B_2 = -2A_2 \tag{35}$$

from Equations 16 and 24. We have assumed $\dot{x}_0 = 0$ which is equivalent to $\dot{r}_i = 0$; hence

$$A_2 = B_2 = 0. \tag{36}$$

Finally, it is easy to obtain

$$\theta_i = \lambda + \frac{\mu}{r_0}\left[l_1\lambda + 2l_2\lambda + 3l_3\lambda - 2A_1(\lambda+1) + B_1\right]. \tag{37}$$

The initial values of r and $\dot{\theta}$ for the true periodic orbit will be denoted by $r_{i,p}$ and $\dot{\theta}_{i,p}$. They are given by

$$r_{i,p} = r_0 + \mu\left[-\frac{r_0}{6(\lambda+1)^2} + k_1 + k_2 + k_3\right]. \tag{38}$$

$$\dot{\theta}_{i,p} = \lambda + \frac{\mu\lambda}{r_0}\left(l_1 + 2l_2 + 3l_3\right). \tag{39}$$

From

$$\Delta r_i = r_i - r_{i,p}. \tag{40}$$

$$\Delta\dot{\theta}_i = \dot{\theta}_i - \dot{\theta}_{i,p}, \tag{41}$$

we derive

$$A_1 = -\frac{\Delta r_i}{\mu} - \frac{2r_0\Delta\dot{\theta}_i}{(\lambda+1)\mu}, \tag{42}$$

$$B_1 = -6(\lambda+1)\frac{\Delta r_i}{\mu} - \frac{3r_0\Delta\dot{\theta}_i}{\mu}. \tag{43}$$

We can now examine the behavior of orbits close to the periodic ones. The explicit expression for θ is, from Equations 16 and 24,

$$\vartheta = \left(\lambda + \frac{\mu}{r_0}B_1\right)t + \frac{\mu}{r_0}\left[\sum_{i=1}^{3} l_i \sin i\lambda t - 2A_1 \sin(\lambda+1)t\right]. \tag{44}$$

Let us define time as $t=t_n$ when $\theta = 2\pi n$, and $t=t_{n-1}$ when $\theta = 2\pi(n-1)$, where n is an integer. Therefore P_n, defined by,

$$P_n = t_n - t_{n-1}. \tag{45}$$

is the period of the n^{th} cycle of a nearly periodic orbit. It follows from Equation 44 that

$$P_n = \frac{2\pi r_0}{\lambda r_0 + \mu B_1} - \frac{\mu}{\lambda r_0 + \mu B_1}\left[\sum_{i=1}^{3} 2l_i \sin\frac{i\lambda P_n}{2}\cos\frac{i\lambda\left(t_n + t_{n-1}\right)}{2} - 4A_1 \sin\frac{(\lambda+1)P_n}{2}\cos\frac{(\lambda+1)\left(t_n + t_{n-1}\right)}{2}\right]. \tag{46}$$

from which we note immediately that the mean period of the nearly periodic orbit is

$$\langle P_n\rangle = \frac{2\pi r_0}{\lambda r_0 + \mu B_1}. \tag{47}$$

So the first term on the right-hand side of Equation 46 is associated with the mean period, but the rest denotes small oscillations of the P_n value around its mean value for various values of n.

Since the amplitudes of various oscillating terms in Equation 46 are small, λP_n may be set equal to 2π in the argument of the sine function. All terms involving l_i vanish as a result of this approximation and Equation 46 can be reduced to:

$$P_n = \langle P_n \rangle + \frac{4\mu A_1}{\lambda r_0 + \mu B_1} \sin\frac{\pi}{\lambda} \cos\left[(\lambda+1)\, t_n - \frac{\pi}{\lambda}\right]. \tag{48}$$

where A_1 and B_1 are given by Equations 42 and 43, respectively, and t_n may be considered to be

$$t_n = n\langle P_n \rangle. \tag{49}$$

Since there is a periodic orbit for each value of λ in the range of interest, we can compare a nearly periodic orbit with any periodic orbit in the former's neighborhood. In our calculation we have fixed a single value of λ for both the periodic and nearly periodic orbit in order to derive A_1 and B_1 from Equations 42 and 43. Obviously a slightly different choice of the value of λ will give different values to these two constants for the same nearly periodic orbit.

As a simple example the two orbits may be compared by starting with the same r_i, i.e., $\Delta r_i = 0$. Then A_1 and B_1 are functions of $\Delta\theta_i$ alone and $\Delta\theta_i$ is related to the difference Δy_0, between the initial value, y_0, of the nearly periodic orbit and that of the exactly periodic orbit. If, furthermore,

$$n \ll \frac{\lambda}{20\Delta\dot{\theta}_i}, \tag{50}$$

Equation 48 reduces to

$$P_n = \frac{2\pi}{\lambda - 3\Delta\dot{\theta}_i} - \frac{8\Delta\dot{\theta}_i}{\lambda(\lambda+1)} \sin\frac{\pi}{\lambda} \cos\frac{(2n-1)\pi}{\lambda}. \tag{51}$$

From Equation 51 values of P_n have been computed up to $n = 28$ for two cases, with λ given by Equation 32. The results are given in the second and fourth columns of Table 3. In both cases $\lambda/\Delta\theta_i$ is of the order of several thousand. Therefore, the use of Equation 51 is justified. For comparison P_n has also been computed by direct integration. This was done by computing successive times, t_n, when the orbit crossed the positive axis. A four point interpolation has been used for obtaining t_n from the integrated tables. In this way, from the initial conditions corresponding respectively to two values of y_0 in Table 3, t_n, and consequently P_n, have been computed and the latter has been tabulated in the third and fifth columns of Table 3. The agreement between the second and third columns as well as that between the fourth and fifth columns may be regarded as satisfactory.

* In computing $\Delta\dot{\theta}_i$ the initial condition given by Equation 33 is considered to correspond to the exact periodic orbit used as the reference for comparison.

SOME REMARKS ON RELATED PROBLEMS

Although the present calculation was performed in order to understand the general effect of the

moon on the motion of the earth's satellites, it will serve equally well in understanding the general behavior of the motion of inner planets and asteroids as a result of the perturbation by the major planets, especially Jupiter. Indeed, the smallness of μ in such cases ($\mu = 9.539 \times 10^{-4}$ for the sun-Jupiter system) will make the result derived with the first order equations a good approximation to the problem. However, because of the relatively large sizes of the orbits of the inner planets, it may be necessary to include in the solution terms involving the third and perhaps higher powers of r_0.

The coefficients k_n and l_n contain in their denominators a factor $(n\lambda)^2-(\lambda+1)^2$ where n is an integer. Thus if

$$n\lambda = \lambda + 1$$

the coefficients k_n and l_n diverge. Therefore, periodic orbits cannot be obtained in this way.

However, the Kirkwood gaps in the asteroid belt concide with positions where asteroids, if present, would have periods commeasurable with the period of Jupiter's orbit. Recently, this problem was investigated theoretically by Brouwer (Reference 8).

The presence of the Kirkwood gaps are obviously due to the perturbation by Jupiter. Since perturbation increases with μ, it follows that stronger gaps would be present in systems of two revolving bodies of increasing values of μ. Hence, we may immediately predict stronger gaps around the earth in the earth-moon system than those around the sun in the asteroid belt in the sun-Jupiter system. Such gaps around the earth can be computed easily from the condition of commeasurability of the moon's period and the period of any satellite in such a zone. Of course, a result of this argument is that these zones should be avoided in launching satellites that are intended to stay in orbit for a long time. Being short, the period of the synchronous orbit is not near any strongly commeasurable gap.

Another interesting consequence of the commeasurable gaps around the earth may be found in the distribution of dust particles in the earth-moon system. It is not now known whether dust particles all move at random or partially revolve around the earth. If the latter should be the case, the presence of zones around the earth void of dust particles like the Kirkwood gaps in the asteroid belt around the sun, would be inevitable. Consequently, their detection may be an interesting subject of investigation in the field of space research.

ACKNOWLEDGMENTS

It is the author's pleasure to express his sincere thanks to Dr. D. Brouwer, Dr. G. Hori, Dr. V. Szebehely, and Dr. T. Y. Wu for their valuable discussions.

ON THE APPLICATION OF PFAFF'S METHOD IN THE THEORY OF VARIATION OF ASTRONOMICAL CONSTANTS*

PETER MUSEN

Cartan's integral invariant is taken as a foundation of the theory of variation of astronomical parameters. The differential equations for the general perturbations are obtained as the first system of Pfaffian equations associated with the linear differential form appearing in the intergral invariant.

The equations for general perturbations of the Gibbsian unit vectors, of the Gibbsian rotation vector and of Euler's parameters are derived. The utilization of the Gibbsian rotation vector represents an extension of Strömgren's and of the author's ideas on special perturbations to the problems of general perturbations. Euler's parameters find their application in Hansen's lunar theory.

The case of redundant elements is treated by introducing constraints and Lagrangian multipliers. Cartan's integral invariant expressed in terms of vectorial kinematic elements represents a powerful tool in the search for new sets of elements and it leads to differential equations having a compact form, which is convenient for the programming and use of electronic machines.

$p = a(1-e^2)$

INTRODUCTION

In treating the problem of general perturbations of planets and satellites it is felt that a general and flexible method is needed which would permit an easy transformation from one system to another and would also facilitate a proper choice of elements under the different circumstances.

The standard way to develop the equations for the general perturbations in elements is based on the computation of the matrix either of Lagrangian or of Poissonian brackets. This computation is relatively simple for the classical elliptic elements, but it can become cumbersome if some algebraic combinations of the classical elements are taken as a new set of elements.

An additional difficulty may arise if, for the sake of the symmetry of the development of the disturbing function, some redundant elements are introduced. As a result, additional constraints appear in the problem. It is necessary to point out, that the presence of these constraints does not necessarily mean that the problem of the determination of the constants of integration will become more complicated. Sometimes the presence of constraints makes this determination easier. Hill's method of general perturbations is a well known example in celestial mechanics where a redundant constant of integration is present.

However, the difficulties associated with the presence of a redundant constant in this particular case should not be generalized to all problems in celestial mechanics. One should not be hesitant to make use of redundant elements if the problem of the determination of constants of integration for all orders of perturbations can be made symmetrical and if the programming can be made more efficient.

In order to have a more general view and to facilitate the search for new types of elements, an application of Pfaff's method is made in this article to the problems of celestial mechanics. This method permits the formation of the equations for the variation of elements in a straightforward manner if these elements are obtained from the classical elements by any type of functional transformation.

Surprisingly, such a direct method has not found wider applications in the theory of variation of astronomical constants. The pioneering work of Bilimovich (Reference 1) stands rather apart from the main stream. Bilimovich succeeded in deducing Milankovich's equations (Reference 2) for the variation of the Laplacian and momentum vectors in a rather simple way. He also deduced the classical equations for the variation of the elliptic elements in a very simple manner.

The existence of Cartan's (Reference 3) integral invariant for dynamical systems is the foundation of the Pfaffian method. Using a hydrodynamical analogy we can say that the theorem of the circulation for an ideal fluid in the phase space is taken as a basis for the theory of perturbations presented herein. The equations for the variation of the elements represent the first system of Pfaffian equations associated with the differential form appearing under the integral sign in the expression for circulation.

In this work we suggest the use of a slightly more general form of Pfaffian equations than in Bilimovich's work by permitting the constraints to be present and by forming the equations with Lagrangian multipliers.

We shall develop the equations for the general perturbations of Gibbsian vectors $\mathbf{P}$ and $\mathbf{Q}$ and also of the elements the author has suggested in his article on Strömgren's (Reference 4) perturbations (Reference 5) and in the articles on Hansen's (Reference 6) lunar theory (References 7 and 16).

In recent times electronic equipment is being used more and more for the purpose of developing general perturbations. We might expect that in the near future the utilization of machines in this domain will become even wider. This fact will have an increasingly greater impact on the theoretical thought and thus the search for different types of new elements is in order now.

PFAFFIAN EQUATIONS OF MOTION WITH REDUNDANT COORDINATES

Let us consider the material system of N points having the position vectors $\mathbf{r}_i$ and the velocity vectors $\mathbf{v}_i$ $(i=1, 2, \cdots, N)$. The Pfaffian linear form associated with this system is

$$\phi = \sum_{i=1}^{N} m_i \mathbf{v}_i \cdot d\mathbf{r}_i - (T - U)\, dt \,. \quad (1)$$

A functional transformation,

$$\mathbf{v}_i = \mathbf{v}_i(\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n; q_1, q_2, \cdots, q_m) \,,$$

$$\mathbf{r}_i = \mathbf{r}_i(\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n; q_1, q_2, \cdots, q_m) \,,$$

with the imposed conditions

$$f_p(\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n; q_1, q_2, \cdots, q_m) = a_p$$

brings Equation 1 to the form

$$\phi \quad \sum_{i=1}^{n} \mathbf{X}_i(\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n; q_1, q_2, \cdots, q_m) \cdot d\mathbf{x}_i$$

$$+ \sum_{j=1}^{m} Q_j(\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n; q_1, q_2, \cdots, q_m) dq_j + F dt \,, \quad (2)$$

where $\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n$ are vectors in k-dimensional Euclidean space and $q_1, q_2, \cdots, q_m$ are scalars.

The condition

$$kn + m - s = 6N$$

must be satisfied. In the process of transformation from Equation 1 to Equation 2 any additive total differential can be neglected

For present purposes we can assume that all constraints are scleronomic. We write the first system of Pfaffian equations, using the notations suggested by Bilimovich, in the form:

$$\sum_{i=1}^{n} (\mathrm{grad}_i \phi - d\mathbf{X}_i) \cdot \delta\mathbf{x}_i + \sum_{j=1}^{m} \left(\frac{\partial \phi}{\partial q_j} - dQ_j\right) \delta q_j + \left(\frac{\partial \phi}{\partial t} - dF\right) \delta t = 0$$

with the additional conditions

$$\sum_{i=1}^{n} \mathrm{grad}_i f_p \cdot \delta\mathbf{x}_i + \sum_{j=1}^{m} \frac{\partial f_p}{\partial q_j} \delta q_j = 0 \quad (i = 1, 2, \cdots, n;\ j = 1, 2, \cdots, m;\ p = 1, 2, \cdots s)$$

imposed on the variations by the constraints. Introducing Lagrangian multipliers, we have

$$\mathrm{grad}_i \phi - d\mathbf{X}_i + \sum_{p=1}^{s} \lambda_p\, dt\, \mathrm{grad}_i f_p = 0 \quad (3)$$

$$\frac{\partial \phi}{\partial q_j} - dQ_j + \sum_{p=1}^{s} \lambda_p\, dt\, \frac{\partial f_p}{\partial q_j} = 0 \,, \quad (4)$$

$$\frac{\partial F}{\partial t} dt - dF = 0 \,. \quad (5)$$

The Lagrangian multipliers $\lambda_p (p=1, 2, \cdots, s)$ can be determined with the help of the equations

$$\sum_{i=1}^{n} \mathrm{grad}_i f_p \cdot d\mathbf{x}_i + \sum_{j=1}^{m} \frac{\partial f_p}{\partial q_j} dq_j = 0, \ (p = 1, 2, \cdots, s). \quad (6)$$

The existence of a Cartan integral invariant on the hypersurface

$$f_p = a_p \quad (p = 1, 2, \cdots, s)$$

defined in (kn+m) -dimensional space serves as a basis for deducing the Pfaffian equations.

Sometimes, for the sake of the symmetry, it might be advantageous to increase beyond six the number of the osculating elements. This is done, for example, by Milankovich (Reference 2), by Herrick (Reference 8) and by the author (Reference 9). Then the relations containing the redundant elements can be understood as the scleronomic constraints and Equations 3–6 can be applied.

PFAFFIAN EXPRESSION FOR PLANETARY MOTION

In this article we deduce Bilimovich's expression for ϕ for disturbed planetary motion using the Eckert-Brouwer (Reference 10) expression for the variation of the position vector of a planet.

Originally the Eckert-Brouwer formula was designed for the purpose of orbit correction. However, experience has shown that this elegant formula can also be used in the vectorial theory of general perturbations as in the present article and in the article published recently by Musen and Carpenter (Reference 11).

We also suggest herein some new sets of elements, canonical and uncanonical, which follow directly from the form of ϕ.

The differential form (Equation 1) in the case of disturbed planetary motion is

$$\phi = v \cdot dr - \left(\frac{v^2}{2} - \frac{\mu}{r} - \Omega\right) dt \ .$$

Making use of the expression for dr as obtained by Eckert and Brouwer,

$$dr = d\psi \times r + \frac{v}{n} dl + \frac{r}{a} da + \left(\frac{r + p - 2a}{ep} r + \frac{r + p}{ep} \cdot \frac{r \cdot v}{a^2 n^2} v\right) de \ ,$$

we deduce

$$v \cdot dr = r \times v \cdot d\psi + \frac{v^2}{n} dl + r \cdot v \frac{da}{a} + \frac{r \cdot v}{ep}\left[(r + p)\left(1 + \frac{v^2}{a^2 n^2}\right) - 2a\right] de \ . \qquad (7)$$

Substituting

$$\begin{aligned} r \cdot v &= \sqrt{\mu a}\, e \sin u \ , \\ r \times v &= R\sqrt{\mu a\left(1 - e^2\right)} \ , \end{aligned} \qquad (8)$$

$$\begin{aligned} v^2 &= \mu\left(\frac{2}{r} - \frac{1}{a}\right) \ , \\ n &= \frac{\sqrt{\mu}}{a^{3/2}} \ , \end{aligned} \qquad (9)$$

into Equation 7 we obtain

$$v \cdot dr = \frac{\mu}{n}\left(\frac{2}{r} - \frac{1}{a}\right) dl + \left(\sqrt{\frac{\mu}{a}}\, e\, da + \sqrt{\mu a}\, 2\frac{a}{r} de\right) \sin u + \sqrt{\mu a\left(1 - e^2\right)}\, R \cdot d\Psi \ . \qquad (10)$$

Differentiating Equation 8 and taking

$$\frac{r}{a} = 1 - e \cos u$$

into account, we have

$$2d(r \cdot v) = \left(e\sqrt{\frac{\mu}{a}} da + 2\sqrt{\mu a}\, de\right) \sin u + 2\sqrt{\mu a}\left(1 - \frac{r}{a}\right) du \ . \qquad (11)$$

Differentiating Kepler's equation we have

$$du = \frac{a}{r} \sin u \, de + \frac{a}{r} \, dl \ . \tag{12}$$

Eliminating du from Equation 11 by means of Equation 12 we obtain

$$2d(r \cdot v) = \left(e \sqrt{\frac{\mu}{a}} \, da + 2 \sqrt{\mu a} \, \frac{a}{r} \, de \right) \sin u + 2 \sqrt{\mu a} \left(\frac{a}{r} - 1 \right) dl$$

Taking Equation 9 into account we deduce

$$2d(r \cdot v) = \left(\frac{v^2}{n} - \sqrt{\mu a} \right) dl + \left(e \sqrt{\frac{\mu}{a}} \, da + 2 \frac{a}{r} \sqrt{\mu a} \, de \right) \sin u \ .$$

Comparing the last equation with Equation 10 we conclude that

$$v \cdot dr = \sqrt{\mu a} \, dl + \sqrt{\mu a (1 - e^2)} \, R \cdot d\psi + 2d(r \cdot v) \ . \tag{13}$$

Decomposing the infinitesimal rotation $d\Psi$ along the axes **P**, **Q**, and **R** we have

$$d\psi = dP \cdot QR + dQ \cdot RP + dR \cdot PQ$$

and Equation 13 becomes

$$v \cdot dr = \sqrt{\mu a} \, dl + \sqrt{\mu a (1 - e^2)} \, Q \cdot dP + 2d(r \cdot v) \ . \tag{14}$$

Neglecting the total differential 2d (**r**·**v**) we have

$$\phi = \sqrt{\mu a} \, dl + \sqrt{\mu a (1 - e^2)} \, Q \cdot dP + F \, dt \tag{15}$$

with $F = \mu/2a + \Omega$. Equation 15 was deduced by Bilimovich on the basis of a different consideration.

EQUATIONS FOR VARIATION OF VECTORIAL ELEMENTS

Milankovich has deduced the vectorial equations for the determination of general perturbations of vectors **c** and **e**.

The vectors **P** and **Q** constitute a better choice for the development of the disturbing function and the computation of the position and velocity vectors.

The elements we choose are

$$l, \ a, \ e, \ P \text{ and } Q$$

For reasons of symmetry we take the expression for ϕ in the form

$$\phi = \sqrt{\mu a} \, dl + \frac{1}{2} \sqrt{\mu a (1 - e^2)} \, (Q \cdot dP - P \cdot dQ) + r \, dt$$

with the three additional conditions

$$P \cdot P = 1, \quad Q \cdot Q = 1, \quad P \cdot Q = 0 \ . \tag{16}$$

The Pfaffian equations (Equations 3–6) for the variation of constants in this particular case become:

$$\text{grad}_P \, \phi - d \left[\frac{1}{2} \sqrt{\mu a (1 - e^2)} \, Q \right] + (uP + wQ) \, dt = 0 \ , \tag{17}$$

$$\mathrm{grad}_{\mathbf{Q}}\,\phi + d\left[\frac{1}{2}\ \sqrt{\mu a\left(1-e^2\right)}\ \mathbf{P}\right] + (v\mathbf{Q} + w\mathbf{P})\,dt = 0\,, \tag{18}$$

$$\frac{\partial \phi}{\partial a} = 0\,, \tag{19}$$

$$\frac{\partial \phi}{\partial e} = 0\,, \tag{20}$$

$$\frac{\partial \phi}{\partial l} - d\sqrt{\mu a} = 0\,, \tag{21}$$

where u, v and w here are the Lagrangian multipliers associated with the constraints (Equation 16).

After some easy transformations we deduce from Equations 17–21:

$$na^2\sqrt{1-e^2}\,\frac{d\mathbf{P}}{dt} + (A + w)\,\mathbf{P} + v\mathbf{Q} + \mathrm{grad}_{\mathbf{Q}}\,F = 0\,, \tag{22}$$

$$na^2\sqrt{1-e^2}\,\frac{d\mathbf{Q}}{dt} + (A - w)\,\mathbf{Q} - u\mathbf{P} - \mathrm{grad}_{\mathbf{P}}\,F = 0\,, \tag{23}$$

$$\frac{1}{2}\,na\,\frac{dl}{dt} + \frac{1}{2}\,na\,\sqrt{1-e^2}\,\mathbf{Q}\cdot\frac{d\mathbf{P}}{dt} + \frac{\partial F}{\partial a} = 0\,, \tag{24}$$

$$\mathbf{Q}\cdot\frac{d\mathbf{P}}{dt} = -\,\mathbf{P}\cdot\frac{d\mathbf{Q}}{dt} = +\,\frac{\sqrt{1-e^2}}{na^2\,e}\,\frac{\partial F}{\partial e}\,, \tag{25}$$

$$\frac{\partial F}{\partial l} - \frac{1}{2}\,na\,\frac{da}{dt} = 0\,, \tag{26}$$

where

$$A = \frac{1}{4}\left(na\sqrt{1-e^2}\,\frac{da}{dt} - \frac{2na^2\,e}{\sqrt{1-e^2}}\,\frac{de}{dt}\right). \tag{27}$$

By multiplying Equation 22 by $\mathbf{P}$ and Equation 23 by $\mathbf{Q}$ we deduce:

$$A + w = -\mathbf{P}\cdot\mathrm{grad}_{\mathbf{Q}}\,F\,,$$

$$A - w = +\mathbf{Q}\cdot\mathrm{grad}_{\mathbf{P}}\,F\,,$$

$$A = +\frac{1}{2}\,\mathbf{Q}\cdot\mathrm{grad}_{\mathbf{P}}\,F - \frac{1}{2}\,\mathbf{P}\cdot\mathrm{grad}_{\mathbf{Q}}\,F\,, \tag{28}$$

$$w = -\frac{1}{2}\,\mathbf{Q}\cdot\mathrm{grad}_{\mathbf{P}}\,F - \frac{1}{2}\,\mathbf{P}\cdot\mathrm{grad}_{\mathbf{Q}}\,F\,. \tag{29}$$

Multiplying Equation 22 by $\mathbf{Q}$ and Equation 23 by $\mathbf{P}$ and taking Equation 25 into account, we have

$$v = -\mathbf{Q}\cdot\mathrm{grad}_{\mathbf{Q}}\,F - \frac{1-e^2}{e}\,\frac{\partial F}{\partial e}\,, \tag{30}$$

$$u = -\mathbf{P}\cdot\mathrm{grad}_{\mathbf{P}}\,F - \frac{1-e^2}{e}\,\frac{\partial F}{\partial e}\,. \tag{31}$$

Substituting Equations 29–31 into Equations 22 and 23 and taking the identity

$$\mathbf{I} = \mathbf{PP} + \mathbf{QQ} + \mathbf{RR}$$

into account, we obtain

$$\frac{d\mathbf{P}}{dt} = -\frac{1}{na^2\sqrt{1-e^2}}\,\mathbf{RR}\cdot\operatorname{grad}_{\mathbf{Q}} F + \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial e}\,\mathbf{Q}\,, \tag{32}$$

$$\frac{d\mathbf{Q}}{dt} = +\frac{1}{na^2\sqrt{1-e^2}}\,\mathbf{RR}\cdot\operatorname{grad}_{\mathbf{P}} F - \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial e}\,\mathbf{P}\,. \tag{33}$$

These two last equations are new. Equations 24 and 26 can be written in the classical form:

$$\frac{da}{dt} = \frac{2}{na}\frac{\partial F}{\partial l}\,, \tag{34}$$

$$\frac{dl}{dt} = -\frac{1-e^2}{na^2 e}\frac{\partial F}{\partial e} - \frac{2}{na}\frac{\partial F}{\partial a}\,. \tag{35}$$

From Equations 27, 28, and 34 we deduce

$$\frac{de}{dt} = +\frac{1-e^2}{na^2 e}\frac{\partial F}{\partial l} + \frac{\sqrt{1-e^2}}{na^2 e}\left(\mathbf{P}\cdot\operatorname{grad}_{\mathbf{Q}} F - \mathbf{Q}\cdot\operatorname{grad}_{\mathbf{P}} F\right). \tag{36}$$

The system Equations 32–36 forms a complete set to be used in the development of perturbations.

From Equations 32 and 33 we see that the constraints (Equation 16) are satisfied. Because of the existence of these constraints the determination of the additive constants of integration associated with Equations 32 and 33 becomes extremely simple. This simplicity justifies in part the choice of $\mathbf{P}$ and $\mathbf{Q}$ as the basic elements. Changing the notation, we shall designate any disturbed element E as a series

$$E + E_1 + E_2 + E_3 + \cdots\,,$$

where E now means the undisturbed value and E_k are the perturbations of k-th order. We deduce from Equation 16:

$$\begin{aligned}
&\mathbf{P}\cdot\mathbf{P}_1 = 0\,,\\
&\mathbf{P}\cdot\mathbf{P}_2 + \tfrac{1}{2}\mathbf{P}_1^2 = 0\,, \qquad (37)\\
&\mathbf{P}\cdot\mathbf{P}_3 + \mathbf{P}_1\cdot\mathbf{P}_2 = 0\,,\\
&\qquad\cdots\cdots\cdots\cdots\cdots
\end{aligned}$$

$$\begin{aligned}
&\mathbf{Q}\cdot\mathbf{Q}_1 = 0\,,\\
&\mathbf{Q}\cdot\mathbf{Q}_2 + \tfrac{1}{2}\mathbf{Q}_1^2 = 0\,, \qquad (38)\\
&\mathbf{Q}\cdot\mathbf{Q}_3 + \mathbf{Q}_1\cdot\mathbf{Q}_2 = 0\,,\\
&\qquad\cdots\cdots\cdots\cdots\cdots
\end{aligned}$$

$$\begin{aligned}
&\mathbf{Q}\cdot\mathbf{P}_1 + \mathbf{P}\cdot\mathbf{Q}_1 = 0\,,\\
&\mathbf{Q}\cdot\mathbf{P}_2 + \mathbf{P}\cdot\mathbf{Q}_2 + \mathbf{P}_1\cdot\mathbf{Q}_1 = 0\,, \qquad (39)\\
&\mathbf{Q}\cdot\mathbf{P}_3 + \mathbf{P}\cdot\mathbf{Q}_3 + \mathbf{P}_1\cdot\mathbf{Q}_2 + \mathbf{P}_2\cdot\mathbf{Q}_1 = 0\,.\\
&\qquad\cdots\cdots\cdots\cdots\cdots
\end{aligned}$$

For $\mathbf{P}_k$, $\mathbf{Q}_k$ ($k=1, 2, \cdots$) we obtain from Equations 32 and 33 equations of the form:

$$\frac{d\mathbf{P}_k}{dt} = f_k\left(\mathbf{P}, \mathbf{Q}, a, l, e; \mathbf{P}_1, \mathbf{Q}_1, a_1, l_1, e_1; \cdots; \mathbf{P}_{k-1}, \mathbf{Q}_{k-1}, a_{k-1}, l_{k-1}, e_{k-1}\right),$$

$$\frac{d\mathbf{Q}_k}{dt} = \phi_k\left(\mathbf{P}, \mathbf{Q}, a, l, e; \mathbf{P}_1, \mathbf{Q}_1, a_1, l_1, e_1; \cdots; \mathbf{P}_{k-1}, \mathbf{Q}_{k-1}, a_{k-1}, l_{k-1}, e_{k-1}\right).$$

Let

$$(\mathbf{P}_k) = \int \mathbf{f}_k \, dt \, ,$$

$$(\mathbf{Q}_k) = \int \boldsymbol{\phi}_k \, dt \, ,$$

where the integration is performed in a formal manner. We can write

$$\mathbf{P}_k = (\mathbf{P}_k) + p_{k1}\,\mathbf{P} + p_{k2}\,\mathbf{Q} + p_{k3}\,\mathbf{R} \, ,$$

$$\mathbf{Q}_k = (\mathbf{Q}_k) + q_{k1}\,\mathbf{P} + q_{k2}\,\mathbf{Q} + q_{k3}\,\mathbf{R} \, ,$$

where p_{k1}, q_{k1} are the constants of integration. The expressions $(\mathbf{P}_k)$, $(\mathbf{Q}_k)$ contain the secular, the mixed and the purely periodic terms, but there are no constant terms.

Let [f] designate the constant part in the multiple Fourier series of some function $f(l, l', l'', \cdots)$. Taking into account

$$[(\mathbf{P}_k)] = [(\mathbf{Q}_k)] = 0 \, ,$$

we deduce from Equations 37–39:

$$\begin{aligned} p_{11} &= 0 \, , \\ p_{21} &= -\tfrac{1}{2}[\mathbf{P}_1^2] \, , \\ p_{31} &= -[\mathbf{P}_1 \cdot \mathbf{P}_2] \, , \\ &\cdots\cdots\cdots\cdots \end{aligned} \tag{40}$$

$$\begin{aligned} q_{12} &= 0 \, , \\ q_{22} &= -\tfrac{1}{2}[\mathbf{Q}_1^2] \, , \\ q_{32} &= -[\mathbf{Q}_1 \cdot \mathbf{Q}_2] \, , \\ &\cdots\cdots\cdots\cdots \end{aligned} \tag{41}$$

$$\begin{aligned} q_{11} &= -p_{12} \\ q_{21} &= -p_{22} - [\mathbf{P}_1 \cdot \mathbf{Q}_1] \, , \\ q_{31} &= -p_{32} - [\mathbf{P}_1 \cdot \mathbf{Q}_2] - [\mathbf{P}_2 \cdot \mathbf{Q}_1] \, . \\ &\cdots\cdots\cdots\cdots \end{aligned} \tag{42}$$

We see from Equations 40–42 that in the process of the determination of the perturbations of k-th order in $\mathbf{P}$ and $\mathbf{Q}$ the three constants p_{k2}, p_{k3}, q_{k3} can be considered as independent. The constants q_{k1} are determined in terms of p_{k2} and of the constants of the lower orders. The constants p_{k1} and q_{k2} are also functions of the constants of the lower orders. Although there are redundant elements there are no redundant constants which cannot be determined easily. For the disturbed position vector $\mathbf{r}$ we have the standard expression

$$r = Pa(\cos u - e) + Qa\sqrt{1 - e^2}\sin u \, ,$$

$$u - e\sin u = l \, ,$$

where all symbols now designate the disturbed elements.

In order to verify the correctness of Equations 32, 33, and 36 we shall deduce them from the corresponding classical equations. From

$$\mathbf{P} = \begin{Bmatrix} +\cos\omega\cos\Omega - \sin\omega\sin\Omega\cos i \\ +\cos\omega\sin\Omega + \sin\omega\cos\Omega\cos i \\ +\sin\omega\sin i \end{Bmatrix} ,$$

$$\mathbf{Q} = \begin{Bmatrix} -\sin\omega\cos\Omega - \cos\omega\sin\Omega\cos i \\ -\sin\omega\sin\Omega + \cos\omega\cos\Omega\cos i \\ +\cos\omega\sin i \end{Bmatrix} ,$$

$$\mathbf{R} = \begin{Bmatrix} +\sin\Omega\sin i \\ -\cos\Omega\sin i \\ +\cos i \end{Bmatrix} ,$$

we have

$$\frac{dP}{dt} = Q\frac{d\omega}{dt} + R\sin\omega\frac{di}{dt} + k \times P\frac{d\Omega}{dt} , \quad (43)$$

$$\frac{dQ}{dt} = -P\frac{d\omega}{dt} + R\cos\omega\frac{di}{dt} + k \times Q\frac{d\Omega}{dt} , \quad (44)$$

and as a consequence of the two last equations:

$$\sin i\frac{d\Omega}{dt} = R \cdot \left(-\frac{dP}{dt}\cos\omega + \frac{dQ}{dt}\sin\omega\right) , \quad (45)$$

$$\frac{di}{dt} = R \cdot \left(+\frac{dP}{dt}\sin\omega + \frac{dQ}{dt}\cos\omega\right) , \quad (46)$$

$$\frac{d\omega}{dt} + \cos i\frac{d\Omega}{dt} = Q \cdot \frac{dP}{dt} = -P \cdot \frac{dQ}{dt} . \quad (47)$$

From

$$\frac{\partial F}{\partial E} = \frac{\partial P}{\partial E} \cdot \mathrm{grad}_P F + \frac{\partial Q}{\partial E} \cdot \mathrm{grad}_Q F ,$$

where

$$E = \omega, \Omega, i ,$$

and Equations 43 and 44, we deduce

$$\frac{\partial F}{\partial \omega} = Q \cdot \mathrm{grad}_P F - P \cdot \mathrm{grad}_Q F , \quad (48)$$

$$\frac{\partial F}{\partial i} = \sin\omega\left(R \cdot \mathrm{grad}_P F\right) + \cos\omega\left(R \cdot \mathrm{grad}_Q F\right) , \quad (49)$$

$$\frac{\partial F}{\partial \Omega} = k \times P \cdot \mathrm{grad}_P F + k \times Q \cdot \mathrm{grad}_Q F . \quad (50)$$

Substituting

$$k = (P\sin\omega + Q\cos\omega)\sin i + R\cos i$$

into Equation 50, we obtain

$$-\sin\omega\left(R \cdot \mathrm{grad}_Q F\right) + \cos\omega\left(R \cdot \mathrm{grad}_P F\right) = -\frac{1}{\sin i}\frac{\partial F}{\partial \Omega} + \mathrm{ctg}\, i\frac{\partial F}{\partial \omega} .$$

From Equations 36, 45–47 and Equations 32, 33, 48–50 we obtain the classical equations:

$$\frac{d\Omega}{dt} = \frac{1}{na^2\sqrt{1-e^2}\sin i}\frac{\partial F}{\partial i} ,$$

$$\frac{di}{dt} = -\frac{1}{na^2\sqrt{1-e^2}\sin i}\frac{\partial F}{\partial \Omega} + \frac{\cos i}{na^2\sqrt{1-e^2}\sin i}\frac{\partial F}{\partial \omega} ,$$

$$\frac{d\omega}{dt} = +\frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial e} - \cos i\frac{d\Omega}{dt} ,$$

$$\frac{de}{dt} = +\frac{1-e^2}{na^2 e}\frac{\partial F}{\partial l} - \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial \omega} .$$

Let the matrix of direction-cosines between (**P**, **Q**, **R**) and (**P′**, **Q′**, **R′**) be:

$$\mathbf{P}\cdot\mathbf{P}' = \alpha_1 , \quad \mathbf{P}\cdot\mathbf{Q}' = \alpha_2 , \quad \mathbf{P}\cdot\mathbf{R}' = \alpha_3 ,$$

$$\mathbf{Q}\cdot\mathbf{P}' = \beta_1 , \quad \mathbf{Q}\cdot\mathbf{Q}' = \beta_2 , \quad \mathbf{Q}\cdot\mathbf{R}' = \beta_3 ,$$

$$\mathbf{R}\cdot\mathbf{P}' = \gamma_1 , \quad \mathbf{R}\cdot\mathbf{Q}' = \gamma_2 , \quad \mathbf{R}\cdot\mathbf{R}' = \gamma_3 .$$

The disturbing function depends upon α_1, α_2, β_1 and β_2. Taking into account

$$\mathrm{grad}_{\mathbf{P}}\,\alpha_1 = \mathrm{grad}_{\mathbf{Q}}\,\beta_1 = \mathbf{P}' ,$$

$$\mathrm{grad}_{\mathbf{Q}}\,\beta_2 = \mathrm{grad}_{\mathbf{P}}\,\alpha_2 = \mathbf{Q}' ,$$

$$\mathrm{grad}_{\mathbf{Q}}\,\alpha_1 = \mathrm{grad}_{\mathbf{Q}}\,\alpha_2 = \mathrm{grad}_{\mathbf{P}}\,\beta_1 = \mathrm{grad}_{\mathbf{P}}\,\beta_2 = 0 ,$$

we obtain:

$$\mathrm{grad}_{\mathbf{P}}\,F = \frac{\partial F}{\partial \alpha_1}\,\mathbf{P}' + \frac{\partial F}{\partial \alpha_2}\,\mathbf{Q}' , \qquad (51)$$

$$\mathrm{grad}_{\mathbf{Q}}\,F = \frac{\partial F}{\partial \beta_1}\,\mathbf{P}' + \frac{\partial F}{\partial \beta_2}\,\mathbf{Q}' , \qquad (52)$$

$$\mathbf{R}\cdot\mathrm{grad}_{\mathbf{P}}\,F = \frac{\partial F}{\partial \alpha_1}\,\gamma_1 + \frac{\partial F}{\partial \alpha_2}\,\gamma_2 ,$$

$$\mathbf{R}\cdot\mathrm{grad}_{\mathbf{Q}}\,F = \frac{\partial F}{\partial \beta_1}\,\gamma_1 + \frac{\partial F}{\partial \beta_2}\,\gamma_2 ;$$

and the Equations 32 and 33 become

$$\frac{d\mathbf{P}}{dt} = -\frac{1}{na^2\sqrt{1-e^2}}\left(\frac{\partial F}{\partial \beta_1}\,\gamma_1 + \frac{\partial F}{\partial \beta_2}\,\gamma_2\right)\mathbf{R} + \frac{\sqrt{1-e^2}}{na^2\,e}\,\frac{\partial F}{\partial e}\,\mathbf{Q} ,$$

$$\frac{d\mathbf{Q}}{dt} = +\frac{1}{na^2\sqrt{1-e^2}}\left(\frac{\partial F}{\partial \alpha_1}\,\gamma_1 + \frac{\partial F}{\partial \alpha_2}\,\gamma_2\right)\mathbf{R} - \frac{\sqrt{1-e^2}}{na^2\,e}\,\frac{\partial F}{\partial e}\,\mathbf{P} .$$

If the frame (**P′**, **Q′**, **R′**) is a basic reference frame, then the last two equations become:

$$\frac{d\mathbf{P}}{dt} = -\frac{1}{na^2\sqrt{1-e^2}}\left(\frac{\partial F}{\partial \beta_1}\,\gamma_1 + \frac{\partial F}{\partial \beta_2}\,\gamma_2\right)\mathbf{R} + \frac{\sqrt{1-e^2}}{na^2\,e}\,\frac{\partial F}{\partial e}\,\mathbf{Q} + \mathbf{P}\times\boldsymbol{\psi}' , \qquad (53)$$

$$\frac{d\mathbf{Q}}{dt} = +\frac{1}{na^2\sqrt{1-e^2}}\left(\frac{\partial F}{\partial \alpha_1}\,\gamma_1 + \frac{\partial F}{\partial \alpha_2}\,\gamma_2\right)\mathbf{R} - \frac{\sqrt{1-e^2}}{na^2\,e}\,\frac{\partial F}{\partial e}\,\mathbf{P} + \mathbf{Q}\times\boldsymbol{\psi}' , \qquad (54)$$

where

$$\boldsymbol{\psi}' = \psi_1'\,\mathbf{P}' + \psi_2'\,\mathbf{Q}' + \psi_3'\,\mathbf{R}'$$

is the absolute angular velocity of rotation of the frame (**P′**, **Q′**, **R′**), and

$$\psi_1' = +\sin\omega'\sin i'\,\frac{d\Omega'}{dt} + \cos\omega'\,\frac{di'}{dt} ,$$

$$\psi_2' = +\cos\omega'\sin i'\,\frac{d\Omega'}{dt} - \sin\omega'\,\frac{di'}{dt} ,$$

$$\psi_3' = \cos i'\,\frac{d\Omega'}{dt} + \frac{d\omega'}{dt} .$$

From Equations 53 and 54 we deduce the following system of scalar equations for the variation of

the direction-cosines:

$$\frac{d\alpha_1}{dt} = -\frac{1}{na^2\sqrt{1-e^2}}\gamma_1\left(\frac{\partial F}{\partial \beta_1}\gamma_1 + \frac{\partial F}{\partial \beta_2}\gamma_2\right) + \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial e}\beta_1 + (\alpha_2\psi_3' - \alpha_3\psi_2') ,$$

$$\frac{d\alpha_2}{dt} = -\frac{1}{na^2\sqrt{1-e^2}}\gamma_2\left(\frac{\partial F}{\partial \beta_1}\gamma_1 + \frac{\partial F}{\partial \beta_2}\gamma_2\right) + \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial e}\beta_2 + (\alpha_3\psi_1' - \alpha_1\psi_3') ,$$

$$\frac{d\alpha_3}{dt} = -\frac{1}{na^2\sqrt{1-e^2}}\gamma_3\left(\frac{\partial F}{\partial \beta_1}\gamma_1 + \frac{\partial F}{\partial \beta_2}\gamma_2\right) + \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial e}\beta_3 + (\alpha_1\psi_2' - \alpha_2\psi_1') ,$$

and

$$\frac{d\beta_1}{dt} = +\frac{1}{na^2\sqrt{1-e^2}}\gamma_1\left(\frac{\partial F}{\partial \alpha_1}\gamma_1 + \frac{\partial F}{\partial \alpha_2}\gamma_2\right) - \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial e}\alpha_1 + (\beta_2\psi_3' - \beta_3\psi_2') ,$$

$$\frac{d\beta_2}{dt} = +\frac{1}{na^2\sqrt{1-e^2}}\gamma_2\left(\frac{\partial F}{\partial \alpha_1}\gamma_1 + \frac{\partial F}{\partial \alpha_2}\gamma_2\right) - \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial e}\alpha_2 + (\beta_3\psi_1' - \beta_1\psi_3') ,$$

$$\frac{d\beta_3}{dt} = +\frac{1}{na^2\sqrt{1-e^2}}\gamma_3\left(\frac{\partial F}{\partial \alpha_1}\gamma_1 + \frac{\partial F}{\partial \alpha_2}\gamma_2\right) - \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial F}{\partial e}\alpha_3 + (\beta_1\psi_2' - \beta_2\psi_1') .$$

Substituting Equations 51 and 52 into Equation 36 we obtain

$$\frac{de}{dt} = +\frac{1-e^2}{na^2 e}\frac{\partial F}{\partial l} + \frac{\sqrt{1-e^2}}{na^2 e}\left(\alpha_1\frac{\partial F}{\partial \beta_1} - \beta_1\frac{\partial F}{\partial \alpha_1} + \alpha_2\frac{\partial F}{\partial \beta_2} - \beta_2\frac{\partial F}{\partial \alpha_2}\right) .$$

Equations 32, 33, and 36 can be applied to the determination of the lunar and solar long period effects in the motion of close satellites. In the case of close satellites the short period terms, depending upon the mean anomaly of the satellite, can be neglected and the remaining portion $[\Omega]$ of the disturbing function can be developed (References 12 and 13) into the series of polynomials in e and in

$$\alpha = \alpha_1 \cos f' + \alpha_2 \sin f' ,$$

$$\beta = \beta_1 \cos f' + \beta_2 \sin f' ,$$

$$\gamma = \gamma_1 \cos f' + \gamma_2 \sin f' .$$

Taking into account

$$\mathrm{grad}_P\,\alpha = \mathrm{grad}_Q\,\beta = 1 ,$$

$$\mathrm{grad}_Q\,\alpha = \mathrm{grad}_P\,\beta = 0 ,$$

we obtain from Equations 32, 33 and 36

$$\frac{dP}{dt} = -\frac{\gamma R}{na^2\sqrt{1-e^2}}\frac{\partial[\Omega]}{\partial \beta} + \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial[\Omega]}{\partial e}Q ,$$

$$\frac{dQ}{dt} = +\frac{\gamma R}{na^2\sqrt{1-e^2}}\frac{\partial[\Omega]}{\partial \alpha} - \frac{\sqrt{1-e^2}}{na^2 e}\frac{\partial[\Omega]}{\partial e}P ,$$

and

$$\frac{de}{dt} = + \frac{\sqrt{1 - e^2}}{na^2 e} \left(a \frac{\partial [\Omega]}{\partial \beta} - \beta \frac{\partial [\Omega]}{\partial i} \right) .$$

A very elegant and convenient development of the disturbing function for close satellites was given by Kaula (Reference 14). The use of the Gibbsian rotation vector $\mathbf{g}$ (Reference 15) was suggested in an article (Reference 5) on the improvement of Strömgren's theory (Reference 4).

The basic vectors $\mathbf{P}$ and $\mathbf{Q}$ can be represented as relatively simple functions of $\mathbf{g}$ and the introduction of $\mathbf{g}$ removes the necessity of keeping constraints (Equation 16) as the additional conditions. The components of $\mathbf{g}$ in the inertial system are

$$g_1 = + \frac{\cos \frac{1}{2} (\omega - \Omega)}{\cos \frac{1}{2} (\omega + \Omega)} \operatorname{tg} \frac{i}{2} ,$$

$$g_2 = - \frac{\sin \frac{1}{2} (\omega - \Omega)}{\cos \frac{1}{2} (\omega + \Omega)} \operatorname{tg} \frac{i}{2} ,$$

$$g_3 = + \operatorname{tg} \frac{1}{2} (\omega + \Omega) .$$

Equation 47 shows that the Pfaffian (Equation 15) can be written as

$$\phi = \sqrt{\mu a}\, dl + \sqrt{\mu a (1 - e^2)}\, (d\omega + \cos i\, d\Omega) + F\, dt . \qquad (55)$$

This form was originally used by Bilimovich. Taking

$$\omega - \Omega = - 2 \arctan \frac{g_2}{g_1} ,$$

$$\omega + \Omega = 2 \arctan g_3 ,$$

and

$$\tan^2 \frac{i}{2} = \frac{g_1^2 + g_2^2}{1 + g_3^2}$$

into account, we deduce from Equation 55

$$\phi = \sqrt{\mu a}\, dl + \frac{2 \sqrt{\mu a (1 - e^2)}}{1 + g^2} s \cdot dg + F\, dt , \qquad (56)$$

where we put

$$s = k + g \times k . \qquad (57)$$

The Pfaffian equation corresponding to $\mathbf{g}$ is

$$\operatorname{grad}_g \left\{ \frac{2 \sqrt{\mu a (1 - e^2)}}{1 + g^2} s \cdot dg \right\} - d \left\{ \frac{2 \sqrt{\mu a (1 - e^2)}}{1 + g^2} s \right\} + \operatorname{grad}_g F\, dt = 0$$

or, after the differentiation is performed,

$$\frac{4na^2 \sqrt{1 - e^2}}{1 + g^2} \left(k \times \frac{dg}{dt} + \frac{sg \cdot \frac{dg}{dt} - gs \cdot \frac{dg}{dt}}{1 + g^2} \right)$$

$$- \left(na \sqrt{1 - e^2} \frac{da}{dt} - \frac{2na^2 e}{\sqrt{1 - e^2}} \frac{de}{dt} \right) \frac{s}{1 + g^2} + \operatorname{grad}_g F = 0 . \qquad (58)$$

Taking into account

$$\mathbf{s}\mathbf{g} \cdot \frac{d\mathbf{g}}{dt} - \mathbf{g}\mathbf{s} \cdot \frac{d\mathbf{g}}{dt} = (\mathbf{g} \times \mathbf{s}) \times \frac{d\mathbf{g}}{dt} ,$$

we can write Equation 58 in the form

$$\frac{4na^2\sqrt{1-e^2}}{1+g^2}\,\mathbf{h} \times \frac{d\mathbf{g}}{dt} - \left(na\sqrt{1-e^2}\,\frac{da}{dt} - \frac{2na^2 e}{\sqrt{1-e^2}}\,\frac{de}{dt}\right)\frac{\mathbf{s}}{1+g^2} + \operatorname{grad}_{\mathbf{g}} F = 0 , \quad (59)$$

where

$$\mathbf{h} = \mathbf{k} + \frac{\mathbf{g} \times \mathbf{s}}{1+g^2} = \frac{\mathbf{k} + \mathbf{g} \times \mathbf{k} + \mathbf{g}\mathbf{g} \cdot \mathbf{k}}{1+g^2} . \quad (60)$$

We have from Equation 59:

$$\frac{4na^2\sqrt{1-e^2}}{1+g^2}\,\mathbf{s} \times \left(\mathbf{h} \times \frac{d\mathbf{g}}{dt}\right) + \mathbf{s} \times \operatorname{grad}_{\mathbf{g}} F = 0 ,$$

or, after developing the triple product,

$$\mathbf{h} \cdot \mathbf{s}\,\frac{d\mathbf{g}}{dt} = \mathbf{h}\mathbf{s} \cdot \frac{d\mathbf{g}}{dt} + \frac{1+g^2}{4na^2\sqrt{1-e^2}}\,\mathbf{s} \times \operatorname{grad}_{\mathbf{g}} F . \quad (61)$$

From Equations 57 and 60 we have

$$\mathbf{h} \cdot \mathbf{s} = 1 , \quad (62)$$

and Equation 61 becomes

$$\frac{d\mathbf{g}}{dt} = \mathbf{h}\mathbf{s} \cdot \frac{d\mathbf{g}}{dt} + \frac{1+g^2}{4na^2\sqrt{1-e^2}}\,\mathbf{s} \times \operatorname{grad}_{\mathbf{g}} F . \quad (63)$$

The Pfaffian equation associated with e is simply

$$\frac{\partial \phi}{\partial e} = 0$$

or

$$-\frac{2na^2 e}{\sqrt{1-e^2}}\,\frac{\mathbf{s} \cdot d\mathbf{g}}{1+g^2} + \frac{\partial F}{\partial e}\,dt = 0 . \quad (64)$$

From Equations 63 and 64 we obtain

$$\frac{d\mathbf{g}}{dt} = \mathbf{h}\,\frac{(1+g^2)\sqrt{1-e^2}}{2na^2 e}\,\frac{\partial F}{\partial e} + \frac{1+g^2}{4na^2\sqrt{1-e^2}}\,\mathbf{s} \times \operatorname{grad}_{\mathbf{g}} F . \quad (65)$$

Multiplying Equation 59 by $\mathbf{h}$ and taking Equations 62 and 34 into account, we deduce

$$\frac{de}{dt} = + \frac{1-e^2}{na^2 e}\,\frac{\partial F}{\partial l} - \frac{(1+g^2)\sqrt{1-e^2}}{2na^2 e}\,\mathbf{h} \cdot \operatorname{grad}_{\mathbf{g}} F . \quad (66)$$

The use of the Gibbsian rotation vector represents an application and an extension of Strömgren's and of the author's ideas from the domain of special perturbations to the domain of general perturbations. The use of the vector $\mathbf{g}$ becomes especially convenient if the basic reference plane

nearly coincides with the osculating orbit plane at the initial epoch. Then the components of $\mathbf{g}$ become small—of the order of perturbations.

Now let a, e, l be the disturbed and **P**, **Q** the un-disturbed elements and put

$$r_0 = Pa(\cos u - e) + Qa\sqrt{1 - e^2}\,\sin u .$$

$$u - e\sin u = l$$

Writing the matrix of rotation Γ, which transforms $\mathbf{r}_0$ into the disturbed position vector $\mathbf{r}$, in the Gibbsian form

$$\Gamma = I + \frac{2}{1 + g^2}\left[g \times I + g \times (g \times I)\right] , \quad (67)$$

we have

$$r = \Gamma \cdot r_0 ,$$

or, in the developed form,

$$r = r_0 + \frac{2}{1 + g^2}\left[g \times r_0 + g \times (g \times r_0)\right] ,$$

or

$$r = \frac{1 - g^2}{1 + g^2} r_0 + \frac{2}{1 + g^2}\left[g \times r_0 + gg \cdot r_0\right] .$$

EQUATIONS FOR VARIATION OF EULER'S PARAMETERS

It is also of interest to deduce the equations for the variation of elements in terms of Euler parameters:

$$\begin{aligned} \lambda_1 &= \sin\tfrac{1}{2} i \cos\tfrac{1}{2}(\omega - \Omega) , \\ \lambda_2 &= \sin\tfrac{1}{2} i \sin\tfrac{1}{2}(\omega - \Omega) , \\ \lambda_3 &= \cos\tfrac{1}{2} i \sin\tfrac{1}{2}(\omega + \Omega) , \\ \lambda_4 &= \cos\tfrac{1}{2} i \cos\tfrac{1}{2}(\omega + \Omega) . \end{aligned} \quad (68)$$

The additional constraint is

$$\lambda_1^2 + \lambda_2^2 + \lambda_3^2 + \lambda_4^2 = 1 . \quad (69)$$

Two of these parameters, namely λ_1 and λ_2, were used by Hansen (Reference 6) in his lunar theory. The author has suggested the use of all four in the theory of artificial satellites (Reference 7) and in a modification of Hansen's lunar theory (Reference 16). Writing the Pfaffian (Equation 55) in the form

$$\phi = \sqrt{\mu a}\, dl + \sqrt{\mu a(1 - e^2)}\,\frac{d(\omega + \Omega) + \tan^2\frac{i}{2}\, d(\omega - \Omega)}{1 + \tan^2\frac{i}{2}} + F\, dt$$

and taking Equation 68 into account, we deduce

$$\phi = \sqrt{\mu a}\, dl + 2\sqrt{\mu a(1 - e^2)}\left(\lambda_1 d\lambda_2 - \lambda_2 d\lambda_1 + \lambda_4 d\lambda_3 - \lambda_3 d\lambda_4\right) + F\, dt . \quad (70)$$

The Pfaffian equations associated with the λ-parameters take the form:

$$\frac{\partial\phi}{\partial\lambda_1} + 2d\left[\sqrt{\mu a(1 - e^2)}\,\lambda_2\right] - w\lambda_1\, dt = 0 \quad (71)$$

$$\frac{\partial\phi}{\partial\lambda_2} - 2d\left[\sqrt{\mu a(1 - e^2)}\,\lambda_1\right] - w\lambda_2\, dt = 0 \quad (72)$$

$$\frac{\partial\phi}{\partial\lambda_3} - 2d\left[\sqrt{\mu a(1 - e^2)}\,\lambda_4\right] - w\lambda_3\, dt = 0 \quad (73)$$

$$\frac{\partial\phi}{\partial\lambda_4} + 2d\left[\sqrt{\mu a(1 - e^2)}\,\lambda_3\right] - w\lambda_4\, dt = 0 , \quad (74)$$

where w is the Lagrangian multiplier associated with the constraint (Equation 69). Putting

$$A = na\sqrt{1-e^2}\,\frac{da}{dt} - \frac{2na^2 e}{\sqrt{1-e^2}}\,\frac{de}{dt}, \tag{75}$$

we can write Equations 71–74 in the form:

$$-A\lambda_2 - 4na^2\sqrt{1-e^2}\,\frac{d\lambda_2}{dt} - \frac{\partial F}{\partial \lambda_1} + w\lambda_1 = 0, \tag{76}$$

$$+A\lambda_1 + 4na^2\sqrt{1-e^2}\,\frac{d\lambda_1}{dt} - \frac{\partial F}{\partial \lambda_2} + w\lambda_2 = 0, \tag{77}$$

$$+A\lambda_4 + 4na^2\sqrt{1-e^2}\,\frac{d\lambda_4}{dt} - \frac{\partial F}{\partial \lambda_3} + w\lambda_3 = 0, \tag{78}$$

$$-A\lambda_3 - 4na^2\sqrt{1-e^2}\,\frac{d\lambda_3}{dt} - \frac{\partial F}{\partial \lambda_4} + w\lambda_4 = 0. \tag{79}$$

From this last set of equations and Equation 69 we have

$$A = -\lambda_2\frac{\partial F}{\partial \lambda_1} + \lambda_1\frac{\partial F}{\partial \lambda_2} - \lambda_3\frac{\partial F}{\partial \lambda_4} + \lambda_4\frac{\partial F}{\partial \lambda_3}, \tag{80}$$

and

$$w = B - 4na^2\sqrt{1-e^2}\left(-\lambda_1\frac{d\lambda_2}{dt} + \lambda_2\frac{d\lambda_1}{dt} + \lambda_3\frac{d\lambda_4}{dt} - \lambda_4\frac{d\lambda_3}{dt}\right), \tag{81}$$

where, for the sake of brevity, we put

$$B = \lambda_1\frac{\partial F}{\partial \lambda_1} + \lambda_2\frac{\partial F}{\partial \lambda_2} + \lambda_3\frac{\partial F}{\partial \lambda_3} + \lambda_4\frac{\partial F}{\partial \lambda_4}. \tag{82}$$

From the Pfaffian equation

$$\frac{\partial \phi}{\partial e} = 0,$$

we deduce, after some transformations,

$$-\lambda_1\frac{d\lambda_2}{dt} + \lambda_2\frac{d\lambda_1}{dt} + \lambda_3\frac{d\lambda_4}{dt} - \lambda_4\frac{d\lambda_3}{dt} = -\frac{\sqrt{1-e^2}}{2na^2 e}\frac{\partial F}{\partial e}, \tag{83}$$

and Equation 81 becomes

$$w = B + \frac{2(1-e^2)}{e}\frac{\partial F}{\partial e}.$$

Substituting this value of w into Equations 76–79 we obtain:

$$\frac{d\lambda_1}{dt} = + \frac{1}{4na^2\sqrt{1-e^2}}\left(\frac{\partial F}{\partial \lambda_2} - \lambda_1 A - \lambda_2 B\right) - \frac{\sqrt{1-e^2}}{2na^2 e}\lambda_2 \frac{\partial F}{\partial e} ,$$

$$\frac{d\lambda_2}{dt} = - \frac{1}{4na^2\sqrt{1-e^2}}\left(\frac{\partial F}{\partial \lambda_1} + \lambda_2 A - \lambda_1 B\right) + \frac{\sqrt{1-e^2}}{2na^2 e}\lambda_1 \frac{\partial F}{\partial e} ,$$

$$\frac{d\lambda_3}{dt} = - \frac{1}{4na^2\sqrt{1-e^2}}\left(\frac{\partial F}{\partial \lambda_4} + \lambda_3 A - \lambda_4 B\right) + \frac{\sqrt{1-e^2}}{2na^2 e}\lambda_4 \frac{\partial F}{\partial e} ,$$

$$\frac{d\lambda_4}{dt} = + \frac{1}{4na^2\sqrt{1-e^2}}\left(\frac{\partial F}{\partial \lambda_3} - \lambda_4 A - \lambda_3 B\right) - \frac{\sqrt{1-e^2}}{2na^2 e}\lambda_3 \frac{\partial F}{\partial e} .$$

Taking Equations 80 and 82 into account we deduce from the last set of equations:

$$\frac{d\lambda_1}{dt} = \frac{1}{4na^2\sqrt{1-e^2}}\left[+\left(\lambda_4^2 + \lambda_3^2\right)\frac{\partial F}{\partial \lambda_2} - \left(\lambda_1\lambda_4 + \lambda_2\lambda_3\right)\frac{\partial F}{\partial \lambda_3} - \left(\lambda_2\lambda_4 - \lambda_1\lambda_3\right)\frac{\partial F}{\partial \lambda_4}\right] - \frac{\sqrt{1-e^2}}{2na^2 e}\lambda_2\frac{\partial F}{\partial e} ,$$

$$\frac{d\lambda_2}{dt} = \frac{1}{4na^2\sqrt{1-e^2}}\left[-\left(\lambda_3^2 + \lambda_4^2\right)\frac{\partial F}{\partial \lambda_1} - \left(\lambda_2\lambda_4 - \lambda_1\lambda_3\right)\frac{\partial F}{\partial \lambda_3} + \left(\lambda_1\lambda_4 + \lambda_2\lambda_3\right)\frac{\partial F}{\partial \lambda_4}\right] + \frac{\sqrt{1-e^2}}{2na^2 e}\lambda_1\frac{\partial F}{\partial e} ,$$

$$\frac{d\lambda_3}{dt} = \frac{1}{4na^2\sqrt{1-e^2}}\left[+\left(\lambda_1\lambda_4 + \lambda_2\lambda_3\right)\frac{\partial F}{\partial \lambda_1} + \left(\lambda_2\lambda_4 - \lambda_1\lambda_3\right)\frac{\partial F}{\partial \lambda_2} - \left(\lambda_1^2 + \lambda_2^2\right)\frac{\partial F}{\partial \lambda_4}\right] + \frac{\sqrt{1-e^2}}{2na^2 e}\lambda_4\frac{\partial F}{\partial e} ,$$

$$\frac{d\lambda_4}{dt} = \frac{1}{4na^2\sqrt{1-e^2}}\left[+\left(\lambda_2\lambda_4 - \lambda_1\lambda_3\right)\frac{\partial F}{\partial \lambda_1} - \left(\lambda_1\lambda_4 + \lambda_2\lambda_3\right)\frac{\partial F}{\partial \lambda_2} + \left(\lambda_1^2 + \lambda_2^2\right)\frac{\partial F}{\partial \lambda_3}\right] - \frac{\sqrt{1-e^2}}{2na^2 e}\lambda_3\frac{\partial F}{\partial e} .$$

A similar set of equations was recently deduced by the author in less direct manner (Reference 16). From Equations 34, 75 and 80 we obtain

$$\frac{de}{dt} = + \frac{1 - e^2}{na^2 e} \frac{\partial F}{\partial l} + \frac{\sqrt{1 - e^2}}{2na^2 e} \left(\lambda_2 \frac{\partial F}{\partial \lambda_1} - \lambda_1 \frac{\partial F}{\partial \lambda_2} + \lambda_3 \frac{\partial F}{\partial \lambda_4} - \lambda_4 \frac{\partial F}{\partial \lambda_3} \right)$$

The disturbed position vector $\mathbf{r}$ is given by the formula:

$$r = \Gamma \cdot \begin{bmatrix} a(\cos u - e) \\ a\sqrt{1 - e^2} \sin u \\ 0 \end{bmatrix},$$

where

$$u - e \sin u = l ,$$

where a, e, l are the disturbed elements. The expression for the matrix Γ in terms of λ_1, λ_2, λ_3, λ_4 is given in Reference 7. We repeat it here for the sake of completeness:

$$\Gamma = [\lambda_{ij}] ,$$

$$\lambda_{11} = + \lambda_1^2 - \lambda_2^2 - \lambda_3^2 + \lambda_4^2 ,$$

$$\lambda_{12} = - 2(\lambda_1 \lambda_2 + \lambda_3 \lambda_4) ,$$

$$\lambda_{13} = + 2(\lambda_1 \lambda_3 - \lambda_2 \lambda_4) ,$$

$$\lambda_{21} = + 2(\lambda_3 \lambda_4 - \lambda_1 \lambda_2) ,$$

$$\lambda_{31} = + 2(\lambda_1 \lambda_3 + \lambda_2 \lambda_4) ,$$

$$\lambda_{22} = - \lambda_1^2 + \lambda_2^2 - \lambda_3^2 + \lambda_4^2 ,$$

$$\lambda_{32} = + 2(\lambda_1 \lambda_4 - \lambda_2 \lambda_3) ,$$

$$\lambda_{23} = - 2(\lambda_1 \lambda_4 + \lambda_2 \lambda_3) ,$$

$$\lambda_{33} = - \lambda_1^2 - \lambda_2^2 + \lambda_3^2 + \lambda_4^2 .$$

We can also form different sets of purely vectorial elements by taking Equation 15 as a basis. Writing Equation 15 in an equivalent form

$$\phi = - \sqrt{\mu a}\, dl + \sqrt{\mu a(1 - e^2)}\, \mathbf{P} \cdot d\mathbf{Q} - F\, dt \tag{84}$$

and putting

$$\mathbf{p} = \sqrt{\mu a}\, \mathbf{P} ,$$

$$\mathbf{q} = \sqrt{1 - e^2}\, \mathbf{Q} - l\mathbf{P} ,$$

we deduce from Equation 84

$$\phi = \mathbf{p} \cdot d\mathbf{q} - F\, dt .$$

Thus $\mathbf{p}$ and $\mathbf{q}$ represent a purely vectorial canonical set of elements. We have

$$\frac{d\mathbf{q}}{dt} = + \operatorname{grad}_{\mathbf{p}} F ,$$

$$\frac{d\mathbf{p}}{dt} = - \operatorname{grad}_{\mathbf{q}} F .$$

CONCLUSION

The Pfaffian method is suggested for use in the search for new sets of elements and in the formation of equations for their variations. The application of vector analysis permits the formation of Pfaffian equations in a very compact and elegant form. A method of integration similar to von Zeipel's method (Reference 17) can be based on the expansion of the Pfaffian differential form in powers of a small parameter.

ON THE SIMULTANEOUS COMPUTATION OF THE SECULAR AND RESONANCE EFFECTS IN THE MOTION OF CELESTIAL BODIES*

PETER MUSEN

The stability of the orbit of a celestial body depends predominantly upon the long period perturbations in its elements. The long period effects produced by the sun and the moon can prolong or shorten the lifetime of a satellite considerably. In every attempt to solve the problem of stability of the asteroidal ring the long period effects must be taken into account. Unfortunately, no convenient expansion of the disturbing function exists for large values of the eccentricity, large values of the inclinations, or large values of the ratio of the semimajor axes of the disturbed and disturbing body. Thus numerical integration must be used.

In the problem of determining orbital stability the disturbing function cannot be used in its standard form, because it contains the combined effects of the long and short period terms. If the short period terms are not removed, then the integration step will be too short, and the accumulation of the errors from rounding off will be too great over a long time interval. Thus, before integration all short period effects were removed from the disturbing function by a numerical process which avoids the development into series. In a previous article by the author the suggestion was made to use Halphen's method to compute the effects caused by the secular terms.

However, the author feels that the results of computation cannot be considered complete if they do not include the near resonance effects. As a result, Halphen's method is extended by inclusion of the near resonance effects caused by the commensurability of the mean motions of the disturbed and disturbing bodies. Liouville's method reduces the problem to a single harmonic analysis. The introduction of a nonsingular set of elements permits the extension of the method to the cause of near circular orbits and to the case of low inclinations of the orbital planes.

LIST OF SYMBOLS

k = the Gaussian constant

ϵ = the angle between the equatorial and the ecliptical planes 1950.0

$\mathbf{r}$ = the position vector of the disturbed body

u = the eccentric anomaly of the disturbed body

f = the true anomaly of the disturbed body

$\ell, \omega, \Omega, \pi, i, e, a,$ = the standard elliptic elements of the disturbed body

$\mathbf{P}, \mathbf{Q},$ = Gibbs' vectorial elements of the disturbed body

σ = the angular distance of the departure point in the orbit plane of the disturbed body from the ascending node

χ = the orbital true longitude of the perigee

$$\xi = e \cos \chi$$

$$\eta = e \sin \chi$$

*Published as *NASA Technical Note* D-2152, June 1964.

L = the mean longitude of the disturbed body
$L_1 = \ell + \chi$ = the orbital mean longitude of the disturbing body

$$X = r \cos(f + \chi)$$

$$Y = r \sin(f + \chi)$$

$$p = \frac{\cos \frac{\Omega + \sigma}{2}}{\cos \frac{\Omega - \sigma}{2}} \tan \frac{i}{2}$$

$$q = \frac{\sin \frac{\Omega + \sigma}{2}}{\cos \frac{\Omega - \sigma}{2}} \tan \frac{i}{2}$$

$$s = \tan \frac{\Omega - \sigma}{2}$$

$\mathbf{r}'$ = the position vector of the disturbing body
u' = the eccentric anomaly of the disturbing body
ℓ', ω', Ω', π', i', e', a', n' = the standard elliptic elements of the disturbing body
$\mathbf{P}'$, $\mathbf{Q}'$, $\mathbf{R}'$ = Gibbs' vectorial elements of the disturbing body
ρ = the distance between the disturbed and the disturbing body
S = the component of the disturbing force in the direction of the radius vector of the disturbed body
T = the component of the disturbing force lying in the orbital plane and normal to the radius vector
W = the component of the disturbing force normal to the orbital plane.

INTRODUCTION

The problem of determining the long period effects in the motions of celestial bodies is a central problem in the determination of orbital stability over a long time interval. Two types of long period perturbations are of primary importance in treating the problem of stability:

1. The effects produced by the secular terms in the disturbing function. The arguments of the secular terms contain neither the mean anomaly of the disturbing body nor the mean anomaly of the disturbed body.

2. The effects produced by the commensurability of mean motions. If the ratio of the mean motions of the disturbed and the disturbing bodies can be approximated by a rational number, then a small divisor will appear when the integration is performed analytically. The terms producing such small divisors are named "the critical terms."

The long period effects as well as their interactions can be determined analytically, but only under the restrictions that the eccentricities or inclinations are small and that only one critical term is present.

The secular effects have been treated numerically with Halphen-Goriachev theory (References 1–4). The only restriction imposed on the elements by this method is that a very close approach between the disturbed and the disturbing bodies cannot be considered. The secular effects of the first and second order were computed by means of numerical integration over an interval of 10–20 years for artificial satellites, and over an interval of many thousands of years for minor planets.

Several unexpected features and large variations of the elements affecting their stability have been discovered (References 4 and 5).

However, the scheme previously used becomes incomplete if there are critical terms in the development of the disturbing function. The effects produced by the critical terms in the elements might become comparable with those produced by the secular terms, and in addition, the problem of the mutual influence of terms of both types arises.

COMPUTATION OF THE SYSTEM OF FORMULAS FOR SECULAR AND RESONANCE EFFECTS

The system of formulas given in this article is based on the application of the method of Liouville (Reference 6) and on Halphen's method. It takes into account the secular as well as the critical effects. The equations for variations of the elements are also given in the form which includes the cases of small eccentricity and small inclination. Let F(u, u′) be a function of the form

$$F(u, u') = \sum_{j=0}^{+\infty} \sum_{j'=-\infty}^{+\infty} \left[A_{j,j'} \cos(jl - j'l') + B_{j,j'} \sin(jl - j'l') \right]. \quad (1)$$

where

$$l = u - e \sin u ,$$

$$l' = u' - e' \sin u' ,$$

and the coefficients $A_{j,j'}$, $B_{j,j'}$ are functions of all the remaining elements. If it is assumed that

$$\frac{n'}{n} \approx \frac{i}{i'}$$

where i and i′ are relative primes, then the critica arguments have the form

$$k(il - i'l') .$$

By using the Liouville substitution (Reference 6),

$$l = i'\sigma' ,$$

$$l' = i\sigma' - \frac{\theta}{i'} ,$$

Equation 1 can be written in the form:

$$F(u, u') = \sum_{j=0}^{+\infty} \sum_{j'=-\infty}^{+\infty} \left\{ A_{j,j'} \cos\left[(ji' - j'i)\sigma' + \frac{j'}{i'}\theta \right] + B_{j,j'} \sin\left[(ji' - j'i)\sigma' + \frac{j'}{i'}\theta \right] \right\}. \quad (2)$$

The angle σ' is not contained in the argument if

$$ji' - j'i = 0 ,$$

or, consequently, if

$$\left.\begin{aligned} j &= pi , \\ j' &= pi' , \end{aligned}\right\} \quad (3)$$

where p=0, 1, 2,⋯. Let us designate the combination of all terms in F(u, u′) which do not contain σ' by $\Psi(\theta)$:

$$\Psi(\theta) = \sum_{p=0}^{+\infty} \left(A_{pi,pi'} \cos p\theta + B_{pi,pi'} \sin p\theta \right) .$$

By taking Equation 3 into account, it may be deduced from Equation 2 that

$$\Psi(\theta) = \frac{1}{2\pi} \int_0^{2\pi} F(u, u')\, d\sigma'$$

$$= \sum_{p=0}^{+\infty} \left(A_{pi,pi'} \cos p\theta + B_{pi,pi'} \sin p\theta \right) . \quad (4)$$

Putting $\theta = 0, \pi, \pi/2, 3\pi/2, \pi/4$, in Equation 4 yields:

$$\Psi(0) = A_{0,0} + A_{i,i'} + A_{2i,2i'} + A_{3i,3i'} + \cdots ,$$

$$\Psi(\pi) = A_{0,0} - A_{i,i'} + A_{2i,2i'} - A_{3i,3i'} + \cdots ,$$

$$\Psi\left(\frac{\pi}{2}\right) = A_{0,0} + B_{i,i'} - A_{2i,2i'} - B_{3i,3i'} + \cdots ,$$

$$\Psi\left(\frac{3\pi}{2}\right) = A_{0,0} - B_{i,i'} - A_{2i,2i'} + B_{3i,3i'} + \cdots ,$$

$$\Psi\left(\frac{\pi}{4}\right) = A_{0,0} + \frac{\sqrt{2}}{2}\left(A_{i,i'} + B_{i,i'}\right) + B_{2i,2i'} + \cdots .$$

It is rarely necessary to go beyond the critical term with the argument $2il - 2i'l'$. Thus, the coefficients $A_{2i,2i'}$, $B_{2i,2i'}$, etc. can be neglected and a set of simple formulas results:

$$A_{i,i'} = \frac{\Psi(0) - \Psi(\pi)}{2} , \quad (5)$$

$$B_{i,i'} = \frac{\Psi\left(\frac{\pi}{2}\right) - \Psi\left(\frac{3\pi}{2}\right)}{2} , \quad (6)$$

$$A_{2i,2i'} = \frac{\Psi(0) - \Psi\left(\frac{\pi}{2}\right) + \Psi(\pi) - \Psi\left(\frac{3\pi}{2}\right)}{4}, \tag{7}$$

$$B_{2i,2i'} = \Psi\left(\frac{\pi}{4}\right) - \frac{\sqrt{2}+1}{4}\left[\Psi(0) + \Psi\left(\frac{\pi}{2}\right)\right] + \frac{\sqrt{2}-1}{4}\left[\Psi(\pi) + \Psi\left(\frac{3\pi}{2}\right)\right]. \tag{8}$$

In the case of a large or moderate eccentricity set

$$u = i'\phi ;$$

then

$$l' = u' - e'\sin u'$$

$$= i\phi - \frac{ie}{i'}\sin i'\phi - \frac{\theta}{i'}, \tag{9}$$

and Equation 4 takes a form more convenient for numerical computations:

$$\Psi(\theta) = \frac{1}{2\pi}\int_0^{2\pi} F(u, u')\,\frac{r}{a}\,d\phi . \tag{10}$$

This last integral is computed as a simple arithmetical mean of the integrands of equidistant values of the angle ϕ. Now a collection of formulas can be established for the actual computation of the effect of resonance in the elements on the basis of the Liouville equations (Equations 5–8). Setting

$$A_1(\alpha) = \begin{bmatrix} +1 & 0 & 0 \\ 0 & +\cos\alpha & -\sin\alpha \\ 0 & +\sin\alpha & +\cos\alpha \end{bmatrix},$$

$$A_3(\alpha) = \begin{bmatrix} +\cos\alpha & -\sin\alpha & 0 \\ +\sin\alpha & +\cos\alpha & 0 \\ 0 & 0 & +1 \end{bmatrix},$$

we can deduce the Gibbs vectorial elements **P**, **Q**, **R** and **P′**, **Q′**, **R′** by means of the formulas:

$$[\mathbf{P}, \mathbf{Q}, \mathbf{R}] = A_1(\epsilon) \cdot A_3(\Omega) \cdot A_1(i) \cdot A_3(\omega) ,$$

$$[\mathbf{P}', \mathbf{Q}', \mathbf{R}'] = A_1(\epsilon) \cdot A_3(\Omega') \cdot A_1(i') \cdot A_3(\omega') .$$

In the case of an artificial satellite the elements ω and Ω are referred to the equator and

$$[\mathbf{P}, \mathbf{Q}, \mathbf{R}] = A_3(u) \cdot A_1(i) \cdot A_3(\omega) .$$

The coordinates of the disturbed body are

$$\left.\begin{aligned} x &= a\mathbf{P}_x(\cos u - e) + a\sqrt{1-e^2}\,\mathbf{Q}_x \sin u , \\ y &= a\mathbf{P}_y(\cos u - e) + a\sqrt{1-e^2}\,\mathbf{Q}_y \sin u , \\ z &= a\mathbf{P}_z(\cos u - e) + a\sqrt{1-e^2}\,\mathbf{Q}_z \sin u , \end{aligned}\right\} \tag{11}$$

and the coordinates of the disturbing body are

$$\left.\begin{aligned} x' &= a'P_x'(\cos u' - e') + a'\sqrt{1-e'^2}\,Q_x'\sin u' \ , \\ y' &= a'P_y'(\cos u' - e') + a'\sqrt{1-e'^2}\,Q_y'\sin u' \ , \\ z' &= a'P_z'(\cos u' - e') + a'\sqrt{1-e'^2}\,Q_z'\sin u' \ . \end{aligned}\right\} \tag{12}$$

The square of the mutual distance is

$$\rho^2 = r^2 + r'^2 - 2\mathbf{r}\cdot\mathbf{r}' \ . \tag{13}$$

Let the critical argument be

$$\theta = il - i'l' \ .$$

Set

$$u = i'\phi \ ,$$

$$u' - e'\sin u' = i\phi - \frac{\theta}{i'} - \frac{ie}{i'}\sin i'\phi \ .$$

The radial component S, the orthogonal component T, and the normal component W of the disturbing force can be considered functions of the angle ϕ and the critical argument θ. Thus

$$rS = km'\left(\frac{1}{\rho^3} - \frac{1}{r'^3}\right)\mathbf{r}\cdot\mathbf{r}' - km'\frac{r^2}{\rho^3} = rS(\phi, \theta) \ , \tag{14}$$

$$rT = km'\left(\frac{1}{\rho^3} - \frac{1}{r'^3}\right)(\mathbf{R}\cdot\mathbf{r}\times\mathbf{r}') = rT(\phi, \theta) \ , \tag{15}$$

$$W = km'\left(\frac{1}{\rho^3} - \frac{1}{r'^3}\right)\mathbf{R}\cdot\mathbf{r}' = W(\phi, \theta) \ . \tag{16}$$

From the following standard equations for variations of the elements

$$\frac{dn}{dt} = -\frac{3k}{a^2}\left(S\frac{ae\sin f}{\sqrt{1-e^2}} + T\frac{a^2}{r}\sqrt{1-e^2}\right) \ ,$$

$$\frac{de}{dt} = \frac{na(1-e^2)}{ke}\left(S\frac{ae\sin f}{\sqrt{1-e^2}} + T\frac{a^2}{r}\sqrt{1-e^2}\right) - \frac{na\sqrt{1-e^2}}{ke}Tr \ ,$$

$$\frac{d\pi}{dt} = \frac{na\sqrt{1-e^2}}{ke}\left[-S\cos f + T\left(1 + \frac{1}{1-e^2}\frac{r}{a}\right)\sin f\right] + 2\sin^2\frac{i}{2}\frac{d\Omega}{dt} \ ,$$

$$\frac{dL}{dt} = -\frac{2nar}{k}S + \left(1 - \sqrt{1-e^2}\right)\frac{d\pi}{dt} + 2\sqrt{1-e^2}\sin^2\frac{i}{2}\frac{d\Omega}{dt} \ ,$$

$$\sin i\frac{d\Omega}{dt} = \frac{nar}{k\sqrt{1-e^2}}W\sin(f+\omega) \ ,$$

$$\frac{di}{dt} = \frac{nar}{k\sqrt{1-e^2}}W\cos(f+\omega) \ .$$

the short period and the secular terms may be eliminated by using the process described above, and the transformed equations will contain only the effect of the critical terms. By designating

$$A_{1,1}' = K_1 , \qquad B_{1,1}' = K_2 , \qquad A_{2i,2i}' = K_3 , \qquad B_{2i,2i}' = K_4 ,$$

the derivative of an element E becomes

$$\frac{dE}{dt} = K_1 \cos\theta + K_2 \sin\theta + K_3 \cos 2\theta + K_4 \sin 2\theta . \tag{17}$$

Let us introduce the following notations:

$$\frac{f(\phi, 0) - f(\phi, \pi)}{2} = f_1(\phi) ,$$

$$\frac{f\left(\phi, \frac{\pi}{2}\right) - f\left(\phi, \frac{3\pi}{2}\right)}{2} = f_2(\phi) ,$$

$$\frac{f(\phi, 0) - f\left(\phi, \frac{\pi}{2}\right) + f(\phi, \pi) - f\left(\phi, \frac{3\pi}{2}\right)}{4} = f_3(\phi) ,$$

$$f\left(\phi, \frac{\pi}{4}\right) - \frac{\sqrt{2}+1}{4}\left[f(\phi, 0) + f\left(\phi, \frac{\pi}{2}\right)\right] + \frac{\sqrt{2}-1}{4}\left[f(\phi, \pi) + f\left(\phi, \frac{3\pi}{2}\right)\right] = f_4(\phi) .$$

These values of the coefficients K_j (j = 1, 2, 3, 4) are deduced:

in dn/dt

$$K_j^{(n)} = -\frac{3k}{2\pi a}\int_0^{2\pi}\left(S_j\, e \sin u + T_j \sqrt{1-e^2}\right) d\phi ; \tag{18}$$

in de/dt

$$K_j^{(e)} = \frac{\sqrt{a(1-e^2)}}{2\pi}\int_0^{2\pi}\left[\sqrt{1-e^2}\ S_j \sin u + T_j\left(-\frac{3}{2}\, e + 2\cos u - \frac{1}{2}\, e\cos 2u\right)\right] d\phi ; \tag{19}$$

in dπ/dt

$$K_j^{(\pi)} = \frac{\sqrt{a(1-e^2)}}{2\pi e}\int_0^{2\pi}\left[-S_j(\cos u - e) + T_j\left(1 + \frac{r}{a}\,\frac{1}{1-e^2}\right)\sqrt{1-e^2}\ \sin u\right] d\phi + 2\sin^2\frac{i}{2}\, K_j^{(\Omega)} ; \tag{20}$$

in dL/dt

$$K_j^{(L)} = \frac{e^2}{1+\sqrt{1-e^2}}\, K_j^{(\pi)} + \sqrt{1-e^2}\, K_j^{(\Omega)}\, 2\sin^2\frac{i}{2} - \frac{2\sqrt{a}}{2\pi}\int_0^{2\pi} S_j\,\frac{r^2}{a^2}\, d\phi ; \tag{21}$$

in dΩ/dt

$$K_j^{(\Omega)} = \frac{1}{2\pi \sin i}\sqrt{\frac{a}{1-e^2}}\int_0^{2\pi} W_j\,\frac{r}{a}\left[(\cos u - e)\sin\omega + \sqrt{1-e^2}\ \sin u\cos\omega\right] d\phi ; \tag{22}$$

in di/dt

$$K_j^{(i)} = \frac{1}{2\pi}\sqrt{\frac{a}{1-e^2}}\int_0^{2\pi} W_j \frac{r}{a}\left[(\cos u - e)\cos\omega - \sqrt{1-e^2}\,\sin u \sin\omega\right] d\phi \,. \tag{23}$$

It is interesting to note that Equations 18–23 are similar in form to the equations for the computation of secular effects. The cases of small inclination and small eccentricity deserve special attention. Equations 20 and 22 contain a "small divisor" if i or e is very small. Instead of the standard orbital elements, a nonsingular set of elements can be introduced. The set of elements

$$\left.\begin{aligned} p &= \frac{\cos\frac{\Omega+\sigma}{2}}{\cos\frac{\Omega-\sigma}{2}}\tan\frac{i}{2}\,, \\ q &= \frac{\sin\frac{\Omega+\sigma}{2}}{\cos\frac{\Omega-\sigma}{2}}\tan\frac{i}{2}\,, \\ s &= \tan\frac{\Omega-\sigma}{2}\,, \end{aligned}\right\} \tag{24}$$

$$\left.\begin{aligned} \xi &= e\cos\chi\,, \\ \eta &= e\sin\chi\,, \end{aligned}\right\} \tag{25}$$

determines the position of the osculating ellipse without the introduction of a singularity for $i=0$ or $e=0$. The use of Equations 25 for the computation of perturbations was suggested by the author in his article on Strömgren's perturbations (Reference 7). In fact, p, q, and s are the components of Gibbs' rotation vector (Reference 8). From the equations

$$\sin i\,\frac{d\Omega}{dt} = \frac{rW}{\sqrt{a(1-e^2)}}\sin(f+\omega)\,,$$

$$\frac{di}{dt} = \frac{rW}{\sqrt{a(1-e^2)}}\cos(f+\omega)\,,$$

$$\frac{d\sigma}{dt} = \cos i\,\frac{d\Omega}{dt}\,,$$

it is deduced that

$$\left.\begin{aligned} \frac{dp}{dt} &= \frac{W}{2\sqrt{a(1-e^2)}}\left[(1+p^2)X + (pq-s)Y\right], \\ \frac{dq}{dt} &= \frac{W}{2\sqrt{a(1-e^2)}}\left[(pq+s)X + (1+q^2)Y\right], \\ \frac{ds}{dt} &= \frac{W}{2\sqrt{a(1-e^2)}}\left[(ps-q)X + (qs+p)Y\right]. \end{aligned}\right\} \tag{26}$$

It can be seen that no small divisor is present, even if the inclination is small. X and Y are the coordinates of the disturbing body in an ideal system of coordinates with the X- and Y-axes in the orbital plane. They can be written in the form:

$$\begin{aligned} X &= r\cos(f+\chi) \\ &= a\left[\left(\frac{1+\sqrt{1-e^2}}{2} + \frac{\xi^2-\eta^2}{2}\,\frac{1}{1+\sqrt{1-e^2}}\right)\cos\lambda + \frac{\xi\eta}{1+\sqrt{1-e^2}}\sin\lambda - \xi\right], \end{aligned} \tag{27}$$

$$\begin{aligned} Y &= r\sin(f+\chi) \\ &= a\left[\left(\frac{1+\sqrt{1-e^2}}{2} - \frac{\xi^2-\eta^2}{2}\,\frac{1}{1+\sqrt{1-e^2}}\right)\sin\lambda + \frac{\xi\eta}{1+\sqrt{1-e^2}}\cos\lambda - \eta\right], \end{aligned} \tag{28}$$

where λ is the eccentric orbital longitude,

$$\lambda = u + \chi \,. \tag{29}$$

Also (Reference 9)

$$\frac{d\xi}{dt} = \sqrt{a(1-e^2)}\left[S\sin(f+\chi) + T\left(1+\frac{r}{a}\frac{1}{1-e^2}\right)\cos(f+\chi) + \frac{r}{a}\frac{1}{1-e^2}\,T\xi\right], \tag{30}$$

$$\frac{d\eta}{dt} = \sqrt{a(1-e^2)}\left[-S\cos(f+\chi) + T\left(1+\frac{r}{a}\frac{1}{1-e^2}\right)\sin(f+\chi) + \frac{r}{a}\frac{1}{1-e^2}\,T\eta\right]. \tag{31}$$

We write the critical argument in the form:

$$\alpha = iL_1 - i'l' \,.$$

Then the Liouville substitution becomes

$$L_1 = i'\sigma' \,,$$

$$l' = i\sigma' - \frac{\alpha}{i'} \,.$$

Considering the disturbing force as a function of σ' and α, set

$$\frac{f(\sigma', 0) - f(\sigma', \pi)}{2} = f_1(\sigma'), \text{ etc.}$$

From Equations 26, 30, and 31 the following expressions are deduced for the coefficients of the critical terms:

$$K_j^{(p)} = \frac{1}{4\pi\sqrt{a(1-e^2)}}\int_0^{2\pi} W_j\left[(1+p^2)\,X + (pq-s)\,Y\right]d\sigma' \,, \tag{32}$$

$$K_j^{(q)} = \frac{1}{4\pi\sqrt{a(1-e^2)}}\int_0^{2\pi} W_j\left[(pq+s)\,X + (1+q^2)\,Y\right]d\sigma' \,, \tag{33}$$

$$K_j^{(s)} = \frac{1}{4\pi\sqrt{a(1-e^2)}}\int_0^{2\pi} W_j\left[(ps-q)\,X + (qs+p)\,Y\right]d\sigma' \,, \tag{34}$$

$$K_j^{(\xi)} = \frac{1}{2\pi}\sqrt{\frac{1-e^2}{a}}\int_0^{2\pi}\left[+S_jY + T_j\left(1+\frac{r}{a}\frac{1}{1-e^2}\right)X + \frac{r^2}{a^2}\frac{1}{1-e^2}\,T_j\xi\right]\frac{a}{r}\,d\sigma' \,, \tag{35}$$

$$K_j^{(\eta)} = \frac{1}{2\pi}\sqrt{\frac{1-e^2}{a}}\int_0^{2\pi}\left[-S_jX + T_j\left(1+\frac{r}{a}\frac{1}{1-e^2}\right)Y + \frac{r^2}{a^2}\frac{1}{1-e^2}\,T_j\xi\right]\frac{a}{r}\,d\sigma' \,. \tag{36}$$

The expression for the position vector of the disturbed body to be used in the computations of the integrands is:

$$r = \frac{A_3(\epsilon)\cdot\Gamma}{1+p^2+q^2+s^2}\begin{bmatrix}X\\Y\\0\end{bmatrix}, \tag{37}$$

where the elements γ_{ij} (i is the row ind· x and j is the column index) of the matrix Γ are determined from the formulas (Reference 10):

$$\left.\begin{aligned}
\gamma_{11} &= +p^2 - q^2 - s^2 + 1 , & \gamma_{21} &= +2(s+pq) , & \gamma_{31} &= +2(sp-q) ,\\
\gamma_{12} &= -2(s-pq) , & \gamma_{22} &= -p^2 + q^2 - s^2 + 1 , & \gamma_{32} &= +2(p+sq) ,\\
\gamma_{13} &= +2(q+ps) , & \gamma_{23} &= -2(p-sq) , & \gamma_{33} &= -p^2 - q^2 + s^2 - 1 .
\end{aligned}\right\} \quad (38)$$

X and Y are given by Equations 27–29. Kepler's equation is replaced by

$$\lambda - \xi \sin\lambda + \eta \cos\lambda = L_1 \qquad (39)$$

in a way similar to Herget's method of writing Kepler's equation for small eccentricities (Reference 11). Similar systems of equations can be established for numerical integration of the secular effects for the case of a small eccentricity or a small inclination.

The effects of the secular and critical terms must be integrated together. Again Halphen's method may be used for the computations of the secular effects. A complete collection of formulas is given in the author's previous article (Reference 3). However, if i or e, or both, are small, the system requires some modification.

For the values, say, $\lambda = 0°, 10°, \cdots, 350°$, compute:

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \frac{1}{1+p^2+q^2+s^2} \begin{bmatrix} P_x' & P_y' & P_z' \\ Q_x' & Q_y' & Q_z' \\ R_x' & R_y' & R_z' \end{bmatrix} \cdot \Gamma \cdot \begin{bmatrix} X \\ Y \\ 0 \end{bmatrix} . \qquad (40)$$

X and Y are defined by Equations 27 and 28. Kepler's equation is taken in the form of Equation 39. Then, as in the previous article, put

$$\alpha = x' + e'a ,$$

$$\beta = y ,$$

$$\gamma = z .$$

Equations 4–9 of Reference 3 remain unchanged, but Equation 10, p. 121, for the variations of the elements must be replaced by:

$$\frac{dn}{dt} = -\frac{3k}{a}\frac{1}{2\pi}\int_0^{2\pi}\left[\frac{S_0(Y\xi - X\eta)}{\sqrt{1-e^2}} + T_0\sqrt{1-e^2}\right]d\lambda , \qquad (41)$$

$$\frac{d\xi}{dt} = \sqrt{\frac{1-e^2}{a}}\frac{1}{2\pi}\int_0^{2\pi}\left[S_0 Y + T_0\left(1+\frac{r}{a}\frac{1}{1-e^2}\right)X + \left(\frac{r}{a}\right)^2\frac{a}{1-e^2}T_0\xi\right]d\lambda , \qquad (42)$$

$$\frac{d\eta}{dt} = \sqrt{\frac{1-e^2}{a}}\frac{1}{2\pi}\int_0^{2\pi}\left[-S_0 X + T_0\left(1+\frac{r}{a}\frac{1}{1-e^2}\right)Y + \left(\frac{r}{a}\right)^2\frac{a}{1-e^2}T_0\eta\right]d\lambda , \qquad (43)$$

$$\frac{dp}{dt} = \frac{1}{2\sqrt{a\left(1-e^2\right)}} \frac{1}{2\pi} \int_0^{2\pi} W_0 \frac{r}{a} \left[\left(1+p^2\right) X + (pq - s) Y\right] d\lambda \ , \tag{44}$$

$$\frac{dq}{dt} = \frac{1}{2\sqrt{a\left(1-e^2\right)}} \frac{1}{2\pi} \int_0^{2\pi} W_0 \frac{r}{a} \left[(pq + s) X + \left(1+q^2\right) Y\right] d\lambda \ , \tag{45}$$

$$\frac{ds}{dt} = \frac{1}{2\sqrt{a\left(1-e^2\right)}} \frac{1}{2\pi} \int_0^{2\pi} W_0 \frac{r}{a} \left[(ps - q) X + (qs + p) Y\right] d\lambda \ , \tag{46}$$

$$\frac{dL_1}{dt} = -\frac{2}{\sqrt{a}} \frac{1}{2\pi} \int_0^{2\pi} \left(\frac{r}{a}\right)^2 S_0 \, d\lambda + \frac{\xi \frac{d\eta}{dt} - \eta \frac{d\xi}{dt}}{1 + \sqrt{1-e^2}} \ . \tag{47}$$

CONCLUSIONS

The combined effects of the secular and critical terms have a deciding influence in determining the orbital stability over a long time interval. Some approximate schemes based on the process of averaging lead to conclusions concerning the stability of the ring of minor planets which definitely require a further check. The proposed scheme will at least give a more accurate answer over an interval of some thousands of years. Our knowledge about the stability of the orbits of artificial satellites is still incomplete. The described method will be programmed in order to investigate these problems. The application of the method of secular effects leads to some conclusions which were not anticipated. It remains to be seen what interesting conclusions will follow from the superposition of all long period terms and from the computations of their direct actions, as well as their interactions, in the problems of orbital stability of the minor planets and artificial satellites.

DETERMINATION OF THE TRIAXIALITY OF THE EARTH FROM OBSERVATIONS ON THE DRIFT OF THE SYNCOM II SATELLITE*

C. A. WAGNER

SUMMARY

The near 24-hour Syncom II satellite (with an almost circular orbit) has been under continuous observation by range and range-rate radar and minitrack stations for 7 months since mid-August 1963, when the orbit was relocated, placing its mean longitude at about 55 degrees west of Greenwich. During the first 4 months of this period, the satellite was allowed to drift free in the gravity fields of the earth, sun, and moon. In this first free-drift period, the satellite experienced a mean daily drift acceleration of its ascending node (with respect to Greenwich) of

$$-(1.27\pm.02)\times10^{-3} \text{ degrees/day}^2. \quad (1)$$

The average growth of the semimajor axis for this period was

$$(.0993\pm.0042) \text{ km/day}. \quad (2)$$

These values, checked by a simulated particle trajectory run on the Goddard ITEM program, confirm a significant longitude-dependent earth-gravity potential. The existence of a "triaxial earth" has been a speculation of geodesists since the early years of this century.

During the last 3 months of this 7-month drift period, starting at the end of November 1963, Syncom II was relocated at about 60 degrees west of Greenwich. In this period, the mean daily drift acceleration of the ascending node was

$$-(1.32\pm.02)\times10^{-3} \text{ degrees/day}^2. \quad (3)$$

The average growth of the semimajor axis for this period was

$$(.0994\pm.0080) \text{ km/day}. \quad (4)$$

Combining the results of (1) through (4) above for the two separate drift periods, it is estimated (on the basis of a triaxial geoid only) that the absolute magnitude of the longitude dependent-gravity coefficient J_{22} is

$$J_{22}=-(1.7\pm.05)\times10^{-6}.$$

This value corresponds to a difference in major and minor earth-equatorial radii of

$$(a_e-b_e)=213\pm6 \text{ feet}$$

The best present estimate of the position of the earth's major equatorial axis is

$$\lambda_{22}=19\pm6 \text{ degrees west of Greenwich.}$$

In view of previous estimates of the higher order tesseral harmonics of the earth's field, the true value of J_{22}, separated from the small influence of gravity anomalies of third and higher order on the reduction for a triaxial earth only at "synchronous" altitudes, will probably be somewhat higher than the -1.7×10^{-6} reported herein. The true value of J_{22}, however, is not likely to be greater than -2.2×10^{-6} or smaller than -1.6×10^{-6}. The true location of the earth equator's major axis is not expected to differ significantly from that reported herein, when all higher tesseral harmonics are accounted for. (See Appendix B.)

*Published as *Goddard Space Flight Center Document* X-621-64-90, April 1964.

The reported value of $J_{22} = -1.7 \times 10^{-6}$ implies that a maximum tangential velocity correction of

$$\Delta V_T = 5.36 \text{ ft./sec./year}$$

is required to keep a satellite with a 24-hour circular equatorial orbit continuously "on station" at a longitude midway between the longitudes of the equatorial major and minor axes of the earth. The original "conservative" Syncom I design requirement of $\Delta V_T = 17$ ft./sec./year correction capability was based on the longitude-dependent earth field of Izsak (January 1961), which is now outdated. (See Appendix B and Reference 4.)

INTRODUCTION

SUMMARY OF PREVIOUS INVESTIGATIONS AND DISCUSSION OF RESULTS

The question of the existence and extent of the longitude-dependence of the earth's external gravity field has concerned geodesists since the early years of this century. (See Reference 1 for example.) The existence of a longitude-dependent field implies the existence of inhomogeneities and states of stress within the earth which are of fundamental importance to all dynamical theories of the earth's interior.

In Appendix B, I have summarized 23 reductions of gravimetric, astro-geodetic, and satellite gravity data reporting longitude-dependent terms in the earth's external gravity field represented as a series of spherical harmonics. Ten of these reductions are based on worldwide surface-gravity measurements only. Although surface measurements have the advantage of providing an excellent sampling of the field in latitude and longitude, they are seriously affected by even small uncertainties in station position with respect to the mean earth geoid, as these are of the same order-of-magnitude as the *reported* geoid deviations caused by longitude-dependent gravity.

Of the 12 satellite reduced tesseral gravity fields, those of Kozai (1962), Izsak (July 1963), Kaula (September 1963), and Guier (1963) show good general agreement in the eastern hemisphere when the constants are used as a set. All of these observers are aware, nevertheless, of the high degree of uncertainty in the reported values of the individual coefficients themselves, this uncertainty being due mainly to unresolved station-datum errors and to the limited sampling of the field from observations on a small number of medium-altitude, medium-inclination satellites.

As late as July 1963, Izsak stated (Reference 2): "It might be some time before one can arrive at definite conclusions regarding the longitude dependence of the earth's gravity field." The presence of Syncom II, high over the earth with a nearly stationary, narrow figure-8 ground track centered close to the equator, dramatically alters this gloomy outlook. The 24-hour satellite is high enough to be unaffected by the earth's atmosphere, yet is close enough to the earth to be protected from the solar wind by the "magnetosphere" of the earth, and to remain essentially unaffected by sun or moon gravity.

In theory, as the ground track is nearly stationary, any small earth-gravity anomaly in longitude will in time, cause significant drift of the ground-track configuration. In theory too, only observations of the longitude of the satellite from a single ground station are necessary to reveal this effect of the "tesseral" gravity field over an extended period of time. Long-term observations of the longitude drift of one or more 24-hour satellites should reveal the exact nature of the tesseral-gravity field to at least the third order without essential difficulty. The great height of the 24-hour satellite tends to cancel out the individual contributions to the longitudinal drift of anomalies higher than about the fourth order. It is fortunate that the initial slow westward drift of the ground track of Syncom II (August 1963 to March 1964) appears to have occurred relatively close to a point midway between the triaxial earth's major and minor equatorial axes where the perturbation of the second tesseral-gravity anomaly, for which the reduction was made, is greatest. A weighted average of the longitude-perturbation fields of Kozai (1962), Zhongolovitch (1957), Kaula (September 1963), and Izsak (July 1963), at the altitude and longitude of Syncom II during this period, shows that the second tesseral should be contributing about 80 to 85 percent of the perturbing force. If further observations of this and other 24-hour satellites confirm this estimate, then the magnitude of the dominant J_{22} potential term, separated from higher order effects, will increase by 25 percent at most from the value reported here, which is based on the assumption

that only the triaxial earth-gravity field is being measured by the drift observations. The reported location of the major equatorial axis of the triaxial earth ellipsoid is not expected to change significantly with this later refinement.

In summary, long-term observations on the drift of Syncom II have already established to a high degree of certainty that:

1. The earth must be considered to be a "triaxial ellipsoid" (for example, having a sea-level surface of this form) for the purposes of 24-hour satellite design. (For broader geodetic purposes; a significant longitude dependent gravity field exists, defining:

$$2.2\times10^{-6}<|J_{22}|<1.6\times10^{-6};$$
$$-25^\circ<\lambda_{22}<-13^\circ.)$$

2. The difference between the major and minor equatorial radii of that ellipsoid is not less than 200 feet nor greater than 225 feet.

3. The location of the major equatorial axis of the "triaxial geoid" is between 13 degrees and 25 degrees west of Greenwich.

It may be added that the study of simulated 24-hour satellite drift in a triaxial earth field, influenced also by sun and moon gravity and by sun-radiation pressure perturbations, shows that the theory of longitude drift presented in this report is substantially unaffected by all perturbations except that due to the earth's elliptical equator and possible higher order longitude-dependent earth-gravity anomalies.

1. Basic Theory of this Reduction

(Determination of the Longitude Drift and Orbit Expansion for a 24-Hour Satellite With a Near-Circular Orbit Affected by a Small But Persistent Tangential Perturbing Force.)

The dominant perturbations of a 24-hour equatorial satellite in a higher order earth-gravity field have been derived many times in the literature (References 3, 4, 5, and 6). In these references, the perturbations were found by directly linearizing the equations of motion themselves and displaying the perturbed motion in appropriate geographic coordinates; no attempt was made to treat the drift of the inclined 24-hour satellite.

In this report, I will depart from this rather involved and difficult-to-visualize procedure of linearization-of-the-equations-of-motion. Instead, I will show how simple it is to derive the dominant drift and orbit-expansion equations for the 24-hour satellite by dealing with what can be called "the perturbation of the 2-body energy" of the geographically stationary satellite by the small but persistent longitude-dependent earth-gravity force. This paper will not discuss in detail the limits of validity of the expressions derived. Instead, to assess the accuracy with which these expressions predict the satellite's behavior, simulated trajectories with typical Syncom II orbit elements have been run on Goddard's particle program "ITEM." These trajectories (Appendix A) confirm the validity of the derived drift equations to an accuracy well within the "noise levels" in the orbital elements reported for Syncom II. The equations are essentially the same as those which P. Musen has derived by a more general but more complex "energy perturbation" method (Reference 7).

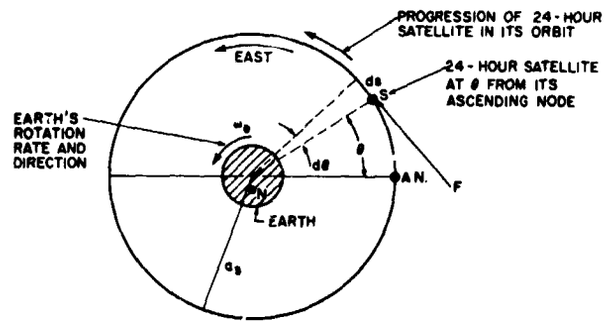

FIGURE 1.—Orbit plane of a 24-hour satellite, looking southerly.

In Figure 1, F is a small earth-gravity perturbation force acting tangentially to an initial circular 24-hour satellite orbit; ds is a small arc length of the satellite's path around the earth. At the beginning of the dynamics, the total energy (the sum of potential and kinetic) of the satellite in a spherical earth-gravity field (Reference 8) is

$$E=-\frac{\mu_E}{2a_s} \qquad (1)$$

where μ_E is the earth's gaussian gravity constant (3.986×10^5 km^3/sec^2). The energy added to the satellite by F per day is

$$\Delta E = \oint F ds = 2\pi a_s \bar{F}, \tag{2}$$

where $\bar{F} = (1/2\pi)\oint F d\theta \cdot F$, in units of force per unit mass, is the orbit averaged energy perturbing force. If the orbit is purely circular, only a tangential perturbation force can cause a change in the total energy. The ITEM simulated trajectories in Appendix A and the real Syncom II orbits both maintain eccentricities of the order of 0.0001 for periods up to 100 days. Equation (2) assumes the eccentricity is zero for the 24-hour satellite of semimajor axis a_s.

From (1), the change in energy of a 24-hour satellite is accompanied by a change in semi-major axis expressed by

$$\Delta E = \frac{\mu_E a_s}{2(a_s)^2}, \quad \text{or}$$

$$\Delta a_s = \frac{2(a_s)^2 \Delta E}{\mu_E}. \tag{3}$$

Substituting (2) into (3), the change in semimajor axis of the 24-hour near-circular orbit, per day, is approximately given by

$$\Delta a_s = \frac{4\pi (a_s)^3 \bar{F}}{\mu_E}. \tag{4}$$

From Kepler's third law, the period of a 24-hour orbit as a function of its semimajor axis is

$$T_s = \frac{2\pi (a_s)^{3/2}}{(\mu_E)^{1/2}}. \tag{5}$$

Thus, if the semimajor axis changes by Δa_s, the period change is given by

$$\Delta T_s = \frac{3\pi (a_s)^{1/2} \nabla a_s}{(\mu_E)^{1/2}}. \tag{6}$$

Substituting (4) into (6), the change in period, per day, of a 24-hour circular orbit is given by

$$\Delta T_s = \frac{12\pi^2 (a_s)^{7/2} \bar{F}}{(\mu_E)^{1/2}}. \tag{7}$$

The apparent net longitudinal drift rate of the 24-hour satellite's ground track with respect to the surface of the earth after the first sidereal day is

$$\dot{\lambda}(t = 1 \text{ sidereal day}) = -\frac{(\Delta T_s) 2\pi}{T_s} (\text{radians/sidereal day}) \tag{8}$$

(See Reference 9 for example). The minus sign is taken in (8) because a gain in period is accompanied by a decrease in net geographic longitude for the initially 24-hour satellite (for example, for the daily geographic position of the ascending node). Combining Equations (7) and (5) in (8) gives

$$\dot{\lambda}(t = 1 \text{ sid. day}) = -\frac{12\pi^2 \bar{F}}{\mu_E/(a_s)^2} \text{ (rad./sid. day)}. \tag{9}$$

As the gain in semimajor axis is small over one day (and, in fact, small compared to a_s, for the entire libration period of the satellite in the triaxial earth field), the drift rate will continue to build up linearly with time initially, adding increments of (9) each day. Thus, the net longitudinal drift acceleration of an initially 24-hour satellite is

$$\ddot{\lambda} = -\frac{12\pi^2 \bar{F}}{\mu_E/(a_s)^2} \text{ (rad./sid. day}^2\text{)} \tag{10}$$

Rewriting (4) as

$$\dot{a} = \frac{4\pi (a_s)^3 F}{\mu_E}, \text{ (length units/sid. day)} \tag{11}$$

gives the expansion rate of the initially 24-hour near-circular satellite orbit due to a small but persistently acting orbit-averaged tangential perturbing force $\bar{F}$.

2. Evaluation of the Perturbing Force

Figure 2 shows the position of the 24-hour satellite with respect to the earth and the celestial sphere. F_r, F_ϕ and F_λ, earth-gravity perturbing forces in the radial, latitude, and longitude directions, are assumed to be acting on the satellite at s. Considering only the earth-gravity perturbation forces arising from the ellipticity of the earth's equator (Reference 10), Appendix B gives these forces as

$$F = \frac{\mu_E (R_0/a_s)^2}{(a_s)^2} \left\{ 9 J_{22} \cos^2 \phi \cos 2(\lambda - \lambda_{2^{2,0}}) \right\} \tag{12}$$

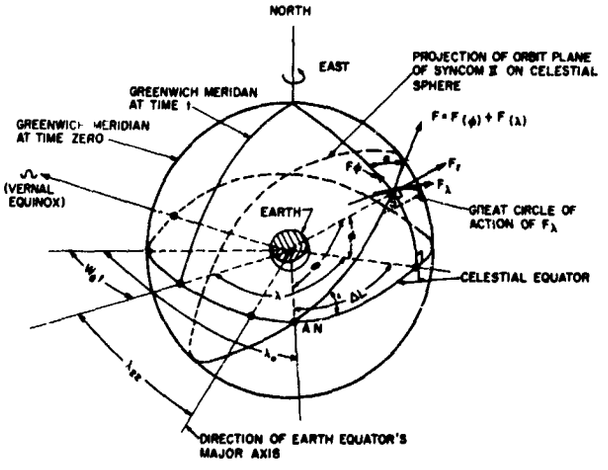

FIGURE 2.—Position of a 24-hour satellite with a near-circular orbit with respect to the earth and the celestial sphere.

$$F_\phi = \frac{\mu_E (R_0/a_s)^2}{(a_s)^2}\{6J_{22}\cos\phi\sin\phi\cos 2(\lambda-\lambda_{22})\}, \tag{12A}$$

$$F_\lambda = \frac{\mu_E (R_0/a_s)^2}{(a_s)^2}\{6J_{22}\cos\phi\sin 2(\lambda-\lambda_{22})\}. \tag{13}$$

As long as the orbit is nearly circular, F_r will have negligible contribution to F. The contribution to F from F_ϕ is:

$$F_{(\phi)} = F_\phi\cos\alpha = K\sin\phi\cos\phi\cos\alpha\cos 2(\lambda-\lambda_{22}) \tag{14}$$

K is a constant for a single orbit.

$$K = 6J_{22}\left(\frac{\mu_E R_0^2}{(a_s)^4}\right). \tag{14A}$$

In the right spherical triangle AN, s, L, note the following trigonometric relations:

$$\cos(i) = \frac{\tan\Delta L}{\tan\theta}, \tag{15A}$$

$$\cos\alpha = \frac{\tan\phi}{\tan\theta}, \tag{15B}$$

$$\sin\phi = \sin(i)\sin\theta, \tag{15C}$$

$$\sin\alpha = \frac{\cos(i)}{\cos\phi}. \tag{15D}$$

From (15A),

$$\Delta L = \tan^{-1}[\tan\theta\cos(i)]. \tag{16}$$

Let the geographic longitude of the satellite at the ascending node (AN) be λ_0. Counting time from this orbital position, the geographic longitude of the 24-hour satellite at s in its near-circular orbit is

$$\lambda = \lambda_0 + \Delta L - \omega_{et} \text{ (Figure 2)}$$

or, using (16),

$$\lambda = \lambda_0 + \tan^{-1}[\tan\theta\cos(i)] - \omega_{et} \tag{17}$$

w_e is the earth's sidereal rotation rate. For the 24-hour satellite (starting the dynamics with S. at A.N., for convenience), $\theta \doteq w_{er}$, so that (17) becomes

$$\lambda = \lambda_0 + \tan^{-1}[\tan\theta\cos(i)] - \theta, \tag{18}$$

approximately. The function $\tan^{-1}[\tan\theta\cos(i)] - \theta$ is even about $\theta=0$ and $\theta=\pi/2$, with a period of π, and behaves like a somewhat distorted sine function (Figure 3 and Appendix C). Call this function $\Delta\lambda$ and note that for $i<33$ degrees, $\Delta\lambda$ is always less than 5°. Thus, using (18) and assuming i is sufficiently small ($i<45°$ proves to be a sufficient restriction on the inclination), $\cos 2(\lambda-\lambda_{22})$ for the 24-hour satellite can be approximated by

$$\cos 2(\lambda-\lambda_{22}) \doteq \cos 2(\lambda_0-\lambda_{22}) - 2\Delta\lambda\sin 2(\lambda_0-\lambda_{22}) = -\cos 2\gamma_0 + 2\Delta\lambda\sin 2\gamma_0. \tag{18A}$$

Similarly, $\sin 2(\lambda-\lambda_{22})$ can be approximated by

$$\sin 2(\lambda_0-\lambda_{22}) + 2\Delta\lambda\cos 2(\lambda_0-\lambda_{22}) = -\sin 2\gamma_0 - 2\Delta\lambda\cos 2\gamma_0 \doteq \sin 2(\lambda-\lambda_{22}) \tag{18B}$$

In Figure 3, γ_0 is the geographic longitude of the node of the 24-hour nearly circular satellite orbit with respect to the minor equatorial axis. With these expansions [(18A) and (18B)], and using (15B), (14) becomes

$$F_{(\phi)} = K\frac{\sin\phi\cos\phi\tan\phi}{\tan\theta}\{-\cos 2\lambda_0 + 2\Delta\lambda\sin 2\lambda_0\}.$$

Using (15C) in the above expression, the contribution to the perturbing force F due to F_φ becomes

$$F_{(\phi)} = K\frac{\sin^2(i)\sin 2\nu}{2}\{-\cos 2\lambda_0 + 2\Delta\lambda\sin 2\lambda_0\}. \tag{19}$$

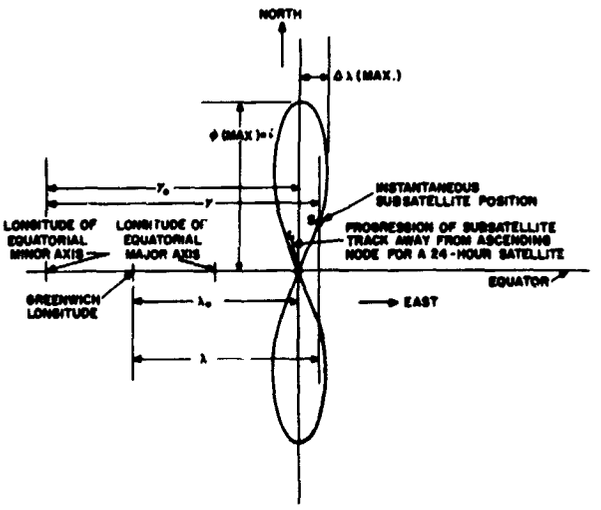

FIGURE 3.—Geographic subsatellite track of 24-hour satellite in a near-circular orbit.

Writing $\Delta\lambda \doteq \Delta\lambda\ (\max) \sin 2\theta$, (19) becomes

$$F_{(\phi)} \doteq K \sin^2 (i)\ [-\cos 2\gamma_0]\ \frac{\sin 2\theta}{2}$$

$$-K \sin^2 (i)\ \Delta\lambda\ (\max)\ [\sin 2\gamma_0 \sin^2 2\theta] \quad (20)$$

Averaging $F_{(\phi)}$ over $0 \leq \theta \leq 2\pi$, (20) gives

$$\bar{F}_{(\phi)} = \frac{1}{2\pi}\int_0^{2\pi} F_{(\phi)} d\theta$$

$$= -\frac{\sin^2 i \Delta\lambda\ (\max)}{2}[K \sin 2\gamma_0] \quad (21)$$

The contribution to F from F_λ is

$$F\omega = F_\lambda \cos (90-\alpha) = F_\lambda \sin \alpha$$
$$= K \sin \alpha \cos \phi \{-\sin 2\gamma_0 - 2\Delta\lambda \cos 2\gamma_0\}, \quad (22)$$

from (13) and (18B). Using (15D) in (22), and noting that $\Delta\lambda \doteq \Delta\lambda\ (\max) \sin 2\theta$, as before, gives the contribution to F from F_λ as

$$F\omega = K \cos (i) \{-\sin 2\gamma_0 - 2\Delta\lambda (\max) \sin 2\theta \cos 2\gamma_0\}. \quad (23)$$

Averaging $F_{(\lambda)}$ over $0 \leq \theta \leq 2\pi$, (23) gives

$$\bar{F}\omega = -K \cos (i) \sin 2\gamma_0. \quad (24)$$

Thus, combining the contributions of the latitude and longitude perturbations to the average perturbation force over a single 24-hour orbit, (21) and (24) sum to produce

$$\bar{F}\ (\text{total}) = -\bar{F}_{(\phi)} + \bar{F}_{(\gamma)}$$
$$= -K \sin 2\gamma_0 \left\{\cos (i) + \frac{\sin^2 (i)\ \Delta\lambda(\max)}{2}\right\}. \quad (25)$$

3. Completion of the Derivation of the Drift Equations

Appendix C shows that

$$\Delta\lambda(\max) = \tan^{-1}[\sec (i)] - 45°.$$

It is also shown there that, to a high degree of accuracy for $i < 50°$,

$$\cos (i) + \frac{\sin^2 \Delta\lambda\ (\max)}{2} \doteq \frac{1+\cos^2 (i)}{2}.$$

Numerically integrated orbits have shown that the drift theory for a 24-hour satellite stemming from (25) is in error by more than 2 percent for $i > 45°$. With this restriction on orbit inclination, using the above approximation for the inclination factor, we can rewrite the longitude drift and orbit expansion equations (10) and (11), evaluating $\bar{F}$ by (25), giving

$$\dot{\gamma} = \frac{12\pi^2 K}{\mu_E/(a_s)^3}\left[\frac{\cos^2 (i)+1}{2}\right] \sin 2\gamma_0,$$
(rad./sid. day²) (26)

$$\dot{a} = -\frac{4\pi (a_s)^2 K}{\mu_E}\left[\frac{\cos^2 (i)+1}{2}\right] \sin 2\gamma_0,$$
(length units/sid. day). (27)

Substituting (14A) into (26) and (27) reduces these expressions to

$$\dot{\gamma} = 72\pi^2 J_{22}(R_0/a_s)^2\left[\frac{\cos^2(i)+1}{2}\right] \sin 2\gamma_0,$$
(rad./sid. day²) (28)

$$\dot{a} = -24\pi J_{22}(R_0/a_s) R_0\left[\frac{\cos^2(i)+1}{2}\right] \sin 2\gamma_0,$$
(length unit/sids. day). (29)

Define a nondimensional change of semimajor axis from a_s during the drift as

$$a_1 = \frac{a - a_s}{a_s} = \frac{\Delta a}{a_s} \text{ so that, } \dot{a}_1 = \frac{\dot{a}}{a_s}. \quad (29A)$$

With (29A), (29) becomes

$$\dot{a}_1 = -24\pi J_{22}(R_0/a_s)^2\left\{\frac{\cos^2(i)+1}{2}\right\}\sin 2\gamma_0, \quad (1/\text{sid. day}) \quad (30)$$

Define:

$$A_{22} = -72\pi^2 J_{22}(R_0/a_s)^2\left\{\frac{\cos^2(i)+1}{2}\right\}, \quad (\text{rad./sid. day}^2). \quad (30A)$$

With (30A), (28) and (30) become;

$$\ddot{\gamma} + A_{22}\sin 2\gamma_0 = 0, \ (\text{rad./sid. day}^2) \quad (31)$$

$$\dot{a}_1 - \frac{A_{22}\sin 2\gamma_0}{3\pi} = 0, \ (1/\text{sid. day}). \quad (32)$$

Note that π in (32) has dimensions of rad./sid. day. It must be understood that (31) describes the *net* daily geographic acceleration of the initially 24-hour satellite with respect to the earth's minor equatorial axis. Stated another way, (31) describes the geographic drift of the entire originally stationary, figure-8 ground track (Figure 3). Similarly, (32) describes the net daily orbit-expansion rate of the 24-hour satellite. In particular, it it convenient to treat the motion of the ascending node of the orbit in geographic longitude as a reference for the entire configuration. In what follows, therefore, γ will refer always to the geographic longitude of the ascending node east of the equatorial minor axis; γ_0 will refer to the initial geographic longitude of the A.N. east of the minor axis, at the start of the dynamics under consideration. (31) and (32) can thus be rewritten in terms of the general nodal longitude position γ, to give the relevant partially uncoupled long-term drift and orbit-expansion differential equations for the near-24-hour near-circular orbit satellite:

$$\ddot{\gamma} + A_{22}\sin 2\gamma = 0, \ (\text{rad./sid. day}^2) \quad (33)$$

$$\dot{a}_1 - \frac{A_{22}\sin 2\gamma}{3\pi} = 0, \ (1/\text{sid. day}). \quad (34)$$

4. General Considerations of the Solutions of the Drift Equation

Equation (33) can be integrated directly for the geographic drift rate by noting that

$$\ddot{\gamma} = \frac{d\dot{\gamma}}{dt} = \frac{d(\dot{\gamma})^2}{2\dot{\gamma}dt} = \frac{d(\dot{\gamma})^2}{2d\gamma}.$$

Thus (33) can be separated to

$$d(\dot{\gamma})^2 = -2A_{22}\sin 2\gamma d\gamma. \quad (35)$$

Since the variables $(\dot{\gamma})^2$ and γ are separated in (35), (35) integrates to

$$(\dot{\gamma})^2 = A_{22}\cos 2\gamma + C_1. \quad (36)$$

With the initial condition that $\dot{\gamma} = \dot{\gamma}_0$ at $\gamma = \gamma_0$, (36) becomes

$$\dot{\gamma} = [(\dot{\gamma}_0)^2 + A_{22}(\cos 2\gamma - \cos 2\gamma_0)]^{1/2}, \quad (37)$$

giving the drift rate of the 24-hour satellite as a function of the initial drift rate $\dot{\gamma}_0$, the earth gravity constant A_{22}, the initial longitude east of the minor axis γ_0, and the instantaneous longitude γ. Returning to the semicoupled system of equations (33) and (34), the explicit dependence of the equations on the location from the minor axis and the magnitude of the equatorial ellipticity may be eliminated by multiplying (33) by $\frac{1}{3}\pi$ and adding the resulting equation to (34), giving

$$\ddot{\gamma} + 3\pi\dot{a}_1 = 0. \quad (38)$$

(38) can be rewritten as

$$\frac{d(\dot{\gamma})}{dt} + 3\pi\dot{a}_1 = 0 = d(\dot{\gamma}) + 3\pi\dot{a}_1 dt = d(\dot{\gamma}) + 3\pi d(a_1) \quad (39)$$

Separation of the variables $\dot{\gamma}$ and a_1 is thus achieved in (39). (39) integrates directly to

$$3\pi a_1 + \dot{\gamma} = C_2. \quad (40)$$

With the initial conditions: $a_1 = 0$, when $\dot{\gamma} = 0$ (the satellite is in the momentarily stationary ground-track configuration); $C_2 = 0$. If γ_0 in (37) is also the longitude of this initially stationary orbit, $(\dot{\gamma}_0)^2 = 0$ there, and (37) in (40) yields for a_1, the semimajor axis change from "synchronism" in the drift motion,

$$a_1 = \pm\frac{(A_{22})^{1/2}(\cos 2\gamma - \cos 2\gamma_0)^{1/2}}{3\pi}, \quad (41)$$

(41) shows explicitly that the semimajor axis is bounded in long-term drift from a stationary orbit. From (33), since $A_{22} > 0$, if $0 < \gamma_0 < 90°$, drift proceeds *towards* the nearest longitude of the earth's equatorial minor axis (in $a-\gamma$ direction). If $-90° < \gamma_0 < 0°$, (33) shows that drift

again proceeds *toward* the nearest minor axis longitude (in $a+\gamma$ direction). Thus, in all cases of drift from a stationary geographic configuration, $\cos 2\gamma - \cos 2\gamma_0$ is a positive function which has a maximum when $\gamma=0$ (when the satellite has drifted over the longitude of the minor axis). Thus (41) gives (for the librations of a 24-hour satellite)

$$a_1 \text{ (max)} = \left| \frac{(A_{22})^{1/2}(1-\cos 2\gamma_0)^{1/2}}{3\pi} \right|. \qquad (42)$$

Again it is noted that π in (42) has units of rad/sid. day. An absolute maximum semimajor axis change in the drift occurs when the "synchronous" condition is established near the longitude of the major equatorial axis. Here, $\gamma_0 = -90°$, $\cos 2\gamma_0 = -1$, and

$$a_1 \text{ (absolute maximum for a librating 24-hour satellite)} = \frac{(2A_{22})^{1/2}}{3\pi} \qquad (43)$$

For the constant $J_{22} = -1.7\times10^{-6}$ (derived in this study from long-term observations on the drift of the Syncom II satellite) and using the additional constants from this study: $i=33°$, $a_s \doteq 42166$ km, $R_0 = 6368.388$ km; (30A) gives

$$A_{22} = 23.2\times10^{-6} \text{ (rad./sid. day}^2\text{)}.$$

(43) then gives

a_1 (absolute max.) $= .72\times10^{-3}$, from which, by (29A),

Δa (absolute max. from a "synchronous" condition near the equatorial major axis, for a satellite of $i=33°$) $= 30.7$ km.

Thus the assumption made in (10) and (11), to approximate the slightly varying semimajor axis by a_s (a constant) throughout the drift motion, appears amply justified.

Figure 4 is a graph of (41) for a_1 vs. γ (the longitude with respect to the nearest minor axis location) as a function of γ_0, the longitude in the initially stationary configuration.

Note that (41) allows equal $\pm$values for a_1 for each γ. Suppose the satellite is initially at $+\gamma_0$ (position 1 in Figure 4) from the nearest location

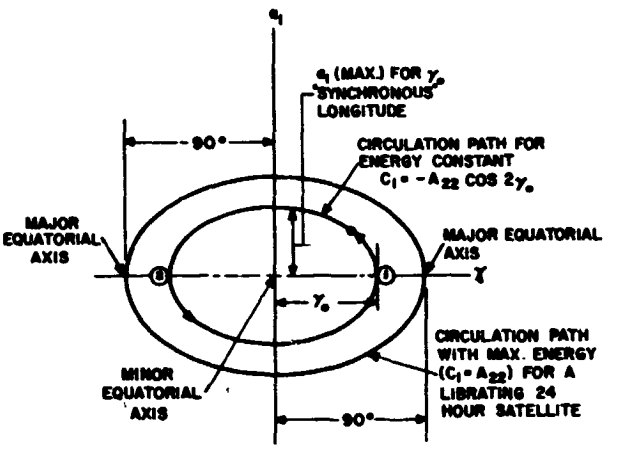

FIGURE 4.—Libration with longitude of the semimajor axis of a 24-hour satellite as a function of the longitude of the initially stationary configuration.

of the minor axis: From (33), $\sin 2\gamma_0$ being positive, the satellite begins to drift west (attaining a negative drift rate) towards the minor axis. But, from (40), since $C_2=0$, $a_1 = -(\gamma)/3\pi > 0$; the drift therefore proceeds counterclockwise in Figure 4, around the central point of the minor axis and $a_1=0$, along the upper portion of the two-valued arc determined from (41).

The same situation holds for the motion beginning or stemming away from the "synchronous" longitude at $-\gamma_0$, position 2 in Figure 4. Here $\sin 2\gamma_0$ is negative, and the drift proceeds at a positive rate to the east. Again from (40), as soon as the satellite leaves position 2, $a_1 = -(\gamma)/3\pi < 0$, and the circulation continues in a counterclockwise direction. Every trajectory in the phase plane $a_1 \leftrightarrow \gamma$ may be conveniently defined by the constant C_1 of the "energy integral" of the drift motion (36). Since (33) is the equation-of-motion defining the large-angle oscillations of a mathematical pendulum (in the case of the 24-hour-orbit satellite, the point of symmetry is the minor axis where $2\gamma=0$), it can be expected that the general solutions in that theory apply to the long-term librations of the "synchronous satellite" (Appendix D). For example, in (36), with a momentarily "synchronous" condition at γ_0 being given by $\gamma_0=0$, the "energy constant" is evaluated as

$$C_1 = -A_{22} \cos 2\gamma_0.$$

With this evaluation, (36) becomes

$$(\dot{\gamma})^2 - A_{22}\cos 2\gamma = -A_{22}\cos 2\gamma_0. \qquad (44)$$

Solving for the initially "synchronous" longitude as a function of any longitude in the drift and the corresponding longitude rate, (44) gives

$$\gamma_0 = \frac{1}{2}\cos^{-1}\left[\cos 2\gamma - \frac{(\dot{\gamma})^2}{A_{22}}\right]. \qquad (45)$$

Since $(\dot{\gamma})^2/A_{22} \geq 0$, the argument of $\cos^{-1}$ in (45) is always less than or equal to 1. Thus, as long as $\cos 2\gamma - (\dot{\gamma})^2/A_{22} \geq -1$, (45) will give a real solution for the momentarily "synchronous" longitude with respect to the minor axis. But, if $\cos 2\gamma - (\dot{\gamma})^2/A_{22} < -1$, there will be no real momentarily "synchronous" configuration for the near-24-hour satellite. With this energy, the world-circulation regime commences, corresponding to the over-the-top, high-energy regime of the mathematical pendulum (Reference 3). The above inequality implies that, for the commencement of "world circulation" for the near-24-hour satellite,

$$(\dot{\gamma})^2 \geq A_{22}(1+\cos 2\gamma), \text{ or}$$
$$(\dot{\gamma})^2 \geq 2A_{22}\cos^2\gamma. \qquad (46)$$

When $2\gamma = 0$, or the satellite is over the minor axis, (46) allows the maximum possible drift rate for a librating 24-hour satellite:

$$\dot{\gamma}(\max)_{\text{for libration}} = (2A_{22})^{1/2}, \text{ (rad./sid. day)}. \qquad (47)$$

For example, using the reported value of $A_{22} = 23.2\times10^{-6}$ rad./day^2 for the inclination of the Spncom II satellite, (47) gives

$$\dot{\gamma}(\max)_{\text{for libration with } J_{22}=-1.7\times10^{-6},\ i=33^\circ} = (46.4\times10^{-6})^{1/2} = .39 \text{ degrees/day}. \qquad (48)$$

5. Approximations to the Exact Drift Solutions for Periods Very Close to Synchronous

Expanding the drift from the "synchronous" longitude ($\gamma = \gamma_0$ in this section) in a Taylor series, with respect to increments of time Δ_t from the momentarily stationary condition,

$$\gamma(\Delta t) = \gamma_0 + \dot{\gamma}_0\Delta t + \ddot{\gamma}_0\frac{(\Delta t)^2}{2} + \dddot{\gamma}_0\frac{(\Delta t)^3}{6} + \gamma_0^{[4]}\frac{(\Delta t)^4}{24} + \gamma_0^{[5]}\frac{(\Delta t)^5}{120} + \gamma_0^{[6]}\frac{(\Delta t)^6}{720} + \gamma_0^{[7]}\frac{(\Delta t)^7}{5040} + \gamma_0^{[8]}\frac{(\Delta t)^8}{40320} + \cdots \qquad (50)$$

Differentiating (33) six times with respect to time, it is clear that all derivatives in (50) can be written as functions of A_{22}, γ_0 and $\dot{\gamma}_0$. Noting that $\gamma(\Delta_t) - \gamma_0 = \Delta\lambda$ (the geographic longitude with respect to the "synchronous" configuration) and $\dot{\gamma}_0 = 0$, (50) can be shown to reduce to the expansion

$$\Delta\lambda = (-A_{22}\sin 2\gamma_0)\frac{(\Delta t)^2}{2} + [(A_{22})^2\sin 4\gamma_0]\frac{(\Delta t)^4}{24} + [(A_{22})^3\sin 2\gamma_0\,(4\sin^2 2\gamma_0 - 1)]\frac{(\Delta t)^6}{180} - [(A_{22})^4\sin 4\gamma_0(34\sin^2 2\gamma_0 - 1)]\frac{(\Delta t)^8}{10080} + \ldots \qquad (51)$$

It is apparent that, as $\Delta_t \to 0$, the higher order terms of (51) become increasingly more insignificant to the total drift, in comparison to the terms of lower order.

In Appendix D, the exact "elliptic integral" of motion from (33) is calculated from a synchronous longitude of 60° east of the minor axis. This calculation demonstrates that the simple term-inclusion-time criterion below gives an adequately converging series to the "exact" drift. In the actual reduction, all higher order terms in (51) which are less in magnitude than the root mean square (rms) error of the observed Syncom II longitudes, are ignored. Section 7 of this report shows that this rms error of longitude determination for the ascending equator crossings of Syncom II from August 1963 to March 1964 has been of the order of $\pm.025$ degrees. Thus, 0.025° is used below in forming the minimum-time-term-inclusion criterion for each term of (51).

A_{22} is assumed to be 23.2×10^{-6} rad./sid. day^2.

A) For inclusion of the $(\Delta t)^4$ term:

$|\sin 4\gamma_0|$ is maximum when $\gamma_0 = \pm 22.5^\circ$ and $\pm 67.5^\circ$.

Therefore,

$$|\Delta\gamma_{\max} \text{ (from the fourth-order term)}| = (A_{22})^2\frac{(\Delta t)^4}{24}. \qquad (52A)$$

Solving (52A) for Δt, when $|\Delta\lambda_{max}$ (4th order)$|$ $=.025°$,

Δt (min. fourth-order term inclusion)
$=(.025\times24/57.3\times[23.2\times10^{-6}]^2)^{1/4}$
$=66.5$ sid. days from "synchronism".

B) For inclusion of the $(\Delta t)^6$ term:

$|\sin 2\gamma_0\ (4\sin^2 2\gamma_0-1)|$ is maximum when γ_0 $=\pm45°$.

Therefore,

$|\Delta\gamma_{max}$ (from the sixth-order term)$|$
$$=(A_{22})^3\frac{(\Delta t)^6}{60}. \qquad (52B)$$

Solving (52B) for Δt, when $|\Delta\lambda_{max}$ (sixth order)$|$ $=.025°$,

Δt (min. for sixth-order term inclusion)
$=(.025\times60/57.3\times[23.2\times10^{-6}]^3)^{1/6}$
$=113.$ sid. days from "synchronism".

C) For inclusion of the $(\Delta t)^8$ term:

$|\sin^4\gamma_0\ (34\sin^2 2\gamma_0-1)|$ is maximum wh $=\pm5914°$.

Therefore,
$|\Delta\lambda_{max}$(from the eighth-order term)$|$
$$=21.2(A_{22})^4\frac{(\Delta t)^8}{10080} \qquad (52C)$$

Solving (52C) for Δt, when $|\Delta\lambda_{max}$ (eight. order)$|$ $=.025°$,

(min. for eight-order term inclusion)
$=(10080\times.025/21.2\times57.3\times[23.2\times10^{-6}]^4)^{1/8}$
$=171.$ sid. days from "synchronism".

Similarly, expanding $a_1\ (t)$ in a Taylor series about the time of "synchronism", $(t_0,\ \gamma_0)$:

$$a_1(t_0+\Delta t)=(a_1)_0+(\dot a_1)_0(\Delta t)+(\ddot a_1)_0\frac{(\Delta t)^2}{2}+(\dddot a_1)_0\frac{(\Delta t)^3}{6}+\cdots. \qquad (53)$$

But, from (34),

$$(\dot a_1)_0=\frac{A_{22}\sin 2\gamma_0}{3\pi}. \qquad (53A)$$

Differentiating (53A) with respect to time,

$$(\ddot a_1)_0=\frac{2\dot\gamma_0A_{22}\cos 2\gamma_0}{3\pi}=0, \qquad (53B)$$

since $\gamma_0=0$. Differentiating (53B) with respect to time,

$$(\dddot a_1)_0=\frac{-4(\dot\gamma_0)^2A_{22}\sin 2\gamma_0}{3\pi}+\frac{2\ddot\gamma_0A_{22}\cos 2\gamma_0}{3\pi}=\frac{-(A_{22})^2\sin 4\gamma_0}{3\pi}, \qquad (54)$$

using equation (33). From the conventional definition of a_1, $(a_1)_0=0$. (53) then becomes

$$a_1\text{ (at }\Delta t\text{ from "synchronism")}=\frac{(A_{22}\sin 2\gamma_0)\Delta t}{3\pi}-\frac{(A_{22})^2\sin 4\gamma_0(\Delta t)^3}{18\pi}+\cdots, \qquad (54A)$$

with the results of (53A), (53B), and (54) in (53).

Section 7 shows that the rms error of semimajor axis determination for Syncom II (including sun and moon "noise") is of the order of ±0.5 km. Therefore, the rms error to be expected in a_1 is of the order of $.5/42166.=1.185\times10^{-5}$. Following the procedure for the longitude drift, 1.185×10^{-5} is used below to determine the minimum time for the inclusion of the terms beyond the first on the righthand side of (54A), to ensure adequate convergence of the infinite series for $a_1(\Delta t)$.

A) For inclusion of the $(\Delta t)^3$ term:

$|\sin 4\gamma_0|$ is maximum when γ_0 $=\pm22.5°$ and $\pm67.5°$.

Therefore,

$|a_{1(max)}$, [from the third-order term of (54A)]$|$
$$=\frac{(A_{22})^2(\Delta t)^3}{18\pi}. \qquad (55)$$

Solving (55) for Δt, when $|a_1$ (max)$|$ $=1.185\times10^{-5}$,

Δt [min. for the third-order term inclusion in (54A)] $=\left[\frac{1.185\times10^{-5}\times18\pi}{23.2\times10^{-12}}\right]^{1/3}$
$=$ 108 sid days from synchronism.

From a "synchronous" configuration at 54.8° west of Greenwich, on or about 6 September 1963, Syncom II drifted to 59.2° west of Greenwich on 28 November 1963, where it was "stopped" by the tangential firing of on-board cold-gas jets. A second free-drift period followed from a "synchronous" configuration at 59 2° west on about 29 November 1963, to 66.3° west on 18 March 1964, where the on-board tangential jets were fired to speed up the westward drift. Of the 34 separate orbits calculated by the Goddard Data and Tracking Systems Directorate for these free-drift periods, only 7 fell outside the minimum 66-day period around a condition of "synchronism",

for which the inclusion of higher order terms in (54A) would be necessary in reducing the drift data according to that theory. The data reduction of Section 7 includes only those orbits falling within the minimum 36-day period around "synchronism". Further refinement of this reduction to include the 7 outside-of-synchronous orbits (according to the criterion of this chapter), will be made in the near future. This refinement is not expected to materially affect the results of this report.

6. Determination of Earth-Equatorial Ellipticity from Two Observations of Drift Acceleration At a Given Longitude Separation

Given two independent near-synchronous drifts (in the sense discussed previously), whose momentarily synchronous longitudes $(\gamma_0)_1$ and $(\gamma_0)_2$ are separated by $\nabla\lambda$. Let the two drift accelerations at these two "synchronous" configurations be $(\ddot{\gamma}_0)_1$ and $(\ddot{\gamma}_0)_2$. The drift accelerations may be determined from drift-data reduction according to the theory of (51).

From (33),

$$(\ddot{\gamma}_0)_1 = -(A_{22})_1 \sin 2(\gamma_0)_1 \tag{56}$$

$$(\ddot{\gamma}_0)_2 = -(A_{22})_2 \sin 2[(\gamma_0)_1 + \nabla\lambda], \tag{57}$$

since $(\gamma_0)_2 - (\gamma_0)_1 = \Delta\lambda = (\lambda_0)_2 - (\lambda_0)_1$. Expanding (57) and dividing by (56) gives

$$\left[\frac{(\ddot{\gamma}_0)_2}{(\ddot{\gamma}_0)_1}\right]\left[\frac{(A_{22})_1}{(A_{22})_2}\right] = \cos 2\nabla\lambda + \sin 2\nabla\lambda \cot 2(\gamma_0)_1 \tag{58}$$

Solving (58) for $(\gamma_0)_1$,

$$(\gamma_0)_1 = \frac{1}{2}\tan^{-1}\left\{\frac{\sin(\nabla\lambda)}{\frac{(\ddot{\gamma}_0)_2(A_{22})_1}{(\ddot{\gamma}_0)_1(A_{22})_2} - \cos 2(\nabla\lambda)}\right\}. \tag{59}$$

The quadrant of $(\gamma_0)_1$ is either the first or the fourth, because drift acceleration is always in the direction of the *nearest* longitude extension of the earth's minor equatorial axis. Once the minor axis is located by (59), the absolute value of J_{22} in the earth's triaxial gravity field can be determined through (56) and (30A), for example, as

$$J_{22} = \frac{(A_{22})_1}{72\pi^2[R_0/(a_s)_1]^2\left[\frac{\cos^2(i)_1+1}{2}\right]} = \frac{(\ddot{\gamma}_0)_1}{72\pi^2 \sin 2(\gamma_0)_1[R_0/(a_s)_1]^2\left[\frac{\cos^2(i)_1+1}{2}\right]} \tag{60}$$

Note that the units of $(\ddot{\gamma}_0)_1$ in (60) must be those of radians/sidereal day^2 so that J_{22} will be dimensionless. Note also that in (59), using the result of (30A),

$$\frac{(A_{22})_1}{(A_{22})_2} \simeq \left[\frac{(a_s)_2}{(a_s)_1}\right]^2\left[\frac{\cos^2(i)_1+1}{\cos^2(i)_2+1}\right]. \tag{61}$$

Using (59), since $(\lambda_0)_1$ is known from the data reduction (the geographic longitude of the "synchronous" configuration), the geographic longitude of the nearest minor axis location can be calculated as

$$\gamma_{22} = (\lambda_0)_1 - (\gamma_0)_1. \tag{61A}$$

Similarly, the geographic longitude of the nearest major equatorial axis location can be calculated from

$$\lambda_{22} = (\lambda_0)_1 - (\gamma_0)_1 + 90^\circ \tag{61B}$$

(See figure 3).

Following the theory of Reference 10, the difference in major and minor equatorial radii of the earth's triaxial geoid (a_0-b_0), is related to the gravity constant J_{22} by

$$a_0-b_0=-6R_0J_{22}. \tag{62}$$

7. Reduction of 27 Syncom II Orbits to Determine the Earth's Equatorial Ellipticity

Appendix A tabulates the 27 Syncom II orbits from which the reduction below was made. Table 1 gives the estimated ascending equator crossings nearest to the epoch of these orbits. These were calculated by hand, and therefore are listed only to 0.01 degrees and 0.01 days. The technique used was to locate from the Nautical Almanac, the geographic longitude of the ascending node at epoch through the reported right ascension of the ascending node for the orbit, and the hour-angle of the vernal equinox calculated at epoch. The geographic longitude of the ascending equator crossing was then estimated by turning the earth back through the orbit angle from the ascending node to the satellite at epoch. This latter quantity was estimated as $\omega-M$ for the near-circular orbit of Syncom II. A correction factor to this orbit angle- -the ratio of the satellite's period to the earth's sidereal period—was applied for orbits whose period was sufficiently different from the earth's. The nodal longitude at epoch, minus this reduced nodal excursion angle, is the estimated "ascending equator crossing nearest to epoch" reported in Table 1. (See Appendix E for an example of this calculation.)

Table 2 gives the Goddard-reported semimajor axes for these 27 orbits. Truncating equations (51) and (54A) at their first righthand terms:

$$\Delta\lambda \text{ (longitude drift from "synchronism")} \doteq -(A_{22}\sin 2\gamma_0)\frac{(\Delta t)^2}{2} \tag{63}$$

$$a_1 \text{ (semimajor axis change from "synchronism")} \doteq A_{22}\frac{\sin 2\gamma_0(\Delta t)}{3\pi}. \tag{64}$$

Let the drift time be given from a certain arbitrary base time by T. Let T_0 be the time of "synchronism" from the base time. Let the drift be given from a certain arbitrary geographic longitude by λ. Let λ_0 be the geographic longitude from this base longitude, of the "synchronous" configuration. Then:

$$\Delta_t = T-T_0, \text{ and}$$
$$\Delta\lambda=\lambda-\lambda_0.$$

With these changes, (63) and (64) become (noting that $a_1=\frac{a-a_s}{a_s}$):

$$\lambda=\lambda_0-\frac{(A_{22})(\sin 2\gamma_0)}{2}-(T^2-2TT_0T_0^2), \text{ or}$$

$$\lambda=\left\{\lambda_0-\frac{T_0^2(A_{22}\sin 2\lambda_0)}{2}\right\}+T\left\{T_0A_{22}\sin 2\gamma_0\right\}+T^2\left\{-\frac{A_{22}\sin 2\gamma_0}{2}\right\}. \tag{65}$$

(Note that from (65), $\dot{\lambda}=-A_{22}\sin 2\gamma_0=\gamma_0$ from (33). This result is valid only for orbits sufficiently close to "synchronous," as discussed previously.)

$$a=a_s+a_s\left[\frac{A_{22}\sin 2\gamma_0}{3\pi}\right][T-T_0], \text{ or}$$

$$a=a_s\left(1-\frac{T_0A_{22}\sin 2\gamma_0}{3\pi}\right)+T\left(\frac{a_sA_{22}\sin 2\gamma_0}{3\pi}\right). \tag{66}$$

TABLE 1.—*Estimated Ascending Equator Crossings Nearest the Epoch of 27 Syncom II Orbits.*

1-16	83.90	7.61			
	~100.0	First free drift period ends at an ascending equator crossing of ~9.15° west of 50.0° west.			

TABLE 2.—*Goddard-Reported Semimajor Axes for 27 Syncom II Orbits.*

First Drift Orbit#	Time from 20.0 Aug. 1963 (days)	Semimajor Axis: (42160.0+Data; km)	Second Drift Orbit#	Time from 26.0 Nov. 1963 (days)	Semimajor Axis: (42160.0+Data; km)
1-1	2.27	4.58	2-1	2.04	5.89
1-2	6.71	4.52	2-2	8.00	7.20
1-3	11.00	6.02	2-3	14.00	7.18
1-4	16.00	6.39	2-4	20.71	8.17
1-5	20.00	6.35	2-5	41.71	8.01
1-6	23.08	6.55	2-6	44.25	9.90
1-7	28.08	7.70	2-7	55.88	11.43
1-8	31.08	7.42	2-8	64.83	11.91
1-9	38.08	7.51	2-9	71.67	12.89
1-10	42.08	8.88	2-10	76.79	13.31
1-11	49.08	9.14	2-11	83.71	14.89
1-12	55.08	9.78			
1-13	63.08	11.51			
1-14	71.00	11.09			
1-15	78.00	12.15			
1-16	84.21	12.51			
	~100.0	First free drift period ends with a semimajor axis of ~42174.5 km.			

(66) and (65) may be written with determinable coefficients as

$$\lambda = d_0 + d_1 T + d_2 T^2, \tag{67}$$

$$a = e_0 + e_1 T, \tag{68}$$

where:

$$d_0 = \lambda_0 - \frac{T^2 A_{22} \sin 2\gamma_0}{2},$$

$$d_1 = (+A_{22} T_0 \sin 2\gamma_0),$$

$$d_2 = -\frac{A_{22} \sin 2\gamma_0}{2}, \tag{69}$$

$$e_0 = a_s\left(1 - \frac{T_0 A_{22} \sin 2\gamma_0}{3\pi}\right),$$

$$e_1 = a_s A_{22} \frac{\sin 2\gamma_0}{3\pi}$$

From (69),

$$T_0 = -d_1/2d_2, \tag{70}$$

$$\lambda_0 = d_0 - \frac{(d_1)^2}{4d_2}, \tag{71}$$

$$\dot{\gamma}_0 = -A_{22} \sin 2\gamma_0 = 2d_2. \tag{72}$$

Alternately, and as an internal check on the theory of the coupling of the drift and orbit expansion,

$$\dot{\gamma}_0 = -A_{22} \sin 2\gamma_0 = \frac{-3\pi e_1}{a_s}, \text{ implying}$$

$$d_2 = 3\pi e_1 / 2a_s. \tag{73}$$

In equation (73), the units of d_2 must be radians/sidereal day^2, and the units of e_1 must be length/sidereal day so that the equation will be dimensionally correct. The semimajor axis at the "synchronous" configuration is calculated from (68) for $T = T_0$:

$$a_s = e_0 + e_1 T_0. \tag{74}$$

For the first drift period (orbits 1–1 through 1–16), the best estimates (in the "least squares" sense) of the coefficients $(d)_1$ and $(e)_1$, obtained by fitting (67) and (68) to the data in Tables 1 and 2, have been found to be:

$$(d_0)_1 = (4.941 \pm .018) \text{ degrees}$$
$$(d_1)_1 = -(.0216 \pm .0010) \text{ degrees/solar day}$$
$$(d_2)_1 = (6.37 \pm .11) \times 10^{-4} \text{ degrees/solar day}^2$$
$$= (6.33 \pm .11) \times 10^{-4} \text{ degrees/sid. day}^2$$

$(e_0)_1 = (4.35 \pm .19)$ km
$(e_1)_1 = (.0993 \pm .0042)$ km/solar day
$(.0990 \pm .0042)$ km/sid. day.

The mean value of the inclination during this period was

$$(i)_1 = 33.018 \pm .005 \text{ degrees.}$$

From (70),

$$(T_0)_1 = \left(16.95 \begin{matrix} +1.09 \\ -1.05 \end{matrix}\right) \text{ days from 29.0 August 1963.}$$

From (71),

$$(\lambda^0)_1 = (4.76 \pm .03) \text{ degrees west of 50.0 degrees west longitude.}$$

From (72),

$$(\dot{\gamma}_0)_1 = -(1.27 \pm .02) \times 10^{-3} \text{ degrees/solar day}^2 = -(2.20 \pm .04) \times 10^{-6} \text{ rad./sid. day}^2.$$

From (74) and the above value of $(T_0)_1$,

$$(a_e)_1 = (42166.0 \pm .2) \text{ km.}$$

For the second drift period (orbits 2-1 through 2-11), the best estimates (in the "least squares" sense) of the coefficients $(d)_2$ and $(e)_2$, obtained by fitting (67) and (68) to the data in Tables 1 and 2, have been found to be:

$(d_0)_2 = (9.156 \pm .017)$ degrees
$(d_1)_2 = -(.0030 \pm .0010)$ degrees/solar day
$(d_2)_2 = (6.59 \pm .11) \times 10^{-4}$ degrees/solar day^2
$= (6.55 \pm .11) \times 10^{-4}$ degrees/sid. day^2

$(e_0)_2 = (5.70 \pm .42)$ km
$(e_1)_2 = (.0994 \pm .0080)$ km/solar day
$= (.0990 \pm .0080)$ km/sid. day.

The mean value of the inclination during this period was

$$(i)_2 = 32.851 \pm .010 \text{ degrees.}$$

From (70),

$$(T_0)_2 = 2.3 \pm .8 \text{ days from 26.0 November 1963.}$$

From (71),

$$(\lambda_0)_2 = 9.15 \pm .02 \text{ degrees west of 50.0 degrees west longitude.}$$

From (72),

$$(\dot{\gamma}_0)_2 = -(1.32 + .02) \times 10^{-3} \text{ degrees/solar day}^2 = -(2.29 \pm .04) \times 10^{-6} \text{ rad./sid. day}^2.$$

From (74) and the above value of $(T_0)_2$,

$$(a_e)_2 = (42165.9 \pm .4) \text{ km.}$$

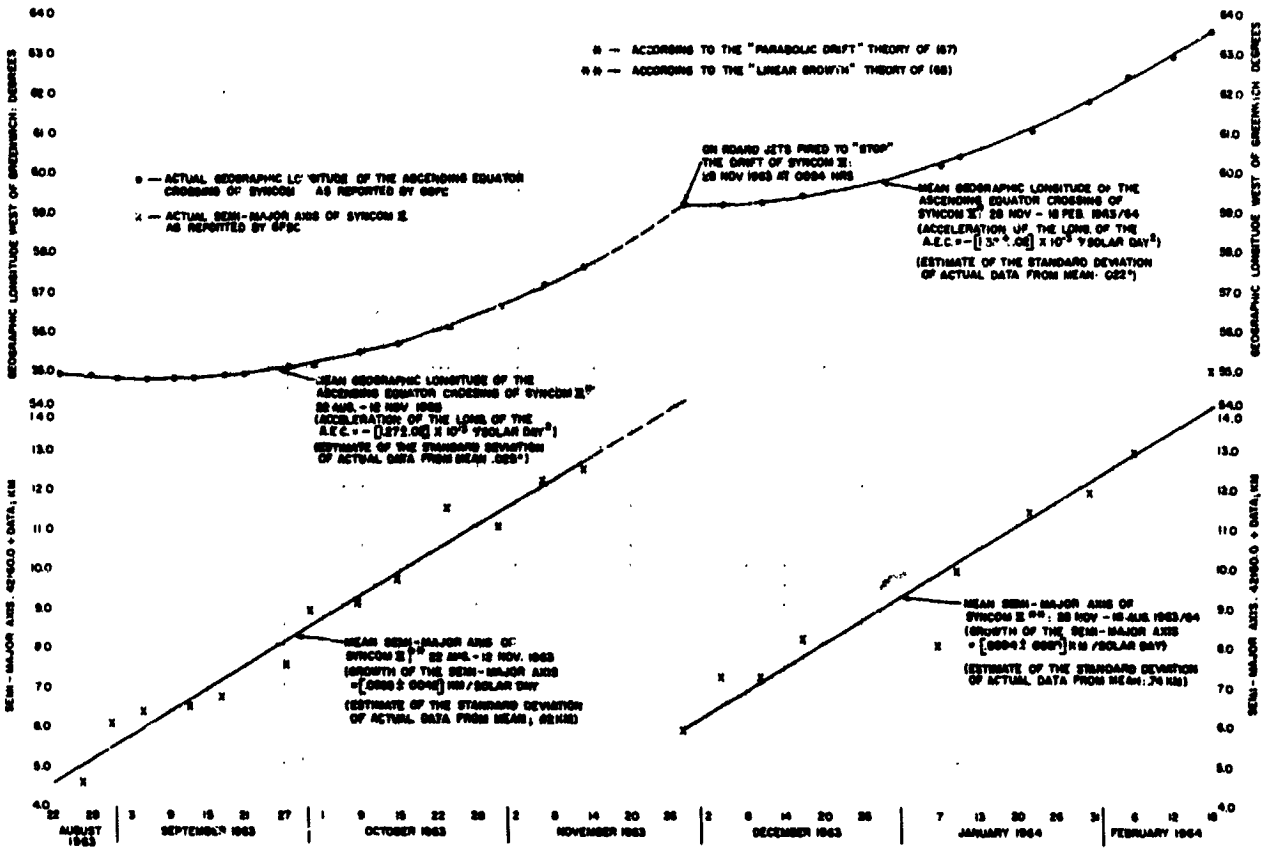

FIGURE 5.—Drift of the ascending equator crossing and growth of the semimajor axis of Syncom II.

(See Figure 5 for a graph of this orbit data and reduction for the two drift periods.) Combining the above results of the two free-drift periods, from (61),

$$\frac{(A_{22})_1}{(A_{22})_2} = (42165.9 \pm .4/42166.0 \pm .2)^2 \frac{[\cos^2 (33.018 \pm .005) + 1]}{[\cos^2 (32.851 \pm .010) + 1]}$$
$$= .99845 \pm .00014.$$

The longitude separation between the two drift periods is given by

$$\nabla\lambda = (\lambda_0)_2 - (\lambda_0)_1 = [-(59.15 \pm .02)] - [-(54.76 \pm .03)] \text{ degrees}$$
$$= -(4.39 \pm .05) \text{ degrees geographic longitude.}$$

Thus

$$2\nabla\lambda = -(8.78 \pm .10) \text{ degrees geographic longitude.}$$

Therefore, from (59), the location of the minor equatorial axis with respect to the "synchronous" longitude during the first free-drift period (54.76 ± .03 degrees west of Greenwich) is

$$(\gamma_0)_1 = \frac{1}{2} \tan^{-1} \left\{ \frac{\sin [-(8.78 \pm .10)]}{\frac{(1.32 \pm .02)}{(1.27 \pm .02)} (.99845 \pm .00014 - \cos [-(8.78 \pm .10)])} \right\}$$

$$= 54 \begin{matrix} +4 \\ -6 \end{matrix} \text{ degrees east of the minor equatorial axis.}$$

From (61B), the best estimate of the location of the major equatorial axis is

$$\lambda_{22} = -55 - \left(54^{+4}_{-6}\right) + 90 = -\left(19^{+4}_{-6}\right) \text{ degrees geographic longitude}$$

From (60), the best estimate of the triaxial gravity coefficient J_{22} is

$$J_{22} = \frac{-(2.20 \pm .04) \times 10^{-6}}{72\pi^2 \left[\sin 2\left(54^{+4^\circ}_{-6^\circ}\right)\right](6378.2/42166.0 \pm .3)^2 \left[\frac{\cos^2(33.018 \pm .005) + 1}{2}\right]}$$

$$= -\left(1.67^{+.07}_{-.03}\right) \times 10^{-6}.$$

The mean equatorial radius, taken as $R_0 = 6378.2$ km, is a compromise between a number of currently used values. It is stated above without error. The likely error in (a_e) has been increased arbitrarily by 0.1 km. to account for the likely uncertainty in R_0.

Using the above estimate of J_{22} from observations on Syncom II drift, the difference between the major and minor equatorial radii of the triaxial geoid is, by (62),

$$a_0 - b_0 = 64^{+3}_{-1} \text{ meters} = 210^{+10}_{-4} \text{ feet.}$$

Comparing the deviation due to earth ellipticity with other higher order earth-gravity deviations (Appendix B and Reference 10), we note that the above figure implies a maximum deviation from the mean earth sphere, due to the ellipticity of the equator, of

$$\Delta R_0 = 105^{+5}_{-2} \text{ feet.}$$

LIST OF SYMBOLS

J_{nm}, λ_{nm} = Spherical harmonic constants (order n, power m) of the earth's gravity potential

F = A gravity force per unit mass acting on a 24-hour satellite

θ = (except in Appendix F) The argument from the ascending node to the satellite position for the 24-hour orbit

a, a_s = The instantaneous semimajor axis, and the "momentarily synchronous" semimajor axis of the orbit of the 24-hour earth satellite. (a_s, estimated to within 2 km, is 42166 km.)

ds = A small arc length of a space trajectory

μ_E = The earth's gaussian gravity constant (3.986×10^5 km^3/sec.^{2})

T_p, T_s = The orbital period for a satellite, and the "momentarily synchronous" period of a 24-hour satellite (i.e., the earth's sidereal rotation period)

λ, r, ϕ = Geographic longitude, geocentric radius, and geocentric latitude of the 24-hour satellites position

$(\dot{}), (\ddot{}), ()^n = \frac{d()}{dt}, \frac{d^2()}{dt^2}, \frac{d^n()}{dt^n}$: time differentials

R_0 = The mean equatorial radius of the earth (6378.2 km)

i = The inclination of the orbit of the 24-hour satellite

λ_0 = The "initial" geographic longitude of the satellite, or the ascending node of the 24-hour satellite's orbit at the start of the dynamics under consideration

ω_e = The earth's sidereal rotation rate ($.7292115 \times 10^{-4}$ rad./sec.)

t = Real time

$\Delta( )$ = A small argument ( )

γ_0 = The geographic longitude (positive to the east) of the ascending node of the 24-hour satellite's orbit with respect to the earth's minor equatorial axis' longitude location, at the start of the dynamics under consideration

γ = The geographic longitude (positive to the east) of the 24-hour satellite, or the ascending node of the satellite's orbit with respect to the longitude of the earth's minor equatorial axis

$a_1 = (a - a_s)/a_s$; a nondimensional semimajor axis change for the 24-hour satellite's orbit, with respect to the "momentarily synchronous" semimajor axis

A_{22} = The driving function causing drift and orbit expansion of a 24-hour satellite in a "triaxial" earth-gravity field; a constant for a given 24-hour orbit inclination

$( )_0$ = The argument ( ) at the start of the dynamics under consideration

$( )_n$ = The argument ( ) at a specified location n (except in Appendix A: ( )s; the argument for the simulated trajectory)

$\nabla\lambda$ = The geographic longitude difference between two "momentarily synchronous" 24-hour satellite configurations

a_0, b_0 The major and minor equatorial radii of the "triaxial" earth $\left(R_0 = \frac{a_0 + b_0}{2}\right.$, according to the definition in Reference 10$\left.\right)$

w = The argument of perigee in a satellite orbit: The orbit angle (from the center of the earth) from the ascending node to perigee

M = The mean anomaly of the satellite in its orbit: The orbit angle (from the center of the earth) from perigee to a point M in the orbit, where $M = \frac{2\pi t}{T_p}$, t being the real time since perigee passage and T_p the period of the satellite's orbit

(e_n), (d_n) = Determinable coefficients in the drift and orbit-expansion equations (67) and (68)

T_0 = The time of "synchronism" from an arbitrary base time of reckoning T

$F(i)$ = The inclination factor in the triaxial driving function A_{22}

V_E = The gravity potential of the earth

g_0, g_s = The radial acceleration of the earth's gravity field at the earth's surface, and at the altitude of the "synchronous" satellite

m = A test mass

$F(k, \phi)$ = The elliptic integral of the first kind with argument (or amplitude) ϕ and modulus k

Λ = The longitude location of the vernal equinox

APPENDIX A

REDUCTION OF SIMULATED PARTICLE TRAJECTORIES FOR EARTH EQUATORIAL ELLIPTICITY

Tables A–1 and A–2 present data taken from a numerically integrated particle trajectory of a triaxial earth in the presence of the sun and moon's gravity field. Only perturbed equations of motion from a periodically rectified Keplerian reference orbit are actually integrated by the digital computer program (called ITEM at the Goddard Space Flight Center). For the 3 months' real orbit time of these trajectories, the accumulated truncation and roundoff error in the numerical integration is believed to be negligible for the purposes of this reduction. The initial position and velocity conditions for these simulated trajectories were the same as those reported for the "actual" Syncom II orbits 1–2 (for the trajectory of Table A–1) and 2–3 (for the trajectory of Table A–2). The program used the earth gaussian-gravity constant

$$\mu_E = 3.9862677 \times 10^5 \text{ km}^3/\text{sec}^2,$$

which is the gravity constant used by the GSFC Data and Tracking Systems Directorate in computing the elements of satellite orbits from radar and Minitrack observations. The best estimates (in the "least squares" sense) of the coefficients $(d)_{s,1}$ and $(e)_{s,1}$, obtained by fitting the drift and orbit expansion equations (67) and (68) to the data in Table A–1, have been found to be

$$(d_0)_{s,1} = 4.841 \pm .004 \text{ degrees}$$

$$(d_1)_{s,1} = -(1.22 \pm .03) \times 10^{-2} \text{ degrees/solar day}$$

$$(d_2)_{s,1} = (6.303 \pm .038) \times 10^{-4} \text{ degrees/solar day}^2$$
$$= (6.268 \pm .038) \times 10^{-4} \text{ degrees/sid. day}^2$$

$$(e_0)_{s,1} = 5.45 \pm 41 \text{ km}$$

$$(e_1)_{s,1} = (.091 \pm .010) \text{ km/solar day}$$
$$= (.091 \pm .010) \text{ km/sid. day.}$$

The mean value of the inclination during this first simulated trajectory period was

$$(i)_{s,1} = 33.005 \pm .003 \text{ degrees.}$$

From (70),

$$(T_0)_{s,1} = 9.68 \pm .30 \text{ days from 26.709 August 1963}$$

From (71),

$$(\lambda_0)_{s,1} = 4.782 \begin{matrix} +.008 \\ -.007 \end{matrix} \text{ degrees west of 50.0 degrees west longitude.}$$

From (72),

$$(\dot{\gamma}_0)_{s,1} = -(1.261 \pm .008) \times 10^{-3} \text{ degrees/solar day}^2$$
$$= -(2.188 \pm .013) \times 10^{-6} \text{ rad./sid. day}^2.$$

TABLE A-1.—*Data from Simulated Trajectory Beginning with the Elements of Syncom II Orbit 1-2.* ($J_{22} = -1.68 \times 10^{-6}$, $R_0 = 6378.388$ km, $\gamma_{22} = -108.0$: *Input into Trajectory Program*)

58.672	12.534	13.07	.785
60.667	12.724	13.69	.784

From (74) and the above value of $(T_0)_{s,2}$,

$$(a_s)_{s,2} = 42166.3 \pm .4 \text{ km.}$$

The best estimates (in the "least squares" sense) of the coefficients $(d)_{s,2}$ and $(e)_{s,2}$, obtained by fitting the drift and orbit expansion equations (67) and (68) to the data in Table A-2, have been found to be

$$(d_0)_{s,2} = 9.224 \pm .004 \text{ degrees}$$

$$(d_1)_{s,2} = (1.830 \pm .028) \times 10^{-2} \text{ degrees/solar day}$$

$$(d_2)_{s,2} = (6.501 \pm .042) \times 10^{-4} \text{ degrees/solar day}^2$$

$$= (6.465 \pm .042) \times 10^{-4} \text{ degrees/sid. day}^2$$

$$(e_0)_{s,2} = 7.19 \pm .37 \text{ km}$$

$$(e_1)_{s,2} = (.111 \pm .010) \text{ km/solar day}$$

$$= (.111 \pm .010) \text{ km/sid. day.}$$

The mean value of the inclination during the second simulated trajectory period is

$$(i)_{s,2} = 32.836 \pm .003 \text{ degrees.}$$

From (70),

$$(T_0)_{s,2} = -(14.07 \pm .30) \text{ days from 10.0 December 1963.}$$

From (71),

$$(\lambda_0)_{s,2} = 9.095 \begin{matrix} +.009 \\ -.009 \end{matrix} \text{ degrees west of 50.0 degrees west longitude.}$$

From (72),

$$(\dot{\gamma}_0)_{s,2} = -(1.300 \pm .008) \times 10^{-3} \text{ degrees/solar day}^2$$

$$= -(2.257 \pm .015) \times 10^{-6} \text{ rad./sid. day}^2.$$

From (74) and the above value of $(T_0)_{s,2}$,

$$(a_s)_{s,2} = 42165.6 \pm .5 \text{ km.}$$

A graph of these trajectory simulations is seen in Figure A-1.

Combining the above results for the two simulated trajectories: from (61),

$$\frac{(A_{22})_{s,1}}{(A_{22})_{s,2}} = [(42165.6 \pm .5/42166.3 \pm .4)^2] \left[\frac{\cos^2 (33.005 \pm .003) + 1}{\cos^2 (32.836 \pm .003) + 1} \right]$$

$$= .99840 \pm .00007$$

$$\nabla\lambda = (\lambda_0)_{s,2} - (\lambda_0)_{s,1} = [-(59.095 \pm .009)] - [-(54.782 \pm .008)],$$

$$\therefore 2\nabla\lambda = -(8.626 \pm .034) \text{ degrees geographic longitude.}$$

Therefore, from (59), the location of the minor equatorial axis with respect to the "synchronous longitude" during the first simulated trajectory (54.782 ± .008 degrees west of Greenwich) is

$$(\gamma_0)_{s,1} = \frac{1}{2} \tan^{-1} \left\{ \frac{\sin [-(8.626 \pm .034)]}{\frac{(1.300 \pm .008}{(1.261 \pm .008} (.99840 \pm .00007) - \cos [-(8.626 \pm .034)]} \right.$$

$$= 52.5 \pm 2.5 \text{ degrees east of the minor equatorial axis.}$$

From (61A), the best estimate of the geographic location of the nearest extension of the equatorial minor axis from the simulated trajectory data is

$$(\gamma_{22})_s = -54.8 - (52.5 \pm 2.5) = -(107.3 \pm 2.5) \text{ degrees geographic longitude.}$$

This compares well with the input value of $(\gamma_{22})_s = -108.0°$ used to compute the simulated trajectories. From (60), the best estimate of the triaxial gravity coefficient J_{22} from the simulated data (according

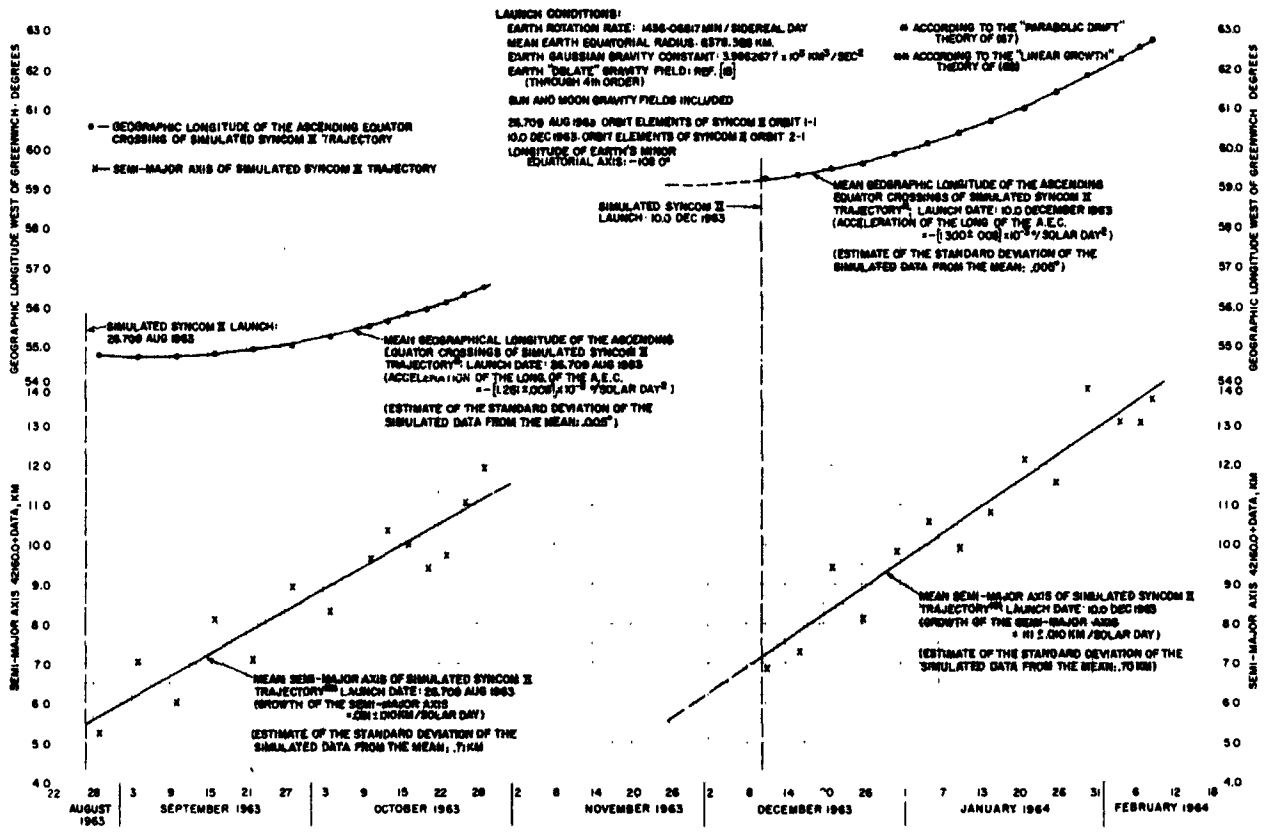

FIGURE A-1.—Drift of the ascending equator crossing and growth of the semimajor axis of simulated Syncom II trajectories.

to the theory of this report) is

$$(J_{22})_s = \left\{ \frac{-(2.188 \pm .013) \times 10^{-6}}{72\pi^2[\sin 2(52.5 \pm 2.5)](6378.388/42166.3 \pm .4)^2 \left[\frac{\cos^2 (33.005 \pm .003) + 1}{2}\right]} \right\}$$

$$= -(1.64 \pm .03) \times 10^{-6}.$$

The mean equatorial radius used in the simulation is $R_0 = 6378.388$ km, the same used to compute the "actual" Syncom II orbits from the radar and Minitrack observations.

The above value of $(J_{22})_s$ compares reasonably well with the input value of $(J_{22})_s = -(1.68) \times 10^{-6}$ used to compute the simulated trajectories.

The model error implicit in the difference between the reduced and inputed geodetic coefficients for the simulated trajectories warrants an adjustment of the J_{22} and λ_{22} reported in Section 7 from the reduction of the "actual" Syncom II orbits. The values below appear sufficient to cover all the *known* uncertainties of this reduction for a triaxial earth:

$$J_{22} \text{ (actual-adjusted)} = -(1.70 \pm .05) \times 10^{-6}$$

$$\lambda_{22} \text{ (actual-adjusted)} = -(19 \pm 6) \text{ degrees geographic longitude.}$$

As Appendix B will show, the principal *unknown* uncertainty of the reduction is the possible influence of higher order earth tesseral anomalies on the drift of Syncom II. When all relevant higher order anomalies in the earth's gravity potential are evaluated, the adjusted values above will probably remain

representative for an "average" triaxial potential field sufficient to consider for the future design of synchronous satellites. As a guess, the author would increase the upper limit of J_{22} to about $-(1.80)\times10^{-6}$ (based on some of the recent gravity potentials in Appendix B) for design purposes, based on an "average" triaxial geoid. A lower limit of $J_{22}=1.60\times10^{-6}$ for this purpose appears justifiable. The variance in the location of the major equatorial axis for the "average" triaxial geoid is not likely to change appreciably from the value quoted for the adjusted figure. The author is presently studying these higher order earth-gravity effects. The accumulated influence on synchronous satellites of all higher order earth anomalies, is believed to be small compared to the 2nd order anomaly. But it appears that close and continuing observations on the drift of these satellites will be rewarded in time by revelation of many of these "tesseral" anomalies to about 4th order with an absolute precision almost as good as that reported here for the 2nd order effect.

APPENDIX B

THE EARTH GRAVITY POTENTIAL AND FORCE FIELD USED IN THIS REPORT: COMPARISON WITH PREVIOUS INVESTIGATIONS

The gravity potential used as the basis for the data reduction in this study is the exterior potential of the earth derived in reference 10 for geocentric spherical coordinates referenced to the earth's spin axis and its center of mass. The infinite series of spherical harmonics is truncated after J_{44}. The nontesseral harmonic constants J_{20}, J_{30} and J_{40} are derived from reference 13.

The earth radius R_0 used in this study is:

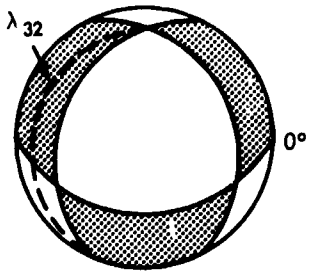
$$R_0 = 6378.388 \text{ km.}$$

The earth's gaussian gravity constant used is:

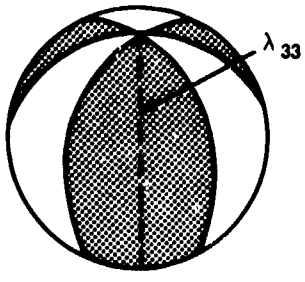
$$\mu_E = 3.9862677 \times 10^5 \text{ km}^3/\text{sec}^2.$$

Neither of these values, taken from reference 14, nor the "zonal geoid" of Reference 13, is felt to be the most accurate known to date. They are the values used by the GSFC Tracking and Data Systems Directorate to calculate the orbit elements of Syncom II from radar and Minitrack observations. They were chosen to insure consistency between the data of this study and these published orbits, inasmuch as the "triaxial" reduction for which this study has been undertaken is not significantly affected by the probable errors in these values. The second-order tesseral harmonic constants used in the simulation studies were

$$J_{22} = -1.68 \times 10^{-6}$$

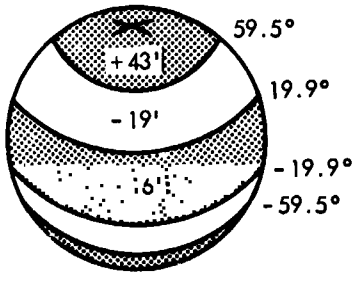


$$\lambda_{22} = -18°.$$

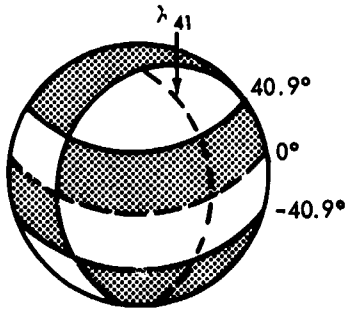


These are the values shown on the "tesseral geoid" below (for the J_{22} harmonic). At a later point in the analysis, the slightly different values reported in the abstract were estimated. The most accurate "zonal geoid" is probably that of Kozai (1962) [See Reference 6], with the following earth constants;

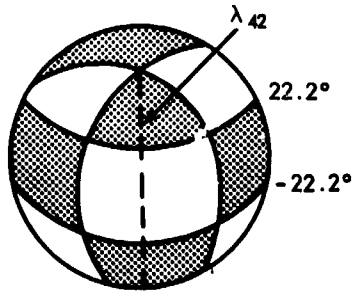
$$R_0 = 6.378.2 \text{ km}$$

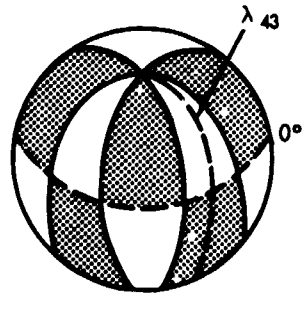


$$\mu_E = 3.98603 \times 10^5 \text{ km}^3/\text{sec}^2.$$

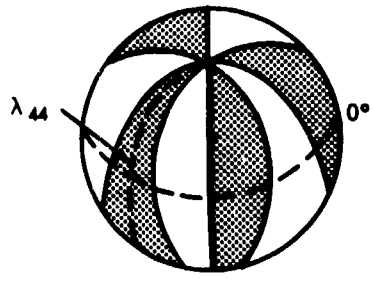


The earth's gravity potential (to fourth order, probably sufficient to account for all significant perturbations on a 24-hour satellite) may be illustrated as follows (following Reference 6, Appendix B):

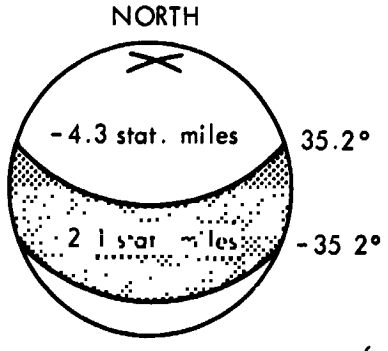


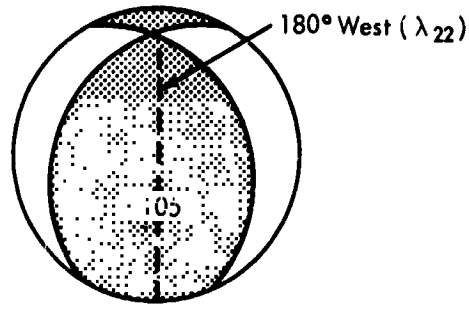


$$-15J_{32}\frac{R_0^3}{r^3}\cos^2\phi\sin\phi\cos 2(\lambda-\lambda_{32})-15J_{33}\frac{R_0^3}{r^3}\cos^3\phi\cos 3(\lambda-\lambda_{33})$$

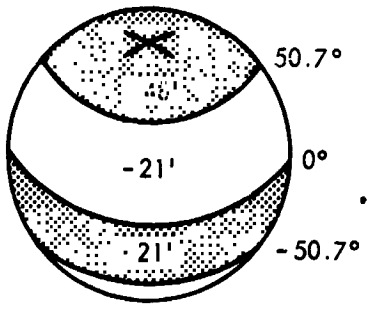


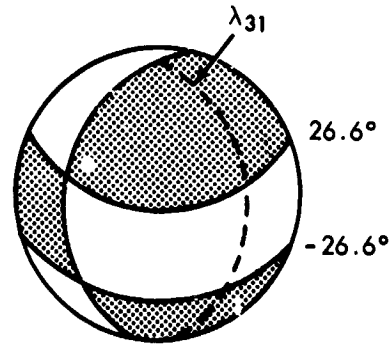
$$-\frac{J_{40}R_0^4}{8r^4}(35\sin^4\phi-30\sin^2\phi+3)-\frac{J_{41}R_0^4}{8r^4}[140\sin^3\phi-60\sin\phi]\cos\phi\cos(\lambda-\lambda_{41})$$





$$-\frac{J_{42}R_0^4}{8r^4}[420\sin^2\phi-60]\cos^2\phi\cos 2(\lambda-\lambda_{42})-\frac{J_{43}R_0^4}{8r^4}840\sin\phi\cos^3\phi\cos 3(\lambda-\lambda_{43})$$





$$-\frac{J_{44}R_0^4}{8r^4}840\cos^4\phi\cos 4(\lambda-\lambda_{44})$$

$$V_E=\frac{\mu_E}{r}\left\{1-\frac{\mu_{20}R_0^2}{2r^2}(3\sin^2\phi-1)-3J_{22}\frac{R_0^2}{r^2}\cos^2\phi\cos 2(\lambda-\lambda_{22})\right.$$

$$\left.-\frac{J_{30}R_0^3}{2r^3}(5\sin^3\phi-3\sin\phi)-\frac{J_{31}R_0^3}{2r^3}\cos\phi\cos(\lambda-\lambda_{31})(15\sin^2\phi-3)\right\} \qquad \text{(B-1)}$$

The earth-gravity field (per unit test mass) whose potential is (B-1) is given as the gradient of (B-1), or

$$\bar{F}=rF_r+\lambda F_\lambda+\phi F_\phi\pm\Delta V_E=r\frac{\partial V_E}{\partial r}+\frac{\lambda}{r\cos\phi}\frac{\partial V_E}{\partial\lambda}+\frac{\phi}{r}\frac{\partial V_E}{\partial\phi}, \qquad \text{(B-2)}$$

or

$$\begin{aligned}Fr=\frac{\mu_E}{r^2}\Big\{&-1+(R_0/)^2[3/2J_{20}(3\sin^2\phi-1)+9J_{22}\cos^2\phi\cos 2(\lambda-\lambda_{22})\\&+2(R_0/r)J_{30}(5\sin^2\phi-3)(\sin\phi)+6(R_0/r)J_{31}(5\sin^2\phi-1)\cos\phi\cos(\lambda-\lambda_{31})\\&+60(R_0/r)J_{32}\cos^2\phi\sin\phi\cos 2(\lambda-\lambda_{32})+60(R_0/r)J_{33}\cos^3\phi\cos 3(\lambda-\lambda_{33})\\&+5/8(R_0/r^2J_{40}(35\sin^4\phi-30\sin^2\phi+3)\\&+25/2(R_0/r)^2J_{41}(7\sin^2\phi-3)\cos\phi\sin\phi\cos(\lambda-\lambda_{41})\\&+75/2(R_0/r)^2J_{42}(7\sin^2-1)\cos^2\phi\cos 2(\lambda-\lambda_{42})\\&+525(R_0/r)^2J_{43}\cos^3\phi\sin\phi\cos 3(\lambda-\lambda_{43})+525(R_0/r)^2J_{44}\cos^4\phi\cos 4(\lambda-\lambda_{44})]\Big\}. \qquad \text{(B-3)}\end{aligned}$$

$$\begin{aligned}F_\lambda=\frac{\mu_E}{r^2}(R_0/r)^2\{&6J_{22}\cos\phi\sin 2(\lambda-\lambda_{22})+3/2(R_0/r)J_{31}[5\sin^2\phi-1]\sin(\lambda-\lambda_{31})\\&+30(R_0/r)J_{32}\cos\phi\sin\phi\sin 2(\lambda-\lambda_{32})+45(R_0/r)J_{33}\cos^2\phi\sin 3(\lambda-\lambda_{33})\\&+5/2(R_0/r)^2J_{41}[7\sin^2\phi-3]\sin\phi\sin(\lambda-\lambda_{41})+15(R_0/r)^2J_{42}(7\sin^2\phi-1)\cos\phi\sin 2(\lambda-\lambda_{42})\\&+315(R_0/r)^2J_{43}\cos^2\phi\sin\phi\sin 3(\lambda-\lambda_{43})\\&+420(R_0/r)^2J_{44}\cos^3\phi\sin 4(\lambda-\lambda_{44})\}. \qquad \text{(B-4)}\end{aligned}$$

*The J_{nn} and λ_{nn} reported in this table except in one or two instances, have been converted from the original author's set of gravity coefficients of which there are all too many forms in the literature. The blanks indicate the author did not consider that particular tesseral harmonic in fitting an earth potential to the observed data.

†Gravimetric or astro-geodetic tesseral geoids. All other geoid's are either pure satellite geoids or use all three kinds of gravity observations.

$$+420(R_0/r)^2J_{44}\cos^3\phi\sin\phi\cos 4(\lambda-\lambda_{44})\}. \qquad \text{(B-5)}$$

The actual sea-level surface of the earth is to be conceptualized through (B–1) as a sphere of radius 6378 km, around which are superimposed the sum of the separate spherical harmonic deviations illustrated. To these static gravity deviations, of course, must be added a centrifugal earth-rotation potential at the earth's surface, to get the true sea level surface (see Reference 10).

From Table B–1 and equation (B–3), the fourth-order tesseral geoids of Kaula (September 1963), Kozai (1962), Izsak (July 1963), and Zhongolovitch (1957) have been evaluated for the longitudinal perturbation force on a 24-hour satellite with zero inclination at $\lambda = -54.75°$ over the earth's surface (see Table B–2). The harmonics contributing to this perturbation are J_{22}, J_{31}, J_{33}, J_{42} and J_{44}. The results of this comparison are:

TABLE B–2.—*Comparison of Longitudinal Perturbation Forces on a 24-Hour Satellite, From Five Tesseral Geoids.*

	Full Field Longitude Acceleration [Units of 10^{-7} g_s*]	Ratio of Triaxial (J_{22}) Longitude Acceleration to Full Field Longitude Acceleration ($\lambda = -54.75°$)
Zhongolovitch (1957)	7.71	1.06
Kozai (1962)	1.08	1.28
Izsak (July 1963)	1.27	1.19
Kaula (Sept. 1963)	1.77	1.11
Wagner (this reduction: March 1964)	2.21	?

*g_s is the radial acceleration of earth gravity at the "synchronous" altitude ($g_s = 0.735$ ft/sec^2).

Judging from the consistency of the acceleration ratios among these investigators, the "actual" value of J_{22} (separated from higher order gravity effects) is probably somewhat higher than the -1.7×10^{-6} reported herein. All the geodesists reporting in Table B–2 agree that the next most influential earth tesseral at "synchronous" altitudes over most of the equator is J_{33}.

Appendix C

EXPRESSIONS FOR THE INCLINATION FACTOR

Equation (25) gives the inclination factor in the drift causing tangential perturbation (due to equatorial ellipticity) on a 24-hour satellite with a near-circular orbit, as

$$F(i) = \cos(i) + \frac{\Delta\lambda(\max)\,\sin^2(i)}{2} \tag{C-1}$$

$\Delta\lambda$(max.) is the absolute value of the maximum longitude excursion of the figure-8 ground track of the 24-hour satellite (with a near-circular orbit) from the geographic longitude of the nodes.

From (18), this longitude excursion function is

$$\Delta\lambda = \lambda - \lambda_0 = \tan^{-1}[\cos(i)\,\tan\theta] - \theta \tag{C-2}$$

Differentiating (C-2) with respect to the argument angle θ, the minimax excursion arguments are found from

$$\frac{d(\Delta\lambda)}{d\theta} = 0 = \frac{\cos(i)\,\sec^2\theta}{1+\cos^2(i)\,\tan^2\theta} - 1. \tag{C-3}$$

Solving (C-3) for sin θ at $\Delta\lambda$ (minimax),

$$\sin\theta_{\Delta\lambda(\text{minimax})} = [\cos(i)+1]^{-1/2}, \text{ from which}$$

$$\tan\theta_{\Delta\lambda(\text{minimax})} = \sec(i), \tag{C-4}$$

(C-4) in (C-2) gives

$$\Delta\lambda(\text{minimax}) = \tan^{-1}[\cos(i)\,\sec(i)] - \tan^{-1}\sec(i).$$

Thus, since only the absolute value of $\Delta\lambda$ (minimax) is required,

$$\Delta\lambda(\max) = \tan^{-1}[\sec(i)] - 45°, \tag{C-5}$$

where the $\tan^{-1}$ is to be taken in the first quadrant. For example: for $i = 30°$, (C-5) evaluates the maximum excursion as

$$\Delta\lambda(\max) = 49.1° - 45° = 4.1°.$$

The nodal argument angle at this maximum longitude excursion is

$$\theta[\text{at } \Delta\lambda(\max)] = \pm 49.1° \text{ from the nodes.}$$

The assumption in (20) that the excursion in longitude from the ascending node could be approximated by

$$\Delta\lambda - \Delta\lambda(\max)\,\sin 2\theta,$$

predicts the maximum excursion argument as

$$\theta[\text{at } \Delta\lambda(\max)] = \pm 45° \text{ from the nodes.}$$

This discrepancy in the assumed longitude excursion function is not serious until $i > 45°$, as simulated trajectories with variable inclination have borne out.

(C–5) can be written as

$$\Delta\lambda(\max) + 45° = \tan^{-1}[\sec(i)], \text{ from which}$$

$$\tan[\Delta\lambda(\max) + 45°] = \sec(i) \doteq \frac{1+\Delta\lambda(\max)}{1-\Delta\lambda(\max)}, \tag{C-6}$$

for $i < 45°$. Solving (C–6) for $\Delta\lambda$ (max),

$$\Delta\lambda(\max) = \frac{1-\cos(i)}{1+\cos(i)}, \tag{C-7}$$

approximately.

Thus the inclination factor becomes approximately

$$\begin{aligned} F(i) &= \cos(i) + \frac{\sin^2(i)[1-\cos(i)]}{2[1+\cos(i)]} \\ &= \cos(i) + \frac{[1-\cos(i)]^2}{2} = \frac{2\cos(i) + 1 - 2\cos(i) + \cos^2(i)}{2} \\ &= \frac{\cos^2(i)+1}{2} \end{aligned} \tag{C-8}$$

For example: For $i = 30°$,

$$F(i)_{\text{from (C-1)}} = .86603 + 4.1/8 \times 57.3 = .8750$$

$$F(i)_{\text{from (C-8)}} = .8750.$$

The agreement of $F(i)$ from forms (C–1) or (C–8) is good to the third decimal place as long as the inclination is less than 45 degrees. At inclinations higher than 45 degrees, however, the drift theory following (20) begins to break down because $\Delta\lambda(\max)$ is no longer a small angle.

Appendix D

DERIVATION OF THE EXACT ELLIPTIC INTEGRAL OF DRIFT MOTION FOR A 24-HOUR SATELLITE WITH A NEAR-CIRCULAR ORBIT: COMPARISON OF THE EXACT SOLUTION WITH THE APPROXIMATE SOLUTIONS FOR PERIODS VERY CLOSE TO SYNCHRONOUS

The differential equation (33) of 24-hour satellite drift is analogous to the equation describing the large-angle oscillations of a mathematical pendulum (see Reference 11), as in Figure D–1.

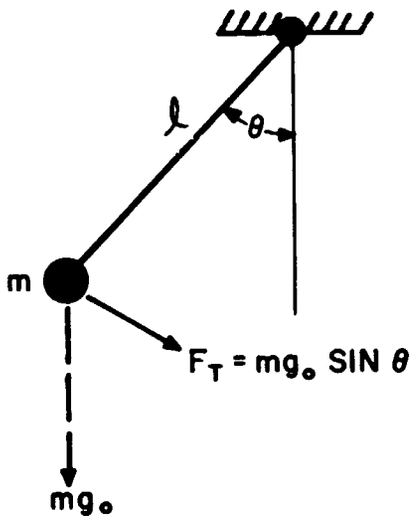

FIGURE D–1.—Configuration of a "mathematical pendulum."

The equation of angular motion of the mass m under the constant gravity force mg_0 is

$$F_T = \mathrm{mg}_0 \sin\theta = m(\dot{\ell}\dot{\theta}) = m\ell\ddot{\theta} \tag{D-1}$$

(D–1) can be rewritten as

$$\ddot{\theta} + (g_0/\ell)\sin\theta = 0. \tag{D-2}$$

From the theory developed in Reference 11 (pp. 327–335), (D–2) has an integral

$$t \text{ (time from } \theta = 0) = (\ell/g_0)^{1/2} F(k, \phi). \tag{D-3}$$

where $F(k, \phi)$ is the elliptic integral of the first kind with argument (or amplitude) $\phi = \sin^{-1}\left[\dfrac{\sin\theta/2}{\sin\theta\ (\max)/2}\right]$, and modulus $k = \sin\theta\ (\max)/2$.

Equation (33):

$$\ddot{\gamma}+A_{22}\sin 2\gamma=0,$$

with maximum libration angle γ_0, can be put in the form of (D–2) by the transformation of the dependent variable

$$\theta=2\gamma, \tag{D-4}$$

with the parameter identification

$$g_0/\ell=2A_{22}. \tag{D-4A}$$

(D–4) implies the identification

$$k=\sin\gamma_0, \qquad \phi=\sin^{-1}[\sin\gamma/\sin\gamma_0]. \tag{D-4B}$$

The pendulum solution (D–3), under the transformation (D–4) and identifications (D–4A) and (D–4B) becomes

$$t \text{ (time of drift libration from } \gamma=0)=(1/2A_{22})^{1/2}\,F(\sin\gamma_0,\,[\sin^{-1}\sin\gamma/\sin\gamma_0]), \tag{D-5}$$

$F(k, \phi)$, in its full integral form, is

$$F=\int_0^{\phi}\frac{d\phi}{(1-k^2\sin^2\phi)^{1/2}}, \tag{D-6}$$

(where $k^2=\sin^2\gamma_0$, $\sin^2\phi=\sin^2\gamma/\sin^2\gamma_0$) for the drift libration. In particular, when $\phi=\pi/2$; then $\gamma=\gamma_0;\dot{\gamma}_0=0$, and the pendulum-drift libration has completed a quarter-period.

Thus, from (D–5) and (D–6), the full period of the long-term drift libration of the 24-hour satellite ground track about the nearest minor equatorial axis longitude is

$$T(\gamma_0)=[8/A_{22}]^{1/2}\int_0^{\pi/2}\frac{d\psi}{(1-\sin^2\gamma_0\sin^2\psi)^{1/2}}. \tag{D-7}$$

The adequacy of the Taylor series expansion approximation of the drift motion in the neighborhood of γ_0, given in equation (51), may be tested against the exact drift solution implicit in (D–5). Table D–1 below gives the evaluation of F for arguments within 5° of $\gamma_0=60°$, using the integral tables in Reference 12.

TABLE D-1.—*Exact and Approximate Drifts of a 24-Hour Satellite from a Stationary Configuration 60° East of the Earth's Minor Equatorial Axis.*

$\gamma_0=60°$	γ (degrees)	γ' (degrees)	γ'' (degrees)	ϕ (degrees)	F (rad.)	ΔF (rad.)	Δt (days from $\gamma=60°$)
$A_{22}=23.2\times10^{-6}$ rad/day^2	60.0	60.0	60	90	2.1565	----------	----------
	59.0	59.003	59.000	81.7967	1.8730	.2835	41.619
	58.0	58.014	58.001	78.3056	1.7564	.4001	58.737
	57.0	57.029	56.999	75.5595	1.6671	.4894	71.846
	56.0	56.051	56.999	73.1938	1.5923	.5642	82.827
	55.0	55.077	54.996	71.0617	1.5265	.6300	92.487

In Table D–1, ΔF is the change in the elliptic integral from the "stationary" configuration at $\gamma=60°$ or $\phi=90°$. $\Delta t=(1/2A_{22})^{1-2}\Delta F$. A_{22} was computed from (30A) with the following gravity-earth

constants and for the inclination of Syncom II:

$$R_0 = 6378.2 \text{ km}$$

$$a_s = 42166 \text{ km}$$

$$J_{22} = -1.7 \times 10^{-6}$$

$$i = 33°.$$

γ' gives the drift position as calculated from the first righthand term of (51) alone (the $(\Delta t)^2$ term). γ'' gives the drift position as calculated from the first two righthand terms of (51). The "actual" Syncom II drift in mid-August 1963 began, apparently, at a γ_0 between 48° and 58° east of the minor axis. Thus, the 16 orbits chosen for the first drift period all should be well represented by the $(\Delta t)^2$-only theory, within the rms error of the longitude observations. Similar exact calculations for $\gamma_0 = 45°$, 50°, and 55° confirm the adequacy of the $(\Delta t)^2$-only theory to apply to the second drift-period orbits. They also prove the contention in section 5 that, for reasonably small excursions from "synchronism," the convergence of the Taylor series (51) is adequate if additional terms are included only when they become of a certain minimum significance to the total drift.

The Orbit elements for Syncom II in Table E-1 were calculated at the Goddard Space Flight Center from radar and Minitrack observations made during the slow drift periods from mid-August 1963 to February 1964.

As an example of the estimation of the ascending equator crossing nearest to epoch, consider the orbit geometry at epoch (Figure E-1).

6 January 1964 at 17.0 hours Universal Time (orbit 2-5).

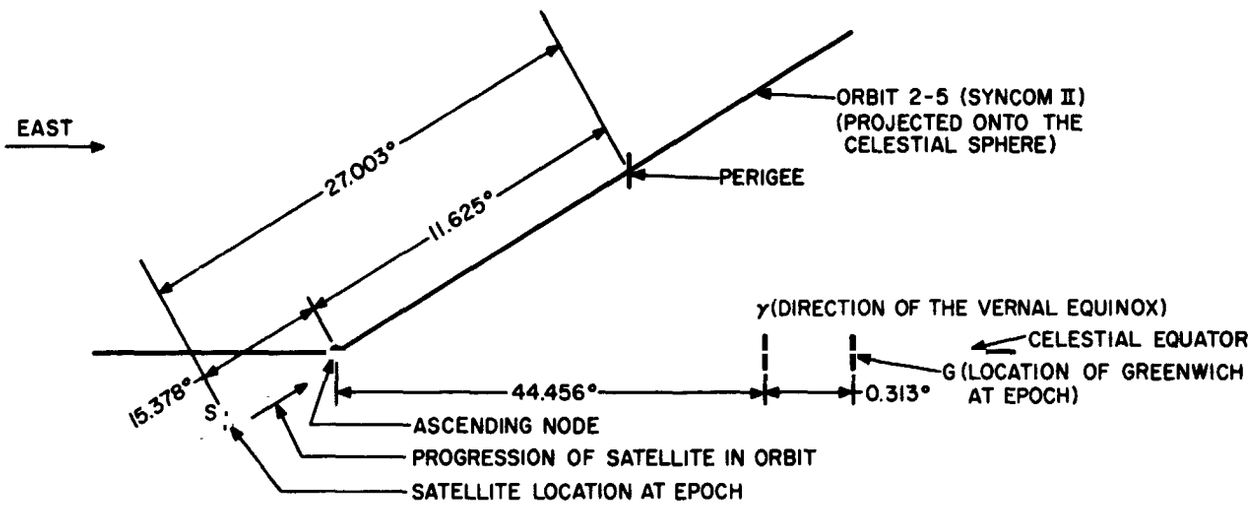

FIGURE E-1.—A portion of the celestial sphere at the epoch of orbit 2-5.

On 6.0 January 1964, the hour angle of the vernal equinox Λ *west* of Greenwich (expressed in hours, with 24 hours = 360°) was

6 hrs. 58 minutes 27.484 seconds (from the Nautical Almanac)

On 7.0 January 1964, the hour angle of Λ was

7 hrs. 2 min. 24.036 sec.

Interpolating, the hour angle of Λ on 6 January at 17 hours Universal Time was

0 hours 1 minute 15.042 seconds, or

0.313 degrees west of Greenwich.

In Figure E–1, the orbit angle 27.003° is taken directly as 360° − the mean anomaly, because the orbit is nearly circular. The reported period for this orbit was

$$T_p = 1436.21696 \text{ minutes.}$$

The earth's sidereal rotation period is taken to be

$$T_{\text{earth}} = 1436.06817 \text{ minutes.}$$

Thus, if the satellite is assumed to traverse orbit 2–5 at a nearly uniform rate, it will reach the celestial equator at a time when the Greenwich meridian has proceeded eastward from the epoch

$$15.378 \times 1436.21696/1436.06817 = 15.380°.$$

Thus, the estimated geographic longitude of the ascending equator crossing nearest to the epoch of orbit 2–5 is

$$\text{Ascending equator crossing longitude} = -(44.456+0.313+15.380)$$
$$= -60.149°.$$

The estimated time of this crossing is

$$15.380°/15°^{/hr.} = 1.025 \text{ hours after the epoch.}$$

The crossing time (Table 1) is thus estimated to be at

6.751 January 1964 (18.025/24+6.0, January 1964).

Appendix F

CALCULATION OF THE RADIATION PRESSURE ON SYMCOM II

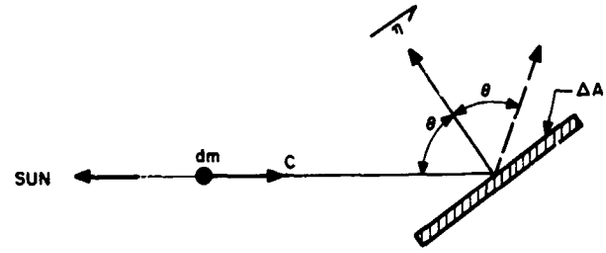

FIGURE F-1.—Flat plate ΔA of satellite surface, with normal η at angle θ with respect to sun's rays.

Consider a flat-plate element ΔA, of the surface of Syncom II, whose normal $\bar{n}$ is at angle θ with respect to the sun's rays (Figure F–1). The sun's radiant energy can be thought of as being made up of a stream of material particles such as dm, moving at the speed of light c. If the energy of each particle is dE, then from Einstein's classical energy-mass equivalence statement,

$$dm = dE/c^2 \tag{F-1}$$

Upon striking the surface, the incident radiation may:

- Reflect completely off the surface at an equal "reflection" angle, undegraded in energy
- Be absorbed into the body of the plate as thermal energy and partially reradiated in all directions from the surface at a reduced flux, depending on the surface and on the thermal properties of the plate and body of the spacecraft
- Be partially "reflected" and absorbed and reradiated, depending on the surface properties of the plate

An estimate of the radiation pressure on Syncom II will be calculated assuming complete light absorption with no reradiation. This is not the most conservative condition but will serve to show the order of magnitude of the effect.

Light-particle dm has $c\,dm$ momentum in the direction of the sun's rays before striking the plate element ΔA. Thus $(c)\,dm$ momentum is transferred to the plate with each light-particle collision. From Newton's second-law, the impulse transferred to the plate in the time of action dt, of dm alone, is;

$$\int_0^{dt} (dF)_{dm}\,dt = (c)dm, \tag{F-2}$$

dF acts on the plate element in the direction of the sun's rays. Assume that the discontinuous collision processes of (F–2) are so frequent as to amount to a smooth transfer of momentum between the stream of light particles and the plate; dt can then be replaced by Δt, a small but finite time interval; $(dF)_{dm}$ by ΔF, a smooth, constant small reactive force on the plate element ΔA; and dm can be replaced by Δm, a small but finite light particle mass impinging on the plate surface ΔA in Δt time. (F–2) then becomes

$$\Delta F(\text{radiation force})\ \Delta t = (c)\Delta m, \text{ or}$$

$$\Delta F(\text{radiation force}) = (c)\frac{\Delta m}{\Delta t}. \tag{F-3}$$

By the mass-energy equivalence relation (F–1) written for the finite small elements involved in the continuous momentum transfer,

$$\Delta m = \Delta E/c^2, \tag{F–4}$$

where ΔE is the energy flux falling on plate element ΔA in Δt time. Clearly,

$$\Delta E = \rho \Delta A \cos\theta(\Delta t), \tag{F–5}$$

where ρ is the sun's energy flux in units of energy/time-area, and $\Delta A \cos\theta$ is the projected area of the element in the direction of the sun's rays. Combining (F–3), (F–4) and (F–5);

$$\Delta F/\Delta A_p = \text{projected area-radiation pressure in the direction of the sun's rays} = p_s = \frac{\rho}{c}, \tag{F-6}$$

($\Delta A_p = \Delta A \cos\theta$ = projected area of the plate element in the direction of the sun's rays.)

The value of ρ outside the earth's atmosphere is estimated to be (see Reference 9)

$$\rho = 95.5 \text{ ft-pounds/ft.}^2\text{-sec.}$$

$$c = 9.835 \times 10^8 \text{ ft./sec.}$$

(F–6) thus becomes;

$$\rho_s \text{ (projected area-solar pressure against a fully absorbing surface in the direction of the sun's rays)} = .9725 \times 10^{-7} \text{ pounds/ft.}^2 \tag{F–7}$$

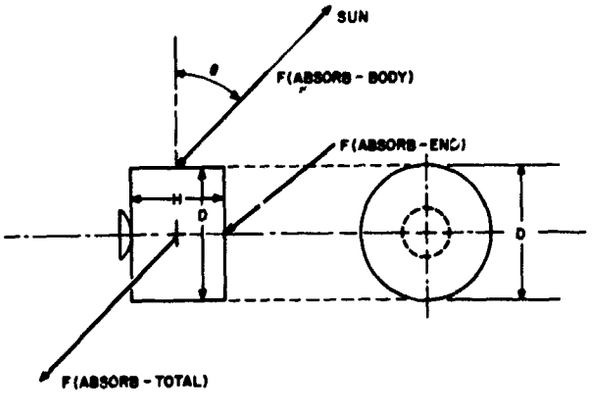

FIGURE F-2.—Configuration of Syncom II with respect to the sun during drift.

Figure F–2 shows the configuration of Syncom II with respect to the sun during the drift. For the cylindrical configuration in Figure F–2, from (F–7);

$$F(\text{absorb-total}) = F(\text{absorb-body}) + F(\text{absorb-end}) = .9725 \times 10^{-7}(HD\cos\theta + \pi D^2 \sin\theta/4) \tag{F–8}$$

The weight of Syncom II in the 24-hour orbit (including the apogee motor) is about 75 pounds. Other parameters are:

$$H = 15''$$

$$D = 28''$$

$$\theta = 21° \text{ (in late August 1963).}$$

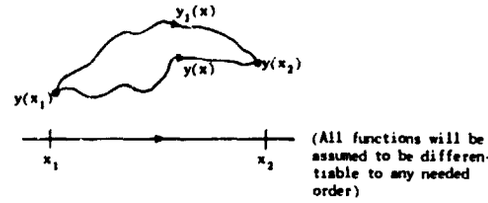
N64-33625

INTRODUCTION TO THE APPLICATION OF VON ZEIPEL'S METHOD

WILLIAM J. WICKLESS, JR.

INTRODUCTION

To understand the application of Von Zeipel's method in the case of a satellite orbiting under the influence of a gravitational field plus small perturbating forces, it is first necessary to summarize the development of several concepts of classical mechanics. Therefore, the first portion of this paper will be a brief resume of material which may be found in greater detail and slightly modified form in Chapters 7–8 of *Classical Dynamics of Particles and Systems* by Jerry B. Marion, Dept. of Physics, University of Maryland. A good knowledge of ordinary differential and integral calculus is assumed.



1. AN INTRODUCTION TO THE CALCULUS OF VARIATIONS

The basic problem of the calculus of variations is determining the unknown function $y(x)$ describing a path between two fixed end points we call $y(x_1)$ and $y(x_2)$ such that

$$I=\int_{x_1}^{x_2} f[y(x), y'(x), x]dx$$

takes on a maximum or minimum. f is a given function of the functions $y(x)$, $y'(x)$ and the independent variable x and the limits of integration are fixed. That is, if we wish to minimize I (say), we wish to find a function $y(x)$ such that if $y_1(x)$ is any other continuous function such that $y_1(x_1)=y(x_1)$, $y_1(x_2)=y(x_2)$ – any other path between $y(x_1)$ and $y(x_2)$ – then:

$$\int_{x_1}^{x_2} f[y(x), y'(x), x]dx \leq \int_{x_1}^{x_2} f[y_1(x), y_1'(x), x]dx$$

Two possible paths between $y(x_1)$ and $y(x_2)$ are sketched above.

Two possible paths between $y(x_1)$ and $y(x_2)$ are sketched above.

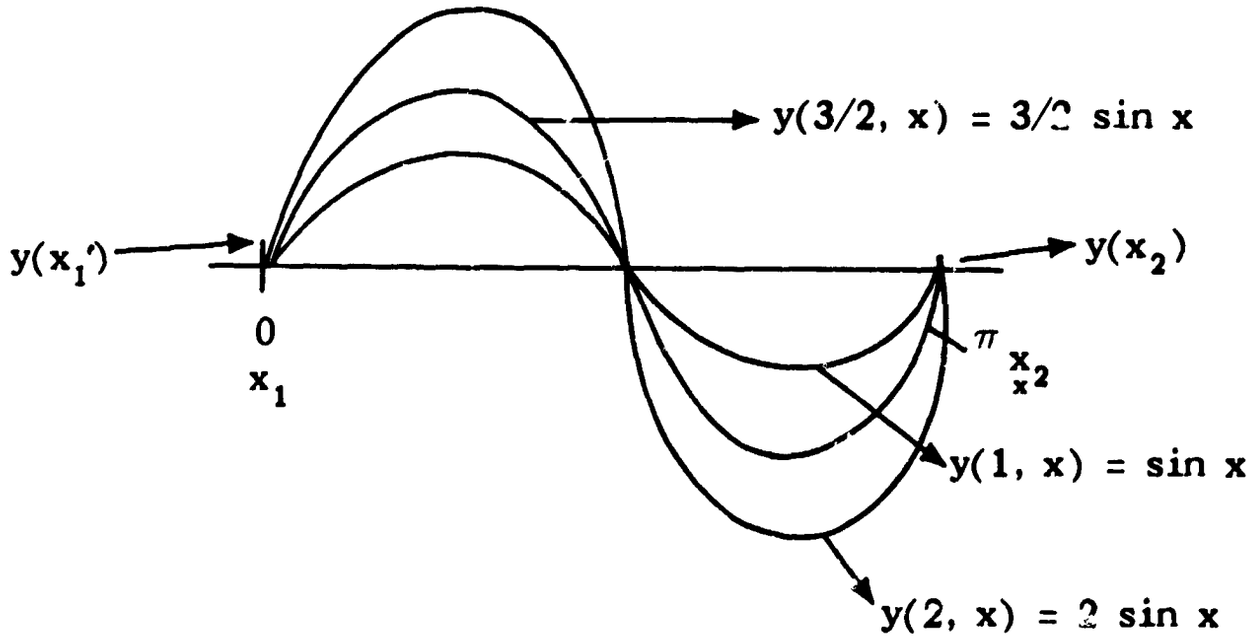
We will consider families of functions, giving possible paths between two fixed points $y(x_1)$, and $y(x_2)$, indexed by a parameter α, α running over a suitable segment of the real line. That is, we will consider families of the form

$$\{y(\alpha, x)\} \quad \begin{matrix} x\epsilon[x_1, x_2] \\ \alpha\epsilon[a, b] \end{matrix} \quad \text{with}$$

$$\left.\begin{matrix} y(\alpha, x_1)=y(x_1)=\text{constant} \\ y(\alpha, x_2)=y(x_2)=\text{constant} \end{matrix}\right\} \text{for all } \alpha\epsilon\,[a, b].$$

Then the integral I becomes a function of the parameter α:

$$I(\alpha)=\int_{x_1}^{x_2} f[y(\alpha, x), y'(\alpha,x), x]dx.$$



For example

$$I(\alpha)=\int_0^{2\pi} x(\alpha \sin x)dx \qquad \alpha\epsilon[1, 2]$$

where

$$y(\alpha, x)=\alpha \sin x$$
$$f[x, y(\alpha, x), y'(\alpha, x)]=xy(\alpha, x)$$
$$x_1=0,\ x_2=2\pi$$
$$y(x_1)=0\ y(x_2)=0$$

*Published as *Goddard Space Flight Center Document X-547-64-347*, September 1964

NOTE: $\alpha \sin(0) = 0$; $\alpha \sin 2\pi = 0$ for all $\alpha \epsilon [1, 2]$; $\{\alpha \sin x\}$ represents the family of paths between the pts $(0, 0) \equiv y(x_1)$, $(2\pi, 0) \equiv y(x_2)$ shown at top.

Now if the integral so written is to have an extremum along some path $y(\alpha_0, x)$

$$\alpha_0 \epsilon [a, b]$$

then

$$\left.\frac{\partial I(\alpha)}{\partial \alpha}\right|_{\alpha=\alpha_0} = 0.$$

This means

$$\left.\frac{\partial}{\partial \alpha}\int_{x_1}^{x_2} f[y(\alpha, x), y'(\alpha, y), x]dx\right|_{\alpha=\alpha_0} = 0.$$

since x is independent of α, the partial may be taken under the integral sign:

$$\left.\int_{x_1}^{x_2} \left[\frac{\partial f}{\partial y}\frac{\partial y}{\partial \alpha} + \frac{\partial f}{\partial y'}\frac{\partial y'}{\partial \alpha}\right]dx\right|_{\alpha=\alpha_0} = 0.$$

Now the above equation may be integrated by parts (see (1), Sec. 7-3) to obtain

$$\left.\int_{x_1}^{x_2} \left[\frac{\partial f}{\partial y} - \frac{d}{dx}\frac{\partial f}{\partial y'}\right]\frac{\partial y}{\partial \alpha}dx\right|_{\alpha=\alpha_0} = 0.$$

As f is assumed to be an arbitrary function of $y(\alpha, x)y'(\alpha, x)x$, the integrand itself must vanish:

$$\left[\frac{\partial f}{\partial y} - \frac{d}{dx}\frac{\partial f}{\partial y'}\right]\left.\frac{\partial y}{\partial \alpha}\right|_{\alpha=\alpha_0} = 0$$

for all $x \epsilon [x_1, x_2]$.

Also since $\{y(\alpha, x)\}$ is an arbitrary family of paths, in general

$$\left.\frac{\partial y(\alpha, x)}{\partial \alpha}\right|_{\alpha=\alpha_0} \neq 0 \text{ along the curve}$$

$$y = y(\alpha_0, x)$$
$$x \epsilon [x_1, x_2]$$

therefore

$$\frac{\partial f}{\partial y)\alpha_0, x)} - \frac{d}{dx}\frac{\partial f}{\partial y'(\alpha_0, x)} = 0$$

for all $x \epsilon [x_1, x_2]$.

This is known as the Euler-Lagrange equation.

II. APPLICATION OF THE EULER-LAGRANGE EQUATION TO PHYSICAL SYSTEMS

It is known that if a particle is allowed to move between two fixed pts in the plane $x(t_1)$ and $x(t_2)$ in the time interval $[t_1, t_2]$ in any of the possible paths given by the family of curves $\{x(\alpha, t)\}$

$$t \epsilon [t_1, t_2] \quad \alpha \epsilon [a, b]$$

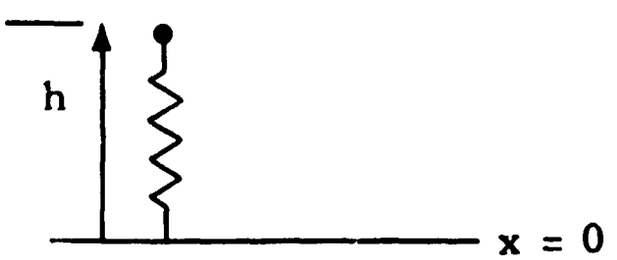
it will actually move in the path $x=x(\alpha_0, t)$ for which

$\int_{t_1}^{t_2}(T-U)dt$ is a relative extreme. (Note that this is a local condition.)

(see (1), Sec. 8.3)

Here T is the kinetic energy of the particle at the point $x(\alpha, t)-T=\frac{1}{2}m\dot{x}^2(\alpha, t)$—and U is the potential energy at the same pt $U=U(x(\alpha, t))$.

$\therefore$ along the path of the particle's motion $\bar{x}(t)=x(\alpha_0, t)$, the Euler-Lagrange equation must be satisfied by the quantity $L=(T-U)$. L is called the *Lagrangian* of the system.



Thus we have

$$\frac{\partial L}{\partial \bar{x}(t)}-\frac{d}{dt}\frac{\partial L}{\partial \bar{x}'(t)}=0.$$

If the Lagrangian of a system is known, the above equation may be integrated giving the path of the particles motion $x=\bar{x}(t)$.

EXAMPLE: Determination of the Equation of Motion for a Harmonic Oscillator

Let a particle of mass m be attached to a spring with spring constant K and relaxed length 0. Choose a co-ordinate system such that the point of equilibrium of the spring is at $x=0$. Let the mass be pulled to a distance h above the $x=0$ level and released at a time $t=0$. Find $x(t)$ (the bar is hereafter dropped for convenience)

Now for any time t, we have $T=\frac{1}{2}m\dot{x}^2(t)$ and $U=\frac{1}{2}Kx^2(t)$.

so $L=T-U=\frac{1}{2}m\dot{x}^2(t)-\frac{1}{2}Kx^2(t)$.

Now if $x(t)$ is the path followed by the particle, the Euler-Lagrange equation must be satisfied, i.e.

$$\frac{\partial L}{\partial x(t)}-\frac{d}{dt}\frac{\partial L}{\partial \dot{x}(t)}=0.$$

Now

$$\frac{\partial L}{\partial x(t)}=-Kx(t);\ \frac{\partial L}{\partial \dot{x}(t)}=m\dot{x}(t)$$

$$\therefore -Kx(t)=\frac{d}{dt}[m\dot{x}(t)]$$

or

$$\ddot{x}(t)+w_0^2x(t)=0 \text{ with } w_0\equiv\sqrt{K/m}.$$

This differential equation may be solved (see any elementary text) to obtain

$$x(t)=A\sin(w_0t+\delta)$$

where $A+\delta$ are constants of integration to be fitted to the initial data—in this case $A=h$, $\delta=\pi/2$.

Now an important thing to notice is that the Lagrangian is a scalar function (being the difference of kinetic and potential energies—both scalar functions). Thus we can, if desired, transform one co-ordinate variable $x(t)$ to a new variable $q(t)$ under some co-ordinate transformation ϕ and we have

$$L(x(t), \dot{x}(t), t)=\bar{L}(q(t), \dot{q}(t), t).$$

(This is actually the defining property of a scalar function).

The Euler-Lagrange equation is still valid:

$$\frac{\partial \bar{L}}{\partial q(t)}-\frac{d}{dt}\frac{\partial \bar{L}}{\partial \dot{q}(t)}=0.$$

Now as one final generalization, it is clear the original analysis could have been carried out to treat the case of a particle with more than one degree of freedom. The Lagrangian then would have been a function of several co-ordinate variables, their derivatives, and possibly the time, i.e.

$$L=L(x_1(t)\cdots x_n(t), \dot{x}_1(t)\cdots\dot{x}_n(t), t).$$

We then could proceed in a similar fashion [see (1), Sec. 7-7] to obtain, instead of the single equation

$$\frac{\partial L}{\partial x}-\frac{d}{dt}\frac{\partial L}{\partial \dot{x}}=0$$

the system of equations:

$$\frac{\partial L}{\partial xj}-\frac{d}{dt}\frac{\partial L}{\partial \dot{x}j}=0$$

$$j=1, 2\cdots N.$$

Now as this Lagrangian is still a scalar function, we may make if desired, a co-ordinate transformation ϕ from the position variables $\{x_1(t)\cdots x_n(t)\}$ to some new set of variables $\{q_1(t)\cdots q_n(t)\}$ and we still have:

$$\bar{L}(q_1\cdots q_n, \dot{q}_1\cdots\dot{q}_n, t)=L(x_1\cdots x_n, \dot{x}_1\cdots\dot{x}_n, t)$$

And also

$$\frac{\partial \bar{L}}{\partial qj}-\frac{d}{dt}\frac{\partial \bar{L}}{\partial \dot{q}j}=0. \quad j=1\cdots n(a)$$

It is important to note that the new variables may be chosen as a set of *any N functions* $q_1(t)\cdots q_n(t)$ at all as long as the Lagrangian may be expressed as $L=L(q_1(t)\cdots q_n(t), q_1(t)\cdots\dot{q}_n(t)t)$. In a real problem, a set of variables $q_1(t)\cdots q_n(t)$ are usually chosen so that L may be easily expressed as $\bar{L}(q_1\cdots q_n\dot{q}_1\cdots\dot{q}_n\, t)$. Then the system (a) is integrated, giving $qj=qj(t,$ constants of integration$)$ $j=1\cdots n(b)$.

Finally the transformation ϕ is inverted and ϕ^{-1} is applied to (b), yielding

$$xj=xj(t) \quad j=1\cdots N.$$

The vector $\vec{r}(t)=(x_1(t)\cdots x_n(t))$ is then the position vector of the particle under consideration.

III. CONSTRUCTION OF THE HAMILTONIAN; THE CANONICAL EQUATIONS OF MOTION

Now let us consider a system in which (1) the Lagrangian is not an explicit function of the time, i.e. $L=L(q_1(t)\cdots q_n(t), \dot{q}_1(t)\cdots\dot{q}_n(t))$ and (2) the q_j's have been obtained from the x_j's by some transformation ϕ that does not explicitly involve the time.

Let us define N new quantities:

$$Pj\equiv\frac{\partial L}{\partial \dot{q}_j} j=1, 2\cdots N. \quad (I)$$

P_j is called the *conjugate momentum* associated with q_j.

Using this definition, the Euler-Lagrange equations for our system may be rewritten in the form

$$\dot{P}j=\frac{\partial L}{\partial q_j} j=1, 2\cdots N. \quad (II)$$

Now let us define a new quantity

$$H\equiv \Sigma P_j\dot{q}_j-L.$$

H is called the *Hamiltonian* of the system, and under assumptions (1) and (2) above, it can be shown that H is equal to the total energy of the particle under consideration. $H=T+U$. (See (1), Sec. 8–8).

Now if H is considered to be a function of q_j, P_j $j=1\cdots N$, then

$$dH=\sum_j\frac{\partial H}{\partial q_j}dq_j+\frac{\partial H}{\partial P_j}dP_j \quad (A)$$

also since

$$H=\sum_j P_j\dot{q}_j-L$$

$$dH=\sum_j P_j\, d\dot{q}_j+\dot{q}_j\, dP_j-\frac{\partial L}{\partial q_j}dq_j-\frac{\partial L}{\partial \dot{q}_j}dq_j$$

using (I) and (II), the above becomes

$$dH=\sum_j[P_j\, d\dot{q}_j-P_j\, d\dot{q}_j]+\dot{q}_j dP_j-\dot{P}_j dq_j$$
$$=\sum_j\dot{q}_j\, dP_j-\dot{P}_j\, dq_j. \quad (B)$$

Now identifying the coefficients of dP_j & dq_j in (A) and (B) we have

$$-\dot{P}_j=\frac{\partial H}{\partial q_j}\dot{q}_j=\frac{\partial H}{\partial P_j} \quad j=1, 2\cdots N.$$

These are called the *cyclic equations of motion.* As in the case of the Euler-Lagrange equations, they may be integrated to obtain the equations of motion of the particle under consideration.

We will now consider our problem—determination of the equations of motion for a satellite orbiting under the influence of a gravitational field plus small perturbations (e.g. the effects of the earth's oblateness.) The following (sec. IV) is a summary of a portion of the material found in the paper "Notes on Von Zeipel's Method" by Giorgio E. O. Giacaglia, published at the Goddard Space Flight Center.

IV. VON ZEIPEL'S METHOD

In the case we are considering, the Hamiltonian may be expressed as a function of six variables (L, G, H, ℓ, g, h) where L, G, H are the conjugate momenta associated with ℓ, g, h respectively. These six variables are called the *Delaunay variables.*

The equations to be integrated for our problem then are:

$$\dot{\ell}=\frac{\partial H}{\partial L}\ \dot{g}=\frac{\partial H}{\partial G}\ \dot{h}=\frac{\partial H}{\partial H}\quad -\dot{L}=\frac{\partial H}{\partial \ell}-\dot{G}=\frac{\partial H}{\partial g}-\dot{H}=\frac{\partial H}{\partial h}$$

here we have just taken the cyclic equations of motion and set $L=P_1$, $G=P_2$, $H=P_3$, $\ell=q_1$, $g=q_2$, $h=q_3$.

In many cases the negative of the Hamiltonian $F=-H$ is introduced; the cyclic equations of motion for our system then become:

$$\dot{\ell}=-\frac{\partial F}{\partial L}\quad \dot{g}=-\frac{\partial F}{\partial G}\quad \dot{h}=-\frac{\partial F}{\partial H}$$

$$\dot{L}=\frac{\partial F}{\partial \ell}\quad \dot{G}=\frac{\partial F}{\partial g}\quad \dot{H}=\frac{\partial F}{\partial h}.$$

Now in solving the above system, it would greatly simplify our problem if we could transform our variables (L, G, H, ℓ, g, h) to a new set of variables $(L', G', H', \ell', g', h')$ in which the new function F could be expressed in a form not explicitly containing one of the new variables (ℓ' say), i.e.

$$F'=F'(L', G', H'-g', h')$$

then

$$\dot{L}'=\frac{\partial F'}{\partial \ell'}=0;\qquad L'=\text{constant}.$$

Here we must remember that, for the cyclic equations of motion to be valid, the new variables must satisfy

$$L'=\frac{\partial L}{\partial \dot{\ell}'}\quad G'=\frac{\partial L}{\partial \dot{g}'}\quad H'=\frac{\partial L}{\partial \dot{h}'}$$

i.e. L', G', H' must be the conjugate momenta with respect to ℓ', g', h'. (This assumption was used to derive the cyclic equations of motion).

If the above equations are satisfied, then $(L', G', H', \ell', g', h')$ are said to be a *canonical set* of variables, and the transformation connecting the primed and unprimed variables is called a *canonical transformation* [assuming $F(L, G, H, \ell, g, h)=F'(L', G', H', -g', h')$ for all times t].

Now finding the desired canonical transformation connecting (L, G, H, ℓ, g, h) to a new set of variables $(L', G', H', \ell', g', h')$ for which $\partial F'/\partial \ell'=0$ is equivalent to finding a function $S=S(\ell, g, h, L', G', H')$, called a *generating function*, satisfying:

$$L=\frac{\partial S}{\partial \ell}\quad G=\frac{\partial S}{\partial g}\quad H=\frac{\partial S}{\partial h}$$

$$\ell'=\frac{\partial S}{\partial L'}\quad g'=\frac{\partial S}{\partial G'}\quad h'=\frac{\partial S}{\partial H'}.$$

This function S will determine an implicit transformation connecting (L, G, H, ℓ, g, h) and $(L', G', H', \ell', g', h')$ and it is known that the new set of variables will be canonical. (See *Planetary Theory* by Brown and Shook, sec. 5–3.)

We now shall give explicit formulas for determining S and F'. Here we first employ the assumption that our satellite is orbiting in a gravitational field, subject to small perturbing forces. We assume the function $F(L, G, H, \ell, g, h)$ can be expanded in a series

$$F=F_0+\sum_{j=1}^{\infty}F_j\lambda$$

where F_0 is the negative of the Hamiltonian calculated in the case of a body orbiting under the influence of gravity alone and λ is a small parameter. (For the calculation of $F_0=\mu^2/2L^2$ where $\mu=K^2M$, with K the Gaussian constant and M the mass of the orbited body; see any intermediate textbook in celestial mechanics.)

We assume similarly:

$$F=F_0'+\sum_{j=1}^{\infty}F_j\lambda^j$$

$$S=S_0+\sum_{j=1}^{\infty}S_j\lambda^j$$

where S_0 is the generating function determining the identity transformation, $S_0=L'\ell+G'g+H'h$. (In the Keplerian case the original set of variables are the ones desired; no transformation is necessary.)

Now to any order in λ, $F(L, G, H, \ell, g, h)=F'(L', G', H'-g', h')$. (Remember F' is not to be an explicit function of ℓ'.)

Look at this equation up to second order in λ, i.e.

$$F_0+\lambda F_1+\lambda^2F_2=F_0'+\lambda F_1'+\lambda^2F_2' \qquad (A)$$

now

$$L=\frac{\partial S}{\partial \ell}=\frac{\partial S_0}{\partial \ell}+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial \ell}=L'+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial \ell}.$$

$$g'=\frac{\partial S}{\partial G'}=\frac{\partial S_0}{\partial G'}+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial G'}=g+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial G}$$

with similar expressions for G, H, h'.

Substituting the above into (A), we have

$$F_0\left(L'+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial \ell}\right)+\lambda F_1\left(L'+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial \ell},\right.$$

$$\left.G'+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial g},\ H'+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial h},\ \ell,\ g,\ h\right)$$

$$+\lambda^2F_2\left(L'+\sum,\ G'+\sum,\ H'+\sum,\ \ell,\ g,\ h\right)$$

$$=F_0'L',\ G',\ H'-,\ g+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial G'}h'+\sum_{j=1}^{\infty}\lambda^j\frac{\partial S_j}{\partial H'}$$

$$+\lambda F_1'(L',\ G',\ H'-g+\Sigma,\ h+\Sigma)+\lambda^2F_2'(L',$$

$$G',\ H'-g+\Sigma,\ h+\Sigma.) \quad \text{(B)}$$

Now expanding the left side of (B) in a Taylor series around L, G, H and F'_1 and F'_2 on the right hand side in a Taylor series around g', h' and keeping only terms up to and including the second order in λ, we have

$$F_0(L')+\frac{\partial F_0}{\partial L}\left[\frac{\partial S_1}{\partial \ell}\lambda+\frac{\partial S_2}{\partial \ell}\lambda^2\right]+\lambda^2F_1(L',\ G',\ H',$$

$$\ell,\ g,\ h)+\lambda^2\left[\frac{\partial F_1}{\partial L}\frac{\partial S_1}{\partial \ell}+\frac{\partial F_1}{\partial G}\frac{\partial S_1}{\partial g}+\frac{\partial F_1}{\partial H}\frac{\partial S_1}{\partial h}\right]$$

$$+\lambda^2F_2[L',\ G',\ H',\ \ell,\ g,\ h]=F_0'(L',\ G',\ H'-g',\ h')$$

$$+\lambda F_1'(L',\ G',\ H'-g,\ h)+\lambda^2\left[\frac{\partial F_1'}{\partial g'}\frac{\partial S_1}{\partial G'}+\frac{\partial F_1}{\partial h'}\frac{\partial S_1}{\partial H'}\right]$$

$$+\lambda^2F_1'[L',\ G',\ H'-g,\ h] \quad \text{(C)}$$

Now equating the coefficients of like powers of λ in (C) we obtain

$$F_0'(L',\ G',\ H'-g',\ l')=F_0(L')=\frac{U^2}{2L'^2} \quad \text{(D)}$$

$$F_1(L',\ G',\ H',\ \ell,\ g,\ h)+\frac{\partial F_0}{\partial L}\frac{\partial S_1}{\partial \ell}$$

$$=F_1'(L',\ G',\ H'-g,\ h) \quad \text{(E)}$$

$$\frac{\partial F_0}{\partial L}\frac{\partial S_2}{F\ell}+\frac{\partial F_1}{\partial L}\frac{\partial S_1}{\partial \ell}+\frac{\partial F_1}{\partial G}\frac{\partial S_1}{\partial G'}+\frac{\partial F_1}{\partial H}\frac{\partial S_1}{\partial h}$$

$$+F_2(L',\ G',\ H',\ \ell,\ g,\ h)=\frac{\partial F_1}{\partial g'}\frac{\partial S_1}{\partial G'}+\frac{\partial F_1}{\partial h}\frac{\partial S_1}{\partial H'}$$

$$+F_2(L',\ G',\ H'-g,\ h). \quad \text{(F)}$$

Now F'_0 is determined by (D) so (E) may be solved by putting F'_1 = part of F_1 independent of ℓ. This means $(\partial F_0/\partial L)(\partial S_1/\partial \ell)=-(F_1-F'_1)$ $=-$(part of F_1 dependent on ℓ). Now F'_1 and S_1 are determined with the desired properties, and therefore (F) may be solved for S_2 by putting F'_2 = part of F_2 independent of ℓ.

This determines F'_2 and S_2 with the required properties. This process may be continued to determine F'_n and S_n to any desired order.

COMMENTS ON HIGH ENERGY X-RAYS BURSTS OBSERVED BY OSO-1*

KENNETH J. FROST

See N64-30227

Instrumentation aboard the first Orbiting Solar Observatory observed five separate instances of high energy X-ray bursts accompanying solar flares. The X-ray bursts were observed in the 20 to 100 Kev range. Data on the types of flares producing the X-ray bursts and the associated microwave radio bursts are presented.

INTRODUCTION

Among the experiments carried by OSO–1 in the pointed section was a scintillation counter designed to detect hard solar X-ray bursts in the 20 to 100 Kev energy range. The scintillation counter consisted of a cylindrical NaI(Tl) crystal 0.3 cm high and 2.24 cm in diameter and an R.C.A. C-7151 photomultiplier tube. The photomultiplier tube and crystal assembly was placed in a cylindrical copper shield which through an opening in the front end provided a field of view of 0.3 steradian. The copper shield had a wall thickness of 1 cm. The 3.8 cm^2 area of the front surface of the crystal was held normal to the solar direction by the pointing of the satellite. An aluminum disc of 0.08 cm thickness was placed over the front surface of the crystal. The efficiency of the detector in the 20 to 100 Kev interval was approximately 0.90.

The electronics associated with the detector consisted of lower and upper level discriminator circuits and a logarithmic ratemeter. The lower and upper level discriminator circuits were set to select only those pulses from the photomultitube which correspond to an energy loss of between 20 and 100 Kev. in the crystal. The pulses accepted by the discriminator circuits where then passed on to the logarithmic ratemeter. The output of the ratemeter was a voltage level between zero and five volts which corresponded to an input count rate between 10 and 10^4 counts per second. The output of the ratemeter was able to respond to changes in count rate that occurred in a time longer than 10 milliseconds.

The satellite telemetry system sampled the voltage level at the output of the ratemeter continuously for two seconds once every twenty seconds. This sampling format was operative during the entire daylight part of an orbit.

DATA

With the return of the first hundred orbits of reduced data the response of the detector to the general spacecraft X-ray background and the response to the regions ot trapped radiation was determined. In addition it was found that the experiment responded to the electron warm spots detected by an electron-proton spectrometer placed aboard the spacecraft by Schrader et al[1]. When passing through regions not including trapped radiation or electron warm spots the detector was found to produce a count rate for a 2 second sample that consistently fell between limits of 10.5 to 14.5 counts per second.

Only 17 March 1962 a short lived increase in count rate occurred while the satellite was passing through a region where the count rate normally fell in the background range of 10.5 to 14.5 counts per second. The increase in count rate started at 19:39:49 U.T. and ended at 19:40:08 U.T. A record of the satellite telemetry signal for the orbit containing this time period indicated conclusively that the fluctuation in count rate was real and could not be attributed to telemetry noise that

had been erroneously digitized by the automatic data reduction system. Reference to the available solar data revealed that a solar flare had been observed by the McMath-Hulbert and Lockheed Observatories between the times of 1934 to 1959 U.T. and 1936 to 2003 U.T. respectively. The flare was observed on the east limb of the sun and was classified by McMath-Hulbert as an importance 1 flare and by Lockheed as an importance 2 flare. Also at this time an impulsive radio burst of three minutes duration beginning at 19:39 U.T. and reaching maximum at 19:40:12 U.T. was observed at 2800 Mc/sec by Ottawa. Furthermore an SID accompanied the flare beginning at 19:40 U.T. and reaching maximum at 19:44 U.T. The very close correlation in the time of these events and the fluctuation of the 20 to 100 Kev count rate suggested that the most plausible explanation of the fluctuation was a burst of energetic X-rays produced by the flare.

During succeeding orbits of the spacecraft four more instances of rapid excursions in count rate were observed during the presence of a flare on the sun which produced an impulsive radio burst in the microwave range and an SID. These excursions in count rate were also interpreted as solar flare X-ray bursts. The history of these five events is presented graphically in Figures 1 through 5[2].

DISCUSSION

Prior to the launch of OSO-1 eight occurrences of high energy X-ray bursts accompanying solar

flares had been observed[3–7]. Kundu has analyzed the radio data associated with each of these events[8]. He has found that an impulsive microwave burst was associated with every X-ray burst whereas type III bursts and other meter wave events did not show as strong a correlation. Furthermore the general character of the microwave spectrum was found to be such that the peak flux observed at wavelengths in the 3 to 10 cm range was stronger than that observed at wavelengths in the 10 to 20 cm range. The radio data associated with the OSO-1 X-ray bursts as indicated in Fig. 1 through 5 appears to lend strong support to Kundu's analysis. Additional information of interest to this analysis is the fact that as far as can be determined from spectral observations in the meter wave range no type III bursts occurred during the X-ray events.

TEMPERATURE OF A GRAY BODY MOST CLOSELY FITTING THE SOLAR EXTRATERRESTRIAL SPECTRUM*

WILLIAM B. FUSSELL AND JOHN B. SCHUTT

A definition of "closeness" of fit of a gray body curve to the sun's extraterrestrial spectrum is presented. F. S. Johnson's data are used for the solar spectrum. For the wavelength interval 0.3 to 2.4 microns (pertinent to thermal design), the magnitude of C_1 calculated for use in Planck's black body formula is 8.6504×10^{-17} watt-cm² at a temperature of 5742 ± 0.5 °K.

INTRODUCTION

The problem of simulating the extraterrestrial solar illumination for testing the thermal design of satellites has recently become of wide interest. If the materials for the satellite surface have been selected, the problem reduces to one of matching the absorbed energy from the simulating source—for each material composing the surface—to the absorbed solar energy for that material. However, many materials have spectral absorptivity curves which vary slowly with wavelength between wavelength limits including most of the sun's energy. A solar simulator which matches the sun's spectrum fairly well on a finely resolved basis, and which matches the total energy exactly, will automatically match the solar absorptivities and the simulated absorptivities closely for these materials. To this end, the black body function was used in constructing a gray body curve for which a solar fit was obtained by parametrically varying the temperature.

METHOD

In establishing a closeness of fit criterion for approximating the sun's extraterrestrial spectrum by that of a black body, it seems pertinent at this point to recall the geometric interpretation of the quantities in the black body equation which can be treated as parameters. Consequently, any criterion which is established by means of parametric variations can only be defined as ultimate when it is the most valid one from geometric considerations.

From the black body definition

$$J_\lambda(T;\, C_1,\, C_2) = C_1\, J_\lambda(T;\, C_2) = \frac{C_1}{\lambda^5\, e^{C_2/\lambda T} - 1}, \qquad (1)$$

where λ is the wavelength in cm, T is the temperature in °K, and C_1 and C_2 are constants (or parameters). Any of the quantities T, C_1, and C_2 may be chosen as a parameter. First consider variations in C_1. It is clear that any change in the magnitude of C_1 shifts the spectral distribution up or down along the ordinate depending on the sign of the chosen change for C_1. Since the parameters C_2 and T are geometrically equivalent (in a reciprocal manner), only one of them need be considered; T was chosen because of its experimental accessibility. Variations in T affect the shape of the black body distribution and, of course, the wavelength at which the maximum spectral intensity occurs. Therefore, any criterion which is to be established for fitting the sun's extraterrestrial spectral distribution to Equation 1 can be determined by means of parametric variations in T and C_1, or a gray body fit.

The most straightforward approach is to find the temperature at which the black body maximum matches the sun's maximum, 0.475 micron. This temperature is readily found to be 6060°K. But this method gives a black body curve which contains a greater integrated energy than the sun's integrated spectral distribution, since by

*Published as *NASA Technical Note* D-1845, August 1964

definition the black body distribution gives an upper limit to the emissive ability of any body at a given temperature. Consequently, an upper bound on the required temperature has been established from this matching process. Next, an estimate of the lower bound can be found. To accomplish this, C_1 and T may be varied in an effort to minimize the residual

$$R = \int |J_\lambda(T;\ C_1,\ C_2) - H_\lambda| d\lambda \quad , \qquad (2)$$

where H_λ and the vertical lines represent the sun's spectral distribution and absolute magnitude, respectively. From Equation 2 the lower bound is found to be approximately 5738°K. It is apparent that Equation 2 alone cannot give the required closeness of fit to the desired accuracy because one criterion cannot be used to minimize a bivariant distribution. The final criterion, the one defined as geometrically ultimate and, consequently, most pertinent from the thermal design viewpoint, is the system:

$$R_{Min} = \text{Min} \int |J_\lambda(T;\ C_1,\ C_2) - H_\lambda| d\lambda \qquad (3)$$

and

$$\int J_\lambda(T;\ C_1,\ C_2) d\lambda = \int H_\lambda \, d\lambda \quad . \qquad (4)$$

The addition of Equation 4, to establish the most meaningful criterion, allows a temperature to be found by using matched areas as the basis. The absolute magnitude in Equation 3 is necessary in order to insure that the total deviation between the two curves is minimized. From Equation 1 it is clear that C_1 can be eliminated in Equation 3 by means of Equation 4, which gives a single relation for the determination of T. These equations give a temperature of 5742 ± 0.5°K and a value of 8.65040×10^{-17} watt-cm² for C_1 for the 0.3 to 2.4 micron (μ) region.

It remains to show that Equation 2 should give results identical to Equations 3 and 4, indicating therefore that 5742°K is the desired temperature. If the spectral region of interest is broken into intervals of $J_\lambda(T;\ C_1) > H_\lambda$ and $J_\lambda(T;\ C_1) < H_\lambda$, where the intervals of the first kind are designated by $\Delta_{1,1}$ and those of the second kind by $\Delta_{2,1}$, then Equations 2 and 3 may be rewritten:

$$\int_{\Delta_{1,1}} |J_\lambda(T;\ C_1) - H_\lambda| d\lambda + \int_{\Delta_{2,1}} |J_\lambda(T;\ C_1) - H_\lambda| d\lambda$$

$$= \int_{\Delta_{1,1}} C_1 \bar{J}_\lambda(T) d\lambda - \int_{\Delta_{1,1}} H_\lambda \, d\lambda - \int_{\Delta_{2,1}} C_1 \bar{J}_\lambda(T) d\lambda + \int_{\Delta_{2,1}} H_\lambda \, d\lambda \quad . \qquad (5)$$

where the first subscript of Δ refers to the interval type and the second is an index which enumerates subintervals. When the derivatives of the right-hand side of Equation 5 (ignore Equation 4) are taken with respect to C_1 and T in an effort to obtain simultaneous equations for C_1 and T, the following results are obtained:

$$\int_{\Delta_{1,1} \cdot \Delta_{2,1}} \bar{J}_\lambda(T) d\lambda = 0$$

and

$$C_1 \int_{\Delta_{1,1} \cdot \Delta_{2,1}} \frac{\partial}{\partial T} \bar{J}_\lambda(T) = 0 \quad .$$

Consequently, Equation 4 must be included in order to define C_1 and obtain the desired results. This implies the equivalence of Equation 2 and the system of Equations 3 and 4. By taking the derivative of the right-hand side of Equation 5 with respect to T and equating the result to zero in order to obtain a minimum (make use of Equation 4), Equation 5 may be rewritten:

$$\int_{\Delta_{1,1}} |J_\lambda(T;\ C_1) - H_\lambda| d\lambda + \int_{\Delta_{2,1}} |J_\lambda(T;\ C_1) - H_\lambda| d\lambda \leq \epsilon \quad . \qquad (6)$$

where ϵ is a number characterizing the fit of the black body curve to the sun's distribution and $\Delta_{1,i}$ and $\Delta_{2,i}$ become the sets $\{\Delta_{1,i}\}$ and $\{\Delta_{2,j}\}$, respectively, with $1 \leq i \leq N$ and $1 \leq j \leq M$. If the fit is exact, $\epsilon = 0$ and the equality sign holds; however, if the fit is not exact, the left-hand side of Equation 5 gives the best fit, which means that Equations 3 and 4 give the desired temperature.

RESULTS

The results given after each method of calculation described in the previous section are for the wavelength range of $0.3-2.4\ \mu$. Calculations were also made for the intervals $0.4-1.2$ and $0.220-7.0\mu$; the former region is of interest for purposes of solar cell illumination, and the latter is a complete cover of Johnson's data.* All results are given in Table 1. The auxiliary range of $0.3-2.0\mu$ is included for comparison purposes.

It is apparent that the best fit (2.97 percent) was obtained for the $0.4-1.2\mu$ region, which indicates that the adjusted black body curve conforms reasonably well to Johnson's data throughout the visible and into the near infrared. Less satisfactory agreement (6.08 percent) was obtained for the region of $0.3-2.0\mu$ because a single black body formula cannot be made to fit the steep rise in emissiveness characteristic of the sun's radiation in the region of $0.34-0.4\mu$. Agreement is enhanced, however, when the region is extended to 2.4μ because the additional $2.0-2.4\mu$ region, where the fit is good, makes the subvisible region ($0.34-0.4\mu$) of somewhat less weight. The fit for the complete range covered by Johnson's data, $0.220-7.0\mu$, is least satisfactory. The black body curve (with only two adjustable parameters) cannot be made to fit the steep rise in the $0.220-0.4\mu$ region as well as the tail of the sun's spectral distribution in the infrared.

Table 1

Results of Gray Body Fit to Solar Extraterrestrial Spectrum.

Range (microns)	T (°K)	C_1 (watt-cm^2)	$\int H_\lambda d\lambda$ (watt/cm^2)	$\int \lvert J_\lambda - H_\lambda \rvert d\lambda$ (watt/cm^2)	$\frac{\int \lvert J_\lambda - H_\lambda \rvert d\lambda}{\int H_\lambda d\lambda} \times 100$
0.4 - 1.2	6142 ± 0.5	6.76111×10^{-17}	9.86137×10^{-2}	2.92699×10^{-3}	2.97
0.3 - 2.0	5730 ± 0.5	8.72019×10^{-17}	1.29419×10^{-1}	7.86669×10^{-3}	6.08
0.3 - 2.4	5742 ± 0.5	8.65040×10^{-17}	1.32629×10^{-1}	7.88560×10^{-3}	5.94
0.220 - 7.0	5693 ± 0.5	8.80334×10^{-17}	1.39424×10^{-1}	1.03376×10^{-2}	7.41

In order to clarify the fit to the solar extraterrestrial spectrum by the above gray body matching technique, a gray body curve was calculated for the $0.3-2.4\mu$ region. The gray body curve of this region for a temperature of 5742°K is compared with the solar data in Figure 1. According to column 6 of Table 1 the areal mismatch of these curves is 5.94 percent when computed relative to the solar constant. It can be concluded that a gray body curve agrees well with the solar data

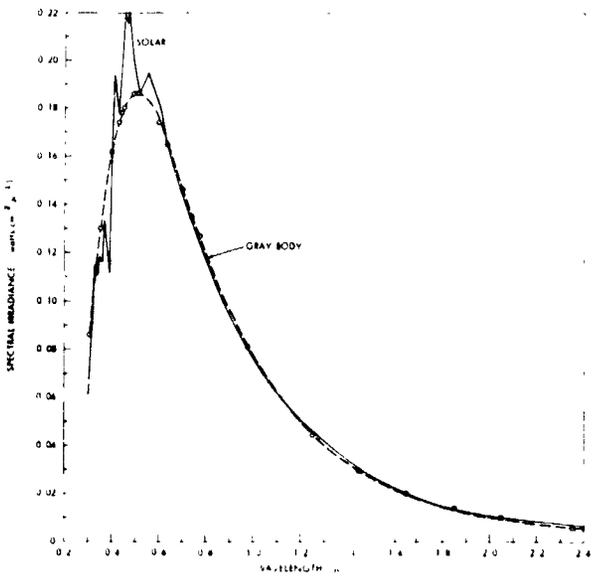

FIGURE 1.—Comparison of a 5742° K gray body curve with the solar extra terrestrial spectrum.

*Johnson, F. S., "The Solar Constant," *J. Meteorology* 11(6): 431–439, December 1954.

curve, except forthe irregular region of 0.41–0.55μ. What has happened is that virtually exact fits occurred at 0.43 and 0.52μ, and the intermediate irregularities could not be fit by a single gray body curve.

DISCUSSION

If the black body approximation to the solar spectrum is to be useful from the thermal design viewpoint, the average absorptance of a spacecraft coating material, as calculated from the black body spectrum, should be fairly close in value to the average solar absorptance of the material. Mathematically expressed, it is desirable that $\bar{a}_{BB} \approx \bar{a}_s$ where

$$\bar{a}_{BB} = \frac{\int_0^\infty a_\lambda J_\lambda(T)d\lambda}{\int_0^\infty J_\lambda(T)d\lambda} , \qquad (7)$$

and

$$\bar{a}_s = \frac{\int_0^\infty a_\lambda H_\lambda d\lambda}{\int_0^\infty H_\lambda d\lambda} , \qquad (8)$$

with

$\bar{a}_{BB}$ = the average absorptance for a black body,
$\bar{a}_s$ = the average solar absorptance,
H_λ = the solar spectral intensity per unit wavelength bandwidth, as given by Johnson,
$J_\lambda(T)$ = the Planck black body spectral intensity for absolute temperature T,
a_λ = the absorptance of the material at wavelength λ.

For simplicity, it is desirable to normalize H_λ and J_λ to H'_λ and J'_λ:

$$H'_\lambda = \frac{H_\lambda}{\int_0^\infty H_\lambda \, d\lambda} ,$$

$$J'_\lambda = \frac{J_\lambda}{\int_0^\infty J_\lambda \, d\lambda} .$$

Equations 7 and 8 now become

$$\bar{a}_{BB} = \int_0^\infty a_\lambda J'_\lambda(T)d\lambda , \qquad (9)$$

and

$$\bar{a}_s = \int_0^\infty a_\lambda H'_\lambda d\lambda . \qquad (10)$$

Arbitrarily, a 10 percent proportional difference in $\bar{a}_{BB}$ and $\bar{a}_s$ will be chosen as the criterion of usefulness; that is, if

$$\frac{|\bar{a}_{BB} - \bar{a}_s|}{\bar{a}_s} = E_p \leq 0.1 , \qquad (11)$$

the black body approximation will be considered useful. Equation 11 is actually

$$\frac{\left|\int_0^\infty \left[J'_\lambda(T)d\lambda - H'_\lambda\right] a_\lambda d\lambda\right|}{\int_0^\infty a_\lambda H'_\lambda \, d\lambda} \leq 0.1 . \qquad (12)$$

It can be seen that the results given in column 5, Table 1 for the quantity

$$\int |J'_\lambda(T) - H'_\lambda| d\lambda = \Delta_p \qquad (13)$$

do not indicate the magnitude of E_p (Equation 11). Consider now the following two cases:

1. If a_λ is approximately constant, then the proportional error E_p becomes

$$E_p = \frac{a_\lambda \left|\int_0^\infty \left[J'_\lambda(T) - H'_\lambda\right] d\lambda\right|}{a_\lambda \int_0^\infty H'_\lambda d\lambda} , \qquad (14)$$

and, since

$$\int_0^\infty J'_\lambda(T)d\lambda = \int_0^\infty H'_\lambda d\lambda = 1 , \qquad (15)$$

it is clear that

$$\int_0^\infty \left[J'_\lambda(T) - H'_\lambda\right] d\lambda = 0 \qquad (16)$$

and $E_p = 0$.

2. If a_λ can be represented by a power series in λ, that is,

$$a_\lambda = (a_\lambda)_0 + (\lambda - \lambda_0)\left(\frac{da_\lambda}{d\lambda}\right)_0 + \frac{(\lambda - \lambda_0)^2}{2!}\left(\frac{d^2 a_\lambda}{d\lambda^2}\right)_0 + \cdots , \tag{17}$$

then

$$E_p = \frac{\left| \int_0^\infty \left[J'_\lambda(T) - H_\lambda \right] \lambda \left(\frac{da_\lambda}{d\lambda}\right)_{0,1} d\lambda \right|}{\int_0^\infty H'_\lambda a_\lambda d\lambda} , \tag{18}$$

in which the error is now weighted by the slope.

DISTRIBUTION IN HELIOGRAPHIC LONGITUDE OF FLARES WHICH PRODUCE ENERGETIC SOLAR PARTICLES*

DONALD E. GUSS

A number of evidences have been found in the past which point to the longitudinal persistence of solar phenomena. The life of active regions on the sun extends over several solar rotations and centers of sunspot formation exist which seem to outlive individual spot groups.[1,2] Also, there are 27-day recurrences of geomagnetic disturbances[3] and neutron-monitor counting-rate data,[4] which sometimes last for as long as 10 solar rotations. More recently Bryant *et al.*[5] and Simpson[6] have found 27-day recurrences in the enhancement of low-energy proton intensity in free space as measured on satellites. It is the purpose of this Letter to point out a similar longitudinal persistence in the occurrence of solar flares which result in solar particle events. In particular, flares from a single 10° interval in heliographic longitude caused most of the large solar particle events over the last solar cycle. This indicates the existence of a center for the formation of active regions which has persisted for more than 73 solar rotations.

Figure 1 shows the heliographic longitude for flares which produced solar-particle events between 16 January 1955 and 23 October 1962 during the last solar cycle. The list of 56 events used is from that compiled by Malitson[7] plus the 23 October 1962 event. The series of flares between 80° and 90° in Fig. 1 produced the largest particle events of the last solar cycle, the event of 23 February 1956, the multiple events of July 1959, the multiple events of November 1960, and the multiple events of July 1961. Using the integrated particle intensities calculated by Malitson and Webber,[8] these events contributed about 75 percent of the integrated particle intensity with energy greater than 30 MeV and about 90 percent of that with kinetic energy >100 MeV detected at the earth during the last solar cycle. In addition, of the ten solar particle events which produced neutron-monitor increases, indicating the presence of significant numbers of particles with kinetic energy greater than about 500 MeV, seven are in this narrow longitude region.

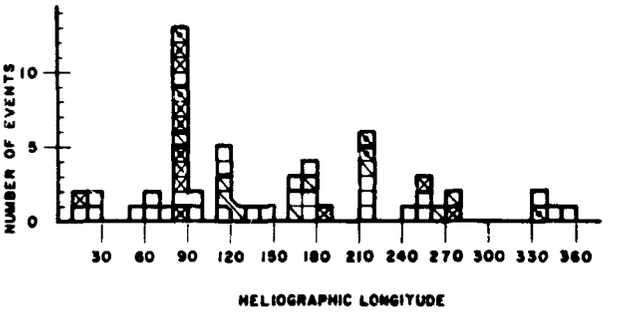

FIGURE 1.—Number of solar particles events vs heliographic longitude with the central meridian during the 23 February 1956 event set to 0°, and assuming a rotation period of 27.04 days. The particle intensity with kinetic energy >30 MeV detected at the earth[8] integrated over the particle event is ⊠, $I \geq 10^8$p/cm²; ⊡, $I \geq 5\times10^6$p/cm²; open squares, $I < 5\times10^6$p/cm². A dot in a square signifies that there was a neutron-monitor rate increase, indicating the presence of a significant number of particles with kinetic energy greater than about 500 MeV. Light lines are used to separate individual events and heavy lines to separate individual active regions.

Trotter and Roberts[9] have noted that the vicinity of the sun where the 23 February 1956 flare occurred had had a prior history of active regions lasting for several rotations, dying out, and returning in new bursts of activity. Hence, this center of activity existed prior to the 23 February 1956 event and persisted beyond the event of 20 July 1961, a period of more than 5.5 years. In his theory of the sun's field Babcock[10] proposes a mechanism to explain the longitudinal

*Published in *Physical Review Letters*, 13(12):363-364, September 21, 1964.

persistence whereby new active regions are likely to arise near old regions. However, it is not clear whether this mechanism is sufficient to explain an active site of such long duration.

The remainder of the events during the last solar cycle also fall into longitude bands, but not so sharply defined. The events between 240° and 280° with one exception occurred between 20 January 1957 and 23 March 1958, indicating the existence of an active site which lasted for more than a year. The events between 210° and 220° are those of March through September 1960, two of which caused ground-level neutron-monitor increases. The interval between 160° and 190° contains events which occurred between 9 August 1957 and 10 May 1959. The large event is that of 10 May 1959. The interval between 110° and 140° includes events from 6 June 1958 to 22 August 1958 and the two small events of 10 September and 28 September 1961.

Finally, there is a dearth of events in the longitude interval between 280° and 80°. Of the 26 larger particle events during the last solar cycle only two, the events of 31 August 1956 and 7 July 1958, resulted from flares in this 160° interval.

In conclusion, flares which produce energetic particles arise predominantly in narrow longitudinal regions which outlive visible active regions. This points to the existence of long-lived active centers beneath the photosphere which periodically manifest themselves on the surface as active regions which produce flares that accelerate solar particles. A single well-defined longitude region was responsible for the most intense particle events of the last solar cycle. The fact that this region can be compressed into a 10° band of longitude with a suitable choice of the period of solar rotation would indicate that this site rotated at constant rate as opposed to the variable rotation of the photosphere. The shorter lived regions, responsible for the smaller events, in general show a wider spread in longitude which could indicate a drift of the producing centers. A study of the meridional distribution of a larger body of data such as solar flares would perhaps result in a further definition of the active centers.

THE EFFECT OF A CORONAL EXPANSION ON THE COMPUTATION OF AN ELECTRON TEMPERATURE FROM EMISSION-LINE INTENSITIES*

WERNER M. NEUPERT

Certain assumptions made in the calculation of a coronal electron temperature from the relative populations in two stages of ionization of an element are examined, with the conclusion that this calculation may not be valid for the particular case of the solar corona, yielding a fictitiously low value if there is an outward expansion of ions from the base of the corona into a region of higher electron temperature. A non-equilibrium formulation for the distribution of ions is presented that may better describe the actual ion distribution in the corona. An approximate calculation shows that an outward radial velocity which is small compared with the average thermal velocity of the ions is sufficient to explain the apparent observed increase in height of the maxima of emission of the Fe ion sequence with increasing stage of ionization.

I. INTRODUCTION

Past observations of the solar corona have resulted, with considerable consistency, in a discrepancy between the electron temperature of the "quiet" or "normal" corona, undisturbed by centers of activity, as obtained (*a*) from the electron density gradient inferred from scattering of photospheric light by electrons and (*b*) from ionization theory. The first method yields values of about 1.6×10^6 °K, whereas the second, from the ratio Fe XIV/Fe X, gives values half as large. Recent measurements by Orbiting Solar Observatory-I indicate that the latter method may lead to inconsistent results, for the ratio Fe XVI/Fe XV, as measured by the satellite, implies an average electron temperature of $1.7-1.8\times10^6$ °K (Neupert 1963). In addition to these values for the electron temperature, a high value of the kinetic temperature, of the order of 2.0×10^6 °K, is obtained from observed line-broadening if it is assumed that the broadening is due entirely to thermal motions. It has often been suggested that the electron temperature computed from the ratio Fe XIV/Fe X is the more accurate value, while that (kinetic) temperature determined from line-broadening is inaccurate because of the presence of nonthermal motions. Although this possibility exists, it has yet to receive observational verification.

Line-broadening measurements also suggest that any temperature gradient in the quiet corona is quite small at heights between $r=1.03\ R\odot$ ($R\odot$ being the solar radius) and a few solar radii, being negative and of the order of 3°K per km for the Fe XIV (5303 Å) line (Billings and Lilliequist 1963). Under such circumstances it becomes difficult to account for the apparent simultaneous existence of low stages of ionization, such as Fe X and Fe XI, and also a stage as high as Fe XVI, observed by OSO-I to be the emitter of two of the more intense emission lines of the extreme ultraviolet spectrum between 170 Å and 400 Å, even in the absence of visible centers of activity. The suggestion has been made (Shklovsky 1951) that limb observations may include regions of differing electron temperature, thereby giving the spectrum a misleading appearance. Such an argument is without doubt correct near centers of activity which manifest an increase in electron temperature by the appearance of the Ca XV (5694 Å) line. However, for the undisturbed corona, the existence of regions having the

*Published in *The Astrophysical Journal*, 139(3):935–940, April 1, 1964.

required range of electron temperatures would require tangential temperature gradients considerably greater than the radial gradient reported by Billings and Lilliequist.

Since it is the ionization theory which leads to an electron temperature considerably less than that obtained by other observational methods, it is of interest to re-examine certain assumptions made in the theory in light of current knowledge of the physical state of the quiet corona. It is the purpose of this paper to suggest that a combination of physical circumstances, at least in the quiet solar corona, may alter the distribution of ions in the various stages of ionization, thereby making the ionization theory invalid as a means of computing an electron temperature for the coronal plasma, and also permitting a broader distribution of ions than is allowed by ionization theory in a nearly isothermal corona. A steady state non-equilibrium formulation, valid for an optically thin plasma, is proposed which appears to be more compatible not only with present optical information about the corona at visible wavelengths but also with certain observations in the extreme ultraviolet spectrum made from rockets and satellites.

II. EFFECT OF A CORONAL EXPANSION

A combination of two physical conditions may lead to a discrepancy in the coronal temperatures derived from line intensities and from line-broadening. These two factors are (1) an average time between ionizations (of heavy ions) which is large compared with the time for equipartition of energy between the ions and the coronal plasma; (2) a mass motion of ions through a region having a high electron-temperature gradient in a period of time equal to or less than the above-mentioned time between ionizations. We will first consider the existence of each of these conditions in the lower corona and then discuss their influence on a theory which assumes ionization equilibrium.

An estimate of the time between ionizations may be obtained from ionization rates iron for ions computed from cross-sections given by Elwert (Massey 1956). These rates increase with increasing electron temperature, from 7.4×10^{-13} sec^{-1} cm^3 at 0.8×10^6 °K to 1.95×10^{-11} sec^{-1} cm^3 at 2.0×10^6 °K for Fe XIII, and decrease with increasing stage of ionization from 2.5×10^{-11} sec^{-1} cm^3 for Fe XI to 3.5×10^{-12} sec^{-1} cm^3 for Fe XV at 1.6×10^6 °K. These rates are higher (by a factor of 4 or more) than those used by Firor and Zirin (1962) but slightly lower than those used by Seaton (1962). We will assume, as do Firor and Zirin, that the dependence of ionization rates on the number of valence electrons is small and may be neglected. A measure of the time between successive ionizations (disregarding recombinations) is then given by

$$\tau_{ion}=\frac{1}{N_e S(T)},$$

where N_e is the electron density and $S(T)$ is the ionization rate in sec^{-1} cm^3. Taking a value for N_e of 2.0×10^8 cm^{-3} and a value for $S(T)$ of 1.0×10^{-11} sec^{-1} cm^3, one finds that a time interval of the order of 500–1000 sec (one to two time constants) is required to ionize, without recombinations, an assemblage of ions from stage i (taken as Fe XIII) to stage $i+1$ in the lower corona at an electron temperature of 1.6×10^6 °K, a value consistent with that obtained from the electron-density gradient. On the other hand, the time required to establish equipartition of energy between protons and heavy ions in the coronal plasma is considerably shorter. This characteristic time can be computed from equations given by Spitzer (1956) and is of the order of 2.0 sec for Fe XIII–proton equilibrium at an electron (and, approximately, proton) density of 2.0×10^8 cm^{-3} and a temperature of 1.6×10^6 °K. It is of interest to note that the formula predicts the heavy ion-proton equipartition time to be less than that for proton-proton equipartition by a factor of 2 (Fe XI) to 4 (Fe XVI) because of the high charge of the heavy ions. The time for equipartition is again inversely proportional to the electron density, leading to the relation

$$\tau_{ion}/\tau_{equi}\sim\text{constant}\gg1$$

for a given ion anywhere in the solar corona.

In considering the second of the two conditions stated above we must restrict ourselves to regions of low magnetic field, thus permitting an expansion of the corona which results in the corpuscular stream deduced by Biermann (1951) from his work on comet tails and was more recently discussed by Parker (1960). Using the continuity equation one can compute the average solar-wind

velocity at any height in the atmosphere once its velocity and particle density at another height have been defined. Using as initial parameters (Parker 1961) a proton density of 1.8×10^7 cm^{-3} and a solar-wind velocity of 66 km/sec at $r=1.43R\odot$ one then finds, near the base of the corona, assuming an electron density of 2.0×10^8 cm^{-3}, a velocity of about 12 km/sec. A recent calculation by Billings and Lilliequist produces a value about half as great. One direct measurement of the solar wind in the lower corona, a radar observation, has been made which yields a velocity similar to the computed values. The Massachusetts Institute of Technology El Campo station has observed, at 38 Mc, a Doppler shift of 4 kc, corresponding to a radially outward velocity of the reflecting electrons of 16 km/sec (James 1963). Knowing the electron density at which a critical frequency is reached, one may compute the velocity at other densities using the continuity equation. At an electron density of 2.0×10^8 cm^{-3} one then obtains 3.5 km/sec. It must be pointed out that these velocities are at variance with those obtained by extrapolation of recent observations made by Mariner II between the orbits of Venus and Earth. From this satellite data one would predict a wind, for the quiet sun, of only 0.06 km/sec in the lower corona. It remains to be seen, however, whether an extrapolation over nearly 1 a.u. using a limited sampling of the interplanetary plasma is valid. For this reason the radar results will be used in this paper. Using a solar-wind velocity of several kilometers per second, one concludes that an ion may travel radially outward a distance of 10^3–10^4 km in the lower corona before undergoing further ionization.

The result of fulfilling both of the above conditions is that an ion, in passing through a region having a steep positive electron-temperature gradient, very quickly attains a thermal velocity characteristic of the higher temperature (condition 1) but carries with it, for a much longer time and radial distance, a history of any previous ionization equilibrium (condition 2). Under such circumstances no theory which postulates equilibrium between ionization and recombinations can furnish a valid value for the electron temperature of the region even if the predominant ionization mechanism is electron impact, and recombination is by radiative capture. A kinetic temperature derived from line-broadening may still be valid, however. Because of the large increase in temperature over a distance of 10000 km or less in the lower solar corona, it appears that the situation here described may well occur throughout most of the region of the corona from which radiation is observed.

At any height in the corona one must then replace the equilibrium equation (Woolley and Allen 1948),

$$N_iN_eS_i^{i+1}(T)=N_{i+1}N_eQ_{i+1}^i(T),$$

where $Q(T)$ is the recombination rate in sec^{-1} cm^3, with the more general equation

$$\nabla\cdot F_i\gtrless 0,$$

where F_i is the flux of ions, in stage i, of each element. In general,

$$\begin{aligned}\nabla\cdot F_i=&(\text{ionizations from } i-1)\\&-(\text{recombinations to } i-1)\\&+(\text{recombinations from } i+1)\\&-(\text{ionizations from } i).\end{aligned}$$

For an optically thin corona of low density in which photoionizations and three-body recombinations are assumed to be negligible one obtains

$$\begin{aligned}\nabla\cdot F_i=&N_{i-1}N_eS_{i-1}^i(T)-N_iN_e[Q_i^{i-1}(T)+S_i^{i+1}(T)]\\&+N_{i+1}N_eQ_{i+1}^i(T),\end{aligned}$$

for each stage of ionization, i, of each element present, together with

$$N(r)=\sum_i N_i(r),$$

where N_i is the number density in each stage of ionization. The summation is made over all stages of ionization of the particular element being considered.

For a spherically symmetric corona expanding with velocity of magnitude $v(r)$ we have, for the total flux of a particular ion crossing a shell of radius r,

$$F_i=4\pi r^2N_i(r)v(r).$$

By requiring a steady-state outward flow, all ions moving outward with the same average velocity, we obtain

$$F_0=\sum_i F_i\approx 4\pi r^2N_e(r)v(r)=\text{constant}.$$

In this case the summation includes all elements present. Using the notation P_i, where P_i is the relative population in each stage of ionization i,

$$P_i \equiv \frac{N_i(r)}{Nr)},$$

we obtain

$$\frac{d}{dr}P_i = \frac{N_e^2}{F_0/4\pi r^2}\{P_{i-1}S_{i-1}^i(T) - P_i[Q_i^{i-1}(T) + S_i^{i+1}(T)] + P_{i+1}Q_{i+1}^i(T)\}$$

for each element and each stage of ionization.

We note that this equation is valid for any local areas, e.g., plages, in which the outward expansion may be different from that of the undisturbed corona, since the coefficient of the right-hand side can be evaluated locally in the corona. This equation is similar in form to that obtained by Burton and Wilson (1961) for a fully contained plasma except for a change in the independent variable from time to position and a change in the coefficient of the right-hand side. An analytic solution is possible under the assumption that only three adjacent stages of ionization are significantly changing for any value of the independent variable, all lower stages having reached a steady-state relative population and all higher states having yet to be populated. Although such an assumption is apparently valid for the plasma treated by Burton and Wilson and permits an analytic solution to be obtained for any stage of ionization, this is not the case for the solar atmosphere. In the latter, ions in the lowest stages of ionization may exist in regions of high optical thickness where the equation given is not even approximately valid. In order to apply the equation to the corona, where it is valid, one therefore requires boundary conditions at the base of the corona where more than three stages of ionization may already be significantly populated. At this boundary the solar atmosphere exhibits considerable fine structure, on which insufficient data are available for a precise evaluation of the equations.

However, it is possible to discuss the general behavior of the system by considering the expansion of an assemblage of ions from a region of low electron temperature of 5×10^5 °K to a hotter region of 1.6×10^6 °K, the change in electron temperature taking place over a distance of only a few thousand kilometers. Examination of the equation for the predominant stage of ionization present at 5×10^5 °K indicates that its relative population will decrease, in the absence of recombinations, by a factor of $1/e$ in a distance of approximately

$$\frac{F_o}{4\pi r^2}\frac{1}{N_e^2 S(T)},$$

which is of the order of 10^3 km. Higher stages of ionization will become more populated with increasing height above the photosphere, reaching an ionization equilibrium characteristic of the higher temperature only in a distance of a few tens of thousands of kilometers. The reliability of this conclusion depends, of course, on the validity of the data we have used. If the solar proton measurements of Mariner II are used, rather than the radar measurement, together with the higher ionization rates of Seaton, the effect being discussed here will be entirely negligible.

III. COMPARISON WITH OBSERVATIONS

A small amount of observational evidence is available which appears to be consistent with the foregoing arguments. Beginning with the lower stages of ionization observed in the corona, it has been found, for the undisturbed corona, that (*a*) the maximum surface brightness of Fe XI emission occurs below 10000 km above the photosphere (February 25, 1952 eclipse) (Athay and Roberts 1955), (*b*) the maximum surface brightness of Fe XIV occurs (statistically) at about 18000 km (Petri 1952), (*c*) the intensity of the Fe XV line at 7059Å decreases much more slowly with distance from the limb than do the lines of Fe X (6374 Å) and Fe XI (7891 Å) (February 15, 1961, eclipse) (Wlerick and Fehrenbach 1961). This observation supports those of Allen (1946) who noted that the equivalent widths of coronal lines with relatively low ionization potentials showed a faster decrease with height above the photosphere than did lines of high ionization potential. Based on the observation by OSO-I that the intensity of emission from Fe XVI requires emission from 0.1 to 0.5 of the solar corona, one might hypothesize, in accordance with the model being presented here, that the maximum in surface brightness of Fe XVI occurs at about 40000 km.

Because of the rapidly decreasing electron density with height in the lower corona, the maximum in intensity of an ion may be very broad and need not be coincident with the maximum in relative population of the ion.

The above observations are, of course, partially consistent with a coronal model, based on ionization equilibrium, which incorporates a positive temperature gradient outward from the chromosphere. Such a model could not be employed beyond 1.03 $R\odot$, however, since at distances greater than this the corona exhibits a negative temperature gradient, in contradiction to what would be expected from observation (*c*).

It is of interest to apply the arguments which have been developed to these observational data, thereby estimating the radial ion velocity in the lower corona. Assuming an average time between ionizations of 500 sec for stages Fe XI–XIV, we obtain, for the average radial velocity of these ions

$$\bar{v}=\frac{10000}{1500}=6.6 \text{ km/sec.}$$

Taking recombinations into account, we can reduce this velocity but by an amount estimated to be no more than 10 to 30 percent. This velocity is comparable to the solar-wind velocity in the lower corona inferred from radar observations. By comparison, the average thermal velocity for Fe ions at 1.6×10^6 °K is 15 km/sec. Since only limb observations of the corona are possible at visible wavelengths, little shift in the forbidden emission lines due to the outward ion velocity should be observable.

IV. CONCLUSION

It appears that even at the low electron densities found in the corona a computation of the electron temperature based on ionization theory may be invalid in regions of outward expansion through an electron-temperature gradient. Such a condition may be responsible, in part, for the difference in coronal temperatures obtained from ionization theory and from line-broadening measurements. Its eventual importance will depend on better estimation of ionization and recombination rates and the velocity of the solar wind. The presence of a coronal expansion does not rule out the existence of turbulence in the quiet corona, which may still account for the difference in temperatures obtained from electron-density gradients and from Doppler broadening of coronal lines.

TIME VARIATIONS IN THE SOLAR EXTREME ULTRAVIOLET SPECTRUM OBSERVED BY OSO-1*

W. M. NEUPERT

1. INTRODUCTION

A grazing incidence spectrometer[1] has been flown as a pointed experiment on OSO-1 to monitor the extreme ultraviolet (EUV) spectrum of the sun. Over six thousand spectra were obtained at the rate of about 100 per day over a period of time from March through May 1962, corresponding to nearly three solar revolutions. Intermittent operation has subsequently provided spectra for a period of greater than one year. This paper presents, in a condensed form, the variations observed in three of the more reliably identified lines of the spectrum: 284-A (Fe XV), 304-A (He II) and 335-A (Fe XVI).

One may consider the solar EUV observations as falling into three categories: a) quiet corona, b) slowly varying components, and c) transient phenomena, such as flares. These categories are also listed in the order of increasing difficulty of making reliable observations. This paper will review some of the observations of slowly varying components that have been made and then present several instances in which transient phenomena have been observed.

2. DESCRIPTION OF SPECTROMETER

During operation the spectrometer was pointed at the center of the solar disk within approximately two min of arc. In this orientation, radiation from the entire solar disk and inner corona passed directly through the entrance slit and struck a concave grating mounted in grazing incidence, the angle of incidence being 88°. The exit slit and detector were mounted on a carriage which was driven on a circular rail so that the exit slit scanned along the Rowland Circle, where the spectrum was focused, from 10–400-A. The 50 micron entrance and exit slits provided a spectral passband of 1.7-A and permitted resolution of lines 0.85-A apart. The detector was a windowless photomultiplier developed by the Bendix Corporation specifically for use in this spectrometer. A tungsten photocathode was chosen to minimize response to wavelengths above 1500-A, and to reduce changes in sensitivity due to variations of the emission properties of the cathode. The instrument calibration was performed (1) by exposing the entire spectrometer to a beam of monochromatic radiation of known intensity and (2) by evaluating the essential components of the spectrometer (grating, detector, etc.), and then computing the sensitivity of the instrument. The first method was used at 44-A using a proportional counter for determining the source intensity. The second method was applied at longer wavelengths (80–400-A). In addition, a comparison was made of the solar fluxes obtained against the fluxes measured by Hall, Damon and Hinteregger[2] with a calibrated rocket instrument. The comparison could only be made in the region of overlap, 250-A to 400-A, and would be meaningful only if the solar radiation was the same. The 2800-Mc mean daily flux recorded by the National Research Council, Ottawa, Canada, was used as an independent estimate of solar flux to choose the satellite data for the comparison. A best fit was made between these methods of obtaining a calibration which yielded values of 8.0×10^{5} photons cm^{-2} $count^{-1}$ at 335-A and 4.2×10^{5} photon cm^{-2} $count^{-1}$ at 284-A. These values are useful for comparing the intensities of the lines at these two wavelengths, but their use to obtain absolute solar fluxes is not recommended.

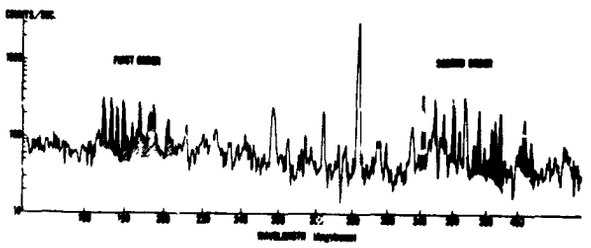

FIGURE 1.—Solar spectrum from 170 A to 400A with second order line images indicated

3. PRESENTATION OF DATA

Figure 1 presents a typical scan obtained over the region of 170–A to 400–A. Several factors reduce the usable spectral range of the spectrometer from its nominal range of 10–A to 400–A. At wavelengths below 100–A the decreasing sensitivity of the spectrometer combined with an increase in scattered light upon approaching the central image made it impossible to distinguish a reliable spectrum on a single scan. However, a combination of several scans, using cross-correlation techniques, has shown the apparent existence of a line emission spectrum in the region from 50–A to 100–A (Neupert, Behring, White and Lindsay[3]). At wavelengths above 342–A the second order images of intense spectral lines observed in first order above 171–A obscure a considerable amount of interesting data. This effect is illustrated in Figure 1 which indicates, by crosshatching, those first order lines which have strong second order counterparts in the recorded spectrum. These second order images were less prominent in earlier rocket results, leading to considerable dissimilarity between the rocket and satellite spectra above 342–A (Neupert and Behring[4]). For these reasons the obviously usable range of the instrument can be considered to be from 170–A to 340–A, a range which can be extended, with special precautions, to cover the interval from 50–A to 400–A.

The brightest emission line in the region from 170–A to 340–A is the Lyman-alpha line of ionized helium at 304–A. In addition, numerous other emission lines appear with combined flux comparable to, or somewhat greater than, that of the helium line. Resonance lines of heavy ions (Mg through Fe) are expected in this region, leading to attempts (Zirin, Hall and Hinteregger[5]), (Neupert and Behring[4]) to identify the more prominent features of the spectrum in terms of such lines. The difficulty of positive identification can be appreciated more if, for example, we realize that the resonance lines of all stages of ionization of iron from Fe X through Fe XVI, with the exception of Fe XV, are expected in the small wavelength interval from 335–A to 390–A. The overlapping of these resonance multiplets combined with second order radiation of shorter wavelengths makes positive identification a formidable task. The resonance lines of Fe X through Fe XIV have not been identified in the extreme ultraviolet (EUV) spectrum although their intensity as predicted by Ivanov-Kholodny and Nikolsky[6] should permit their observation. Tousey[7], working with a spectrum having higher resolution, reports that no Fe XIV multiplet can be found in his record. Because of these difficulties, discussion will center around three of the more intense and more reliably identified lines of the spectrum, the Fe XV ($3s^2\ {}^1S_0 - 3s\,3p\ {}^1P1_0$) line at 304–A. The location of these lines is indicated in Figure 2.

4. SLOWLY VARYING COMPONENTS OF THE EUV SPECTRUM

The months of March and April of 1962, were auspicious for a study of the solar EUV spectra in that observations could be made on both a quiescent and a disturbed solar atmosphere. During the second week in March the sun was especially quiet, the Zurich Provisional Relative Sunspot number being zero on 11 March. As the month progressed solar rotation carried several centers of activity across the visible hemisphere of the sun. Definite enhancements in the solar spectrum were associated with these centers of activity.

Figure 2 presents two scans of the EUV spectrum taken approximately ten days apart. During the first of these observations (13 March) only one small region of activity was present on the solar disk. In spite of this low level of activity it is observed that the Fe XV and Fe XVI lines persist as two of the more prominent features of the spectrum. The second spectrum (23 March) was obtained while several large and well-developed centers of activity were present on the disk.

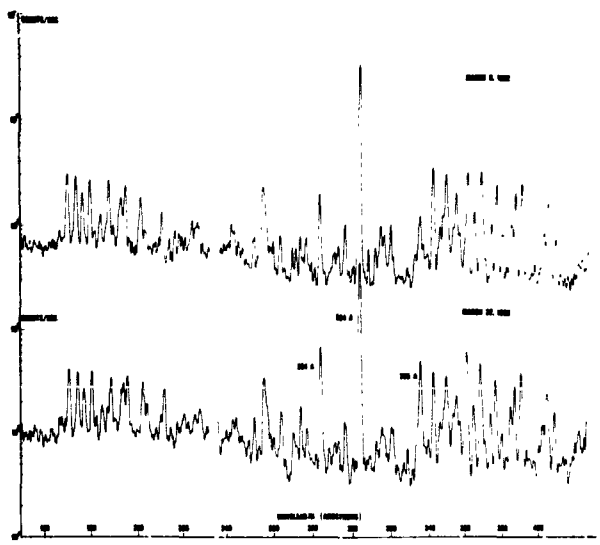

FIGURE 2.—Comparison of two spectral scans taken under different solar conditions

Comparing these two spectra we observe that the emission lines have increased in intensity but not all by the same amount. The Fe XV and XVI lines, already prominent even in the near absence of solar activity, have increased in intensity appreciably more than any other line observed with certainty in this spectral range. The He II line has also increased but by a lesser amount.

Time variations of these three lines as observed for the first 1066 orbits of operation are given in Figure 3, in which each datum point represents the average of one orbit's observations (six to eight scans). Error bars indicating one standard deviation in the data are given for each wavelength. Also indicated are the times of appearance and disappearance of the major plage areas as cataloged by the McMath-Hulbert Observatory. The first increase in the counting rates above the "quiet sun" values is associated with the appearance of McMath Plage No. 6366 on the east limb on 11 March. The counting rate for the He II (304–A) line increases gradually to a maximum on 23 March, after which it drops rather abruptly to an apparent plateau. This sudden drop cannot be unambiguously attributed to the disappearance of plage region 6366 on the west limb, for it follows quite directly after an unusual flare of importance 3 observed in plage region 6370 on 22 March, for which data are not given in the figure. A gradual decline in readings is observed from 29 March to 7 April. A similar enhancement, followed by a return to near preplage rates, occurred in April. Since the spectrometer did not carry an internal standard it is impossible to state positively that its counting characteristics did not change over the period of observations. The consistent behavior of the data, however, as demonstrated in Figure 3, leads to the conclusion that no significant change in sensitivity occurred throughout the period of observation. (Subsequent analysis of real time data after one year in orbit supports this conclusion, even for the longer time interval).

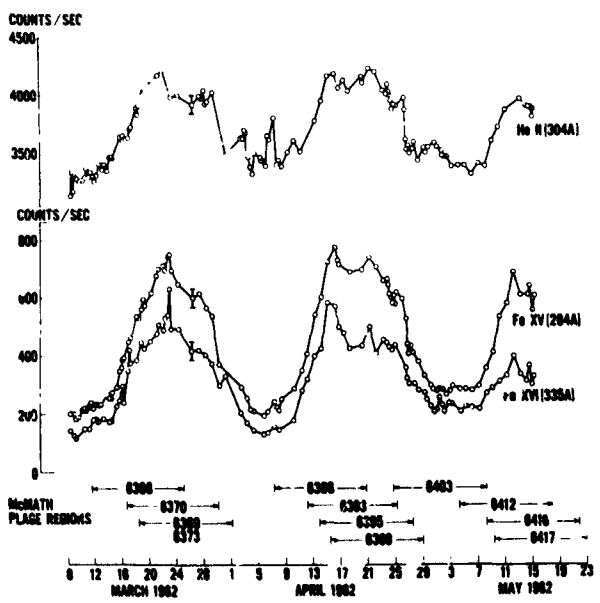

FIGURE 3.—OSO–1 data for three spectral lines compared with appearance and disappearance of major plage areas.

Also shown in the figure are the variations with solar activity of the coronal Fe XV (284–A) and Fe XVI (335–A) lines, the relative increases being considerably larger than for the He II (304–A) line. A definite, although small, enhancement associated with the appearance of plage No. 6366 is observed in both the Fe XVI and Fe XV lines. The possibility exists that the coronal emissions appear slightly earlier as might be expected since the coronal emission must take place at greater heights than the emission of ionized calcium radiation. The most obvious increase in intensity of these lines is associated with the appearance, in succession, of plage areas numbered 6370, 6369 and 6373 on 17 March through 19 March. The counting rates then increased gradually throughout this period indicating that the enhanced emission was not from a point source but rather from

an extended volume having as its base an area at least as large as the underlying calcium plage. The disappearance of area 6366 on 25 March results in a slight decrease in counting rates, followed by a general decline from 29 March through 3 April as the other plage areas are carried off the visible hemisphere of the sun by the solar rotation.

5. DISCUSSION OF SLOWLY VARYING COMPONENTS

The relationship of these observed counting rates to several ground-based measurements of solar activity is presented in Figures 4 and 6. In Figure 4 the He II radiation is compared with

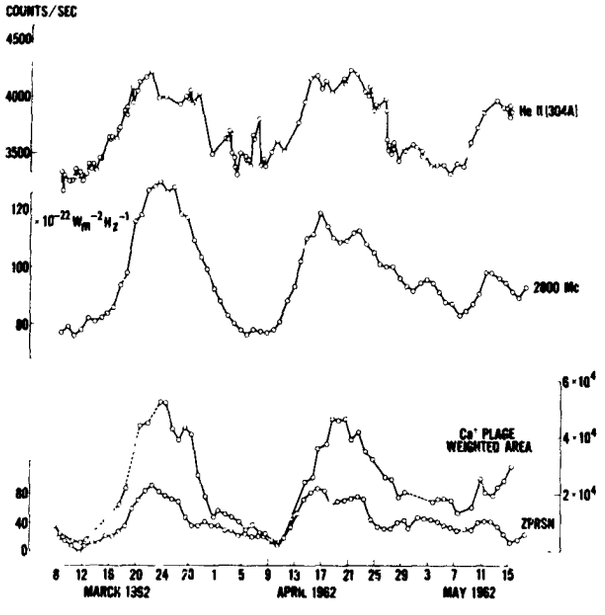

FIGURE 4.—Relationship of observed counting rates for the He II Lyman-alpha line to ground-based measurements of solar activity.

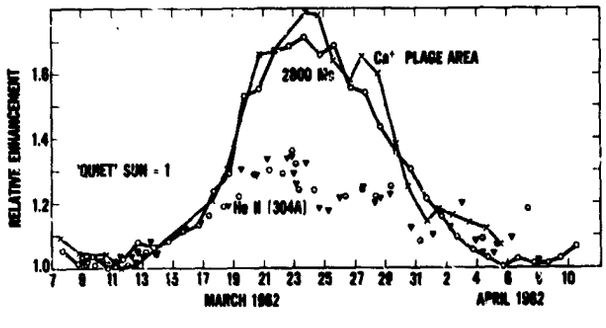

FIGURE 5.—Comparison of 304 A data, normalized to a "quiet sun" value of one, with weighted calcium plage data and 2800 Mc radio observations.

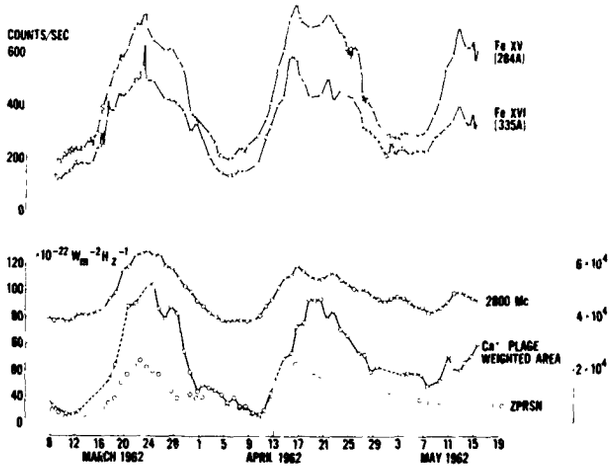

FIGURE 6.—Relationship of observed counting rates for the 284 A and 335 A line to ground-based observations.

daily values of the solar flux at 2800–Mc, and with the Zurich Provisional Relative Sunspot Number (ZPRSN). Also shown is an estimate of the calcium plage area, each area being weighted by the estimated intensity of the area on a scale from 1 to 5 and by the cosine of its longitude from the central meridian. Values for this computation were supplied by the McMath-Hulbert Observatory.

A more detailed comparison is made in Figure 5 in which the radio and He II fluxes have been adjusted by dividing each observation by the rate observed for the "quiet sun." In addition, the weighted Ca^+ plage intensity has been adjusted to coincide with the 2800 Mc enhancement on 21 March. This plot shows more clearly the close relationship which has been known for some time between the 2800 Mc radiation and the plage areas and also shows the divergences of the He II (304–A) line from both of these. A better agreement between plages and the 304–A line is obtained if only the plage areas, with no weighting factors for intensity or longitude from central meridian passage is used. In Figure 6 the daily values of solar flux at 2800 Mc and the Zurich Provisional Relative Sunspot Number are compared with the coronal lines of Fe XV (284–A) and Fe XVI (335–A). The estimated weighted calcium plage area is also shown.

The spectral lines chosen for presentation here were selected because they are reliably identified with particular ions, not because they convey, more than any other line in the spectrum, changes

in solar flux which occur with the appearance of plage areas. These three lines represent the extremes which have thus far been observed in the spectral region from 171–A to 400–A; only a few faint lines have smaller non-flare variations than the He II Lyman-alpha line, while no other outstanding lines have increases as great as those observed for 284–A and 335–A.

An attempt has been made to compute an electron temperature for the corona, as nearly as possible undisturbed by centers of activity, from the observed ratio of intensities of the Fe XV and Fe XVI lines. Such a calculation has validity only if both radiations originate in the same region of the corona at some well-defined electron temperature and only if an ionization-recombination equilibrium, as assumed by theory, is actually present. It is found that an electron temperature of 1.75 ± 0.10 million degrees in that part of the corona assumed to be the source of both Fe XV and Fe XVI best fits the observed data. This result contrasts sharply with the value of 800,000 °K usually obtained from observation of the forbidden lines of Fe X and Fe XIV.

It has been estimated that the emission of Fe XV and Fe XVI radiation associated with a plage area is approximately 150 to 200 times that of an equivalent area of the quiet sun. The corresponding value for the 304–A line is 15. Assuming that the increase in emission is due to a density increase only, one finds it necessary to hypothesize an increase in electron density by a factor of 12 to 14 over each plage for the two iron lines. The fact that a large range of intensity variations is observed demonstrates, however, that an increase in electron density alone is not sufficient to explain the behavior of the spectrum. On the other hand, the constancy of the ratio Fe XVI/Fe XV as one extrapolates to zero plage area argues against a significant change in electron temperature over plages. One can only conclude, at this time, that those regions (or region) of the corona emitting Fe XV and Fe XVI radiation occupy a relatively greater volume of the corona over plages and centers of activity.

The initial analysis of only three lines (He II 304–A, Fe XV 284–A, Fe XVI 335–A) indicates that the relative prominence of spectral lines may depend upon the age of the center of activity which is responsible for the increased radiation. As an example of this, one may observe (Figure 6) that the maximum emission in the Fe XV line apparently occurs later in time than the maximum for the 2800 Mc flux, or for the plage areas, observed during March, April and May. In addition to such a slowly changing effect, one may note that localized perturbations appear (7–9 March and 16–17 April) for which the relative

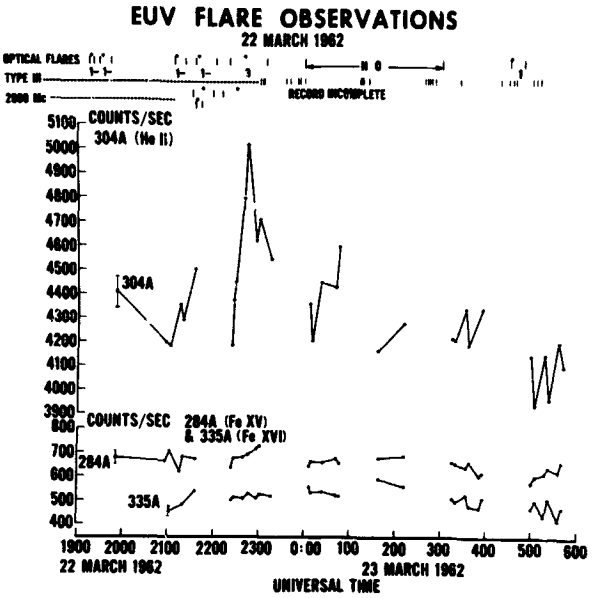

FIGURE 7a.—Increases in EUV line emission associated with optical flares.

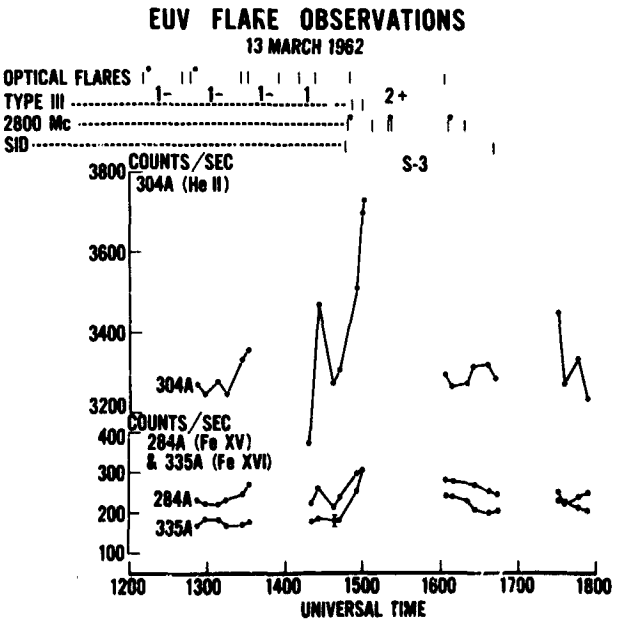

FIGURE 7b.—Increases in EUV line emission associated with optical flares.

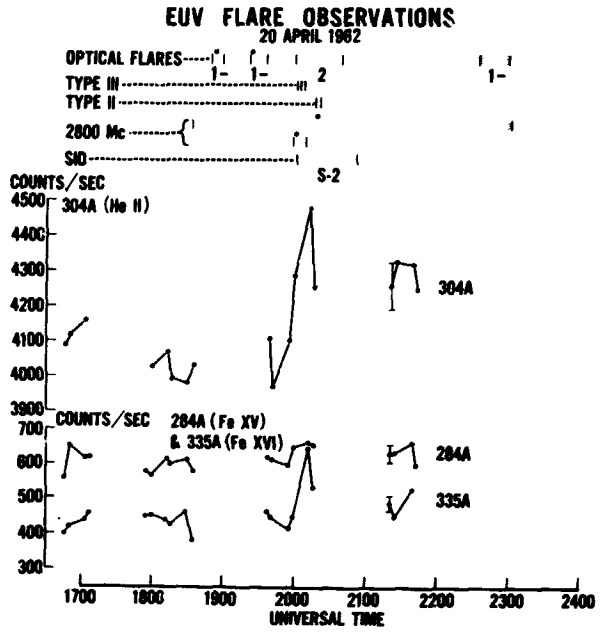

FIGURE 7c.—Increases in EUV line emission associated with optical flares.

increases in the helium and the iron lines are considerably different. In these instances we are apparently observing phenomena localized at particular levels in the solar atmosphere.

6. EUV FLARE OBSERVATIONS

It is difficult to obtain reliable EUV flare observations with the type of spectrometer used in OSO–1 because the flare radiation is seen as only a small increase in the radiation from the entire solar disk, and because the long time required to scan the spectrum (8 min) severely limits the time resolution with which the flare can be observed. In spite of these difficulties, several increases in the EUV radiation have been associated with flares. Three such instances are shown in Figures 7 a,b,c. Supplementary information for these events is given in Table I.

6.1. 22 March, 1962 (Flare of Importance 3)

From the observations of the He II line at 304–A made one minute before and three minutes after maximum in H-alpha one may conclude that the maximum at 304–A certainly occurs no earlier than H-alpha maximum and may occur later. No changes at 284–A and 335–A can be associated with this flare, optically of importance 3 but geophysically of much lesser importance.

6.2. 13 March, 1962 (Flare of Importance 2+)

Peak phase of this flare apparently occurred near satellite sunset. The last valid observations before sunset indicate that the EUV flare radiation reaches a maximum after the 2800 Mc radio burst. Increases are noted for all three lines, with the ratio 335–A/284–A apparently increasing at or near maximum phase of the optical flare. The enhancement in the coronal lines may continue after cessation of the visible flare.

6.3. 20 April, 1962 (Flare of Importance 2+)

EUV observations are poorly situated in time relative to the optical maximum of this flare. It appears, therefore, that the EUV emission maxima may have been significantly greater than the maximum reading actually recorded. In spite of this shortcoming, an increase in the Fe XVI radiation, relative to Fe XV can again be observed.

7. DISCUSSION OF FLARE OBSERVATIONS

A considerable number of additional events have apparently been observed, some associated with optical flares, others not. However, the data for these events have not been sufficiently analyzed to establish their validity. The increase of the ratio Fe XVI/Fe XV is most frequently associated with solar events producing ionospheric disturbances. The increase in this ratio suggests that some volume of the solar atmosphere, associated with the flare, has been raised to a higher electron temperature.

It is interesting to note that the EUV maxima coincide more closely with the optical maxima and with ionospheric affects than they do with centimetric radio bursts. The association with ionispheric effects is understandable if we assume that the hard X-rays, which themselves may be line emission at short wavelengths, and which are causing these ionispheric disturbances, have the same common thermal origin in flares as does EUV flare radiation observed by the OSO–1 spectrometer. On the other hand, the coincidence with optical H-alpha maxima cannot be explained in the same manner since the hydrogen radiation must originate in a cooler region of the solar atmosphere.

DISCUSSION

Maron: In comparing the active sun and the quiet sun, is your finding that the variations in fluxes from the lines in the higher ionization states of iron have greater amplitude than the lower states? Is this not most simply interpreted as saying that the relative density change is greatest in the regions of highest temperature?

Dr. Neupert: Yes, that is a possible conclusion. However, we cannot discriminate between this hypothesis and one in which the electron temperature profile of the corona changes above the active region in such a manner that a greater relative volume is at the higher temperature.

Zirim: Just one remark. I have the impression that you have essentially a factor of two increase in the total radiation from the whole sun coming from a flare which essentially is .1 percent of the area, or something like that, which impresses me with a very large change. Is that so, would you say?

Dr. Neupert: We can associate changes of 50 percent or more during flares only with the Fe XVI and Fe XV lines. Many lines show no statistically reliable change. For the event on March 13 we can demonstrate, by averaging our data over one complete orbit, that several other lines do show changes. Rapid variations of 10 percent to 20 percent in the faint lines would be unobservable because of statistical fluctuations. We should probably use the H-alpha area of a flare only as a lower limit in estimating the size of the EUV emitting region.

Guerjoy: Would you clarify for me how long, how large an area of the sun you are looking at?

Dr. Neupert: We are looking at the entire solar disc and out to about a quarter of a solar radius from the limb. So we are looking at the entire disc plus the inner corona with this instrument.

Chubb: Can you say something about how the variability of the lines around 170 angstroms is as compared to, say, the 304 and the iron lines?

Dr. Neupert: The variations with solar plage area of the lines between 170–A and 200–A are less than those of the 284–A and 335–A lines. They are comparable to or somewhat more than that of the helium line. We have not analyzed flare data for these lines but it is our experience that lines which increase most due to the presence

of a center of activity also increase the most during flares.

Dr. Lindsay: I note that you have averaged about 16 lines in this region over a period of about a month, as I recall. Why don't you report at least the integrated or the average of these lines varies?

Dr. Neupert: We have made integrations over the spectrum for two days. Not for the 13th of March and 23rd of March, but for two days on which activity was similar to those which we had in the second slide. The increase in counting rate was of the order of 50 to 80 percent. This is an increase due to the presence of centers of activities on the sun's disc, not increase due to flares.

THE UV LINES OF FE XIV IN THE SOLAR CORONA

R. STOCKHAUSEN

Knowledge of the structure of the solar corona can be increased by observations of the many emission lines in the far ultraviolet. However, identification of these lines is made difficult by the lack of knowledge of many of the atomic parameters relevant to these lines. Garstang's (1962) calculations of energy levels and oscillator strengths for Fe XIV allow predictions of lines strengths and wave lengths for the lines of this ion.

Collision cross-sections of the optically permitted lines are related to the oscillator strengths by the expression given by Van Regemorter (1962)

$$Q(n, m) = \frac{1}{k_n^2} \frac{8\pi}{\sqrt{3}} \frac{I_H}{\Delta E} f(nm)\ g\pi a_o^2 \qquad (1)$$

For levels not connected to the ground level by an optically allowed transition, electron exchange collisions are the only excitation mechanism. In a manner similar to Osterbrock (1963) these exchange cross-sections can be estimated by

$$Q_e(in, jm) < Q_o(in, jm)$$

$$= \frac{\pi}{k_n^2} \begin{cases} (2\ell+1)\ [g_{jm}/\Sigma_m g_{jm}] \\ (2\ell'+1)\ [g_{jm}/\Sigma_m g_{jm}](g_j/g_i) \end{cases} \qquad (2)$$

$$\text{or } \frac{\pi}{k_n^2} \begin{cases} (2\ell+1) \\ (2\ell'+1)\,(g_{jm}/g_{in}) \end{cases}$$

whichever of the four is smaller. Here $i\ n$ is the n^{th} level of term i and $j\ m$ is the m^{th} level of term j. The term in square brackets comes from the assumption that the levels of term j are populated in proportion to this weight factor.

In his work with nebular ions, Osterbrock has taken $Q_e = 0.1 Q_0$. On the basis of the rapid decrease, with increasing energy of the colliding electron, of the cross-sections for exchange collisions in He I (St. John, Miller, and Lin 1964) and the decrease of exchange cross-sections along the iso-electronic sequences shown in Table VIII of Seaton (1958), Dr. Osterbrock has suggested that a value of Q_e nearer to $Q_e = 0.01 Q_0$ may be more appropriate for Fe XIV. With the uncertainties involved, parallel calculations were made under three assumptions:

$$Q_e = \begin{cases} .0 \\ .1Q_0 \\ .01Q_0 \end{cases} \qquad (3)$$

The total cross-section is then the sum of (1) and (3).

Having the collision cross-sections, production rates of the UV lines can be calculated. Following the notation of Seaton (1963), the rate of excitation from level i to level j followed by spontaneous transition to level k is given by

$$\alpha_{ik} = q_{ij} C_{jk} \qquad (4)$$

where q_{ij} is the collisional excitation rate of j from i and C_{jk} is the probability of going to k from j. For the UV lines of Fe XIV, C_{jk} does not involve collisional de-excitation due to the high spontaneous transition probabilities, and the low coronal electron densities.

Table 1 gives the production rates for UV lines due to transitions ending in the two levels (1 denotes $^2P^\circ_{1/2}$ and 2 denotes $^2P^\circ_{3/2}$) of the ground term. Results are given for two temperatures and three values of the exchange cross-section. Excitations are assumed to take place only from the ground level.

The sum of the production rates to the upper level ($^2P^\circ_{3/2}$) of the ground term is important in that it gives the excitation rate (due to cascade) of the coronal green line, λ5303. It can be seen that there is a slight discrepancy between these

cascade excitation rates and those given in Table 6 of Seaton (1963). In a private communication, Dr. Seaton has noted a numerical eror in his work.

Inclusion of the exchange collisions has a significant effect on the production rates only for those levels which have low f values with respect to the ground level, and then only for the case $Q_e=0.1Q_0$.

The product of these production rates and the energy of the respective emitted photons, normalized so that the ${}^2P^o_{1/2}-{}^2P_{3/2}$ transition is unity, gives the predicted relative line strengths of the expected UV lines. These strengths are given in Table 2. Table 3 gives the predicted wavelengths and the wavelengths assigned by Neupert and Smith (1964) from observations of the NASA satellite OSO-I. These identifications were made on the basis of time variations of the line strengths and wavelength separations of the multiplet members. Also included are the observed relative line strengths for two periods of observation in 1962. Quiet Sun (average of March 8, 9, 10) is a period of low solar activity and April 20 is a period of high solar activity. These observed line strengths are also normalized to the ${}^2P^o_{1/2}-{}^2P_{3/2}$ line. This line was about 1.5 times more intense on April 20 than during the Quiet Sun period. At this stage of the reductions, the observed relative line strengths are accurate to only a few tenths (in these units).

	3/2	3/2	223.1	211.5	1.3	1.8
	3/2	5/2	222.0			

In comparing the observations and predictions, it must be noted that the satellite observations do not cover the spectral region occupied by the $^2P^\circ-{}^4P$ multiplet. For the $s^2P(^2P^\circ)$ multiplet, $-sp^2(^2D)$ no lines of the predicted strengths or with the correct time behavior appear to be present at the predicted wavelengths, however the instrumental sensitivity is decreasing in this region.

Since these observed strengths are a result of contributions from the entire solar disc, and due to the uncertainties in the data, only semi-quantitative comparisons with the calculated strengths will be made. Most apparent is the relatively large spread in predicted strengths as compared

to the observed strengths. Using a temperature of 5×10^6 does not significantly reduce this spread. Exchange collisions do not seem important for most cases. However, for the $s^2p(^2P^o)-s^2d(^2D)$ multiplet the ratio of the ratio of the sum of the predicted intensities of the 3/2−3/2 and 3/2−5/2 lines to the 1/2−3/2 line (ratio=8.8:11.2 for $T=10^6$ and $Q_e=0.1Q_0$) is closer (but still in the wrong sense) than for the case where $Q_e=0$.

The possibility of blends cannot be ruled out absolutely, but since the time variations of all these line strengths was quite similar, it is assumed that blends have a small effect. One possibility for the discrepancies in relative strengths is some kind of self-absorption. Due to the very low rate of collisional de-excitation (relative to spontaneous transitions), "true" absorption is not to be expected. Repeated reabsorptions of the UV photons in the corona can change the relative strengths since after each absorption the atom has a choice of making a transition to either of the ground levels. This has the effect of making the relative strengths more nearly equal, which is the desired effect in this case.

This effect has been discussed for the corona by Pecker and Thomas (1963) and Pottasch (1964). Since the number of times a photon is scattered in leaving the corona is τ^2, the optical depth must be greater than unity to have any effect at all. Pottasch (1964) has calculated optical depths for some of the transitions involved here (using an electron density of $2\times10^8\text{cm}^{-3}$). These values ($\tau\approx10^{-1}$ to 10^{-2}) are too small to have any effect on the relative line strengths.

Neupert, Behring and Lindsay (1963) have shown that the UV line strengths seem to be correlated with plage regions and other solar activity. It may be that a higher electron density than that used in Pottasch's calculations may be more appropriate. However, even the electron densities measured by Aly, Evans, and Orrall (1962) in a bright coronal condensation ($\lesssim3\text{X}10^9\text{cm}^{-3}$) are too small to give self-absorption for most of the lines. One possible solution to the problem would be an inhomogeneous corona in which the dense elements had electron densities in the neighborhood of 10^{10}cm^{-3}.

There is one other interesting observation from OSO-1 that needs to be explained. The UV line intensities vary by a factor of two or three for different conditions of solar activity, while the intensity ratios vary by about 50 percent or less. In terms of an inhomogeneous model, this might be explained as each dense element being optically thick (thereby giving the correct intensity ratios). An increase in solar activity would merely mean an increase in the number of dense elements (thereby increasing the intensities of the lines, but having less effect on the intensity ratios. Further reduction of data and calculations should allow a more quantitative discussion of the observations

I am grateful to W. Neupert and E. Smith for discussions of the observations and for the relative line strengths prior to publication, to S. Kastner for helpful discussions and to D. Osterbrock for several discussions, especially those concerning the exchange cross-sections and the self-absorption mechanism.

SOLAR X-RAYS: A COMPARISON WITH MICROWAVE RADIATION

W. A. WHITE

Analysis of data from the OSO–1 satellite shows that solar X-rays shortward of 10 Angstroms exhibit a violent dynamic behavior which however contains within counterparts of the somewhat less dramtic behavior of the solar microwave flux. Specifically, the solar X-ray flux contains: (1) a slowly-varying component, (2) "gradual rise and fall" bursts, and (3) impulsive bursts. The OSO–1 data shows the first two to be related to their microwave counterparts, and the emperical relations are given in this paper. Observations at 10 Angstroms of the third component (impulsive bursts) could not be associated directly with microwave observations owing to the extreme disparity in sensitivities of the two methods of observation of this phenomenon. However, observations by Frost (reported at this Symposium) of solar X-rays in the 20 Kev—100 Kev region do show a direct counterpart of the microwave impulsive burst.

1. INTRODUCTION

With the launching of the OSO–1 on March 7, 1962, it became possible for the first time to point instruments at the sun accurately and continuously for entire daylight portions of a satellite orbit; for the 550-Km orbit of OSO–1 these observing time intervals were the order of one hour each, separated by darkness intervals of about two-thirds of an hour. The observing periods were long enough to disclose some interesting dynamic effects which would be difficult to study otherwise.

2. SENSOR CHARACTERISTICS

OSO–1 provided coverage of the solar X-ray radiation near a wavelength of 10 Angstroms by means of an ion chamber whose characteristics are given in Table 1.

TABLE 1

Window Material	Beryllium
Window Thickness	0.005 inch
Total Window Area (Two chambers in parallel)	3.38 cm^2
Absorbing Gas	Xenon
Gas Pressure	780 mm
Ion Chamber Dept at Normal Incidence	2.19 cm
Ion Pairs per erg	2.8 $(10)^{10}$

*Published as *Goddard Space Flight Center Document X-610-64-42*, February 1964.

The conversion efficiency as a function of wavelength is shown in Fig. 1.

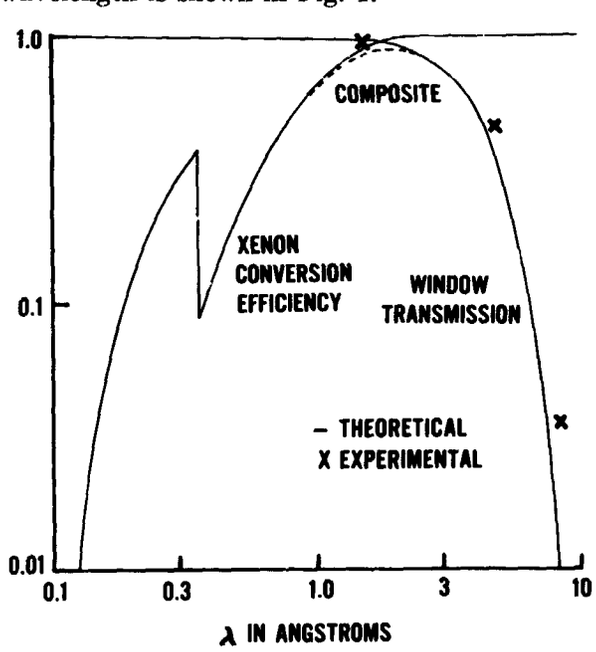

FIGURE 1.—OSO–1 ion chamber conversion efficiency as function of wavelength.

Amplified ion-chamber current was sampled for 2 seconds every 20 seconds by the telemetry.

The full-scale sensitivity of such a broad-band sensor is, of course, dependent upon the shape of the input spectrum. It has been shown[1] that

for non-flare periods it is reasonable to assume a spectral shape consistent with a $2.8(10)^{6}K$ plasma composed of ionized hydrogen and helium in the ratio of their solar abundances. Over the frequently used band limits of 2–8Å, the full-scale sensitivity is then $3.6(10)^{-4}$ ergs cm^{-2} sec^{-1}.

3. COMPONENTS OF THE SOLAR X-RAY FLUX

Changes in the solar X-ray flux as observed by OSO–1 occurred over a broad range of time scales; from fractions of a second to many weeks. In particular, counterparts to the microwave slowly-varying component and to the microwave "gradual rise and fall" burst are clearly seen.

The markedly dynamic character of the solar X-ray flux as contrasted with the 2800–Mc radiation should be emphasized; for instance, on only 3 occasions out of 70 days (7 March through 15 May, 1962) was the X-ray flux "quiet") i.e., free from bursts) for an interval of as much as 8 hours.

3.1 Slowly-Varying Component

Solar rotation markedly affects the X-ray flux. In fact, if one defines the non-burst X-ray flux background as the minimum flux reached in a 6-hour interval and evaluates this for a succession of such intervals, one finds that for the spring of 1962 the OSO–1 data empirically fits the relation

$$\Phi_{2-8A} = k_1 \quad (\Phi - \Phi_0)_{2800Mc} \text{ erg cm}^{-2} \text{ sec}^{-1} \qquad (1)$$

That is, the daily mean non-burst X-ray flux is proportional to the difference between the daily mean of the 2800–Mc flux and a value of 2800–Mc flux which is presumably a "quiet sun" asymptote for the appropriate phase of the solar cycle.[2] Note that any such quiet sun asymptote in the X-ray flux is *zero*, at least to the sensitivity and accuracy of this empirical fit. Apparently a truly quiet sun, stripped of plage, would be dark in X-rays while still emitting an appreciable 2800–Mc flux. Fig. 2 shows the measured mean non-burst X-ray flux and the index values calculated from Eqn. (1) with $K_1 = 1.4(10)^{-5}$, $(\Phi)_{2800\ Mc}$ in units of $10^{-22} Wm^{-2}(c/s)^{-1}$, and $(\Phi_0)_{2800Mc} = 73$ such units.

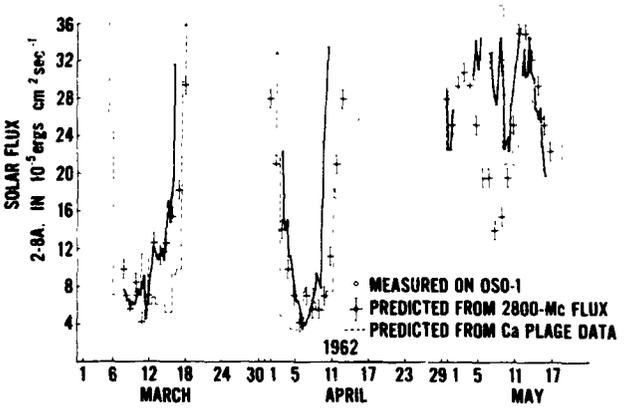

FIGURE 2.—Slowly-varying component of solar x-ray flux

It is fruitful to look in more detail at the relationship between the calcium plages and the X-ray flux. For example, is the brightness of a plage in Ca emission a measure of its brightness in X-rays? If so, we might expect a relationship somewhat as follows:

The brightness of a plage in Ca *K* emission is expressed by an Intensity Number assigned by the McMath-Hulburt Observatory apparently on the basis of a subjective estimate of relative densities on a patrol photograph; as such, it is likely to be approximately logarithmic.

The other routinely reported parameter characterizing a Ca plage is its area. Since we are dealing at X-ray wavelengths with a volume source, an assumption has to be made regarding the dependence of the X-ray source volume upon the area of the plage. It is found from the OSO–1 data that it is much better to assume that the thickness of the X-ray source is proportional to the mean plage diameter, than to assume a constant thickness. The volume of the i^{th} plage is then given by

$$(dV)_i \propto (A_i)^{3/2}$$

where A_i is the reported area.

The hypothesis that the X-ray flux arises from such a plage-associated volume sources with X-ray brightness proportional to Ca *K* brightness can be written as

$$\Phi_{2-8A} = K_2 \sum_i (A_i)^{3/2}(b) I_i \text{ erg cm}^{-2} \text{ sec}^{-1} \qquad (2)$$

where A_i is the volume of the i^{th} plage in thousandths, I is the McMath Ca *K* intensity number, and k_2 and b are constants to be empirically determined from the OSO–1 data.

[1] White, W. A., "Solar X-rays: Slow Variations and Transient Events" —COSPAR IV, Warsaw, June 1963. NASA GSFC Document X-614-63-195.

[2] A. E. Covington and G. A. Harvey, Astrophys. Jour. *132* (1960) 435.

The best fit to date is plotted in Fig. 2, for plages of area $\geq$ 1 thousandth, for

$$k_2 = 0.134\ (10)^{-5},$$

and for

$$b = 2.$$

Plage data reported by the McMath-Hulburt Observatory and published in the CRPL Bulletin was used, with times of rising and setting of the X-ray sources calculated from plage Central Meridian Passage minus and plus 7.8 days respectively. This corresponds to an assumed source height extending to some 21,000 Km above the photosphere.

Two types of gross discrepancy can be seen between the X-ray flux and the hypothetical indices derived from plage and 2800–Mc data. The first type, exemplified by the periods March 12–14, April 10–14, and May 1–2, show too low a value for the plage-derived index. Each of these periods saw the birth of one or more small plages upon the disc which were not included in the index computation of Fig. 2. The second type of discrepancy is seen during the period May 3–7 for which the index derived from the 2800–Mc flux is low. This period included a large plage (McMath 6412) which was reported to be declining in Ca *K* intensity; this plage contained a single sunspot which was seen to die on the disc.

3.2 Gradual Rise and Fall Bursts

Superimposed upon the X-ray slowly-varying component and occurring so frequently as to make difficult the finding of intervals completely free from their effects, are X-ray bursts analogous to the "gradual rise and fall" bursts seen in solar microwave radiation. A complete statistical analysis of the X-ray bursts observed by OSO–1 has not yet been made, but typical on-scale bursts (see Fig. 3) have rise times of 2 to 4 minutes and fall times of 10–20 minutes. However, many bursts carry the experiment output offscale; for these, the duration of the event can be as long as 6 hours. A comparison of the X-ray data with 2800–Mc records (kindly made available by A. E. Covington) taken at Ottawa shows that all 2800–Mc gradual bursts had a time-coincident counterpart in the X-ray data. A peak amplitude on only 1 or 2 units of 10^{-22} $W\ m^{-2}$ sec^{-1} at 2800-Mc

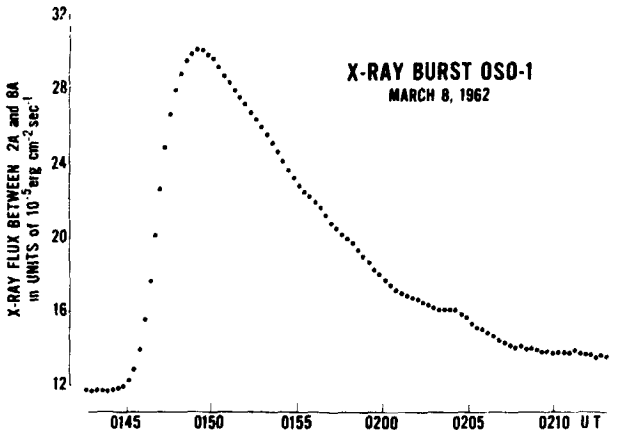

FIGURE 3.—X-ray burst OSO–1 March 8, 1962

was in all cases accompanied by an off-scale X-ray burst; larger bursts at 2800–Mc were of course also off-scale in X-rays, but again times of onset and recovery were found to agree with the corresponding times for the accompanying X-ray burst.

It is important to note that the relationship between burst flux at 2800–Mc and at 2–8 A is different from the relationship between the slowly-varying component at 2800–Mc and at 2–8 A. As has been shown (Eqn. 1), a change in 2800–Mc slowly-varying component of 1 flux unit is accompanied by a change in 2–8 A flux of about 1.4 $(10)^{-5}$ erg cm^{-2} sec^{-1}; whereas a burst type change at 2800–Mc of 1 flux unit is accompanied by a change in 2–8 A flux of at least $30.(10)^{-5}$ erg cm^{-2} sec^{-1}. This increase in the X-ray/microwave ratio of more than 20 times is suggestive of a different physical process being responsible for the two phenomena.

Several apparent associations of certain X-ray bursts into groups displaying a definite pattern were observed; Fig. 4 shows such grouping. Similar groupings are present in the data for the first week in April 1962; in fact, the one particular March group shown in Fig. 4 appears to have an exact April counterpart 27.1 days later with identical time-separations between events and with identical peak excursions above mean background level. In addition to these two groups, two others each having 4 members and one other having 3 members were found. For all five groups, the envelope joining the peaks of the bursts within a group is a straight line of slope $\pm 1.51(10)^{-9}$ erg cm^{-2} sec^{-2} for wavelengths be-

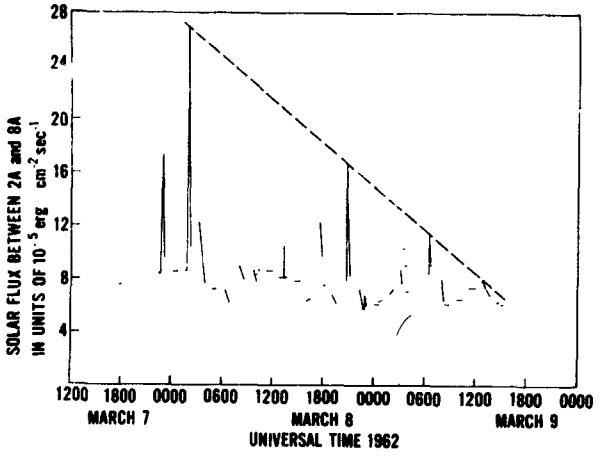

FIGURE 4.—Solar x-rays (2–8A) showing grouping of x-ray bursts.

tween 2 and 8A; three groups displayed positive slopes, two groups negative.

3.3 Impulsive Bursts

Several instances of very fast bursts (entire duration less than 2 minutes) were seen by Frost (reported at this Symposium) from an OSO–1 sensor responsive to photons of energy greater than 20 Kev. For every one of these instances the lower-energy ion-chamber channel was off-scale prior to and during the time interval of the impulsive burst. It is indeed unfortunate that we are thus unable to obtain an X-ray/microwave ratio for an impulsive burst to compare with the values obtained for gradual bursts and for the slowly-varying component.

IV. IONOSPHERE AND RADIO PHYSICS

N66 37955

D REGION FORMATION*

ARTHUR C. AIKIN

I. INTRODUCTION

That part of the terrestrial ionosphere which lies below 85 km is termed the "*D* region." Observations of ion and electron densities have been made at altitudes as low as 40 km so that this altitude can be taken as the lower boundary of the region. The mean molecular mass of the neutral atmosphere is essentially constant throughout the *D* layer and the distribution of the principal constituents, molecular oxygen and nitrogen, can be described by the hydrostatic equations relating density, pressure, and temperature. There are also several minor constituents of importance such as atomic oxygen, which reaches its peak concentration above 85 km, ozone and various oxides of nitrogen.

One of these minor constituents nitric oxide has an ionization potential such that it will be ionized by the strong hydrogen Lyman alpha line of the solar spectrum at 1216A. Lyman alpha together with short wavelength X-rays and galactic cosmic radiation are considered to be the ionizing sources of the undisturbed *D* region. Enhancement of 2 to 8A X-rays during solar flares causes large increases of electron density. These increases are termed sudden ionospheric disturbances or "SID's." Other equivalent terms in common use are cosmic noise anomaly (CNA) and sudden phase anomaly (SPA), although these terms refer to the effect on a specific type of measurement.

Electrons in the energy range 10 to 200 kev are precipitated in the auroral zone, which extends between 60° and 70° geomagnetic latitude. These electrons are the primary source of the aurora and cause large increases in *D* and lower *E* region ionization. Protons of 10 to 100 Mev produced in the course of large solar flares arrive at the earth a few hours after onset of the flare. The resultant increases in ionization occurring over the entire polar cap and extending south to a geomagnetic latitude of 65° are termed "Polar Cap Absorption" events or PCA. After the sudden commencement of a magnetic storm, which occurs about 20 hours after a strong flare, the polar cap radio wave absorbing region is extended to a geomagnetic latitude of 55°. Some sudden commencement events are accompanied by dumping of electrons in the auroral zone.

Electron density distributions, observed during some of the ionizing events discussed here, are illustrated elsewhere in this book (Electron Density Distribution by R. E. Bourdeau). A description of the ionization and recombination processes taking place in the homosphere under the influence of different radiations is given in the following sections.

II. ATMOSPHERIC ABSORPTION OF PHOTONS AND CHARGED PARTICLES

In order for radiation to penetrate to the *D* region it must have an absorption cross section of less than 10^{-19}cm^2 in air. Molecular oxygen is the limiting agent in this regard. In fact ultraviolet radiation having a wavelength shorter than the first ionization potential of O_2 at 1026.5A is precluded. At longer wavelengths the penetration of photons to sufficiently low altitudes can occur only in the atmospheric windows near 1216, 1187, 1167, 1157, 1143 and 1108A. For these wavelengths unit optical depth occurs near 10^{20} molecules cm^{-2} of vertical column. When the number of molecules in a vertical column is sufficient to reduce a flux of photons to 1/e of its incident value, unit optical depth is attained.

At wavelengths longer than 1800A the penetration of radiation is also possible between the bands of the Schumann-Runge system of O_2.

*Published as *Goddard Space Flight Center Document X-615-64-64*, March 1964. This work is a contribution to the "International Dictionary of Geophysics" Pergamon Press, Oxford, England.

However, ionization by these wavelengths requires constituents for which the ionization potential (IP) is low, such as sodium (IP–2413A) and calcium (IP–2028A).

For wavelengths shorter than 12.4A (1 kev) the absorption cross section rapidly decreases below 10^{-19}cm^2. It is found that the wavelength region most useful in the production of ionization between 70 and 85 km is 2 to 8A. The wavelength interval between 8 and 13A as well as near 35A does not penetrate to the *D* region since it is absorbed between 85 and 100 km resulting in the base of the *E* region. Radiations more energetic than 10 kev penetrate below 70 km as illustrated in figure 1. Here unit optical depth is plotted as a function of photon energy.

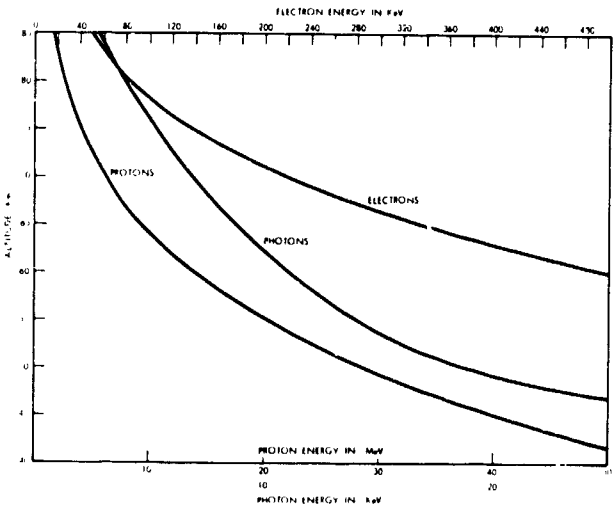

FIGURE 1.—Depth of penetration in the terrestrial atmosphere as a function of energy for photons, electrons and protons.

Nicolet and Aikin (1960) have compiled a table of the total absorption cross sections in O_2, N_2, A, and air for wavelengths between 10 and 0.1A. Both the photoelectric and Compton scattering cross sections for photons with energies greater than 10 kev, have been tabulated by Grodstein (1957). Above 1A, Compton scattering can be neglected and the absorption of a photon releases an electron whose energy depends on the ionization potential of the atom. If the electron is ejected from the *K* shell of the atom, the Auger effect must also be considered as a mechanism for producing additional electrons.

When an incident photon has an energy, $h\nu$, which exceeds the threshold of ionization for the *K* shell of O_2 and N_2 ($\sim$500 ev), the ejected photoelectrons will have a kinetic energy of $\frac{1}{2}$ mv^2 $=h\nu-500$. Since the average kinetic energy that is required of an electron to produce an ion pair is 35 ev, the efficiency of ionization, ϵ, of a photon which interacts by the photoelectric effect can be computed.

The behavior of charged particles in the earth's atmosphere is complicated by the presence of the earth's magnetic field. This field determines the latitude dependence for the energy deposition point of charged particles and modifies the incident particle energy spectrum. However, in order to know what energies are required of various charged particles to contribute to the ionization of the *D* region, it is sufficient to consider the range in gm/cm^2 of air of the particles.

Experimental data on the range of protons in air has been given by Bethe and Ashkin (1953). For energies less than 500 Mev Maeda and Singer (1961) have employed the following empirical formula

$$R(\text{gm/cm}^2) = E^{1.78}/420 \qquad (1)$$

where E is the proton energy in Mev. This expression can be used to estimate the depth of penetration as a function of proton energy as illustrated in figure 1. It is seen that protons in the energy range 2 to 40 Mev dissipate most of their energy in the altitude region 85 to 45 km. Maeda and Singer (1961) have also given an approximate range for electrons of energy less than 0.2 Mev

$$R(\text{gm/cm}^2) = E^{1.96}/0.75 \qquad (2)$$

based on the data of Katz and Penfold (1953).

III. THE PRODUCTION OF IONIZATION BY SOLAR PHOTONS

In the previous section a discussion was given of the absorption of photons in air and the subsequent production of ion pairs by the photoelectric and Compton processes. For the case of monochromatic solar radiation, the number of ion pairs produced cm^{-3}sec^{-1} at an altitude z is

$$q_p = n_j \epsilon'_j \sigma Q_\infty \exp(-\tau) \qquad (3)$$

where σ'_j is the effective ionization cross section in

cm^3 of the j constituent, n_j is the number density cm^{-3} of that constituent, Q_∞ is the number of photons/cm^2/sec vertically incident on the earth's atmosphere and ϵ is the efficiency of ionization. The optical depth, τ, is the sum of the products of the absorption cross section, σ_{Ak}, and the total number of absorbing molecules of species k between the height z and the sun. It is given by the expression

$$\tau = \sum_k n_k \sigma_{Ak} H_k \sec \chi \qquad (4)$$

where χ is the solar zenith angle, n_k is the number of molecules of species k at height z and H_k is the local scale height of molecule k. The quantity $n_k H_k \sec \chi$ represents the total number of absorbing molecules between the height, z and the sun for a plane earth. However, for solar zenith angles greater than 85° it is necessary to take into account the curvature of the earth. This has been considered in various calculations for the sunrise effect in the ionosphere. Chapman (1931) has derived a function which can be used in place of sec χ in equation 4 provided that the scale height is constant. The peak altitude for the production of ion pairs can be obtained by differentiating (3). For an overhead sun this occurs for the condition

$$\tau = 1 + \beta \qquad (5)$$

where $\beta = dH/dz$ is the gradient of the scale height H_k. Since β is small at the height levels of interest, the altitude of the electron production peak is approximately the altitude of unit optical depth which is shown in figure 1.

Both satellite and rocket observations have been made of solar X-rays in the 2 to 8A region. Measurements employing rocket-borne Geiger counters sensitive to the total intensity in this wavelength range, have been conducted for several years by the U.S. Naval Research Laboratory, (Friedman (1962)). The results have demonstrated that the flux varies considerably depending on the degree of solar disturbance. Utilizing this data Nicolet and Aikin (1960) divided the 2 to 8A range into 3 wavelength bands centered at 2, 4, and 6A. Their results are given in table 1 for various solar conditions ranging from solar sunspot minimum to class 3 solar flares. Measurements of the spectral distribution in the 4 to 8A range have been carried out on rockets by Pounds and Sanford (1962) and on the Ariel I satellite by Pounds, et al (1963). The results of these measurements are in agreement with table 1.

TABLE 1.—*Variations in the X-Ray Intensities According to Various Solar Conditions*
Energies in erg cm^{-2} sec^{-1}

Condition of the Sun	2A	4A	6A
Completely Quiet	10^{-8}	10^{-7}	10^{-6}
Solar Minimum			
Quiet	10^{-7}	10^{-6}	10^{-5}
Lightly Disturbed	10^{-6}	10^{-5}	10^{-4}
Solar Maximum			
Disturbed	10^{-5}	10^{-4}	10^{-3}
Special Events	10^{-4}	10^{-3}	10^{-2}
Flares			
Class 3 Flares	10^{-3}	10^{-2}	10^{-1}

The cause of sudden ionospheric disturbances was at one time attributed to enhancement of hydrogen Lyman alpha radiation (1216A). However, a rocket experiment by Chubb et al (1957), during the course of a flare, established that although the intensity of 2 to 8A X-rays was enhanced, no appreciable change occurred in the Lyman alpha flux. Satellite observations have shown that the 2 to 8A flux enhancement is quite different from one event to another. Furthermore the enhancement of the X-ray flux may last much longer than the optical portion of the flare and take hours to decay to its preflare value. Also increases in the short wavelength range below 2A have been observed coincident with radio noise bursts at the commencement of a strong flare by various workers including Peterson and Winckler (1959). Nicolet and Aikin (1960) have shown that the radiation below 2A will be important only if its ionizing effect is greater than the effect of cosmic rays, which are the normal source of ionization below 70 km.

Since the X-ray flux emitted by the sun at sunspot minimum is insufficient to cause any appreciable ionization, another mechanism must be found to explain the formation of the D region during quiet sun conditions. The hypothesis that the D region might be formed by the ionization of nitric oxide by Lyman alpha radiation was postulated by Nicolet (1945). It was shown in

section II that Lyman alpha is absorbed in the *D* region. Watanabe (1954) has measured the ionization cross section of nitric oxide at 1216A and found it to be 2×10^{-18}cm^2. It then remains to establish the presence of a sufficient quantity of nitric oxide in the mesosphere.

Nitric oxide is a minor constituent of the mesosphere. The most important processes determining the nitric oxide distribution involve atomic nitrogen, which is produced by dissociative recombination of N_2^+ and NO^+ (see section VI). When the concentration of atomic nitrogen is sufficiently great, the density of NO will be determined by the reactions of N with O_2 and NO namely

$$N+O_2 \rightarrow NO+O \qquad (6)$$

$$N+NO \rightarrow N_2+O \qquad (7)$$

The ratio of the rate coefficients of these reactions has been measured by Clyne and Thrush (1961) and found to be 0.28 exp(−3450/T), where T is the gas temperature in °K. The density of nitric oxide is then

$$n(NO)=0.28n(O_2)\exp(-3450/T) \qquad (8)$$

Barth (private communication) has detected nitric oxide bands in the dayglow spectrum. Nitric oxide concentrations at least as large as those given by (8) can be deduced from the intensity of the dayglow. It has been demonstrated by Nicolet and Aikin (1960) that even concentrations of the order of 10^{-10} of the total number density are sufficient to account for *D* region ionization in the absence of X-rays. Inn (1961 a and b) has suggested that the photoionization of vibrationally excited O_2 by Lyman alpha may contribute significantly to the ion density of the *D* region.

IV. THE COSMIC RAY PRODUCTION FUNCTION

Galactic cosmic radiation is also an important factor in the formation of the *D* region. The ionizing effect of cosmic rays was first considered by Nicolet (1958). If $q_0(\phi)$ is the ionization rate for $n_0=2.6\times10^{19}$ molecules cm^{-3} at geomagnetic latitude ϕ, then the ionization rate for a number density n is

$$q(\phi)=q_0(\phi)n/n_0 \text{ cm}^{-3}\text{ sec}^{-1} \qquad (9)$$

Van Allen (1952) has shown that $q_0(\phi)$ is reduced by a factor of 10 at the geomagnetic equator compared to a latitude of 70° namely between 30 and 300 ion pairs cm^{-3} atm^{-1} sec^{-1}. The time variation of cosmic rays has been summarized by Webber (1962). The important factor to bear in mind is that $q_0(\phi,z)$ is 50 percent larger at sunspot minimum compared to sunspot maximum. Figure 2 shows the results of a calculation of the ion pair production function $q(\phi,z)$ for a $q_0(\phi)$ equal to 269 ion pairs cm^{-3} atm^{-1} sec^{-1}.

V. IONIZATION BY LOW ENERGY ELECTRONS AND PROTONS

The number of ion-pairs, q_β, cm^{-3} sec^{-1} produced at a height, z, by charged particles with an energy distribution between E_{min} and E_{max} may be expressed as

$$q_\beta=\frac{\rho(z)}{0.032}\int_{E_{min}}^{E_{max}} K_e(E)i(E,z)dE \qquad (10)$$

where $\rho(z)$ is the atmospheric density in gm cm^{-3} at altitude z. The formula for energy loss by

ionization, $K_e(E)$, has been approximated by Maeda and Singer (1961) to be

$$K_e(\mathrm{E}) = \frac{-dE}{dR} = 0.38E^{-0.96} \qquad (11)$$

for electrons and

$$K_p(\mathrm{E}) = \frac{-dE}{dR} = 236E^{-0.78} \qquad (12)$$

for protons, where R is the range in gm/cm^2 and E is expressed in Mev. The number of charged particles of energy, E, arriving at a height z is $i(E,z)$ cm^{-2} sec^{-1} kev^{-1}. It can be found if the incident spectrum of the particles is known. Since the particles enter the atmosphere at various angles with respect to the earth's magnetic field and have a spatial distribution, it is necessary to calculate $i(E,z)$ by integrating over both the pitch and solid angles.

Maeda (1963) has shown that

$$i(E,\ z) = \int_0^{\theta} \int_0^{\pi/2} j(E)\ \exp\left[-\frac{x}{\lambda(E)\cos\alpha}\right] \sin\alpha d\alpha d\theta \qquad (13)$$

where θ is the solid angle, α is the pitch angle, x is the atmospheric depth at height z, and $\lambda(E) = (3.15)10^{-7}E^{2.2}$ is the attenuation mean free path. For the case of an auroral absorption event a possible representation of the differential energy spectrum is $j(E) = (1.6)10^{12}E^{-5.2}$ particles cm^{-2} sec^{-1} ster^{-1} kev^{-1}. This type of spectrum and flux of particles has been observed by McIlwain (1960). However, there were no accompanying measurements of electron density in the D region. The production function q_β for this type of input spectrum is illustrated in figure 2.

Aikin and Maier (1963) have calculated the ionizing effect of bremsstrahlung produced by the electron differential energy spectrum described above. The cross section per atom for production of photons of energy hν by an electron of energy E is

$$\phi(E,\ h\nu)d\nu = (8/3)\alpha\ \rho_0^2 Z^2 mc^2 \frac{1}{\nu E} \ln\frac{\{\sqrt{E}+\sqrt{E-h\nu}\}^2}{h\nu} d\nu \qquad (14)$$

for energies less than 510 kev (Heitler, 1954). Here α represents the fine structure constant, ρ_0 the classical radius of the electron and Z the charge of the nucleus. The differential energy spectrum of photons $dQ(h\nu)$ emitted at an atmospheric depth x in a thickness dx is

$$dQ(h\nu)d\nu = K\int_{E=h\nu}^{\infty} \phi(E_{h\nu},h\nu)i(E,x)dE\ dxd\nu \qquad (15)$$

where K is the number of atoms per gram. Note that only electrons of energy $E \geq h\nu$ contribute to the photon flux at energy $h\nu$. The resulting ion-pair production function is also illustrated in figure 2.

Although most auroral absorption events are caused by electrons, accompanying proton fluxes have also been observed. Large solar flares are sources of large fluxes of protons and heavier particles, which produce polar cap absorption events. These events have been discussed by Bailey (1957, 1959) and Webber (1962). Calculations of the type discussed above for electrons can be carried out to estimate the ionizing effect of solar flare protons incident on the atmosphere. Reid (1961) has performed such a calculation for a power law differential energy spectrum of the form $j(E) = K\,E^{-4}$. However, Webber (1962) finds a better fit to the experimental data if use is made of an exponential spectrum of the form

$$i(P) = Ke^{-P/P_0} \qquad (16)$$

where P is the rigidity of the particles. P_0 may range from 50 to 200 Mv, depending on the geomagnetic latitude at which the ionization is observed. For instance observations of the absorption of cosmic noise for latitudes greater than 70° require a rather steep particle spectrum or a $P_0 < 100$ Mv. For geomagnetic latitudes of 65° or less a $P_0 > 150$ Mv is required. This requirement can also be met by introducing a geomagnetic cutoff into a power law spectrum. Curve 5 of figure 2 is taken from Webber (1962) and illustrates the electron production function for an integral intensity of solar protons of 0.05 particles/cm^2 ster sec for energies greater than 100 Mev. A rigidity spectrum is assumed and P_0 is taken to be 50 Mv. More recently Webber and Freier (1963) have shown that α particles should be included in the calculation of the production function for polar cap events.

VI. LOSS PROCESSES

The distribution of ions and electrons in the *D* region depends on the interactions of these particles with one another as in the case of recombination and on interactions with constituents of the neutral atmosphere. In the latter instance, negative ions may be formed through the process of electron attachment, also charge transfer and ion-atom interchange reactions modify the distribution of various species of ions. At the present time the problem is complicated by a lack of experimental data. Although some measurements of positive ion density have been reported, the technique is presently in the development stage. No data are available on the species of positive and negative ions found in the mesosphere. The problem is further complicated by the difficulty of duplicating lower ionospheric conditions in laboratory experiments for the determination of reaction cross sections. There are a large number of possible reactions, but only those which are currently in use will be discussed here.

Dissociative recombination involves an electron and ion through the reaction

$$XY^+ + e \rightarrow XY^* \rightarrow X' + Y' \qquad (17)$$

where * and ′ denote excited states of the molecule and atoms respectively. The three ions of importance in the *D* region are O_2^+, N_2^+, and NO^+. The rates of dissociative recombination of O_2^+ and N_2^+ have been measured by Kasner, et al (1961), who employed a mass spectrometer for the identification of ions. Values of $\alpha_D(O_2^+) = (1.7 \pm 1)10^{-7}$ cm^3 sec^{-1} and $\alpha_D(N_2^+) = (3 \pm 1)10^{-7}$ cm^3 sec^{-1} were reported for a nitrogen partial pressure $\lesssim 1$ mmHg at 300°K. Although the rate coefficient for dissociative recombination is temperature dependent, see Bates and Dalgarno (1962), the temperature employed in the laboratory measurements is close enough to the mesospheric temperature of about 200°K that this dependence can be ignored.

The measurements of the dissociative recombination coefficient $\alpha_D(NO^+)$ are not so well developed as those for O_2^+ and N_2^+. Guntan and Inn (1961) have reported a value of $(1.3)10^{-6}$ cm^{3}sec^{-1} and Doering and Mahan (1962) a value of $(3^{+17}_{-2})10^{-7}$cm^{3}sec^{-1}. Since both these measurements were conducted at partial pressures of NO > 0.1 *mmHg*, where the formation of complex ions is possible and no mass spectrometer measurements were made of the ions, there is some doubt as to whether these measurements really refer to $\alpha_D(NO^+)$. Ionospheric experiments tend to support a slower rate of recombination and indicate that $\alpha_D(NO^+)$ should be less than either $\alpha_D(O_2^+)$ or $\alpha_D(N_2^+)$. Nicolet and Aikin (1960) employed the value of (3) 10^{-9} cm^3 sec^{-1} for $\alpha_D(NO^+)$ but revised estimates of the nitric oxide densities and measurements of electron densities together with solar radiations would tend to support a rate in the neighborhood of $1-5\ 10^{-8}$ cm^3 sec^{-1}, (Aikin, et al, (1963)).

Gali, et al (1963) have investigated the ion-molecule reactions

$$N_2^+ + O_2 \rightarrow NO^+ + NO(\gamma) \qquad (18)$$

and

$$O_2^+ + N_2 \rightarrow NO^+ + NO(\gamma_2) \qquad (19)$$

where the rate coefficients γ_1 and γ_2 were assigned an upper limit of $(2.1)10^{-13}$cm^3/sec for both these reactions. The ratio of the neutral particle to electron density in the *D* region is such that these would be important reactions for rate coefficients as low as 10^{-18} cm^2/sec. The net result of these processes is to make NO^+ the dominant species of positive ion in the *D* region. Therefore, an in situ ion mass spectrometer measurement cannot be used to establish the validity of the Lyman alpha hypothesis for the formation of the quiet sun *D* layer. The reaction

$$N_2^+ + O_2 \rightarrow O_2^+ + N_2(\gamma^3) \qquad (20)$$

is also energetically possible and may have a rate coefficient as high as 10^{-16} cm^3 sec^{-1}.

Electrons can attach themselves to oxygen molecules through the three-body process

$$e + O_2 + O_2 \rightarrow O_2^- + O_2 \qquad (21)$$

to form negative ions of O_2. Chanin, et al (1962) have measured the rate of this reaction. At *D* region temperatures a value of $a(O_2) = 1.5 \times 10^{-30}$cm^6 sec^{-1} is found. Burch, et al (1958) have studied the rate of photodetachment of electrons from O_2 as a function of wavelength of the radiation. They estimate that for the solar spectrum a photodetachment coefficient of

$$d(O_2) = 0.44 \text{ sec}^{-1}$$

is applicable for O_2^-. Branscomb, et al (1958) have made a similar study for atomic oxygen from which they deduce a radiative attachment coefficient, $a(O)$, of electrons to atomic oxygen of $(1.3)10^{-15}$ cm^3 sec^{-1} and a photodetachment rate, $d(O)$, of 1.4 sec^{-1}.

The problem of the removal of negative ions in the absence of photodetachment is unclear at the present time. Phelps and Pack (1961) have measured the rate of collisional detachment of O_2^- in the presence of O_2 and find a rate coefficient, η, of (4) 10^{-20} cm^3 sec^{-1}. It was also found that N_2 was ineffective as a detaching agent.

Associative detachment of the form

$$O_2^- + O \rightarrow O^3 + e \qquad (22)$$

has also been proposed as a possible mechanism for the removal of negative ions. Possible values of the rate coefficient, ρ, of this reaction range from 10^{-14} cm^3 sec^{-1} to 10^{-10} cm^3 sec^{-1}. A similar process involving O^- may take place.

The remaining process to be considered is mutual neutralization of a positive and negative ion. This process is of the form

$$XY^+ + WZ^- \rightarrow XY + WZ \qquad (23)$$

The rate coefficient, α_i, has been measured in the laboratory for the mutual neutralization of NO^+ and NO_2^- by Mahan and Person (1964). A value of (2.1) 10^{-7} cm^3 sec^{-1} was obtained. At altitudes below 45 km the Thompson three-body process must be considered. This reaction is of the form

$$XY^+ + WZ^- + M \rightarrow XY + WZ + M \qquad (24)$$

and has a rate coefficient of

$$\alpha_T = 8 \times 10^{-3} p / T^{5/2} \text{cm}^3\text{sec}^{-1}$$

here p is the pressure in *mmHg* and T the temperature in °*K*.

The continuity equations governing the altitude distribution of each species of ion and electrons in the *D* region can be written so that the processes discussed above are included together with the appropriate ion-pair production function. Such a set of simultaneous differential equations can be solved with the aid of a computer, however, usually the approximation is made that $dN/d^3 = 9$, i.e., that quasi-equilibrium exists throughout the *D* region.

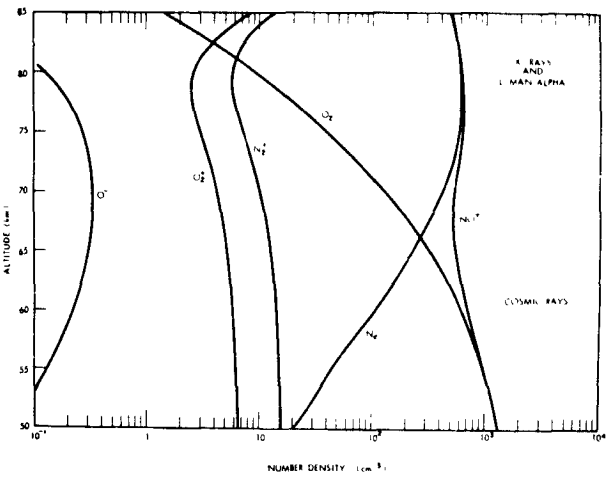

FIGURE 3.—Ion and electron density distributions for the rate coefficients listed in table II.

The results of an exact solution of such a set of equations are illustrated in figure 3 for a geographic latitude of 38°. Here the relative importance of Lyman alpha, cosmic rays, and x-radiation in the formation of the *D* region under conditions of a completely quiet sun is shown for a solar zenith angle of 55°. The effect of reactions (18) through (20) in changing N_2^+ and O_2^+ into NO^+ when the rate coefficients are 10^{-18} cm^3 sec^{-1} is clearly demonstrated. This will enhance the electron density, since the dissociative recombination coefficient of NO^+ has been taken to be almost an order of magnitude below that of O_2^+ and N_2^+. Table 2 summarizes the numerical factors employed in the calculation.

TABLE 2.—*Rate Coefficients Employed in the Calculations for Figure 3*

Symbol	*Rate*
αDO_2	1.7×10^{-7}cm^3/sec
αDN_2	2.8×10^{-7}cm^3/sec
αDNO	3×10^{-5}cm^3/sec
γ_1	10^{-18}cm^3/sec
γ_2	10^{-18}cm^3/sec
γ_3	10^{-18}cm^3/sec
$a(O_2)$	1.5×10^{-30}cm^6/sec
$d(O_2)$	0.44 sec^{-1}
$a(O)$	1.3×10^{-15}cm^3/sec
$d(O)$	1.4 sec^{-1}
η	4×10^{-20}cm^3/sec
ρ	10^{-13}cm^3/sec
α_i	10^{-7}cm^3/sec

The nitric oxide density is 10^{-10}n(M).

VII. THE NOCTURNAL *D* REGION AND THE SUNRISE EFFECT

In the absence of ionization sources other than cosmic rays, the *D* region electron density decays to low values at night. Thus, it is extremely difficult to obtain electron density measurements during this period. However, observations are possible in the auroral zone with the aid of cosmic noise absorption techniques. This has led to a comparison of the sunlit and dark *D* regions under the action of the same flux of ionizing particles. In this way the different processes affecting the negative ion distribution can be examined. Let us first discuss the behavior of the undisturbed *D* region at sunrise.

A good deal of information concerning the electron density distribution has been determined from the phase and amplitude of 16 kc/sec waves reflected from the ionosphere at near vertical incidence. Bracewell (1952) has noted that the amplitude of such a wave begins to decrease at a time when the sun's rays grazing the earth illuminate an area 60 km above the ground. There is no corresponding decrease in phase at this time. Rather a decrease in phase path begins just before ground sunrise with the major portion of the drop occurring after ground sunrise, the total change in height amounting to 15 km. These results were interpreted by Bracewell and Bain (1952) as being due to a double-layered *D* region.

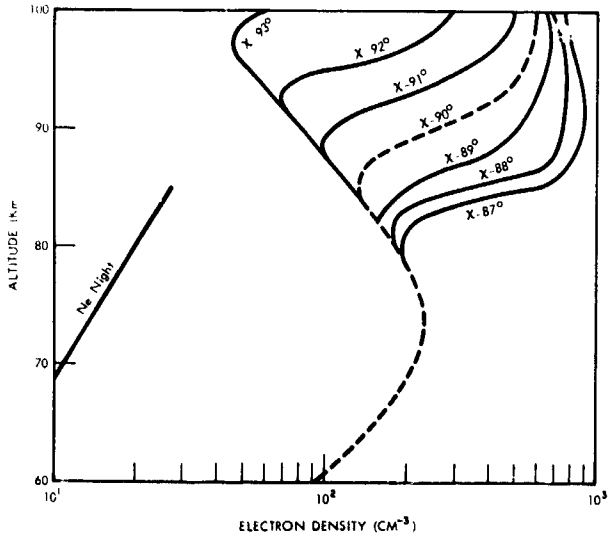

FIGURE 4.—The electron density distribution at sunrise for different solar zenith angles and the nocturnal electron density distribution.

The origin of the double layer lies in the ability of solar radiation in the visible wavelength region to penetrate to the lower *D* region and photodetach electrons from O_2^- ions, which are produced as the result of cosmic ray ionization. This layer centered around 73 km will thus appear before Lyman alpha and X-rays have had a chance to penetrate into the *D* region. As the solar zenith angle decreases these radiations produce a second *D* region above the cosmic ray layer thus forming a two-layered *D* region. Eventually the two layers merge to form the normal daytime *D* region. The theoretical variation of the electron density distribution at sunrise is illustrated in figure 4 which is taken from Aikin (1962).

As noted previously most *D* region calculations are performed using the equilibrium solutions of the continuity equations for electrons and the various species of ions. This has led to the definition of the negative ion to electron ratio λ. During the day, λ can be approximated as the ratio of the rate of attachment to photodetachment which for O_2^- is

$$\lambda_{O_2^-} = (3.4)10^{-30}[n(O_2)]^2 \qquad (25)$$

and for O^-

$$\lambda_{O^-} = 10^{-15}n(O) \qquad (26)$$

Even in the upper *D* region where atomic oxygen reaches the peak of its concentration, λ_{O^-} is less than 10^{-2}. On the other hand $\lambda_{O_2^-}$ is equal to 1 near 70 km so that O_2^- is the primary negative ion in the *D* region as shown in figure 3.

The diurnal variation of cosmic noise absorption during auroral and polar cap events has recently been used to derive information on the rate coefficients affecting the ratio λ. For a constant flux of ionizing particles it has been demonstrated (see e.g., Bailey (1957)), Hultquist (1963), Webber (1962), that the ratio of day to night absorption $A_D/A_N = 1+\lambda_N/1+\lambda_D$ where λ_N is the night average value of λ at the height where the absorption occurs and λ_D is the day average for the same altitude range. This expression is valid only for the case where the absorption occurs in a relative narrow altitude range of about 5 km. The more general case has been considered by Reid (1961).

Because the fluxes of auroral particles are highly variable, a statistical analysis must be employed to find the ratio A_D/A_N for auroral absorption events. Holt and Landmark (1963) deduce a value of 2, while Hultquist (1962) deduced yearly averages between 0.89 and 1.38 with a 4 year average of 1.16.

Polar cap absorption events yield higher values of A_D/A_N than auroral absorption observations. Webber (1962) has summarized riometer data from a large number of polar stations and finds that for geomagnetic latitudes greater than 70° $A_D/A_N \cong 6.5 \pm 1$ and for 65° or less $A_D/A_N \cong 5 \pm 1$. The difference in the two cases being accounted for in the rigidity and therefore atmospheric penetration of the protons. Since the protons penetrate to greater atmospheric depths than auroral electrons, the cosmic noise absorption during polar cap events occurs at altitudes where λ is more of a determining factor for the absorption. Various authors have shown that collisional detachment values must exceed the laboratory estimates by 3 orders of magnitude to explain the observations. Whitten and Poppoff (1962) have suggested that associative detachment may replace collisional detachment as the negative ion removal process during darkness.

The variation of polar cap absorption events during twilight periods has given rise to speculation that a negative ion other than O_2^- is found in the *D* region. It has been observed that nighttime values of absorption are reached despite the fact that the sun did not set at heights greater than 50 km (see for example Reid and Collins (1959), and Eriksen, et al (1960)). These observations led Reid and Leinbach (1962) and Eriksen et al (1960) to suggest that the dominant negative ion during twilight was not O_2^- but rather an ion with a much larger electron affinity requiring ultraviolet light for photodetachment.

Clearly the explanation of the diurnal variation of auroral and polar cap absorption depends on a more exact knowledge of the particle spectrum and species of negative ion as well as the inclusion of solar radiations in the calculations of cosmic noise absorption. There is, however, laboratory evidence for the existence of a negative ion with a high value of electron affinity. Curran (1962) has demonstrated that the electron affinity of NO_2^- is greater than 3.82 ev. For photodetachment to occur by solar radiation whose wavelength range is in the near ultraviolet an electron affinity of about 4 ev is required. Thus NO_2^- is a possible candidate. However, since the NO_2 concentration is predicted to be only a fraction of the nitric oxide concentration and Curran (1962) has found that direct attachment of electrons to No_2 is unimportant, charge exchange processes involving O^- and O_2^- must be operative in order to form an appreciable amount of NO_2^-. Curran (1962) has given a rate coefficient of 10^{-9} to 10^{-10}cm^3/sec for the formation of NO_2^- by

$$O^- + NO_2 - NO_2^- + O \qquad (27)$$

Inasmuch as O^- is thought to be a negative ion of minor importance, the reactions

$$O_2^- + O \rightarrow O^- + O_2 \qquad (28)$$

and

$$O_2^- + NO_2 \rightarrow NO_2^- + O_2 \qquad (29)$$

should also be considered.

The theory of formation of the D region is by no means complete. While the sources of ionization and their efficiency of ion pair production have been reasonably well established, the chemistry of a nitrogen-oxygen system under the influence of different radiations is not well understood. A great deal more investigation is required in order to establish the role of the various reactions discussed here. In situ measurements are becoming increasingly more important not only because of the promise of measuring difficult parameters such as negative ions, but also because the necessary s multaneous determination of several parameters can be effected. Such phenomena as auroral absorption events and ionization by X-ray enhancements during the course of solar flares cannot be adequately explained without recourse to such experiments.

SOME RESULTS OF ROCKET EXPERIMENTS IN THE QUIET *D* REGION*

A. C. AIKIN, J. A. KANE AND J. TROIM†

Two electron density profiles have been obtained for the quiet day mid-latitude *D* region by means of ground to rocket radio propagation experiments. These profiles are interpreted between 85 and 70 km in terms of solar Lyman alpha ionization of nitric oxide. The role of 2 to 10 Ångstrom X-rays is shown to be unimportant to the formation of the *D* region for the quiet solar conditions present during the two rocket flights. The electron collision frequency in the *D* region is shown to be subject to significant variations which are correlated to pressure varia- of the stratosphere.

INTRODUCTION

A theory of the formation of the *D* region was proposed by Nicolet and Aikin in 1960. The sources of *D* region ionizations under conditions of a quiet sun were explained by solar Lyman alpha ionizing nitric oxide in the altitude region between 85 and 70 km, while ionization below 70 km was attributed to cosmic rays. In the present paper, the results of two rocket experiments are presented together with an interpretation of these results which is consistent with that theory.

Measurements of the atmospheric attenuation of Lyman alpha flux as a function of altitude are used to determine the electron collision frequency profile for each flight. It is shown that the collision frequency is subject to significant variations which are correlated with meteorological processes occurring at the 30 km level of the stratosphere. With a knowledge of the collision frequency, electron density profiles are deduced from the results of radio propagation experiments. Based on satellite data the contribution of 2 to 8 Ångstrom solar X-rays to the ionization of the *D* region is estimated. Finally a discussion of the different nitric oxide data available since 1910 is given in terms of the effect on the *D* region recombination coefficient.

The experimental method is based upon the Nike-Apache sounding rocket. The results from two such rocket flights at Wallops Island, Virginia, latitude 38°, are reported here. The first, labeled 14.107, was fired at 1430 hours EST on March 8, 1963, and the second, 14.108, was fired at 1530 hours EST on April 9, 1963. The solar zenith angles were 53° and 55° respectively.

LYMAN ALPHA FLUX

On both flights Lyman alpha flux was measured by means of a lithium fluoride window ionization chamber filled with carbon disulfide gas. For Q_∞, the Lyman alpha flux incident upon the earth's atmosphere, a value of $(3\pm1)\times10^{11}$ photons cm^{-2} sec^{-1} was obtained. This value is consistent with the results of Friedman *et al.*, (1963) who have shown that the Lyman alpha flux is not strongly dependent upon solar activity.

PRESSURE AND ELECTRON COLLISION FREQUENCY DETERMINATION

The Lyman alpha flux $Q(z)$ that penetrates the atmosphere to an altitude z is given by

$$Q(z)=Q(\infty)e^{-\sigma\int_z^\infty N(z)dz} \qquad (1)$$

where, assuming O_2 to be the dominant source of absorption, σ is the absorption cross section of an O_2 molecule and $N(z)$ is the O_2 number density.

*Published as *Goddard Space Flight Center Document X-615-64-173*, June 1964.

†Norwegian Defense Research Establishment, Kjeller, Norway.

Since the partial pressure of O_2 at an altitude z is defined as

$$PO_2(z) = \int_z^\infty N(z) M g dz \qquad (2)$$

equation (1) can be rewritten as

$$Q(z) = Q(\infty) e^{-\frac{\sigma PO_2(z)}{Mg}} \qquad (3)$$

where M is the mass of an O_2 molecule and g is the gravitational acceleration. A measurement of the ratio $Q(\infty)/Q(z)$ yields therefore the partial pressure of O_2 from which, assuming a constant ratio between oxygen and nitrogen partial pressures, the total pressure is derived.

The derived pressures can be used to obtain the collision frequency of electrons with neutral molecules. Phelps (1960) from laboratory measurements has shown that ν, the electron collision frequency in air for monoenergetic electrons, is proportional to the electron energy. From this and the gas law it follows that for monoenergetic electrons of energy kT, the collision frequency is proportional to the atmospheric pressure. The relationship is

$$[\nu]_{AIR} = 9 \times 10^7 p(\text{mm } Hg) \text{sec}^{-1} \qquad (4)$$

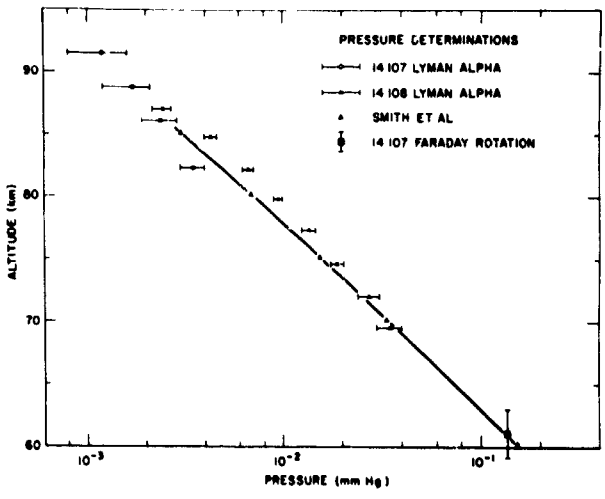

FIGURE 1.—Atmospheric pressure versus altitude at Wallops Island measured at 14:30 hours (14.107) and 19:00 hours (Smith et al.,), March 8, 1963, and at 15:30 hours, April 9, 1963 (14.108).

The results of the pressure determinations on flights 14.107 and 14.108 are shown on Figure 1. The resolution in the pressure measurements, indicated by the horizontal bars, is determined by the precision to which the Lyman alpha ion chamber aspect angle is known. Included in this figure is the pressure profile determined by Smith *et al.*, (1964) who performed a rocket-borne grenade experiment at Wallops Island five hours after flight 14.107. It is believed that the indicated pressure differences in these three measurements are real and indicate the presence of meteorological effects in the mesosphere.

METEOROLOGY

From Equation (4) of the previous section it can be expected that the D region collision frequency profile will be subject to the diurnal, seasonal and latitudinal variation of mesospheric pressure that the work of Stroud and Nordberg (1961) and others has revealed.

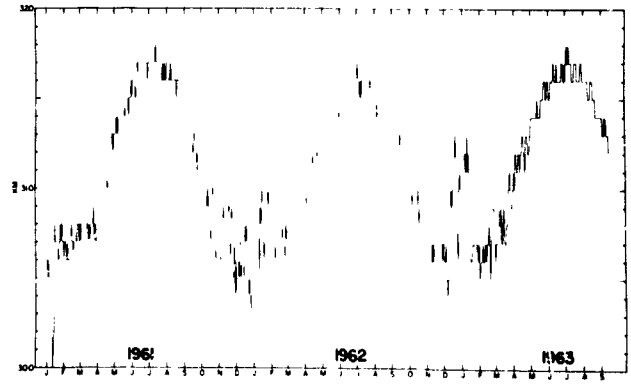

FIGURE 2.—Seasonal variation of the altitude of the 10 millibar pressure level at Wallops Island.

In Figure 2 is shown for Wallops Island a plot of the altitude of the 10 millibar pressure level for a three year period. In addition to the very apparent seasonal variation comparable short term variations are present, particularly during winter. The Meteorologische Abhandlunge Vol. XL, 1963, from which these data are taken shows that a sudden warming event occurred in the stratosphere over Canada on April 4. By April 9 the effects of this event could be noticed at Wallops Island where the altitude of the 10 millibar level increased from 30.80 km on March 8 to

31.16 km on April 9 while the temperature of this level increased from −47°C to −36°C. These stratospheric changes lend support to our April 9 collision frequency profile since the mesosphere is linked to the stratosphere through the pressure relation

$$p(z) = p_0 e^{-\int_0^z dz/H(z)} \quad (5)$$

where the scale height H(z) is proportional to the temperature T(z). Although no measurements of T(z) exist for 14.108 a reasonable model can be constructed which leads to mesospheric pressures of the required magnitude.

Convincing evidence for the existence of an ionosphere-stratosphere interaction has been given by Bossolosco and Elena (1963) who have shown that a strong correlation exists between the temperature at the 10 millibar level and mid-latitude winter radio wave absorption at frequencies around 2 Mc/s. Their results show a temperature increase of 20° at the 10 millibar level correlated with a factor 2 increase in absorption. Our results would seem to indicate that this effect, the so called winter absorption anomaly, is due simply to an increase in mesospheric pressure. However, since radio wave absorption involves the electron density as well as collision frequency, and since both the electron production and loss mechanisms are pressure dependent, such a conclusion must be withheld until quantitative calculations have been made.

ELECTRON DENSITY PROFILES

The electron density profiles reported here were obtained by means of radio propagation techniques employing ground to rocket transmissions. In flight 14.107 linearly polarized signals were transmitted from the ground at frequencies of 3.0 and 4.9 Mc/s. The mechanical spin of the rocket of about 3 cycles per second was used to rotate the rocket-borne receiving antennas through the polarization patterns of the arriving waves. The telemetered signal strengths exhibited a fading pattern, the frequency of which was the sum of the rocket spin frequency and the ionospheric Faraday rotation frequency. A comparison of the period of this fading pattern with the mechanical spin period, independently measured by means of a solar aspect sensor, yielded the Faraday rotation of the plane of polarization.

Under the condition of quasi-longitudinal propagation, the plane of linear polarization, defined by the angle ψ, rotates with rocket altitude z

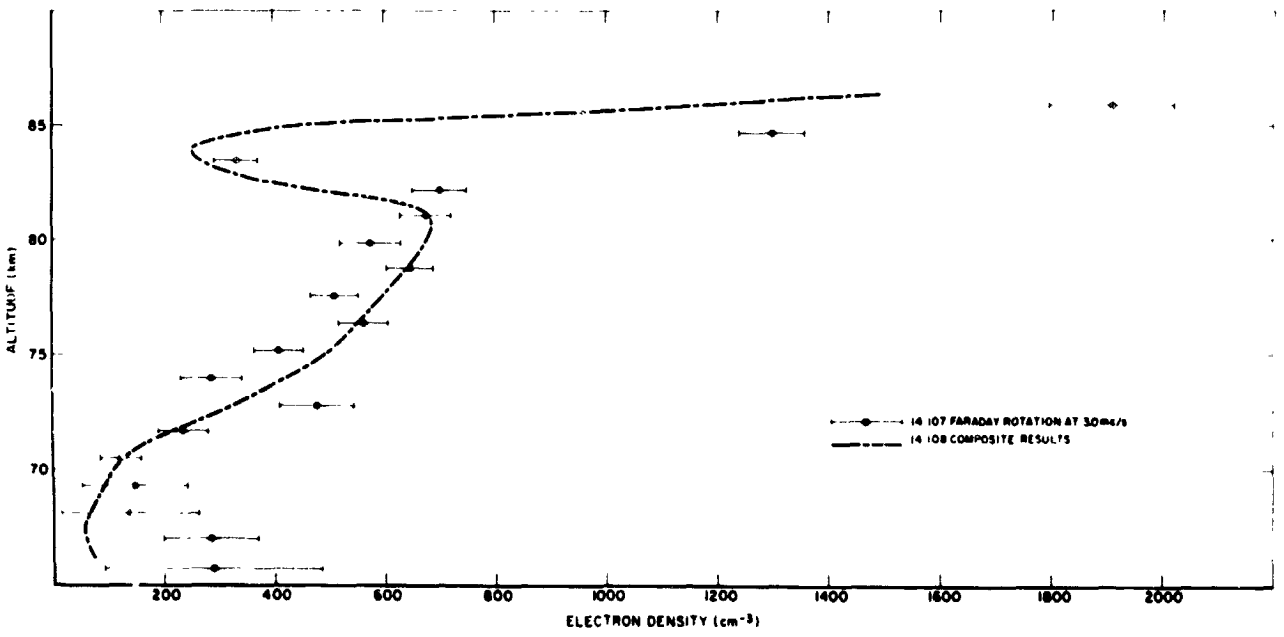

FIGURE 3.—Electron density versus altitude for March 8, 1963 (14.107). Dashed curve is a composite of the results shown in Figure 4.

according to an expression of the form

$$\frac{d\psi}{dz} = N_e(z)F(\omega, \omega_H, \nu(z)) \qquad (6)$$

where $N_e(z)$ is the electron density and F is a function of the exploring frequency ω, the gyrofrequency ω_H and the collision frequency ν. The explicit form of F involves the Dingle integrals of the generalized Appleton-Hartree formula (Sen and Wyler, 1960). Before $F(z)$ can be evaluated it is necessary to have a collision frequency model, the determination of which was described in section 2. The Faraday rotation experiment by itself allows the collision frequency to be determined at a single altitude. This follows from the fact that the function $F(\omega, \omega_H, \nu(z))$ changes sign at a unique value of ν/ω. By noting the altitude at which the reversal in the sense of the Faraday rotation occurred on flight 14.107 a value of $\nu = 13.8 \times 10^6 \text{sec}^{-1}$ was deduced for an altitude of 61 ± 2 km. As seen in Figure 1 this value is consistent with the March 8 pressure profile obtained from the grenade experiment of Smith *et* al., (1964).

The electron density results of the 14.107 Faraday rotation experiment at 3.0 Mc/s are shown in Figure 3. Each point is the average electron density in an altitude interval of approximately one kilometer. The horizontal bar indicates the probable uncertainty in the determination of this average value. This uncertainty is due to random echoes from above the D region distorting the Faraday pattern. This effect was more severe on the 4.9 Mc/s Faraday experiment which yielded electron densities in agreement with those shown in Figure 3, but with uncertainties two to three times as large.

In flight 14.108 linearly polarized signals were transmitted at frequencies of 1.8 and 4.9 Mc/s. A 3.0 Mc/s signal was also transmitted from ground to rocket on flight 14.108, but in this case the transmitted pattern was alternately switched between opposite circularly polarized modes, which in the ionosphere were differentially absorbed. Denoting the received signal strength of the two polarization modes as E_0 and E_X, the altitude variation of the logarithmic ratio $ln(E_0/E_X)$ can be expressed as

$$\frac{d}{dz}\ln(E_0/E_X) = N_e(z)G(\omega, \omega_H, \nu(z)) \qquad (7)$$

where again $N_e(z)$ is the electron density and $G(z)$ is an altitude dependent function involving the Dingle integrals and requiring a collision frequency model for explicit evaluation.

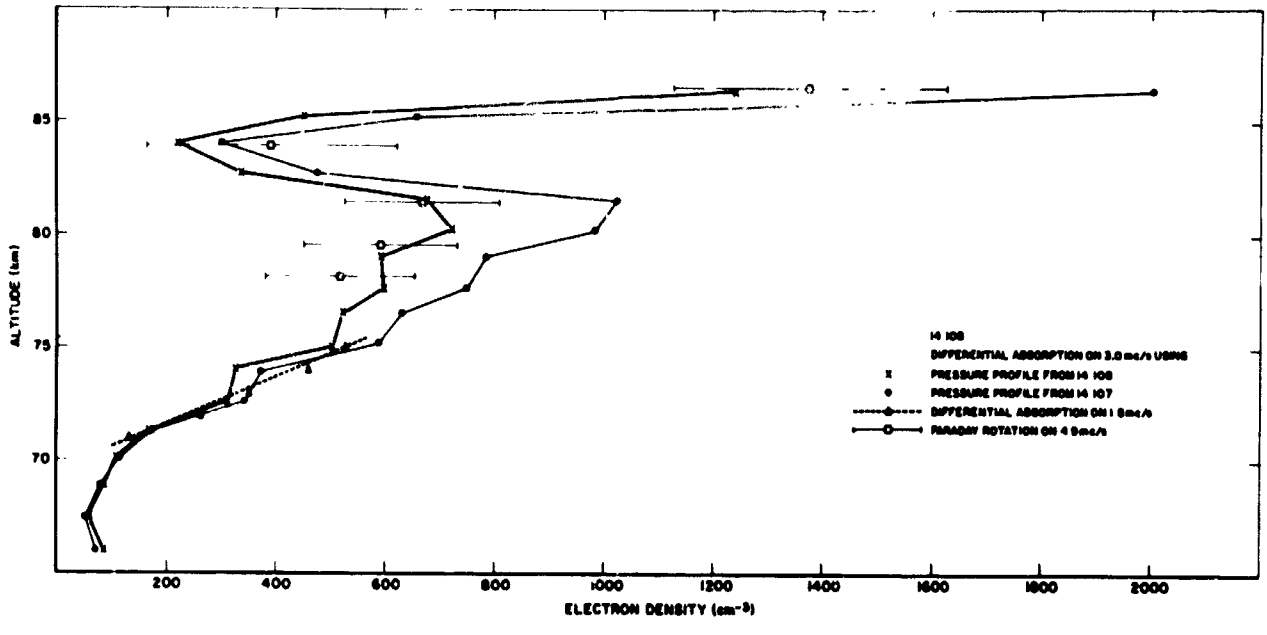

FIGURE 4.—Electron density versus altitude for April 9, 1963 (14.108) showing the effect of the choice of collision frequency model used to interpret radio absorption data.

In addition to a direct comparison of circularly polarized E_0 and E_X signal strengths, it is possible to obtain differential absorption data also from the Faraday pattern of a linearly polarized signal. This follows from the fact that the maximums in the Faraday pattern represent the sum, while the nulls represent the difference of the E_0 and E_X signal strengths. This technique was the basis of the 1.8 Mc/s experiment.

The results of the three propagation experiments on flight 14.108 are shown in Figure 4. The electron densities deduced from the 4.9 and 1.8 Mc/s propagation experiments are relatively insensitive to the choice of collision frequency profile. This is not true however for the 3.0 Mc/s differential absorption experiment. In Figure 4 are shown two electron density profiles deduced from the 3.0 Mc/s differential absorption measurement, the open circle points were computed using the Figure 1 pressure values of Smith, while the values shown as crosses were computed using a 50 percent higher pressure profile. It is seen that consistency between the results of the 14.108 Faraday experiment on 4.9 Mc/s and the 14.108 differential absorption experiment on 3.0 Mc/s requires collision frequency values which between 75 and 80 km are approximately 50 percent higher than those observed one month previously. This requirement is satisfied by the Lyman alpha data shown in Figure 1. For comparison with the 14.107 electron densities the results from 14.108 are plotted as the dashed line in the previous Figure 3. The similarity of the two profiles is apparent, particularly with respect to the minimum at the mesopause (83 km). Possible causes of the minimum at the mesopause include a temperature dependent nitric oxide distribution, and the attachment of electrons to dust. This latter hypothesis has some support from the work of Witt *et al.*, (1962) who reported the detection of dust in the vicinity of the mesopause, and the work of Frocco and Smullin (1963) who reported scattering of a laser beam in this altitude region.

In order to interpret the electron density profiles presented here it is necessary to have a knowledge of the ion pair production function for each of the ionizing radiations affecting the *D* region. This is the subject of the following sections.

COSMIC RAY IONIZATION

The contribution of cosmic rays to the ionization content of the normal *D* region has been considered by Nicolet and Aikin (1960). They showed an ion production rate which was important below 70 km and which involved a variation of a factor 10 between the geomagnetic latitudes of 0° and 70°. For a geomagnetic latitude of 50°, based on the work of Webber (1962), a slightly revised ionization rate of 180 ± 30 ion pairs/sec/atmosphere can be assumed for the altitude region between 60 and 85 km for the 1963 portion of the solar cycle. Combining this value with a model atmosphere yields the altitude dependence of the cosmic ray ionization rates shown as the lower portion of the curves labelled q_{O_2} and q_{N_2} in Figure 5.

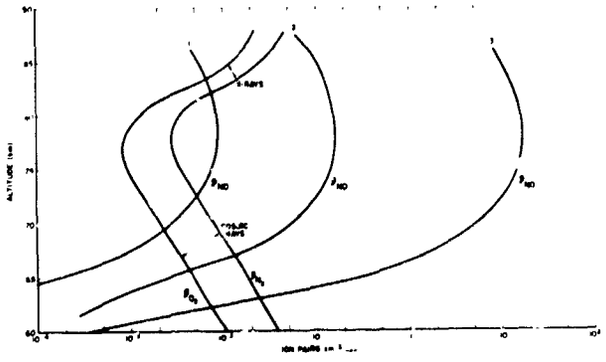

FIGURE 5.—Calculated ionization production function versus altitude. Curves labeled 1, 2, and 3 show the effect of Lyman alpha flux on three different nitric oxide distributions.

X-RAY IONIZATION

The major atmospheric constituents of the *D* region can be ionized by solar X-rays in the 2 to 8Å wavelength region. The importance of this process will depend, however, upon the degree of solar activity. Instrumentation failure prevented a direct measurement of 2–8Å X-rays during our flights. Thus it is necessary to rely on estimates of the flux. The basis of these estimates are the 2800 Mc flux as measured at Ottawa, the McMath-Hulbert calcium plage data, and the Zurich provisional sunspot number. White (1964) has compared direct measurements of X-ray flux from the OSO–1 satellite with these indices and derived an empirical relation for

estimating the X-ray intensity. From these data White estimates that the 2 to 8Å flux was the same to within 50 percent during both our rocket flights and had an integral value of 1.9×10^{-4} ergs/cm²sec.

From Ariel I satellite, Pounds *et al.*, (1961)

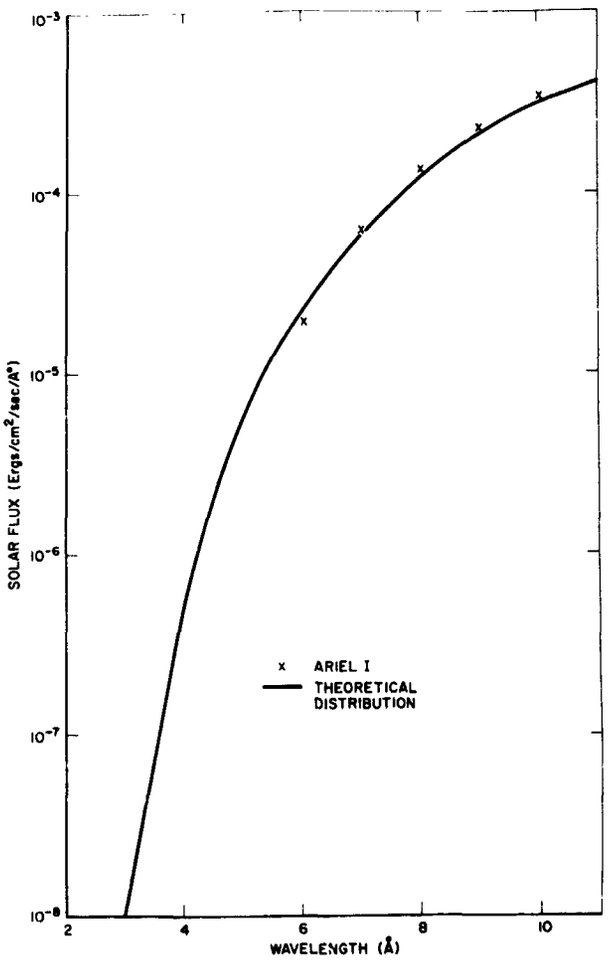

FIGURE 6.—Quiet sun spectrum in the 2 to 10 Ångstrom wavelength interval. Solid curve is the spectral distribution $J(\nu)d\nu = Ae^{-h\nu/kT}d\nu$, with T equal to 2.8×10^6°K.

have obtained solar spectra between 6 and 11Å. The crosses in Figure 6 show a typical non-flare spectrum in which the integrated intensity below 8Å was 1.3×10^{-4}ergs/cm²/sec. According to White (1963) both the Ariel I and OSO-1 non-flare data can be fitted to a frequency spectrum of the form $J(\nu)d\nu \propto e^{-h\nu/kT}d\nu$ with T equal to 2.8×10^6 °K. This is shown as the solid curve of Figure 6.

Using the ionization cross sections given by Nicolet and Aikin (1960) together with a model atmosphere derived from the Smith pressure profile and the spectral distribution of Figure 6 (normalized to an integral value of 1.9×10^{-4}ergs/cm²/sec), the ion pair production function due to X-rays can be calculated as a function of altitude. The results are shown as the upper portion of the curves labelled q_{O2} and q_{N_2} in Figure 5. Before the relative importance of ion pair production by X-rays can be evalutated, it is necessary to have some knowledge of the concentration of nitric oxide, which is the trace constituent ionized by the Lyman alpha flux.

NITRIC OXIDE

For sufficiently large concentrations of atomic nitrogen estimates of the nitric oxide distribution can be based upon the processes

$$N+O_2 \rightarrow NO+O \qquad (8)$$

and

$$N+NO \rightarrow N_2+O \qquad (9)$$

which have rate coefficients b_1 and b_2 respectively. The density of NO in the D region is then determined by

$$n(NO) = (b_1/b_2)n(O_2) \qquad (10)$$

Nicolet and Aikin (1960) adopted 5×10^{-10} as the ratio b_1/b_2. The ion-pair production function resulting from such a distribution is shown as curve 1 of Figure 5. A laboratory measurement of b_1/b_2 by Clyne and Thrush (1961) yielded a value of 9×10^{-9}. The ion-pair production function for this nitric oxide distribution is labeled curve 2 in Figure 5. Barth (1964) has made a direct measurement of the nitric oxide concentration in the upper atmosphere and has obtained a value of 6.2×10^7cm^{-3} between 75 and

TABLE 1

Curve #	b_1/b_2	n(NO)(cm^{-3})	α(cm³/sec)
1	5×10^{-10}	4×10^4	2×10^{-8}
2	9×10^{-9}	6×10^5	3×10^{-7}
3	9×10^{-7}	6×10^7	3×10^{-5}

85 km. If this density is used in Equation (10) for an altitude of 80 km, then a $b./b_2$ ratio of 9×10^{-7} is obtained. The resulting production function is shown as curve 3 in Figure 5. Table 1 summarizes the nitric oxide information for an altitude of 80 km. Also tabulated for this altitude are three derived values of the recombination coefficient α. This parameter is the topic of the following section.

RECOMBINATION COEFFICIENT

The electron densities of Figure 3 are elated to the ion production functions of Figure 5 by the equation

$$N_e^2 = \Sigma_i q_i/\alpha_i \qquad (11)$$

where α_i is the effective recombination coefficient of the i^{th} species of positive ion. Biondi (1964) has indicated that O_2^+ and N_2^+ recombine dissociatively with a rate coefficient of 2×10^{-7}cm^3 sec^{-1}, while NO^+ has a recombination coefficient of less than 5×10^{-7}cm^{3}sec^{-1}. The values of recombination coefficient derived from curves 1 and 2 of Figure 5 and given in Table 1 are consistent with dissociative recombination of NO^+ as the electron loss process of the D region. Curve 3 requires the introduction of loss processes not previously considered in *D* region theory since 10^{-6}cm^{3}sec^{-1} is the upper limit assigned to dissociative recombination by both laboratory measurements and theoretical determinations.

By using in Equation (11) the recombination coefficients given by Biondi together with the ion production functions shown in Figure 5, it is seen that the ionization due to X-rays can dominate the quiet *D* region only above 83 km and even than only for the case of a nitric oxide distribution corresponding to curve 1 of Figure 5.

CONCLUSION

Electron density and collision frequency profiles have been obtained for the quiet day mid-latitude *D* region. The electron collision frequency is subject to significant variations of a meteorological nature. The electron density profiles agree with the theory that for a reasonably quiet sun solar X-rays are unimportant, and Lyman alpha ionization of nitric oxide is the major contributor to the ionization content of the *D* region. Although existing theory can explain these measured profiles, the recent nitric oxide measurements of Barth (1964) would, if accepted, require a reevaluation of the electron-ion less processes.

HYDROGEN IONS*

SIEGFRIED J. BAUER

Whistler observations which first indicated surprisingly large electron densities at several earth radii (cf. "Whistlers and Exospheric Structure" by L. R. O. Storey) led to the interpretation that the outer ionosphere consists predominantly of hydrogen ions (protons) and electrons. Consequently, the name "protonosphere" has been suggested for this region of the earth's outer atmosphere (Johnson, 1960). The hydrogen ions of the protonosphere are now considered to be the result of charge exchange between ionospheric oxygen ions and neutral hydrogen of the telluric geocorona (Johnson, 1961), rather than due to photoionization. While the protonosphere was originally envisioned (Johnson, 1960) to be a direct extension of the ionospheric F region, where oxygen ions predominate, it has been established recently that a region of helium ions whose extent varies with temperature and solar cycle, intervenes between the regular ionosphere and the protonosphere (cf. "Helium Ions" by W. B. Hanson).

It was first pointed out by Dungey (1955), that the charge exchange process

$$H+O^+ \rightleftarrows H^+ + O \qquad (1)$$

may be of importance in the upper atmosphere. Johnson, (1960) was the first to argue that this process represents the major source of hydrogen ions constituting the protonosphere. Since oxygen and hydrogen have nearly the same ionization potential, reaction (1), which is of the accidental asymmetric resonance type, occurs about as rapidly either way and therefore presents the source and sink for H^+. It has been suggested (Rapp, 1963) that the cross-section for process (1) is large enough (10^{-15} to 10^{-16}cm^2) so that (1) occurs rapidly enough to be the most important chemical reaction involving hydrogen ions in the upper atmosphere. (In interplanetary space, photoionization and radiative recombination obviously will become the controlling processes.) Hanson, Patterson and Degaonkar (1963) have recently inferred from experimental data a rate coefficient $K=3.9\times10^{-10}$cm^{3}sec^{-1} for reaction (1), corresponding to a reaction cross-section of 7.6×10^{-16}cm^2; these values are considered to be correct within a factor of three.

The altitude distribution of an ion, such as H^+, is governed by the equation of continuity

$$\frac{\partial(H^+)}{\partial t}=q(H^+)-L(H^+)-\text{div } F(H^+) \qquad (2)$$

where $q(H^+)$ is the production rate and $L(H^+)$ is the loss rate of hydrogen ions and $F(H^+)$ is the flux of H^+ resulting from diffusion under gravity.

For the steady state, $\frac{\partial(H^+)}{\partial t}=0$, and considering mainly an upward or downward flux of hydrogen ions (i.e. in the z direction), equation (2) can be expressed by

$$q(H^+)-L(H^+)-\frac{\partial F(H^+)}{\partial z}=0 \qquad (3)$$

While equation (3) is not readily amenable to an analytic solution, but has to be solved numerically (cf. Bates and Patterson, 1961; Hanson, 1963, Hanson et al, 1963) there are two simple limiting cases to (3): 1) where diffusion of hydrogen ions can be neglected, *chemical equilibrium* ($q=L$) will prevail, and 2) at high enough altitudes where diffusion is the predominant process, *diffusive equilibrium* will prevail $\left(\frac{\partial F(H^+)}{\partial z}=0\right)$

1. Chemical Equilibrium Distribution of H^+

Noting that both production and loss of H^+ are controlled by the charge exchange reaction (1), we can write (cf. Bates and Patterson, 1961)

$$Kn(H)n(O^+)=\sigma Kn(H^+)n(O) \tag{4}$$

where K is the rate coefficient and $\sigma=8/9$ is the value for the ratio of the products of the statistical weights. Thus, the chemical equilibrium distribution for hydrogen ions is given by:

$$n(H^+)=\frac{9}{8}\frac{n(H)}{n(O)}n(O^+) \tag{5}$$

where $n(X)$ is the number density of the neutral constituent X which is distributed exponentially according to its scale height $\underline{H}(X)=kT/m(X)g$, with k Boltzmann's constant, T the absolute temperature, $m(X)$ the mass of the constituent and g the acceleration of gravity; the number density of oxygen ions, $n(O^+)$ is distributed according to its scale height (assuming predominance of O^+) $\underline{H}(O^+)=k(T_e+T_i)/m(O)g$, where T_e and T_i are the electron and ion temperature, respectively, which may be different from each other. The distribution above a reference level h_0 where $n(H^+)=n_0(H^+)=9n_0(H)n_0(O^+)/8n_0(O)$ and above which all constituents are distributed exponentially, is given by

$$n(H^+)=n_0(H^+)\exp\left[z/\underline{H}(7)\right] \tag{6}$$

where Z is the geopotential altitude above the reference level $\left(z=\int_{h_0}^{h}(g/g_0)dh\right)$ which takes into account the variation of the acceleration of gravity g with altitude, and $\underline{H}(7)$ is the scale height corresponding to an effective mass of 7 AMU, (resulting from the combined scaled heights), and to the acceleration of gravity at the earth's surface g_0. (It is assumed that all constituents entering into the *R.H.S.* of (5) are in diffusive and thermal equilibrium; e.g., $\underline{H}(O^+)=2\underline{H}(O)$). Thus, it is obvious that H^+ in chemical equilibrium is *increasing* with altitude.

2. Diffusive Equilibrium Distribution of H^+

It is now generally known that the diffusive equilibrium distribution of an ion (such as H^+) in a mixture is not independent of the other ionic constituents because of the presence of an electrostatic field which is set up to prevent further charge separation between electrons and ions diffusing under gravity. This electrostatic field, which depends on the mean ionic mass of the mixture and on the electron and ion temperatures, is sensed by all ions in the mixture and tends to counteract the gravitational force. This fact has been known to astrophysicists for many years (cf. Eddington, 1926), but has been revived more recently (Dungey, 1955; Mange, 1960) in connection with the terrestrial ionosphere. According to this concept, the distribution of H^+ in diffusive equilibrium is given by

$$n(H^+)=n_0(H^+)\exp\left[-\int_0^z\left(\frac{1}{\underline{H}(H^+)}-\frac{\tau}{1+\tau}\frac{m_+g_0}{kT_i}\right)dz\right] \tag{7}$$

where $\underline{H}(H^+)=\dfrac{kT_i}{m(H^+)g_0}$, $\tau=T_e/T_i$ is the ratio of electron to ion temperature and $m_+=\Sigma m_i n_i/\Sigma n_i$ is the mean ionic mass of the mixture. Since the upper ionosphere consists of a ternary ion mixture (H^+, He^+, O^+) we also can write (7) as

$$n(H^+)=n_0(H^+)\exp\left[-\int_0^z\frac{dz}{H(H^+)}\right] \tag{8}$$

where $H(H^+)=\underline{H}(H)(1+\tau)\dfrac{n(O^+)+n(He^+)+n(H^+)}{n(H^+)-\tau[14n(O^+)+2n(He^+)]}$

Thus, it is easily seen that, e.g. for the case of thermal equilibrium ($\tau=1$), $H(H^+)<0$, if $n(H^+)<2[n(He^+)+7\ n(O^+)]$ and approaches $2\underline{H}(H)$ when H^+ becomes the predominant ion. As long as H^+ is a minor constituent, it is *increasing* with altitude. In fact, in a predominantly O^+ ionosphere the initial increase of H^+ in diffusive equilibrium follows almost the same scale height as the one corresponding to chemical equilibrium (6) and in this case, the predominance of chemical or diffusive equilibrium is undistinguishable from the behavior of the altitude distribution alone. Figure 1 shows the behavior of the distribution of H^+ in diffusive (and thermal) equilibrium in the presence of He^+ and O^+ at a temperature of $T=1200°K$. For the simple computation of the diffusive and thermal equilibrium distribution of an ion in a mixture, the following formula is quite

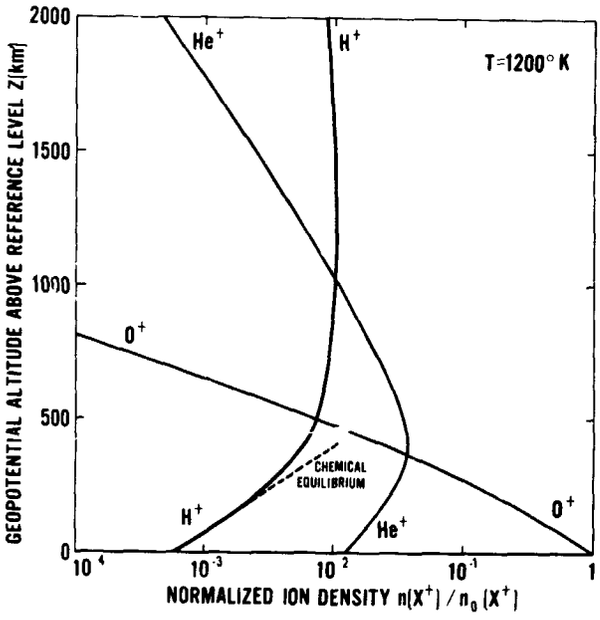

FIGURE 1

useful (cf. Hanson, 1962; Bauer, 1962):

$$n(X_k^+) = n_0(X_k^+) \exp[-z/H_k] \cdot \left[\frac{\Sigma_t n_0(X^+)}{\Sigma_t n_0(X^+) \exp(-z/H_t)}\right]^{1/2} \quad (9)$$

(Although the electron temperature often differs from the ion temperature, calculations based on thermal equilibrium generally can provide an adequate representation of the altitude distribution of an ion in diffusive equilibrium.)

The actual distribution of hydrogen ions in the upper atmosphere is one which more closely corresponds to a steady-state distribution (3) with a non-vanishing flux of ions. Figure 2 shows an observed H^+ distribution (Taylor, Brace, Brinton and Smith, 1963) which has been interpreted by Hanson et al, (1963) in terms of a steady-state distribution, corresponding to a rate coefficient for the charge exchange reaction of 3.9×10^{-10}cm^{3}sec^{-1} and an upward flux of hydrogen ions at 900 km of $F(H^+) = 1.3\times10^7$cm^{-2}sec^{-1}.

The altitude where diffusion becomes predominant compared to chemical processes in controlling the distribution of H^+ can be estimated by comparing the rate of the downward flux of hydrogen ions $\left(-\frac{\partial F(H^+)}{\partial z}\right)$, with the loss rate due to charge exchange with atomic oxygen (cf. Bates and Patterson, 1961) leading to the criterion

$$Kn(O) = \frac{D(H^+, O^+)}{2[\underline{H}(O)]^2} \quad (10)$$

where $D(H^+, O^+) = 8.4\times10^{15}(T/1500°)^{5/2}/[n(H^+) + n(O^+)]$, (Hanson, 1963) is the diffusion coefficient for Coulomb diffusion of protons through a predominantly O^+ ionosphere, and the other quantities have their previously defined meaning. For the condition representing the data of Taylor et al, (1963) shown in Figure 2, the transition from predominantly chemical to diffusive control would occur at an altitude of about 600 km and since the diffusion process is controlled by oxygen ions one would expect that one scale height, $\underline{H}(O^+) = 2\,\underline{H}(O)$, above and below this level diffusive and chemical equilibrium respectively, would prevail. This estimate is in good agreement with the conclusions of an analysis of the behavior of the ratio of $n(H^+)/n(He^+)$ of the same data by Bauer (1964). It was first shown by Hanson and Ortenburger (1961) that oxygen ions represent an effective barrier to the diffusion of H^+ because of Coulomb interaction between ions. Thus, the "critical level" defined by the criterion

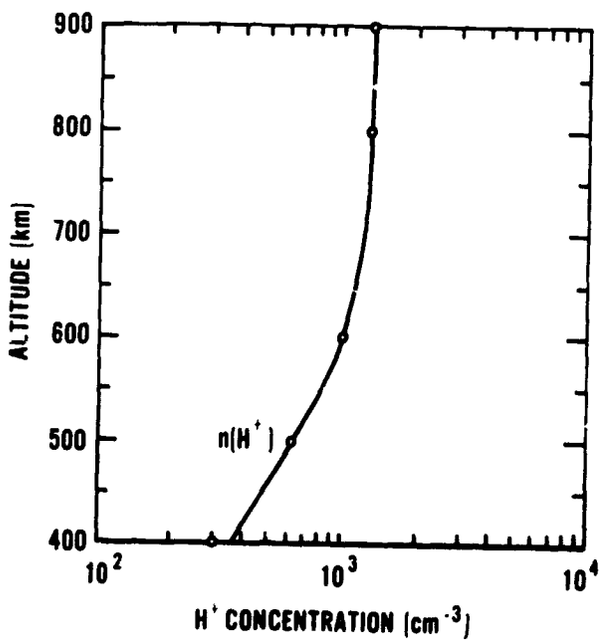

FIGURE 2

in (10) may be considered the base of the protonosphere.

Since the charge exchange process (1) controls the hydrogen ion concentration at the lower altitudes, the time-dependent boundary condition for the proton distribution at higher altitudes is given to a first approximation by the ratio of $n(H)/n(O)$ (cf. (5)). It is well known that the neutral hydrogen concentration is quite sensitive to the atmospheric temperature because of the thermal escape of neutral hydrogen. Thus, the concentration of hydrogen at a fixed level of say 500 km will be higher at low temperatures than at high temperatures. Consequently, the ratio $n(H)/n(O)$ at 500 km may vary by a factor of 100 for a temperature change of about 1000°K (Bates and Patterson, 1961; Kockarts and Nicolet, 1963). Considering a ternary ion mixture (0^+, He^+ and H^+) and boundary conditions varying with temperature according to the variation of the neutral species corresponding to these ions at 500 km (Bauer, 1963; Kockarts and Nicolet, 1963) the altitude domain where H^+ is the predominant ion can be described qualitatively as shown in Figure 3.

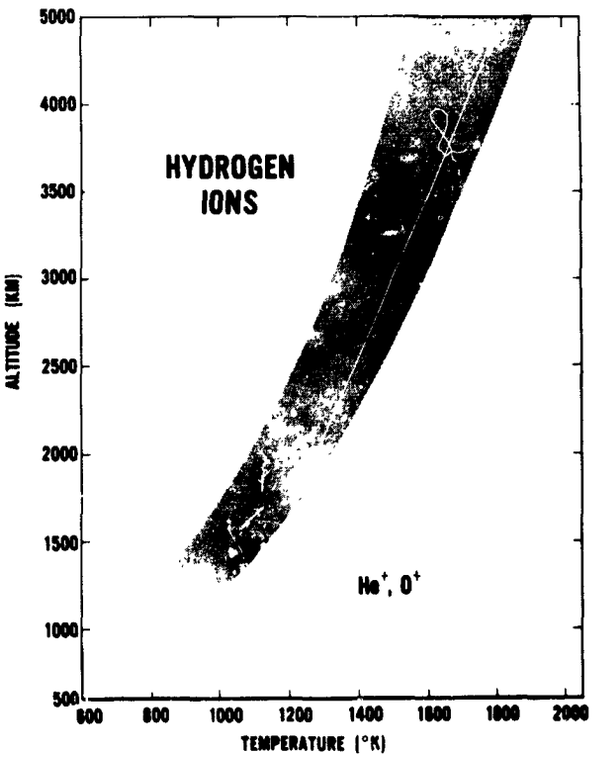

FIGURE 3

While such a concept is roughly indicative of the longer term temperature variations it may not be representative for diurnal variations, since the response time of the change in the hydrogen concentration to a change in temperature, at least at the lower temperatures, is of the order of tens of hours (Bates and Patterson, 1961). Although there is some indirect evidence of large diurnal variation in the concentration of hydrogen based on nighttime profiles of ion and electron density (Donley, 1963; King et al, 1963) which indicate a preponderance of H^+ already at altitudes below 1000 km, a large diurnal variation is difficult to explain in view of the long response time of hydrogen. Hanson and Ortenburger, (1961) have pointed out that because of the inhibiting effect of Coulomb diffusion, the protons cannot follow diurnal variations of the oxygen ions in the ionospheric F region and thus, the protonosphere is essentially decoupled from the upper ionosphere. In fact, the diurnal variation in the protonosphere based on whistler observations is only of the order of at most 30 percent. Since the total content of H^+ throughout the protonosphere is estimated to be about 7.5×10^{12} protons cm^{-2} (Hanson and Ortenburger, 1961), a 30 percent variation would imply an average flux of 5×10^7 ions $cm^{-2}sec^{-1}$ into the ionospheric F region during a 12-hour period. This flux would be, in general, upward during the day and downward during the night. The upward flux during the daytime, however, seems to be limited by the flux of neutral hydrogen from the lower atmosphere which is of the order of 2.5×10^7 atoms $cm^{-2}sec^{-1}$ (cf. Hanson and Patterson, 1963). As mentioned before, an upward flux of 1.3×10^7 protons $cm^{-2}sec^{-1}$ has been inferred by Hanson et al (1963) from the daytime proton distribution measured by Taylor et al (1963), (cf. Figure 2). Consequently, it appears (Hanson and Patterson, 1963) that, although nighttime condition may allow a sufficient flux of protons to account for a 30 percent change in the hydrogen ion content of the protonosphere, the return flow required during the day does not appear to be feasible. Thus, it also seems unlikely that fluxes of protons between hemispheres affect the ion density at the $F2$ peak as has been suggested (Rothwell, 1962) since the observed proton fluxes are small compared with the normal flux through the $F2$ peak

which is estimated to be of the order of 2×10^8 to 10^9 ions $cm^{-2}sec^{-1}$ (Hanson and Patterson, 1963).

While the general behavior of hydrogen ions is already reasonably well understood, quantitative data especially those concerning its time variation are still inadequate. However, this situation will hopefully be remedied as the result of additional measurements with rockets and satellites.

MEAN DIURNAL VARIATION OF THE TOPSIDE IONOSPHERE AT MID-LATITUDES

S. J. BAUER AND L. J. BLUMLE

About 500 ionograms obtained with the Alouette satellite have been used to construct the mean diurnal variation of the mid-latitude topside ionosphere. Since this diurnal variation is based on observations from October to December 1962, quasiseasonal effects had to be removed. The data are presented in form of electron density contours at fixed altitudes for two latitude ranges 35°N–40°N and 40°N–45°N. These two latitude ranges, which are approximately separated at the 75°W meridian by the 70° magnetic dip line, show remarkable differences in the detailed behavior of electron density as a function of time and altitude. From the scale heights of these mean distributions, it is apparent that there is absence of thermal equilibrium, at least during the day, and that light ionic constituents become important in the altitude region from 500 km to 1000 km, especially during the night. In addition, there is the suggestion of latitude gradients in the electron temperature and mean ionic mass.

INTRODUCTION

Prior to the launching of the Canadian topside sounder satellite *Alouette*, our knowledge of the vertical structure of the ionosphere above the F_2 peak was based on occasional rocket flights and incoherent radar backscatter observations from the ground, both of which are limited to specific locations. The topside sounder satellite provides us for the first time with a tool for the study of the topside ionosphere and its variation with latitude *and* time. Since the topside sounder operates only on command, observations are restricted to times when the satellite is within appropriate range of a telemetry and command station. We have made use of soundings of the topside ionosphere taken while the satellite was within range of the NASA telemetry station at Blossom Point, Maryland. The latitude coverage obtainable from this station is between 20°N and 55°N. We have concentrated on the study of ionograms obtained at mid-latitudes (35°N to 45°N), for which our data were most complete. As the result of the orbital characteristics of the Alouette satellite and combining north- and southward passes, about three months are required to obtain a complete diurnal variation of the ionospheric parameters. This paper presents the mean diurnal behavior of the mid-latitude topside ionosphere for the three-month period from October to December 1962.

DIURNAL VARIATION OF ELECTRON DENSITY AT CONSTANT ALTITUDES

About 500 ionograms taken on magnetically quiet days during the first three months of Alouette's operation and covering the latitude range from 30°N to 50°N (and longitudes 50°W to 100°W) were selected for the present study. The ionograms were converted to electron-density profiles by means of the exponential lamination method described by *Fitzenreiter and Blumle*, (1964). For the study of the diurnal behavior of the topside ionosphere, a presentation in terms of electron density at constant altitudes was chosen. In this way a mean behavior could best be defined from the large number of data points. It became apparent that because of the latitude variation of the topside ionosphere, latitude ranges of not more than 5° latitude should be used, otherwise the spread in the electron density data points at constant altitudes would often be greater than the separation of electron density contours at successive 100 km altitude increments. Since below 35°N and above 45°N the data available were not sufficient to define a complete diurnal variation, only the two latitude ranges from 35°N to 40°N

*Published as *Goddard Space Flight Center Document X-615-64-99*, April 1964

and from 40° to 45°N will be presented in this paper. The "mean" contours of electron density at 100 km height intervals are based on individual data points; the maximum spread of individual data points around the density contours at fixed heights is of the order of ±25 percent. Figure 1 shows an example of such mean contours every 200 km up to the satellite altitude for the latitude range 40°N to 45°N. It can be seen that these mean contours have some oscillations superimposed which need not represent actual diurnal behavior, since the entire "diurnal" variation is based on three months of data. Thus, the mean

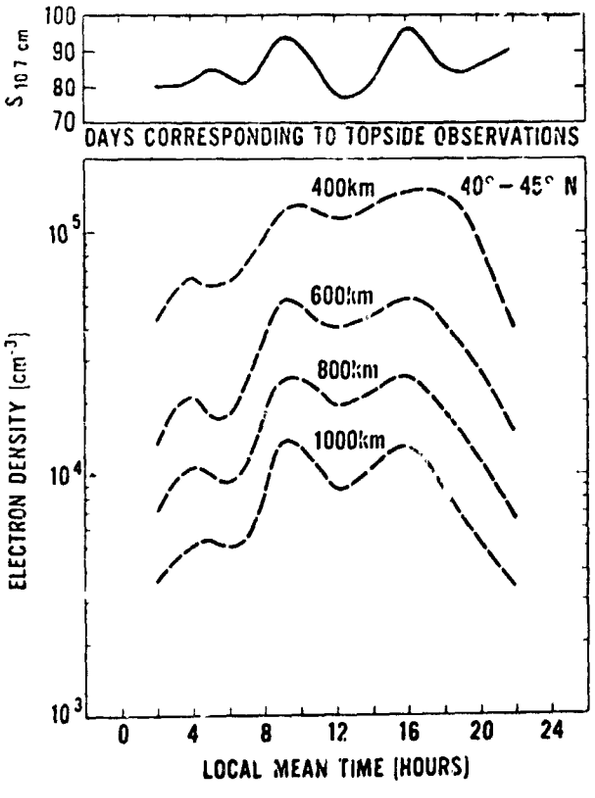

FIGURE 1.—Mean diurnal variation of electron density at constant altitudes based on actual data points and flux of 10.7 cm solar radiation (in units of $10^{-22} W/m^2/cps$) at times corresponding to the ionospheric measurements, indicating "quasi-seasonal" effects (27 day cycle).

contours presented in Figure 1 will also include quasi-seasonal effects, e.g., the 27 day cycle. This becomes quiet apparent, if the flux of the solar 10.7 cm radiation, $S_{10.7}$, which is an indicator of solar activity, is plotted for the days corresponding to the individual data points for electron density at the indicated local times. The smoothed variation of $S_{10.7}$ is plotted in the top portion of Figure 1 and it is evident that the electron density at fixed altitudes behaves in a similar fashion. At first, it may seem surprising that the topside electron density should be closely related to the 10.7 cm flux from the sun, since there is no obvious correlation of this parameter with the density at the F_2 peak, or below. However, it should be realized that at lower altitudes where production and loss of ionization play a predominant role, the detailed correlation of electron density with short term solar variations as indicated by the 10.7 cm flux may be obscured by the fact that both, production and loss are affected by the variation of the appropriate neutral constituents and is thus effectively cancelled out. At altitudes above the F_2 peak, where the distribution is controlled by diffusion, and thus by the scale height, this effect may appear more directly since the scale height and temperature are known to be directly correlated with the 10.7 cm flux. Correspondingly, the "seasonal" effect superimposed on the diurnal variation was removed using the behavior of the

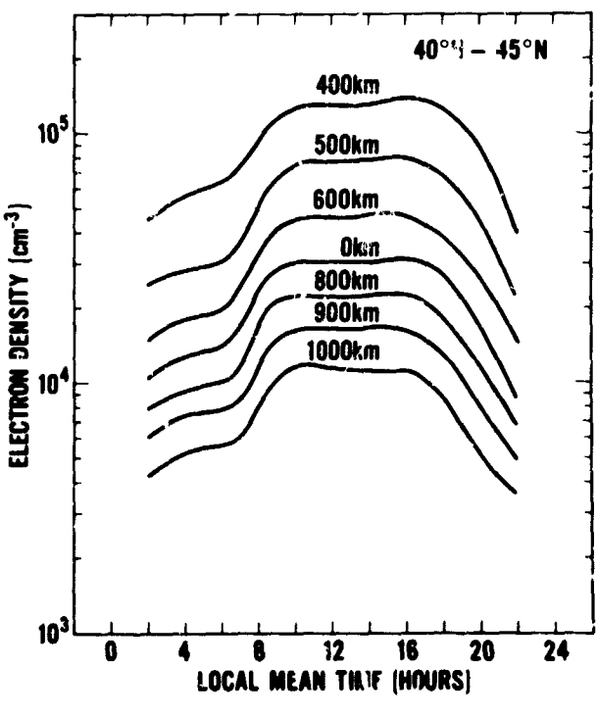

FIGURE 2.—Diurnal variation of electron density at constant altitudes for the latitude range 40° N to 45° N. (Corrected for quasi-seasonal effects).

10.7 cm solar flux as an indicator and normalizing the mean diurnal variation to a condition of $S_{10.7}=85\times10^{-22}W/m^2/cps$. This was accomplished by making a percentage correction of the electron density contours appropriate to the variation of $S_{10.7}$. The mean diurnal variation of electron density at fixed altitudes, corrected for quasi-seasonal effects, is shown in Figure 2 for the latitude range 35°N to 40°N and in Figure 3 for

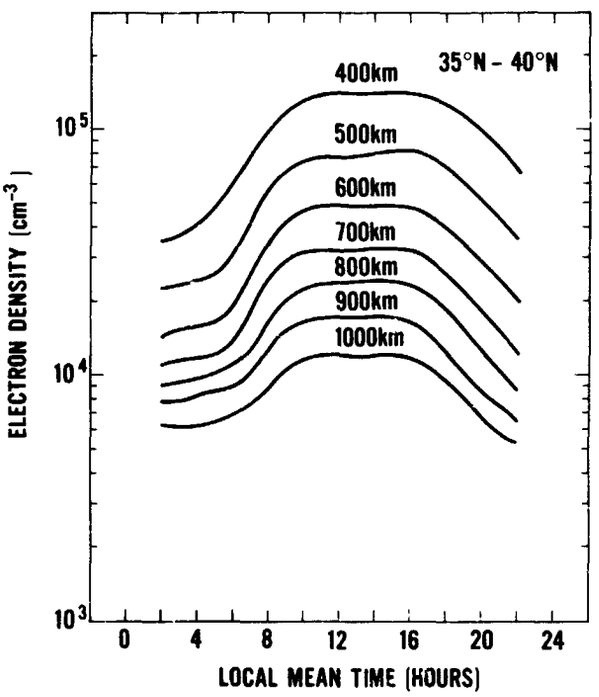

FIGURE 3.—Diurnal variation of electron density at constant altitudes for the latitude range 35° N to 40° N. (Corrected for quasi-seasonal effects).

40°N to 45°N. While the daytime values for the two latitude ranges are virtually identical, the electron density contours show a quite different behavior during the rest of the day. (The fact that there are no data between 2200 and 2400 LMT is the result of poor performance of the topside sounder during these night hours as the result of leakage of terrestrial noise which causes blocking of the receiver (*Atkins and Chapman*, 1963)). In comparing the behavior of the mean diurnal variation at the two latitude ranges, which can be termed in the geographical sense as *mid*-latitudes, one has to keep in mind, that magnetically this latitude range at the 75°W meridian is already representative of rather high dip angles; e.g., at 39°N, 75°W, the magnetic dip is I=70°. It appears that this dip represents somewhat of a boundary between "normal" and "auroral" type of ionosphere. This is definitely evidenced in the behavior of spread F (*Calvert and Schmid*, 1964) and thus is possibly also indicative of the role of corpuscular effects in the ionosphere (cf. *Mariani*, 1963). Similar conclusions have been drawn on the basis of a comprehensive study of the behavior of the "bottomside" ionosphere (*Wright*, 1962). The different behavior of the topside in the two latitude ranges, which are only 5° apart, yet include the "dip-boundary" can best be illustrated by comparing the amplitude of the diurnal variation at selected fixed heights at the 35°N to 40°N latitude range with that at 40°N to 45°N. This

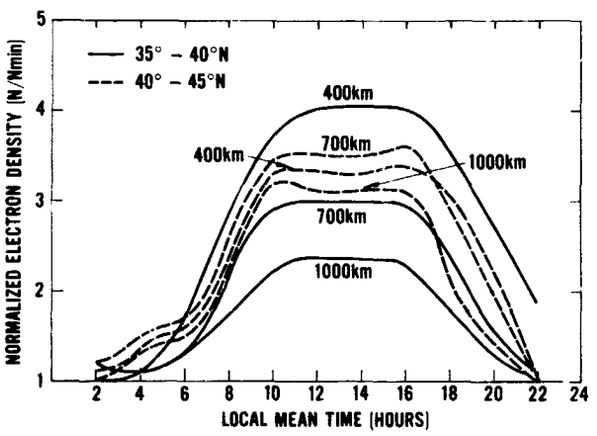

FIGURE 4.—Time variation of normalized electron density at fixed altitudes illustrating the variation with altitude of the diurnal amplitude for the two latitude ranges.

is shown in Figure 4, where the normalized electron density, i.e. the ratio of electron density at a particular local time to the minimum value of electron density at selected altitudes is plotted as a function of local mean time for both latitude ranges. It is quite obvious that the diurnal amplitude is decreasing with altitude for the latitudes 35°N to 40°N, while for 40°N to 45°N the diurnal amplitude is virtually independent of altitude. Furthermore, the absolute value of the amplitude at 400 km is higher at 35°N to 40°N than at 40°N to 45°N. The variation of the diurnal amplitude at latitudes 35°N to 40°N as a function of altitude is qualitatively what is expected from theoretical considerations (*Gliddon and Kendall*, 1962), how-

ever the actual decrease with altitude of the ratio of maximum to minimum density from a value of 4 at 400 km to a value of 2.3 at 1000 km is still much slower than theoretical estimates. It should be noted, however, that although the theoretical model of the F_2 region by Gliddon and Kendall is based on the solution of the time-dependent continuity equation, it is not strictly applicable to the topside ionosphere because it assumes an isothermal atmosphere whose temperature also does not show a diurnal variation. It is quite evident from Figure 4 that the diurnal behavior of the topside ionosphere, especially at latitudes greater than 40°N, is quite different from simple model concepts. The reason for the discrepancies is obviously the importance of a variable scale height as the result of diurnal variation of temperature, absence of thermal equilibrium between electrons and ions and a varying ion composition.

The above conclusion that a variable scale height is indeed responsible for the altitude behavior of the diurnal amplitude of electron density at fixed levels, is more readily apparent in "mean" vertical profiles of electron density (derived from cross sections of the electron density contours at fixed heights, as shown in Figures 2 and 3).

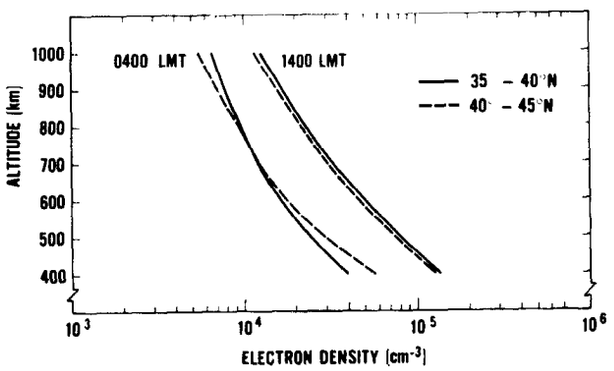

FIGURE 5.—"Mean" electron density profiles of the mid-latitude topside ionosphere corresponding to times of the diurnal temperature maximum (1400 LMT) and minimum (0400 LMT).

Figure 5 shows such "mean" profiles for the two latitude ranges at 0400 LMT and 1400 LMT, the times corresponding to the diurnal minimum and maximum of the atmospheric temperature. The problems concerning a variable scale height of the topside ionosphere and the implications from the observations presented here will be discussed in the following section.

DERIVED QUANTITIES: SCALE HEIGHT, ELECTRON TEMPERATURE AND ION COMPOSITION

The spacing of electron density contours at fixed altitudes shown in Figures 2 and 3 is a measure of the scale height of the electron-ion gas. It is well known that in the topside ionosphere this scale height is given by

$$H' = \frac{k(T_i+T_e)}{m_+ g} = \left[-\frac{1}{N}\frac{\partial N}{\partial z} \right]^{-1}$$

where k is Boltzmann's constant, T_e and T_i are the electron and ion temperature respectively, m_+ is the mean ionic mass and g is the acceleration of gravity. From the diurnal variation of the mean electron density contours it is thus also possible to infer the diurnal variation of the scale

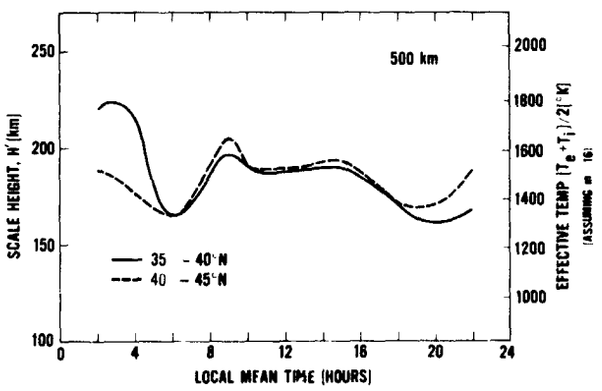

FIGURE 6.—Electron-ion scale heights at 500 km for the two mid-latitude ranges as a function of local mean time, together with corresponding scale for the effective charged particle temperature $(T_e+T_i)/2$ assuming $m_+ = 16$. The interpretation of scale heights in terms of electron temperature T_e and mean ionic mass m_+ is discussed in the text.

height. Figure 6 shows the scale height H' at an altitude of 500 km for the two latitude ranges under consideration as a function of local mean time. In addition, a scale is given for the effective charged particle temperature $(T_e+T_i)/2$, assuming a mean ionic mass $m_+ = 16$. The latter assumption may be justifiable at the given alti-

tude, at least during the daytime. In examining the variation of H' as a function of local time one has to keep in mind that this variation is the result of variation in *electron- and ion-temperature, and ion composition.* Referring to the temperature scale, it is obvious that the effective charged particle temperature is in excess of the neutral gas temperature T_n for the given three-month period, when T_n was about 1000°K during the day, and about 700°K at night (cf. *Nicolet*, 1963). Thus, it is quite evident that thermal equilibrium is absent, at least during the day (when $m_+ = 16$ may be a reasonably good assumption). If we assume that $T_i = T_n \approx 1000°$, the electron temperature T_e is of the order of 2000°K during most of the day with an even higher value around 0900 LMT. (If m_+ is less than 16, then T_e is reduced proportionately; thus, the above value represents an *upper* limit). It is interesting to note, that actual measurements of T_e near the F2 peak for the same latitude range obtained from Blossom Point telemetry read-outs of the S-6 aeronomy satellite (*Brace, Spencer and Dalgarno*, 1964) during spring and summer of 1963, are in excellent agreement with our inferred electron temperatures. Even the maximum at 0900 LMT and the subsequent plateau in the electron temperature appear in both data. Thus, we are confident, that our assumptions are reasonable. Furthermore, there is the suggestion of a latitude gradient in the scale height during the day when we are able to infer electron temperature. The electron temperature appears to be higher at latitudes greater than 40°N than below that, a conclusion, again in agreement with the actual measurements of electron temperature by *Brace et al* (1964). During the early morning hours (0200 0500 LMT) the electron-ion scale height H' is higher than, or at least comparable to, the daytime values. This cannot be explained in terms of temperature since there is good reason to believe that atmospheric heating *is* lower at night (assuming that the main heat source is solar EUV with a possibly constant, corpuscular component super imposed on it). The more plausible explanation is that the large scale height during this time period is the result of a change in the ion composition, indicating the presence of the lighter ionic constituents He^+ and H^+. The latitudinal gradient in scale height is reversed during this time period, implying that in terms of ion composition, the preponderance of the light ions is weighted towards lower latitudes. This inference finds support in observations of ion composition on the Ariel satellite (*Bowen et al*, 1964). If such a latitude gradient of ion composition does indeed exist even during the day, then the latitude-gradient in electron temperature would be even larger than that apparent from the daytime scale heights for the two latitude ranges. Ion composition, or rather the mean ionic mass m_+ at 500 km, can be inferred from the scale height if assumptions are made concerning the electron and ion temperatures. Assuming first, that thermal equilibrium prevails during the night, then at 0400 LMT (corresponding to the diurnal temperature minimum) $T_e = T_i = T_n \approx 700°K$ for the time period under consideration. Accordingly, the mean ionic mass at 500 km is $m_+ \approx 8$ *AMU* at latitudes 40°N to 45°N and $m_+ \approx 7$ *AMU* at latitudes 35°N to 40°N. The trend seems to be reversed in the late evening hours when the scale heights are greater at higher latitudes than at the lower latitudes. However, the assumption of thermal equilibrium may not hold even during the night, since electron temperatures $T_e \approx 1000°K$ have been observed at nighttime (*Brace et al*, 1964) which are in excess of the estimated neutral gas temperature for the corresponding time period. In this case the mean ionic masses quoted above would be increased to $m_+ \approx 10$ *AMU* (40°N to 45°N) and $m_+ \approx 8$ *AMU* (35°N to 40°N). In any event, it is quite obvious that the light ionic constituents must become important during the night even at altitudes as low as 500 km.

It is interesting to compare the scale heights at 500 km with the scale heights at 800 km derived in the same fashion. During the night (0400 LMT) the ratio of the scale heights $H'(800)/H'(500) \approx 2.5$ at 35°N to 40°N and about 2.1 at 40°N to 45°N, while during the day (1400 LMT), this ratio is about 1.9 at the lower latitudes and 1.6 at the higher latitudes. Taking into account the altitude variation of the acceleration of gravity g, and making the same assumptions concerning the electron and ion temperature as before, it is again possible to infer the mean ionic mass at 800 km. Table 1 summarizes the inferred mean ionic mass at the two latitude ranges, considered here.

TABLE 1.—*Inferred Mean Ionic Mass* m_+

		0400 LMT		1400 LMT	
Altitude	$T_e/T_{i,n}$	35°–40°N	40°–45°N	35°–40°N	40°–45°N
500 km	1	~7 AMU	~8 AMU		
	>1	~8 AMU	~10 AMU	(16 AMU)	(16 AMU)
800 km	1	~3 AMU	~4 AMU	~6 AMU	~7 AMU
	>1	~3.5 AMU	~5 AMU	~9 AMU	~11 AMU

It is obvious from Table 1 that light ionic constituents (H_e^+, H^+) must become important at 800 km even during the day; during the night H^+ must be an important constituent, at least at the lower latitudes. To infer the relative abundance of ionic constituents becomes somewhat hazardous, since the additional assumption would have to be made that the light ions are in diffusive equilibrium, an assumption which may not be justified even at altitudes as high as 700 km (*Bauer*, 1964). Thus, the mean ionic mass m_+ can only be used as an *indicator* of the presence of ions lighter than O^+, while no reliable and unique data on the abundance of the individual light ions can be inferred from the electron-ion scale height under the present circumstances.

CONCLUSIONS

Although it is not possible by means of satellite observations to obtain directly the true diurnal variation of the topside ionosphere, a *mean* diurnal variation can be constructed with proper precautions from daily observations over an extended period of time. The mean diurnal variation of the topside ionosphere at mid-latitudes based on Alouette observations from October to December 1962 exhibits the following features:

1. There is a significant difference in the diurnal behavior between the latitude ranges 35°N to 40°N and 40°N to 45°N, the boundary of which appears to be associated with the 70° magnetic dip line.

2. The vertical cross section of the topside ionosphere is indicative of an electron-ion scale height *variable* with altitude, latitude and time.

3. There is definite evidence of absence of thermal equilibrium, at least during the daytime, with $T_e/T_{i,n} \approx 2$ at 500 km.

4. The mean ionic mass inferred from the scale height indicates that the light ionic constituents H_e^+ and H^+ are already of importance during the day at 800 km and during the night at an altitude as low as 500 km.

5. There is some indication of opposite latitude gradients in electron temperature and mean ionic mass, the electron temperature increasing with latitude.

ELECTRON DISTRIBUTION IN THE IONOSPHERE*

N66 37957

ROBERT E. BOURDEAU

1. INTRODUCTION

Under average conditions, the electrons with thermal energies that form the ionosphere result from photoionization of the upper atmosphere by ultraviolet and x-radiation from the sun and possibly by corpuscular radiation. These electrons are lost by recombination with ions simultaneously produced. The loss rate is slow enough that the ionosphere persists throughout the night especially at the higher altitudes.

In addition to the above-described production and loss mechanisms, gravitational and electromagnetic forces contibute to the determination of the altitude distribution of electrons the combination of all these factors is such that several regions with distinctive features are formed. This natural subdivision permits a discussion of the ionospheric electron distribution to be subdivided accordingly. Specifically, as will be done here, it allows for separate discussions of the D (50–85 kilometers), the E (85–140 km) and the F (140–1000 km) regions and of the outer ionosphere which extends from 1000 km to several earth radii.

The electron density (N_e) typically varies from $10^3 cm^{-3}$ in the D region, to $10^5 cm^{-3}$ in the E region, reaches a maximum of $10^6 cm^{-3}$ at 300 km in the F region and then decreases monotonically to $10 cm^{-3}$ at a distance of several earth radii. The principal changes from a given electron density profile will occur with time of day, with season, with temporal position within the solar cycle and with latitude. The relative importance of each of these effects depends upon the ionospheric subdivision under discussion. The dynamic nature of the ionosphere is evidenced by the fact that one of these effects can produce an order of magnitude variation in N_e at specified altitudes. The problem of orderly discussion is complicated further by the very large variations that result from solar storms and from energetic particle precipitation into the auroral region.

In organizing the discussion, it would have been natural to choose a condition of maximum or minimum solar activity and then treat the variations about it. However, observational evidence at least for the regions below 85 and above 300 km is weighted heavily toward the middle of the current solar cycle. For this reason, the term "average profile" is used here for a noontime, mid-latitude ionosphere at an epoch midway between solar maximum and solar minimum conditions. "Average profiles" will be developed for each of the four subdivisions prior to discussions of temporal and latitudinal changes about them. Solar storm and auroral phenomena shall be discussed but treated as special events.

2. AN AVERAGE D REGION ELECTRON DENSITY PROFILE

The D region, even though the most accessible, is the most difficult to study experimentally because it contains the lowest ratio of electron to neutral gas density. The difficulty principally is embodied in the separation of the electron density and collision frequency parameters, which simultaneously contribute to measured phenomena. Separation of these two parameters has been accomplished by experiments involving radio propagation between the earth and a rocket. Ground-based experiments have been carried out by cross-modulation and partial-reflection techniques. One common denominator of ground-based methods is that the altitude dependence of electron density is extracted from the experimental data only by assuming an electron collision

*Published as *Goddard Space Flight Center Document X-615-64-29*, January 1964. This work was also published in "International Dictionary of Geophysics" Pergamon Press, Oxford, England

frequency profile, usually that measured with rocket experiments by Kane (1961). Rocket-borne dc probes have been used but the theoretical analysis is based on the assumption of a collision-free plasma sheath, an unlikely condition at D region altitudes.

Few D region profiles have been reported for the "average" conditions. An average profile applicable to a quiet midday ionosphere is pre-

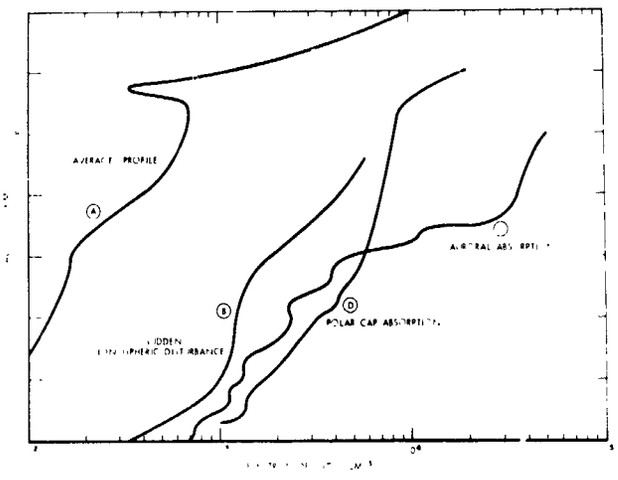

FIGURE 1.—D region electron density profiles

sented as curve A in Figure 1. It was constructed from the space flight results of Aikin et al (1963) and of Hall (1963) and from the ground-based observations of Belrose (1961) and of Barrington et al (1962). Except for the latter results above 75 km, there is agreement to better than a factor of two between all data sets. The agreement is encouraging in view of the somewhat different times and locations at which the data were obtained.

The "average" profile is characterized by two separate gradients which could permit different nomenclature for the region below 70 km and the region between 70 and 85 km. It additionally is characterized by an often seen minimum located close to the mesopause (about 84 km) which tends to separate the D and E regions. The maximum value of N_e in the D region (N_mD) for the stated conditions averages 700 electrons cm^{-3}.

A note of caution needs to be injected in the discussion of this average D region profile. The data on which it is based were obtained at what would be considered mid-latitudes from the standpoint of a neutral atmosphere. However, it must be emphasized that most of the results were obtained at magnetic dips greater than 70°. Consequently, it justifiably could be argued from the viewpoint of ionospheric physics that the profile is more representative of polar conditions, in the absence of solar storms and of auroral and magnetic disturbances.

3. VARIATIONS FROM THE AVERAGE D REGION ELECTRON DENSITY PROFILE

Observational D region data are so sparse that temporal and latitudinal variations are principally hypothetical. Excluding special events, the *diurnal* variation is the major effect, the D region being essentially non-existent at night, at least from the standpoint of the N_e parameter. The results of Barrington et al (1962) indicate rapid formation of the D region just after layer sunrise.

We only can conjecture about the *solar cycle* variation at this time. If the prevailing theory* for D region formation is correct, then a solar cycle change of less than a factor of two in the entire reference N_e profile would be expected because of the relative constancy of the responsible ionizing radiation (cosmic rays below 70 km and Lyman alpha radiation between 70 and 85 km). Moderate (less than a factor of 2) *latitude* variations should exist in the lower D region, in accordance with the latitudinal dependence of the flux of cosmic rays.

We turn now to the large electron density enhancements that occur in the D region during special events and which generally are associated with radio-blackouts. Belrose and Cetiner (1962) have measured the enhancement during a Sudden Ionosphere Disturbance* (Curve B of Figure 1), an event occurring on the sunlit side of the earth simultaneously with the appearance of a flare and having a time duration of about one hour. It is seen that there is a general increase in N_e of about a factor of 10 during such periods of enhanced X-ray activity. Even larger electron density increases have been observed with rocket experiments flown in connection with high latitude phenomena. Jespersen et al (1963) have obobtained N_e data during an auroral absorption

*See D Region Chapter.

event* (curve C of Figure 1) which is associated with a magnetic disturbance and the precipitation of energetic electrons into the D region. Jackson and Kane (1959) obtained an electron density profile (curve D of Figure 1) during a Polar Cap Absorption* (PCA) event which is produced by energetic proton precipitation following certain types of solar flares. It should be noted that the PCA data were obtained during the early phases of the event. Ground-based measurements of radio absorption indicate much larger electron density enhancements during the main phase of a PCA.

Knecht (1963) has called attention to a fourth type of anomalously high D region absorption event observed frequently during the winter at temperate geographic latitudes. Electron density increases of up to a factor of ten have been reported in instances not associated with magnetic disturbances or a PCA event. In general, since these and seasonal variations in N_e have been inferred from ground-based techniques, the N_e profiles likely should be treated as qualitative because the measured phenomena might also represent temporal changes in the electron collision frequency parameter, which was assumed to be constant in deriving N_e.

4. AN AVERAGE E REGION ELECTRON DENSITY PROFILE

The altitude interval ascribed here to the E region lies between 85 and 140 km. The largest body of data concerning its behavior has been obtained by use of the conventional ground-based ionosonde. These results are particularly important to our understanding of the geographic and temporal variations of the E region under sunlit conditions. Unfortunately, the ionosonde experiment is not well suited for the determination of the detailed altitude dependence of E region electron densities, especially under nighttime conditions.

Our knowledge of the fine structure of the E region electron density profile has come from rocket experiments. These have been of two general types: radio propagation between the rocket and the earth and direct-sampling probes. It generally is recognized that the propagation experiments produce the most accurate profiles because they are relatively free of possible errors originating from the disturbance introduced into the medium under study by the rocket carrier. However, quite recently the probe experiments have been "calibrated" by including them on the same rocket flights that contain propagation experiments. This lends confidence to the validity of nighttime electron density profiles discussed in the succeeding section and which have been obtained from probe experiments because of their inherent high sensitivity.

An E region N_e profile representing the average obtained by many rocket experiments is identified as the upper portion of curve A in Figure 2. It is evident that the E region profile contains two distinct altitude intervals. The first (85–100 km) is characterized by one of the largest positive electron density gradients a(bout 10^4 electrons cm^{-3} per kilometer) found in the ionosphere. Most theoreticians ascribe the electrons found in this altitude interval to the combined effects of Lyman β (1026 Å) and x-radiation (100–30 Å).† The second region (100–140 km), believed to result from the combined effects of x-rays and of radiation principally in the 1027–911 Å portion of the ultra-violet spectrum,† is characterized by a relatively constant electron density. In fact, it is the absence of a significant "valley" in the daytime profiles that represents one of the most important results of the early rocket experiments. This feature has made it quiet difficult to discuss separately the E and F regions of the ionosphere.

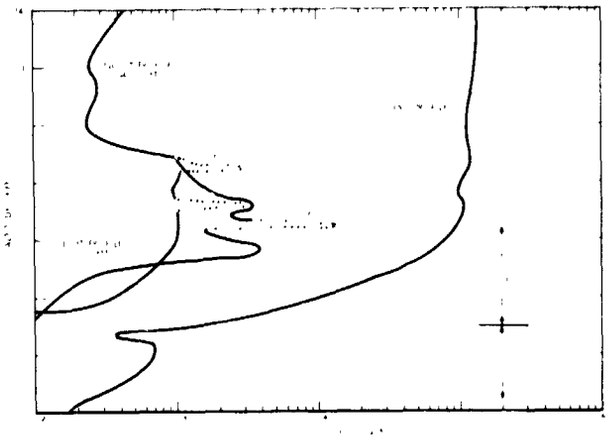

FIGURE 2.—D and E region electron density profiles

†See E Region Chapter.

5. VARIATIONS FROM THE AVERAGE E REGION ELECTRON DENSITY PROFILE

The major change from the average E region profile is *diurnal* in nature. It is possible from ionosonde data to construct a detailed temporal variation at specific latitudes of the maximum electron concentration (N_mE) in the E region for the sunlit hours. There is a symmetrical variation about a noontime value of 1.2×10^5 electrons cm^{-3} down to 5×10^4 electrons cm^{-3} near the sunrise and sunset hours. Two nighttime profiles obtained from rocket experiments by L. G. Smith (1962) are presented in Figure 2, curve B representing an evening condition and curve C a predawn situation. With the exception of the much lower value of N_mE, the features that best distinguish the nignttime profiles from the average profile are (a) the existence of a "pronounced" value above 110 km which extends into the F1 region and (b) the irregular fine structure. Profiles diurnally spaced as in Figure 2 have been used to infer the rate of destruction of electrons in the E region. They are believed to be lost mainly by recombination with diatomic ions.* An effective E region recombination coefficient of $2\times10^{-8}cm^3sec^{-1}$ has been computed from data such as that contained in Figure 2.

Solar cycle, seasonal and *latitude* variations of N_mE are small compared to a complete diurnal variation. This conclusion from ionosonde data is quite important since it tends to narrow the hypotheses concerning formation of that portion of the E region lying above 100 km to those which include ionization sources having quite stable long term characteristics. Additionally, there is an important implication in favor of a time independent structure of the neutral atmosphere. Ionosonde data indicate that the noontime value of N_mE is only about 50 percent larger during sunspot maximum than during sunspot minimum. There are seasonal variations in N_mE of up to a factor of two at midlatitudes with the maximum occurring in June and the minimum in December in the northern hemisphere.

The perturbations in E region electron density during solar flares, magnetic storms and auroral events are known from ionosonde data to be small compared to the above-described diurnal, solar cycle and seasonal effects. This most likely is because such events are associated with energetic radiation which penetrates into the D region before ionization results. The most frequent E region anomaly is not necessarily associated with such events. Rather, it exhibits a rather random temporal variation which has led to the nomenclature of sporadic-E or E_s ionization.

One common form of E_s ionization is a thin layer in which the electron density is considerably higher than the region immediately below and above. Rocket experiments have best described the altitude characteristics of this type of E_s ionization, examples of which are illustrated by the dashed portions of the nighttime profiles shown in Figure 2. It is seen that the N_e enhancement can be as large as 6 and that the thickness of the layer measured at half the peak electron density can be smaller than 0.5 km. Larger N_e enhancements have been observed and there is evidence that the horizontal extent sometimes is measured in hundreds of kilometers. Another common form of E_s ionization is characterized by large electron density gradients lying below a region of relatively constant electron density.

Smith (1957) and Seddon (1962) have reviewed the occurrence probability of E_s ionization. Seddon finds that the preferred altitudes are 100, 105, 111, 117 and 129 km, three of which are approximately confirmed by the nighttime profiles shown in Figure 2. Smith finds that E_s is principally a nighttime phenomenon in and near the auroral zone but conversely that it is more a permanent daytime feature in a narrow band centered at the geomagnetic equator. Here we caution again that auroral characteristics might extend to magnetic dips as low as 70° and consequently in North America down to what normally is considered mid-latitudes. At the middle magnetic latitudes, the E_s occurrence probability is mostly seasonal in nature with the predominance is summer months.

There undoubtedly are several causative mechanisms for E_s phenomena, the most likely being the combined existence of wind shear and magnetic field for the mid-latitudes and two stream plasma instability for the equatorial and perhaps the auroral zones (cf Knecht, 1963).

*See E Region Chapter.

6. AN AVERAGE F REGION ELECTRON DENSITY PROFILE

Of all the ionospheric subdivisions, the F region is the most variable. Diurnal, solar cycle and latitudinal effects can each produce changes of almost an order of magnitude. Additionally, seasonal variations are quite large. Thus, it should not be surprising if the average F region profile presented here is rarely observed.

The average F region profile, constructed from rocket results obtained under the appropriate conditions, is superimposed on the average D and E region profiles as curve A in Figure 3. As

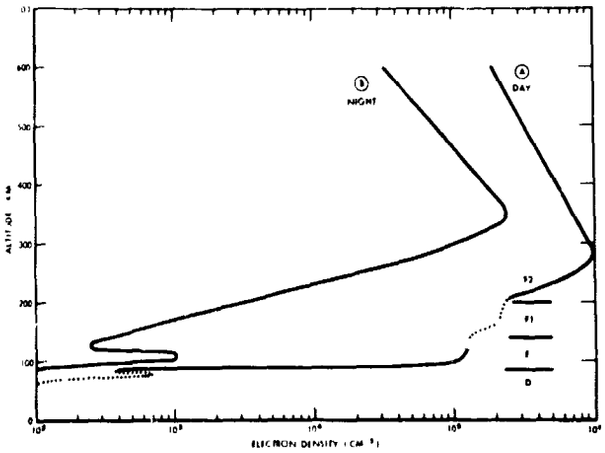

FIGURE 3.—Typical D, E, and F region electron density profiles

shown, the F region contains the altitude ($h_{max}F2$) of the maximum electron concentration ($N_{max}F2$) found in the ionosphere. Average values for $h_{max}F2$ and $N_{max}F2$ are 280 km and 10^6 electrons cm^{-3}, respectively. The daytime sub-peak region can be divided into two altitude intervals, the bases of which are identified by positive electron density gradients. The classical nomenclature for these subdivisions are F1 (approximately 140–200 km) and F2 (above 200 km).

It is likely that the electrons in the F region are produced by the same portion of the ultraviolet spectrum as for the upper E region. The N_e gradients that identify the F region probably are the result of changes from electron loss through direct recombination to loss mechanisms involving an intermediate process of ion-atom interchange prior to recombination.

In addition to electron production and loss, a third process (diffusion) becomes effective at higher F2 altitudes and contributes to the formation of the F2 peak. Diffusion or motion of the electron-ion gas can take place in accordance with gravitational or electro-magnetic forces. Diffusion is more effective than electron production or loss at altitudes above the F2 peak and is the reason for the exponential decrease of N_e with altitude.*

Our average F2 region can be defined in the Northern Hemisphere as lying between 40° and 70° magnetic dip. This permits us to minimize the corpuscular radiation effects that influence auroral ionosphere and also to neglect diffusion of the thermal electrons horizontally along magnetic field lines, a low latitude phenomenon. In this restricted reference latitude region, the tendency is for the upper ionospheric electrons to be distributed in accordance with diffusive equilibrium. Specifically, the profile above $h_{max}F2$ is heavily dependent on the mean ionic mass and the average of the electron and ion temperatures. The reference upper ionosphere profile in Figure 3 is characteristic of that obtained in the presence of a single ionic constituent (O^+) and an average isothermal electron-ion temperature of 1600°K.

7. VARIATIONS FROM THE AVERAGE F REGION ELECTRON DENSITY PROFILE

The existence of a distinct F1 region is only a daytime feature of the ionosphere. Furthermore, there is ionosonde evidence that even its very existence under daytime conditions is seasonally dependent. Its occurrence probability is highest in summer at solar maximum and is extremely low in winter at solar minimum. When it does exist, the maximum electron density values ($N_{max}F1$) show only a small dependence on temporal position within a solar cycle.

The behavior of $N_{max}F2$ and of $h_{max}F2$ is extremely complicated. At mid-latitudes, during winter months, $N_{max}F2$ decreases by a factor of about 4 from day to night. This diurnal effect is accompanied by an increase in $h_{max}F2$ of about 70 km. These features are brought out in Figure 3 by comparison of curves A and B which respectively represent day and night conditions. It

*See F Region Chapter.

should be noted that at night the breadth of the F2 peak is smaller and more importantly, that above the F2 peak there is a more rapid decrease of N_e with altitude. The more rapid decrease is brought about by a corresponding reduction of the electron and ion temperatures.

It is known from ionosonde data that, at mid-latitudes in winter, there is up to an order of magnitude decrease in N_{max} from solar maximum to solar minimum. The solar cycle effect is smaller in summer than in winter. To illustrate further the extreme variability of the F region we are faced with a seasonal anomaly, wherein for a given epoch there is a decrease in N_{max} of up to a factor of four from winter to summer.

Because it only has been recently explored to any extent, detailed temporal variations of the upper F region consist only of diurnal studies based principally on Alouette Topside Sounder Satellite results. Observational Alouette data (Bauer and Blumle, 1964) illustrating the diurnal variation of N_e for altitudes between 400 and 1000 km are shown in Figure 4. They are applicable to October-December, 1962, and thus are more representative of solar minimum conditions. The data apply only to geographic latitudes 35–40°N over North America which lie within our definition for average F2 conditions. The most striking feature is that the diurnal variation decreases with altitude. This may be caused by the relative importance of the O^+, He^+, H^+ ions which vary between night and day in such a way that the lighter constituents become more important at night. The lower mean ionic mass at night tends to overcome the effect of lower charged particle temperatures and lower values of $N_{max}F2$ in determining the electron density at higher altitudes.

As we have implied previously, there is a pronounced latitude effect on the F2 region. The existence of an ionospheric equatorial anomaly was first detected by ionosonde experiments which since have provided details of its bottomside characteristics. A more detailed description of the anomaly has come from the dramatic results of the Alouette Topside Sounder Satellite. An idealized representation of the diurnal behavior of this anomaly over South America is illustrated in Figure 5 (Jackson, 1964). It was prepared by combining the satellite results of Lockwood and Nelms (1964) with ionosonde data by Wright (1962). Plotted are idealized isoelectronic contours as a function of altitude and latitude for

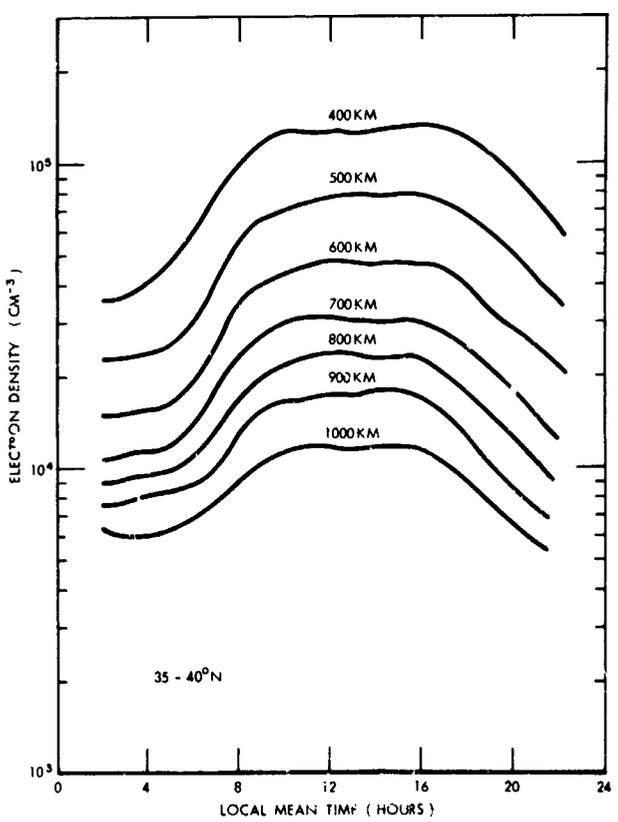

FIGURE 4.—Diurnal variation of electron density in the upper ionosphere (Bauer and Blumle, 1964)

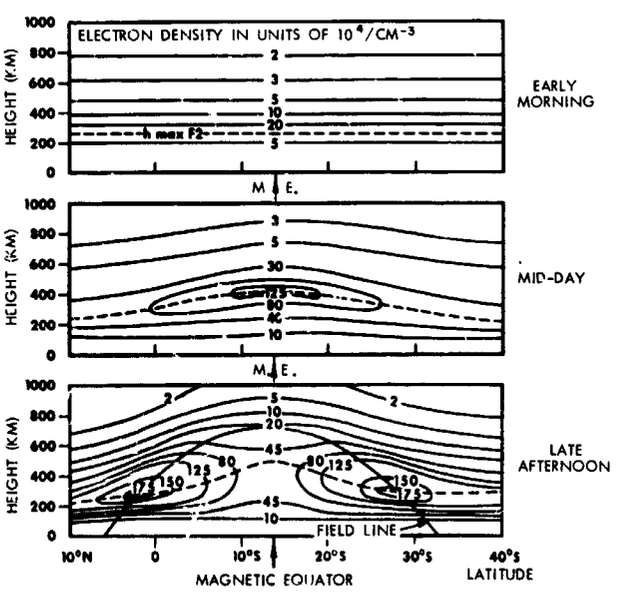

FIGURE 5.—Idealized representation of the equatorial anomaly (Jackson, 1964)

three diurnal conditions representative of the late 1962 period.

It is seen from Figure 5 that the anomaly is mainly a daytime feature. For midday conditions, a pronounced dome or peak in electron density occurs over the geomagnetic equator with a corresponding increase in $h_{max}F2$. In late afternoon, the equatorial dome is the dominant feature only at altitudes above 600 km. Below this altitude, two N_e peaks are located symmetrically about the geomagnetic equator along a specific magnetic field line. King et al (1963) have made satellite studies of the anomaly near Singapore with somewhat different results. They find that the formation of the double peak occurs much earlier in the day for the easterly longitudes. The diurnal behavior of the equatorial anomaly suggests that its characteristics are closely related to the competition between electron production which tends to maximize N_e at the sub-solar latitudes and diffusion along magnetic field lines which tends to produce a symmetrical N_e distribution about the geomagnetic equator.

The equatorial anomaly causes the appearance of small ionization ledges to appear on N_e altitude profiles wherever the appropriate magnetic shell appears. The appropriate shell for this case using the McIlwain (1961) notation occurs at magnetic L values which vary from 1.06 to 1.18. This particular field-aligned ionization enhancement has been varified experimentally by direct measurements of N_e on the Ariel satellite (Sayers et al, 1963) and by Alouette satellite results (King et al, 1963). The latter have identified additional field-aligned ledges detected from the Ariel and/or Alouette satellite results with the region of maximum flux of electrons from the artificial radiation belt ($L=1.22\pm .02$), with the heart of the inner radiation belt ($L=1.6\pm0.1$) and with the most intense portion of the outer radiation belt ($L\cong4.0$). Other ledges appear at $L=2.2\pm0.1$ and at $4.5<L<6.5$.

At higher latitudes, the electron scale height at 500 km increases markedly with latitude from what would be inferred from Figure 4 (King et al, 1963). There also is evidence (Bauer and Blumle, private communication) that at the higher latitudes the diurnal variation of N_e above $h_{max}F2$ is relatively constant with altitude, in contrast with the middle latitude results represented by Figure 4.

8. ELECTRON DENSITIES AT VERY HIGH ALTITUDES

Very few electron density distributions have been obtained for the region above 1000 km at magnetic dips 40°–70°. The few that do exist (cf Hanson, 1962; Bauer and Jackson, 1963; Donley, 1963) have been interpreted in terms of an isothermal ionosphere in diffusive equilibrium.

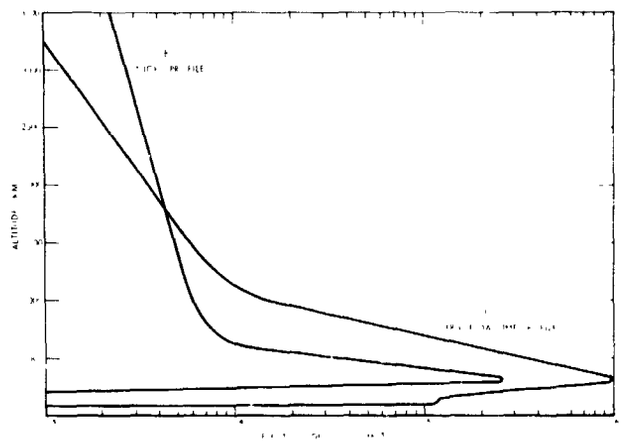

FIGURE 6.—Electron density profiles in the outer ionosphere at mid-latitudes

In Figure 6, two such profiles, one for a daytime (curve A) and the other for a nighttime conditions (curve B) have been superimposed on a typical lower ionosphere profile. The distribution above 1500 km for the daytime case corresponds to what would be expected for a plasma predominated by He^+ ions and for an average electron-ion temperature of 1600°K. This infers that protons for the daytime ionosphere in the middle of the solar cycle do not become effective below 3500 km (cf Hanson, 1962). The distribution above 1000 km for the nighttime case, on the other hand, corresponds to H^+ ions and an average electron-ion temperature of 800°K. The two profiles suggest that electrons are more abundant at the very high altitudes for a nighttime than for a daytime condition. It should be remembered, however, that the available rocket data on which these profiles depend were obtained at different portions of the solar cycle. Still, it is also possible to infer greater electron densities at night at altitudes above 1500 km by extrapolating profiles

constructed from the diurnal F region variations of Figure 4. This conclusion does not necessarily apply at other than mid-latitudes.

More extensive observations of magnetospheric electron densities have resulted from whistler observations. Carpenter (1963) has summarized the whistler measurements of magnetospheric electron densities for equatorial latitudes. His "smoothed" curve is presented in Figure 7.

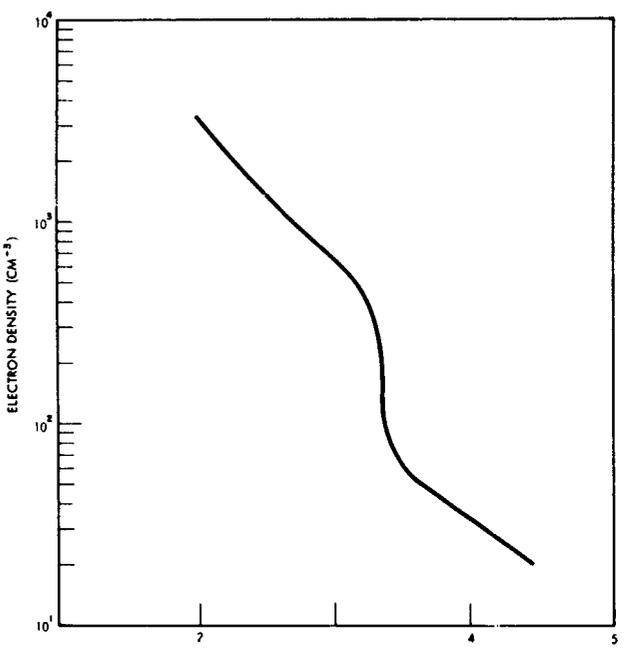

FIGURE 7.—Equatorial profile of magnetospheric electron density (Carpenter, 1963)

The most pronounced characteristic is the knee located at about $3R_E$ where the density drops by a factor of 6 or more. Carpenter finds these results to be consistent with the above-described rocket results, with the USSR results from the Lunik II spacecraft (Gringauz et al, 1960), and with the ground-based incoherent backscatter results of Bowles (1962). He suggests that the position of the "knee" is quite variable, moving from $2R_E$ during high magnetic activity to 7–8 R_E during low magnetic activity. One important implication from Figure 7 is that if one defines the ionosphere as a region containing a significant number of very low energy electrons, then the ionosphere extends out to several earth radii.

9. ACKNOWLEDGEMENTS

The stimulating discussions with J. E. Jackson of the Goddard Space Flight Center during the preparation of this review is gratefully acknowledged. The author also is grateful to S. J. Bauer and L. Blumle for access to their data prior to publication.

RESEARCH WITHIN THE IONOSPHERE*

ROBERT E. BOURDEAU

As in the other space sciences, our understanding of the mechanisms which govern the characteristics of the earth's ionosphere has been enriched by the recent, golden opportunities to perform experiments on rockets and satellites which pass through the medium under study. This understanding also has been improved by the use of new and exciting ground-based experiments.

Traditionally, the ionosphere is defined as that portion of the upper atmosphere which contains a significant number of charged particles with thermal energies (tenths of an electron volt or less). Ionospheric charged particles, electrons and ions, result from ionization of the neutral constituents by ultraviolet and X-radiation from the sun and possibly by corpuscular radiation. The electrons are lost by recombination with the positive ions that are simultaneously produced. The loss rate is slow enough that the ionosphere persists throughout the night especially at the higher altitudes. Because of the high electron number density, the ionosphere classically is associated with its effects on radio communication processes.

In addition to the above-described production and loss-mechanisms, gravitational and electromagnetic forces contribute to ionospheric characteristics. The combination of all these factors is such that several regions with unique features are formed. This natural subdivision permits a discussion of the ionosphere to be subdivided. Specifically, as will be done here, it allows for separate discussions of the D (50–85 kilometers), the E (85–140 km) and the F (140–600 km) regions and of the upper ionosphere which extends from 600 km to several earth radii.

The D, E and that portion of the F region which lies below about 300 km were identified and named as a result of research with the classical tool of ionospheric research, the ground-based ionosonde. With this "low-frequency radar," one measures the time between transmission of a radio signal from the earth to reception of the echo reflected from the ionosphere. The electron density at the point of reflection is proportional to the square of the frequency. Therefore, when this is done as a function of frequency it is possible to obtain electron density as a function of altitude. We have learned much about the temporal and latitudinal behavior of the electron distribution in the lower ionosphere through long term world-wide use of ionosonde apparatus.

It is the purpose of this paper to summarize recent advances in our understanding of the ionosphere with emphasis on those that have come about as a result of the ability to place observatories in the medium under study. This necessarily involves relating the detailed altitude, latitude and temporal variations of all characteristics of the thermal-charged particles to gravitational and electromagnetic forces, to possible ionizing sources, and to the nature of the neutral atmosphere from which the ions and electrons are created.

THE NEUTRAL ATMOSPHERE

The neutral atmosphere classically is divided into regions in accordance with the variation of temperature with altitude. The altitude dependence of temperature is represented for average daytime conditions[7] in Fig. 1a. Free electrons are found in significant abundance only above 50 km. Consequently, the regions of the neutral atmosphere that are of major interest to the ionospherici st are the mesosphere, which lies between the temperature maximum at 50 km and the minimum near 85 km, and the thermosphere (above 85 km).

*Published in *Science*, 148 (3670): 585–594, April 30, 1965.

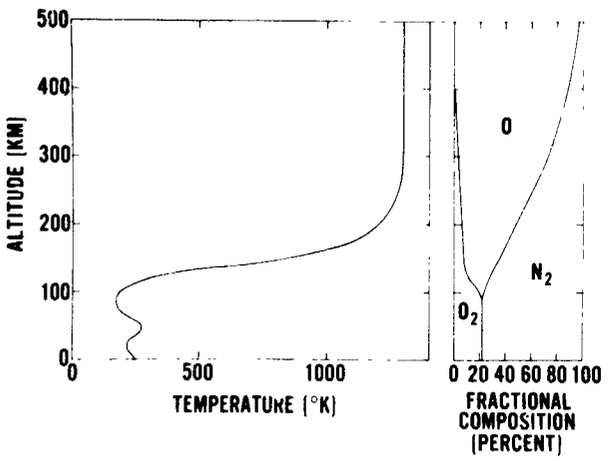

FIGURE 1.—Altitude dependence of neutral gas temperature and fractional composition (Johnson, 1962).

Mesospheric temperatures have been deduced principally from rocket-borne pressure gages and by sound-velocity experiments using rocket-borne grenades. These data show that the mesosphere exhibits large latitudinal and seasonal variations.[1] The large increase of temperature in the lower thermosphere is due principally to the absorption of solar ultraviolet radiation. Heat conduction keeps the temperature nearly constant above 200 km.[2] Thermospheric temperatures have been deduced mainly from atmospheric density measured by use of gauges flown on rockets[3] and satellites[4,5] and indirectly by studying satellite orbital decay.[6]

From the standpoint of theories of formation of the ionosphere, the most important parameter of the neutral atmosphere is its composition. An average percentage distribution of the major constituents is presented[7] as a function of altitude in Fig. 1b. Below 100 km, mixing controls the relative abundance of the neutral constituents and consequently molecular oxygen and nitrogen predominate. Above this altitude, dissociation of atomic oxygen takes place as a result of the absorption of ultraviolet radiation by O_2. At the higher altitude mixing becomes unimportant and the constituents are in diffusive equilibrium, each component being distributed independently of the others. The distribution of the constituents can be calculated theoretically from [illegible] hydrostatic equation using an assumed altitu[illegible] for diffusive separation and assumed atmospheric temperatures.

In Fig. 1b, it is shown that the molecular constituents diminish in importance with increasing altitude so that atomic oxygen dominates the atmosphere at 500 km. Above 500 km, the lighter gases become important. Up until an analysis of atmospheric drag on the ECHO I satellite, it was believed that there is a transition directly from an oxygen to a hydrogen atmosphere. However, this analysis[8] first suggested the existence of an intervening helium layer. The importance of neutral helium at the higher altitudes was first confirmed[5] by mass spectroscopy on the Explorer 17 satellite, some time after ionized helium had been detected from rocket[9] and satellite[10] experiments. The thickness and altitude of the helium region should be a strong function of atmospheric temperature.[11] This is reflected in the graphs (Fig. 2a) of mean molecular weight as a function of altitude for the diurnal

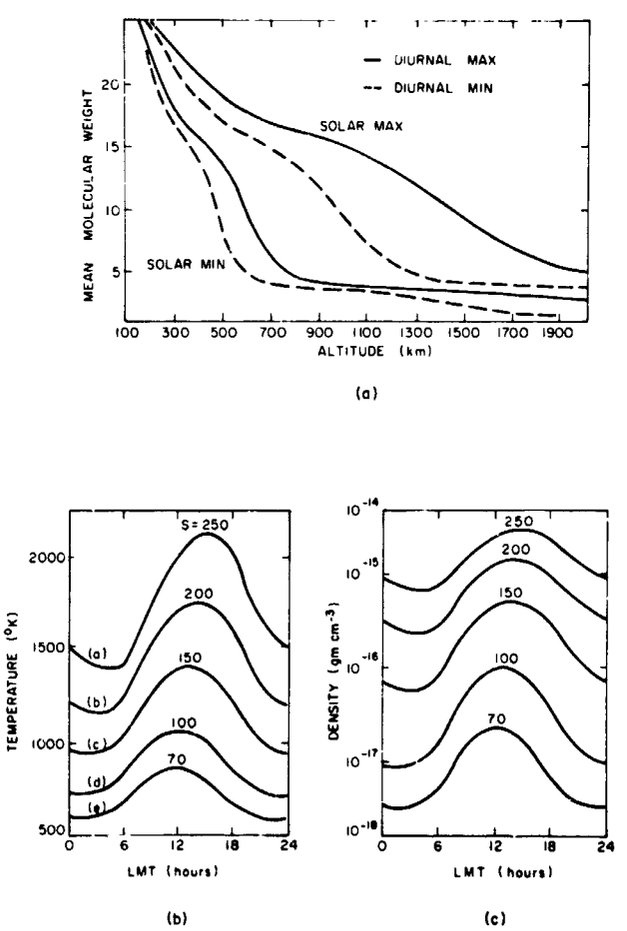

FIGURE 2.—Time-dependent model of neutral gas (a) mean molecular weight, (b) thermospheric temperature, and (c) 600 km density, Harris and Priester (1962).

and solar cycle extremes.[12] The region is believed to be diminishingly thin, for example, at night during the year of minimum solar activity.

The structural behavior of the atmosphere shown in Figs. 1b and 2a has been inferred principally from total density measurements using rocket-borne gages and analyses of satellite drag. Early rocket-borne mass spectrometers[13] qualitatively established that diffusive equilibrium controls the composition at the higher altitudes. However, with the early experiments was associated a high probability of errors due to surface recombination within the instruments. Consequently, it has been only in the last year that quantitatively significant measurements of the O/O_2 and O/N_2 ratios were obtained by direct sampling.[5,14,15]

Satellite drag observations show that the temperature and density of the isothermal region of the thermosphere varies considerably with time of day and with the 11-year solar cycle (Figs. 2b and 2c). The five curves[12] in Figs. 2b and 2c are for different levels of solar activity, an index of which is the 10.7 cm flux (S) measured at the earth's surface. Values for S range from 70 at sunspot minimum to 250×10^{-22} $w\ m^{-2}$ $(\text{cps})^{-1}$ during the year of maximum solar activity.

THE NORMAL D REGION

The D region, which occupies approximately the same altitude interval as the mesosphere (50–85 km), is the lowest region where a significant number of free electrons are found. Here, the relatively dense atmosphere results in a high frequency of collisions between the electrons and the neutral constituents. Consequently, there is a high probability that electromagnetic energy which has been transferred to the electrons will be lost irretrievably in these collisions. Thus, the D region acts as an absorber of radio waves and from this standpoint is the most important ionospheric subdivision. Yet it is the least studied experimentally, primarily for two reasons: (a) the difficulty of devising experiments which are valid in such a weakly ionized medium and (b) the trend on the part of most ionosphericists to perform the more esoteric satellite experiments in the upper ionosphere.

In this section, we shall discuss only the "normal" D region constraining the conditions geographically to mid-latitudes and temporally to times free of solar flare effects. It wasn't until quite recently that even a preliminary model for the altitude distribution of electrons in the normal D region has evolved, despite the fact that the region is accessible with relatively inexpensive rockets.

The normal D region abundance is too low to permit study by use of the conventional ground-based ionosondes. However, breakthroughs have been accomplished as a result of the development of more complex ground-based radio propagation experiments.[16,17] However, one common denominator of ground-based methods is that the altitude dependence of electron density (N_e) is extracted from the data only by assuming an electron collision frequency (ν) profile since both N_e and ν simultaneously affect the measured radio propagation phenomena. On the other hand a collaborative effort on the part of a team of Goddard and Scandinavian investigators[18,19] has resulted in novel experiments involving transmission of radio signals from the ground to rocket-borne receivers. The in-situ reception featured by these complex experiments permits unique separation of N_e and ν with adequate sensitivities for the low densities found in the normal D region.

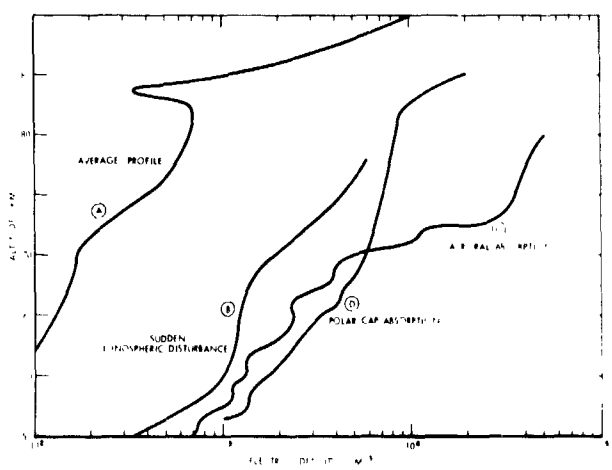

FIGURE 3.—D region electron density profiles.

In Fig. 3, we have combined the few available rocket and ground-based observations to generate an average N_e profile for the normal daytime D region (Curve A). This profile is only one of the

important pieces of information required to explain how the region is formed. To complete the task requires that one relates N_e to the competition between electron production and loss for each discrete altitude.

Electron production (q) can be computed from a knowledge of (a) the intensity of the ionizing radiation, (b) the density of the ionizable constituents responsive to this radiation and (c) the absorption cross-sections of the ionizable constituents. The problem of estimating q is complex because the cross-section of each individual constituent is a different function ofwavelength if solar radiation is the ionizing source or of electron or proton energy for the case of corpuscular radiation.

In the D region, electron loss is believed to occur mainly through dissociative recombination of electrons with positive ions leading to an excited but neutral constituent. To estimate electron loss requires a knowledge of the recombination rates which are different for each ion species.

As a result mainly of rocket measurements of solar radiation, theoretical models[20] narrow the sources of the normal D region to three individual or combined possibilities. It generally is accepted that the lower part (50–70 km) is produced by the action of cosmic rays on the principal neutral constituents (O_2 and N_2). If so, this region should show a strong latitude dependence. There is some disagreement as to the relative roles of the remaining two sources in ionizing the upper part of the D region. Here, one possibility involves the ionization of O_2 and N_2 by 2−8 Angstrom X-rays, an extremely variable source with a very low intensity (not exceeding 10^{-3} erg cm^{-3} sec^{-1} for a flareless sun). The other possibility is Lyman alpha radiation (1216A), the only ultraviolet source for which there is a favorable cross-section and which by rocket tests has been observed to penetrate into the D region. This stable but intense source measured in a few ergs cm^{-3} sec^{-1} acts only upon a trace constituent, nitric oxide. Rocket and satellite measurements indicate that the X-ray fluxes at the extremes of the solar cycle vary by more than two orders of magnitude.[21] Therefore, the relative importance of X-rays and Lyman alpha radiation to the formation of the normal D region may depend on position in the solar cycle.

There have been few spaceflight input-output experiments where the ionization source and the ionization characteristics have been simultaneously measured. According to some observers[18] who measured N_e on a rocket simultaneously with Lyman alpha flux, X-radiation can be ruled out as a significant source of the normal D region at least for the minimum of the solar cycle. To be certain of the relative importance of these two sources at all times, we desperately need laboratory investigations which can resolve existing uncertainties in our knowledge of the absorption cross-sections and recombination rates.

An important tool in ionospheric research is the ion spectrometer, a very difficult experiment to carry out in the D region—so difficult that it has been carried out only once[22] and this during the last year. Other than possible contaminants borne aloft by the rocket, the major ionic constituent observed below 83 km was NO^+. This observation supports the Lyman alpha hypothesis but does not rule out, a priori, ionization by X-radiation because of the possibility of ion-molecule interaction.[23] For example, O_2^+ produced directly by X-rays can react with an N_2 molecule to form an NO^+ ion and an NO molecule. Thus, until the various reaction rates are better known, the ion spectrometer observation does not permit a choice between the Lyman alpha or the X-ray hypothesis.

SPECIAL D REGION EVENTS

There are many phenomena which can enhance the D region electron abundance by up to more than two orders of magnitude with associated electromagnetic wave attenuation strong enough to produce radio blackouts. Simultaneously with the appearance of a solar flare, increased absorption is observed in the D region on the sunlit side of the earth for periods lasting up to approximately one hour. The causative mechanisms for these sudden ionospheric disturbances (S.I.D.) were not established until investigators accurately timed rocket launchings during the course of a flare and observed enhanced X-ray activity penetrating as low as 30 km.[24] The dominant role of solar X-rays in the production of S.I.D.'s has been confirmed by correlating visible flares with satellite observations of enhanced X-ray fluxes and with increased radio absorption.[21] An order of

magnitude increase in D region ionization during an S.I.D. has been measured with ground-based techniques[16] (Curve B of Fig. 3) and estimated theoretically.[20]

At high latitudes, enhanced radio absorption occurs during auroras. This is attributable to enhanced ionization resulting from direct and indirect (bremsstrahlung) effects of precipitating energetic electrons.[23] Evidence for up to a two order of magnitude increase in electron density has been obtained[19] by timing rocket flights to occur during such auroral absorption events (Curve C of Fig. 3). Another type of absorption takes place above the auroral zone and has been correlated with satellite measurements[25] of enhanced energetic proton fluxes during certain types of solar flares. There has been one rocket measurement[26] of enhanced electron densities during such polar cap absorption events (Curve D of Fig. 3).

Increased radio absorption associated with solar flares is often observed in the winter at middle latitudes. The causes of these events are uncertain. It has been suggested from ground-based observations[16] that these are associated with increases in electron density. However, absorption may also be associated with changes in electron collision frequency. Significant changes in ν have been correlated with measured pressure variations in the stratosphere as a result of two rocket flights during which the measured electron densities were approximately the same, thus suggesting a meteorological influence on the D region.[18]

THE E REGION

Although ground-based ionosondes have been valuable in detailing the temporal and latitudinal variations of the maximum amount of ionization found in the E and F regions, the important altitude variation of N_e has come about as a result of rocket probing using both radio propagation[27,28] and plasma probe experiments.[29,30] Typical day and night N_e profiles composed from such measurements are presented in Fig. 4. These show that at night the D region essentially disappears, the E region electron abundance has decreased by a hundredfold but that there is a strong persistence of the upper F region.

In addition to N_e measurements, significant contributions to our understanding of the physics

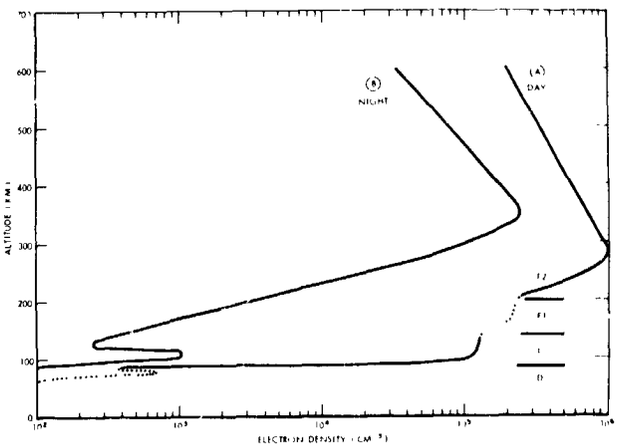

FIGURE 4.—Typical D, E, and F region electron density profiles.

of the ionosphere have come about as a result of vertical cross-sections taken of the intensity of solar radiation[31] and of ionic composition.[32,33] In an important work,[31] solar radiation measurements have been used together with a model neutral atmosphere to estimate the altitude dependence of (a) electron production rate for discrete portions of the X-ray and ultraviolet spectra (Fig. 5a) and (b) the rate of production of each of the

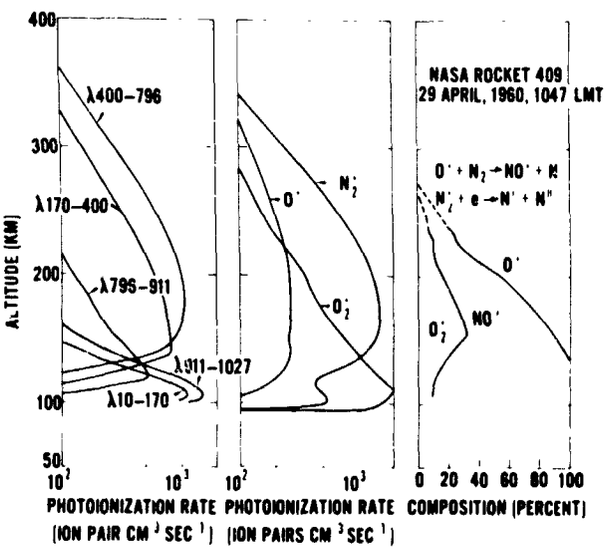

FIGURE 5.—Comparison of ion production rates (Watanabe and Hinteregger, 1962) with rocket measurement of ionic composition (Taylor and Brinton, 1961)

ion species (Fig. 5b). We see that the ions formed at the highest rate are O_2^+, N_2^+ and O^+. Spectrometer observations[32] typically represented in Fig. 5c, on the other hand, show that N_2^+ is a

minor ionic constituent despite the predicted high production rate. They also show that NO^+ is a dominant E region constituent even though it is not significantly produced by direct ionization. Most models[34] attribute the loss of N_2^+ to the combined effects of dissociative recombination with electrons and of ion-atom interchange ($N_2^+ + O \rightarrow NO^+ + N$). The existence of NO^+ generally is explained by ion-atom interchange involving N_2^+ and O^+.

It should be apparent that our understanding of the formation of the daytime E region has been vastly improved by the above described rocket measurements. Yet, models do disagree considerably as to even the relative importance of X-ray and ultraviolet radiation in the E region. Laboratory measurements of the various rate coefficients and additional rocket flights are needed to resolve these differences.

It wasn't until quite recently that rocket experiments were made sensitive enough for extensive studies of the nighttime E region. In Fig. 4, it is shown that N_e drops below 10^3 cm^{-3} and that the region is characterized by a ledge at about 100–110 km with a valley of ionization just above. It is suggested[33] by a comparison of the results from ion spectrometers flown both during the day and for the first time at night that the maintenance of the nighttime E region is explained by slow decay through dissociative recombination without resort to a nighttime source of ionization. There also is experimental evidence from rockets for metallic ions of meteoric origin in the 100–110 km region.

A frequent anomaly of the E region is sporadic E or E_s ionization. One common form of E_s is a layer as thin as 0.5 km in which N_e is considerably higher than the region immediately below and above, leading to reflection of radio signals at (Fig. 6) abnormally high frequencies. These layers exist at preferred altitudes[35] in the region 100–120 km. Some theories[36] explain E_s ionization as the result of the combined effects of wind shear and electromagnetic forces. A correlation has been found between wind shear measured on one rocket carrying a sodium vapor release experiment and E_s ionization detected on a second rocket launched almost simultaneously.[29] However, the exact relationship between E_s ionization and wind shear is not clear at this time.

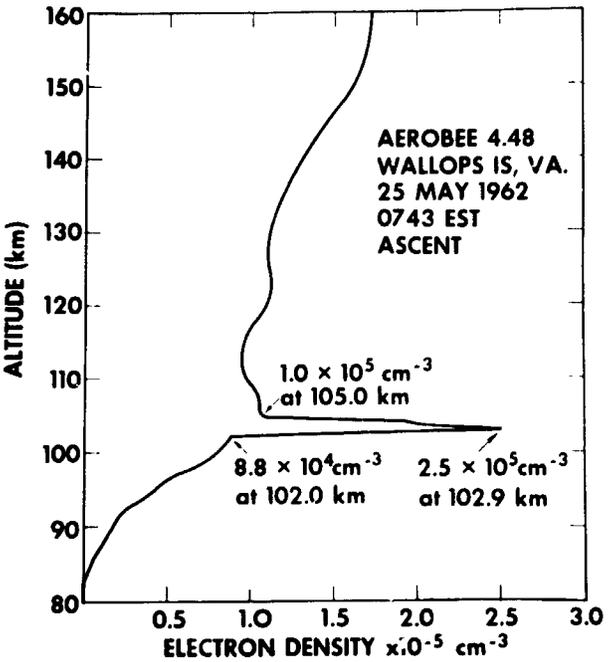

FIGURE 6.—Rocket detection of sporadic-E layer (Smith, 1962).

THE F REGION

As shown in Fig. 4, the F region contains the altitude of maximum electron density (Nm). The region is subdivided into the F1 and F2 regions because a ledge often appears in the daytime 140–200 km region.

It is important to note by comparing Figs. 4 and 5a that the altitude of maximum electron density lies well above the height of maximum electron production. These rocket results confirm previously established theoretical models which ascribe the formation of the F2 peak to charge transport mechanisms of importance comparable to photochemical processes. Specifically, these models ascribe the F2 peak formation to the competition between electron production, a height dependent decrease in electron loss rate and charge transport.

The rocket solar radiation and ion composition measurements (see Fig. 5) show that the origin of F region electrons lies principally in the production of O^+ ions by solar ultraviolet radiation. The dominant F region loss process is believed to be radiative recombination, a two-step process involving firstly ion-atom interchange between O^+ ions and N_2 molecules and secondly recombination of the resulting NO^+ ions with electrons. The slowness of this two-step process is a partial

explanation for the strong persistence of the nighttime F region. The possibility that the electron loss rate decreases more rapidly with altitude than the production rate is an explanation for the experimental observations that N_{max} lies above the altitude of maximum production.

Because photochemical, gravitational and electromagnetic forces all are effective, the behavior of the F region is extremely complicated. Ionosonde data taken over the last three decades show that the diurnal seasonal, solar cycle and latitude effects each produce large variations in the magnitude and altitude of N_m.[34] These observations have been related to time-dependent neutral atmospheres deduced from satellite drag measurements (Fig. 2) to estimate ionization, loss and diffusion rates.[37,38]

As the density of the neutral constituents decrease, the importance of photochemical processes diminish. Thus, charge transport processes become dominant and bring about the observed decrease of N_e with altitude. Gravitational forces, for example, act upon the ions which, by coulomb attraction, cause the electrons to diffuse downward. In this case, the hydrostatic law can be invoked and the electron distribution is controlled by the average electron-ion temperature and the type of ion.

Before rockets and satellites penetrated the upper ionosphere, it was believed that a transition takes place from O^+ ions directly into the protonosphere. However, rocket[9] and satellite[10] experiments indicated that a region of helium ions separated these regions in the daytime during the middle of the solar cycle. Subsequent rocket results[39] suggest that the helium ion region disappears at night. It had been predicted[11] on the basis of the different behavior of the escape rates of hydrogen and helium that both the altitude and thickness of the helium ion region would diminish with decreasing temperature, implying a strong latitudinal and solar cycle dependency.

The role of charged particle temperatures and of ionic composition in controlling the ionosphere is illustrated by rocket measurements of charged particle density taken out to very high altitudes and presented in Fig. 7. Both a daytime and a nighttime result are illustrated. The exponential portions of both profiles provide evidence for a constant electron-ion temperature throughout

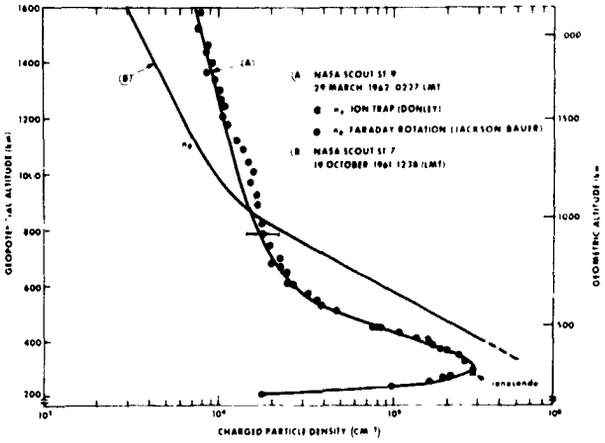

FIGURE 7.—Daytime (Bauer and Jackson, 1962) and nighttime (Donley, 1963) measurements of electron density.

the region with values of 1300° and 800°K, respectively. The change of slope in both cases is interpreted as the result of a transition from O^+ to lighter ions, He^+ being dominant above this transition for the daytime case but H^+ dominant at night. It is seen that the lower altitude of the transition and the relatively high importance of H^+ causes the surprising result that at very high altitudes the nighttime densities exceed those measured in the daytime. This may not be representative of a true diurnal variation because the two sets of data were obtained in different days.

SATELLITE STUDIES

Three different types of satellites have been used for ionospheric research each performing a different task. With Direct Measurements Satellites, one uses environmental sampling techniques to measure many ionospheric parameters, but only in the immediate vicinity of the spacecraft. The US Satellite EXPLORER VIII and the British Satellite ARIEL I each contained three major experiments for such studies. The first of these measures electron temperature by techniques similar to those developed by Langmuir in his laboratory studies of gaseous discharges. The second measures the local electron density by use of the radio-frequency impedance characteristic of a probe immersed in the medium. The third type of experiment involves the use of gridded ion traps whose principle of operation is similar to that flown on SPUTNIK III. Here, the high satellite-to-ion velocity permits the trap to act as

a poor man's ion spectrometer such that both ion composition and temperature are obtained.[10]

The second category of satellite (topside sounding) involves the ingenious use of an orbiting ionosonde. As with the classical tool of ground-based ionospheric research, one measures the time between transmission of a radio signal to reception of the reflected echo. For the satellite case the reflection is from the topside of the ionosphere. By sweeping the transmitted frequency, an electron density profile for the region between the F2 maximum and the satellite altitude is measured continuously along the satellite's path. Soundings of the upper ionospheric regions have been made in a near polar orbit for two years with the Canadian Satellite ALOUETTE I, which features a swept-frequency sounder. With a swept-frequency device, one obtains good altitude resolution. The recently-launched US EXPLORER XX features fixed-frequency sounding where vertical resolution is sacrificed so as to better study horizontal irregularities.

The third type of satellite observation involves the study at the earth's surface of the arrival characteristics of radio signals transmitted from the spacecraft at frequencies which penetrate the ionosphere. Faraday rotation and doppler phenomena permit the measurement of the total electron content in a cross-section between the satellite and the receiving site. The first satellite exclusively devoted to this method is Explorer XXII, launched too recently for results to be reported here.

SATELLITE RESULTS

The major results that have come from satellite studies lie in the unique observations of the latitudinal and diurnal behavior of the regions above the F2 peak and of magnetic-field aligned irregularities.

Evidence for magnetic field control of ionospheric electron densities first came about from the use of ground-based ionosondes, which since have provided details of the bottomside characteristics of the now familiar equatorial anomaly. The morphology of this anomaly has now been obtained to altitudes of about 1000 km. In Fig. 8 are presented results[41] from the Alouette satellite of electron density as a function of magnetic

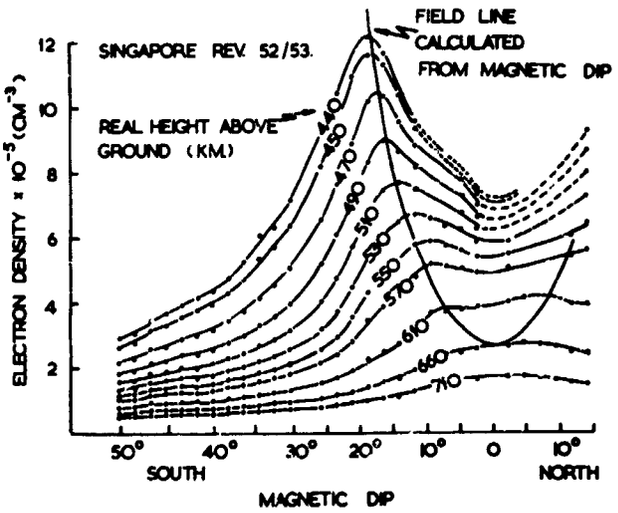

FIGURE 8.—Contours of electron density at constant altitudes measured above Singapore at 1000 LMT (King et al, 1963).

dip for discrete altitudes. These esults specifically are for the eastern hemisphere at 1000 local time. A general increase of electron density in the equatorial regions results from diffusion along the nearly horizontal magnetic field lines. For the particular time of day illustrated, the electron density reaches a maximum at the geomagnetic equator for altitudes above about 600 km. Below this altitude, two peaks are symmetrically located along a specific field line. The equatorial anomaly is predominantly a daytime feature of the ionosphere. The altitude above which only a single peak is formed has been termed the "dome" of the anomaly. The altitude of the dime over Singapore varies from 600 km in the early morning and evening hours to a mid-afternoon maximum of about 1000 km.[41] Similar measurements[42] suggest that the anomaly builds up later in the day along the 75th West Meridian. The diurnal behavior of the equatorial anomaly suggests that its characteristics are closely related to the competition between electron production which tends to maximize N_e at the subsolar point and diffusion along magnetic field lines which tends to produce a symmetrical N_e distribution about the geomagnetic equator.

Another latitude feature of the topside ionosphere are electron density troughs which appear to be a common phenomenon at middle latitudes during ionospheric storms associated with magnetic disturbances. This is illustrated by Fig. 9,

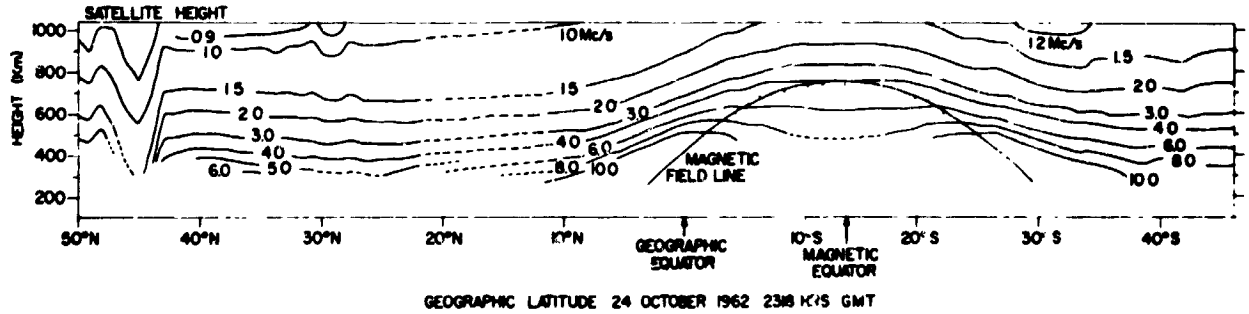

FIGURE 9.—Contours of constant plasma frequency measured with the ALOUETTE satellite (Lockwood and Nelms, 1964)

a plot of Alouette satellite measurements[42] of the frequency of reflections contours. In this illustration, applicable to 65° West Longitude, the trough is less than 5° wide and centered at 45°N.

Evidence for strong magnetic control of the upper ionosphere was first inferred from electron densities measured with an rf probe on the ARIEL satellite.[43] From these observations was inferred the existence of enhanced ionization lying along three specific magnetic field shells, one of which is accounted for by the above-described equatorial anomaly. The existence of these shells of enhanced ionizations were confirmed and others discovered by the ALOUETTE satellite.[41] Some of these have been associated with the American artificial radiation belt, the heart of the inner radiation belt and near the region of maximum flux of energetic particles in the outer radiation belt. All of these observations suggest that ionization by fast particles should now be considered along with ultraviolet radiation as an ionization source for the F2 region.

A very common anomaly of the F region is the "spread F" condition, where the region shows a diffuse character generally attributed to patches of ionization having concentrations different than

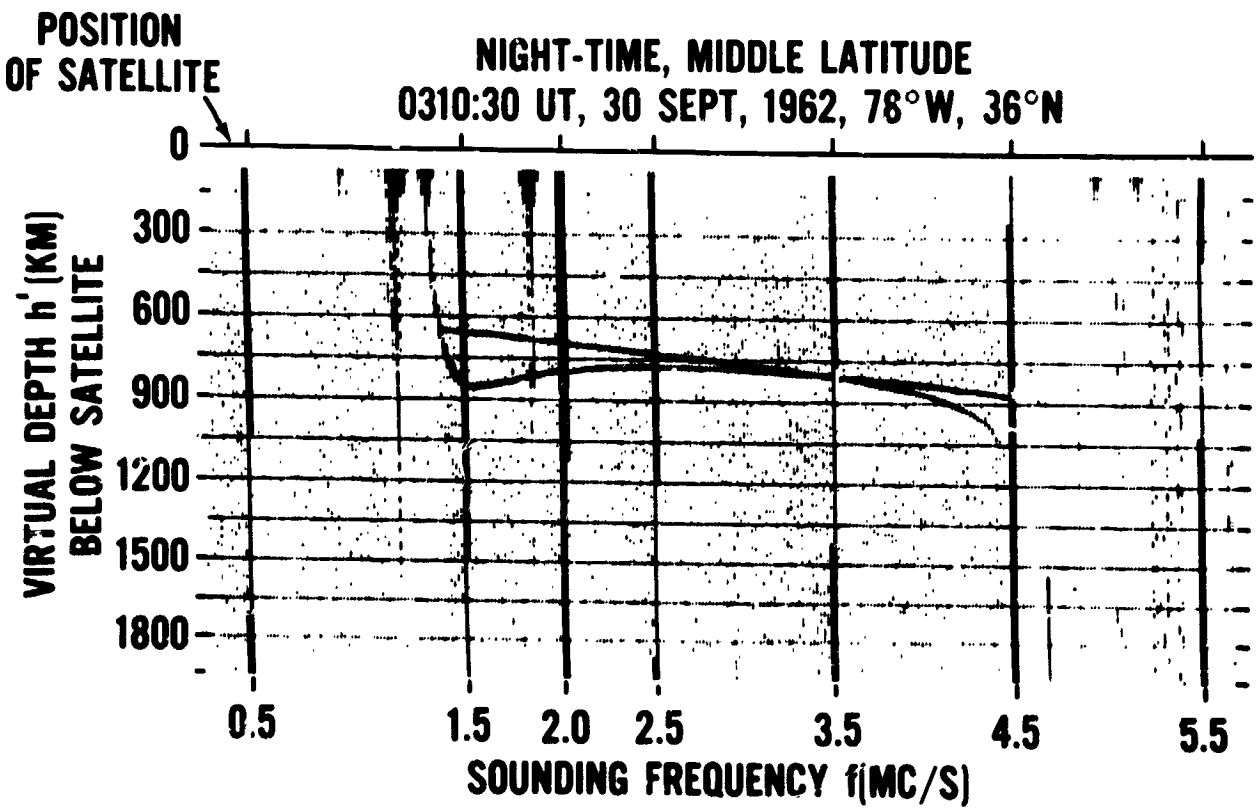

FIGURE 10.—Typical [illegible] from ALOUETTE satellite taken in the absence of spread-F.

the immediate surroundings. An ALOUETTE satellite ionogram typical of a homogeneous ionosphere is presented in Fig. 10, the two traces corresponding to the ordinary and extraordinary

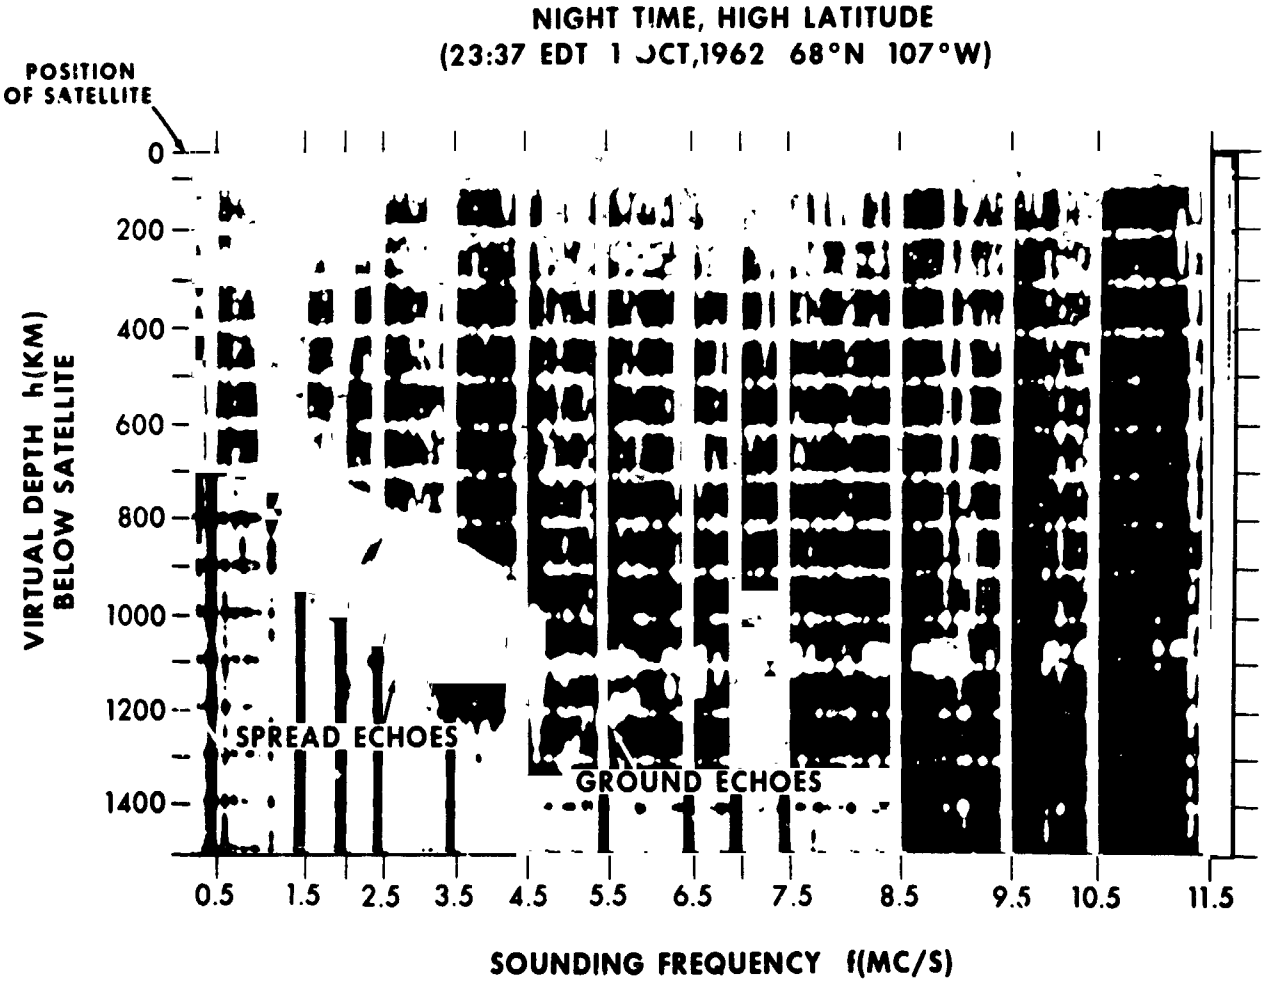

FIGURE 11.—ALOUETTE satellite ionogram taken during the presence of spread-F.

modes of radio-propagation. The effectiveness of spread-F in producing multiple echoes is illustrated by comparing this ionogram with that shown in Fig. 11 which was taken during spread-F conditions. The occurrence probability of spread-F has been the subject of a thorough analysis with the ALOUETTE satellite. This analysis[44] confirms previous ground-based ionosonde studies which showed that the phenomenon is almost a permanent feature of the high latitude ionosphere, occurs only during the night near the equator and that it occurs relatively seldom at mid-latitudes.

Referring back to Fig. 9, we observe that the electron density is not a strong function of magnetic latitude between about 15 and 45°N geographic latitude. In this region, we can expect that an important charge transport mechanism is due to gravity in which case the electron distribution is a strong function of the mean ionic mass and the average electron-ion temperature. The diurnal variation of the electron distribution in this region has been studied[45] by the use of the ALOUETTE satellite. (Fig. 12). These studies have shown the amplitude of the diurnal variation becomes smaller with increasing altitude. This would confirm a conclusion based on the rocket results shown in Fig. 7 that because of the increased relative importance of the light ionic constituents, the electron densities above 1000 km at night are higher than for a daytime condition. The diurnal variation shown in Fig. 12 have been

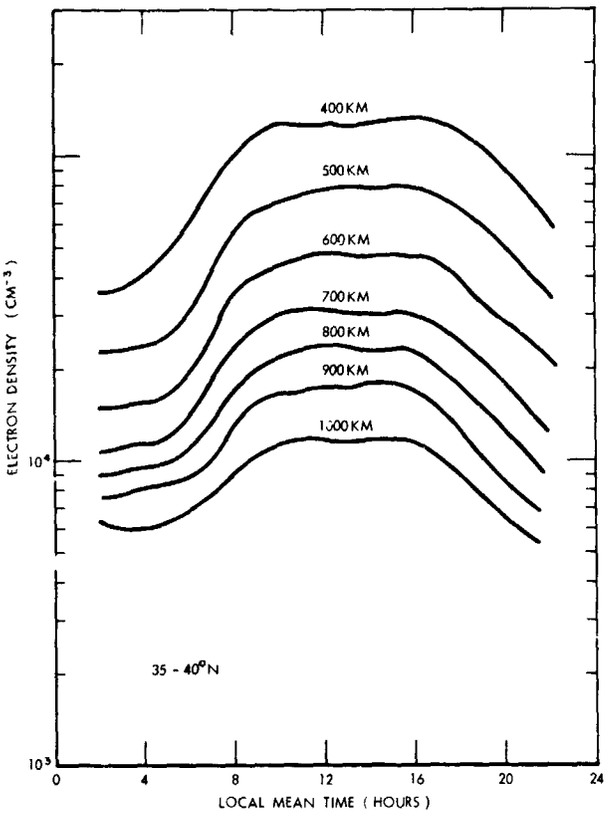

FIGURE 12.—Diurnal variation of electron density in the topside ionosphere (Bauer and Blumle, 1964).

treated in terms of ionic composition and charged particle temperature, one possible result being that for daytime at 500 km the principal ion is O^+ with an average electron-ion temperature of about 1500°K, while at night the lighter ionic constituents become important even at altitudes as low as 500 km.[45]

CHARGED PARTICLE TEMPERATURES IN THE UPPER IONOSPHERE

Because electron (T_e) and ion (T_i) temperatures are important to the behavior particularly of the region above 300 km, it is important to perform experimental observations of these parameters. Upon their creation, photoelectrons will possess energies in excess of the ambient electrons. They attempt to share this excess energy with the ambient electrons either by direct elastic collisions or after some of the excess energy has been lost through previous inelastic collisions with the ambient neutral particles or positive ions. As a result, there is a tendency for the ambient electron gas to be hotter than the neutral gas, at least in the daytime. It generally is accepted that at the lower altitudes where the neutral gas density is relatively high, the ion and neutral gas temperatures will be identical. At the higher altitude where the percentage ionization is becoming appreciable, there is a possibility that the ions are in better thermal contact with electrons than with the neutral particles and consequently the ion temperature can be elevated above the neutral gas temperature.[46]

Measurements made with the EXPLORER VIII satellite first indicated a strong diurnal control of ionospheric electron temperatures.[47] Later results with the ARIEL satellite[48] and with ground-based radar incoherent backscatter apparatus[49] confirmed this diurnal dependency. The ARIEL results and a comparison of radar backscatter observations at two locations[49,50] showed that there also is a strong dependency of T_e upon magnetic latitude. Both the diurnal and latitudinal control of T_e were subsequently confirmed[5] with the EXPLORER 17 satellite. The observations together show that the daytime ratio of T_e to the neutral gas temperature can reach values up to 2 depending on latitudinal and temporal conditions.

Since newly-created electrons share their excess energy with the ambient electrons, it follows that N_e and T_e should be strongly coupled. The latitudinal behavior of T_e for the daytime ionosphere thus can be explained in terms of magnetic field control of the electron density at least at moderate altitudes. But, it has been observed that T_e increases with altitude above 600 km.[48] This would not be expected if direct effects of solar ultraviolet radiation constitute the only source of daytime charged particle heatings. The observations[48] are consistent with the hypothesis[46] of possible indirect effects of ultraviolet radiation, specifically a mechanism whereby all of the newly-created electrons do not deposit their energy in the lower F region where they are created but where some are permitted to diffuse along magnetic field lines and deposit the energy at high altitudes. Another important observation[5,48] is that the electron temperature is somewhat higher than the neutral gas temperature at night. This requires a nighttime source of particle heating having an

intensity which is a small fraction[48] of the daytime ultraviolet source.

THE UPPER IONOSPHERE

In this paper, the higher altitudes have been subdivided into the F region where O^+ ions dominate and the upper ionosphere where light ionic constituents are more abundant. Most observations show that on the average, the transition altitude between these two regions is about 600 km. EXPLORER VIII[51] and ARIEL[52] satellite results show that the transition is from O^+ to He^+ and then to H^+ as the altitude increases, at least during the middle of the solar cycle. These results also show that the thickness and altitude of the helium ion region decrease drastically from day to night. Other results show a more complicated behavior in which for nighttime conditions, and for all diurnal times during the year of minimum solar activity, helium ions are never dominant. The exact morphology of upper ionospheric composition is not yet clear.

It has been suggested[53] that the mean ionic mass is a function of the ion temperature. There already exists evidence[49] that the ion temperature in the upper ionosphere is controlled by the electron temperature which we have shown exhibits a complicated diurnal and latitudinal behavior. It is becoming clear that theoretical models of the F region, the upper ionosphere and the interdependence of these two regions need to be updated to include (a) gravitational forces into which are inserted charged particle temperatures and ionic composition that are temporally and latitudinally variable; (b) the possibility of an ionization source related to fast particles which is superimposed in the ultraviolet source and which contributes to the maintenance of the nighttime ionosphere and (c) the possibility of indirect ionization from ultraviolet radiation, specifically the effect of photoelectrons diffusing from the lower F region along magnetic field lines to deposit their energy at the higher altitudes. Thus although satellite and ground-based studies in recent years have provided a preliminary description of the charged particle parameters at high altitudes, the observations need to be extended and correlated with measurements of photoelectron and fast particle fluxes before adequate theories of formation of these regions can be formulated.

THE TEMPERATURE OF CHARGED PARTICLES IN THE UPPER ATMOSPHERE*

R. E. BOURDEAU

Three general methods of investigating charged particle temperatures in the upper atmosphere have been used: (a) direct measurements from rockets and satellites; (b) indirect determination using electron scale heights measured from rockets and satellites; (c) ground-based radar incoherent backscatter experiments. The latitude, altitude and temporal trends of these results are reviewed and the implications discussed.

Observations by all three methods are consistent in showing that the electron temperature increases with latitude for both daytime and nighttime conditions. Moderate differences between the daytime electron and neutral gas temperatures are indicated to altitudes well above the F2 peak for a winter mid-latitude ionosphere at an epoch between solar maximum and solar minimum conditions. Much larger daytime differences are observed for summer months and for solar minimum conditions. All of these trends reflect corresponding changes in the electron density.

The daytime observations are consistent with ultraviolet radiation as the predominant heat source if the possibility of photoelectrons diffusing along magnetic field lines and depositing their excess energy elsewhere is included. A nighttime heat source small compared to the daytime ultraviolet effect is required to explain the observations.

INTRODUCTION

At the first Florence meeting of COSPAR, early direct measurements of electron temperature T_e were reported from rockets (Aono et al, 1961) and from the Explorer VIII Satellite (Bourdeau, 1961). The Japanese rocket results suggested temperature equilibrium between electrons and neutral constituents in the E region of the daytime ionosphere. Low values of T_e in the daytime E region subsequently were confirmed by US rocket experiments (Spencer et al, 1962). *However*, other rocket T_e measurements (Smith, 1961; Aono et al, 1962; Brace et al, 1963) showed that significant departures from temperature equilibrium are more often observed than not in the E region even at night. The results of Spencer et al (1962) showed that departures from temperature equilibrium extended well into the daytime F region.

Early measurements of charged particle temperatures applicable to the region considerably above the F2 peak at midlatitudes for solar conditions when the 10.7 cm flux index ($S_{10.7}$) was 150 $WM^{-2}CPS^{-1}$ were reviewed by Bauer and Bourdeau (1962) and Bourdeau (1963). Implications of temperature equilibrium at high altitudes which they optimistically derived from the data critically depended on the assumed neutral gas temperature (T_g). When these early direct measurements of T_e and of the average electron-ion temperature $(T_e+T_i)/2$ obtained from electron density profiles now are compared with more recent reference atmospheres moderate values for T_e/T_g of about 1.3 are indicated at midday even to altitudes above 1000 km for the indicated level of solar activity. These observations are in approximate agreement with the theoretical model of Hanson (1962) who assumed electron density values close to these particular observational conditions.

More extensive charged particle temperature observations for different epochs of the solar cycle now have been made by use of ground-based radar incoherent backscatter experiments, by additional direct measurements from rockets and satellites and indirectly from electron density profiles obtained from rockets and the Alouette Topside Sounder Satellite. In general, the trend is toward

*Published as *Goddard Space Flight Center Document X-615-64-103*, May 1964.

much larger departures from temperature equilibrium than indicated in the theoretical models and in the earlier observations especially at the higher altitudes.

It is timely then, as is done in this report, to compare these trends with the introduction of latitude and temporal electron density variations in the early theoretical models.

FACTORS CONTROLLING THE ELECTRON TEMPERATURE

The principal factors controlling T_e are:

Heat Input

1. Solar Ultraviolet Radiation
   - A. Locally-deposited energy
   - B. Diffusing photoelectrons ($Z>300$km)
2. Corpuscular Radiation

Heat Loss

1. Inelastic collisions with neutral constituents ($Z<250$km)
2. Elastic collisions with ions ($Z>250$ km)
   - A. Ion temperature controlled only by neutral constituents
   - B. Ion temperature also controlled by electrons ($Z>600$ km)
3. Coulomb collisions of photoelectrons with ambient electrons

Thermal conductivity in the electron gas ($Z>600$ km)

Theoretical charged particle temperature models based on solar ultraviolet heating alone have been developed by Hanson and Johnson (1961), Hanson (1962) and Dalgarno et al (1962). Of these, Hanson's model is the most complete in that he introduced the possibility of (a) photoelectrons diffusing along magnetic field lines and depositing their energy elsewhere, (b) the loss of ion temperature control by the neutral constituents and (c) the importance of thermal conductivity in the electron gas at high altitudes. The indicated altitudes where these factors are important represent Hanson's estimates based on his assumed model atmosphere and electron density profile.

The models of Hanson and of Dalgarno et al each used a single electron density profile and both depended on rocket measurements of ultraviolet radiation intensity (Hall et al, 1962) to estimate the heat input, Q. The EUV intensity used applies to a level of solar activity corresponding to $S_{10.7}\cong 100$. The heat input is the product of the EUV intensity, the ionization cross-sections and the density of the ionizable constituents and of the heating efficiency. Both theoretical charged particle temperature models exhibit approximately the same altitude behavior wherein low values of T_e/T_g are indicated in the E region, with the ratio reaching a maximum of about 2.0−2.5 at 200 km and decreasing in the upper F region. A principal and important difference is that the model of Dalgarno et al has T_e-T_g essentially vanishing above 300 km where Hanson's model permits values for T_e/T_g of about 1.2 constant at extremely high altitudes.

Because the observational evidence is most heavily weighted for altitudes above the F2 peak, the most important effect to examine is the efficiency of cooling to positive ions. On the assumption that cooling occurs only by elastic collisions to atomic oxygen ions, the electron temperature is given (Hanson, 1962) by:

$$\frac{T_e-T_i}{T_e^{3/2}}\cong\frac{2.1\times 10^6 Q}{N_e^2} \qquad (1)$$

where Q is the heat input to the electrons expressed in ev cm^{-3} sec^{-1} and N_e is the electron density. For values of Q greater than a critical value (Q_c) given by

$$Q_c\cong 2\times 10^{-7} N_e^2 T_i^{-1/2}, \qquad (2)$$

there is no solution to (1) and T_e is not limited by energy transfer to positive ions (Hanson and Johnson, 1961). If $Q=Q_c$, $T_e>2T_i$ and if $Q\gg Q_c$, very large "runaway" values of T_e will result and heat conduction in the electron gas is an important effect.

SOLAR CYCLE VARIATIONS OF T_e

In Figure 1 are illustrated daytime mid-latitude electron density profiles typical of December 1960 and 1962, respectively. The principal differences to note are the much higher values of N_{max} and h_{max} for the 1960 period, and the constant electron scale height for the 1960 case in contrast to the

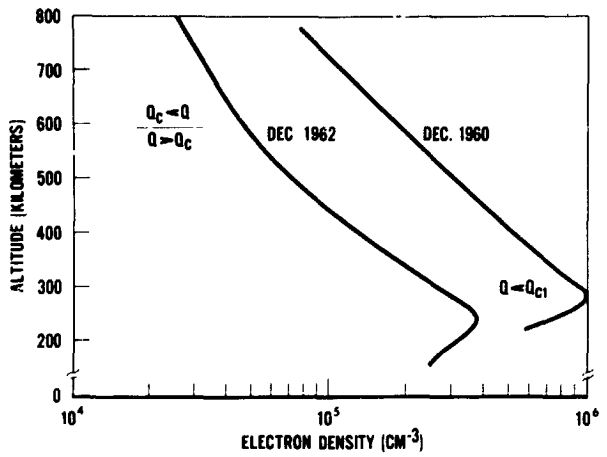

FIGURE 1.—Typical winter mid-latitude electron density profiles.

continually varying scale height for the 1962 profile. The monthly mean of the solar 10.7 cm flux during December 1960 was 150 $WM^{-2}CPS^{-1}$.

In Figure 2 is presented the mid-latitude diurnal electron temperature variation directly measured

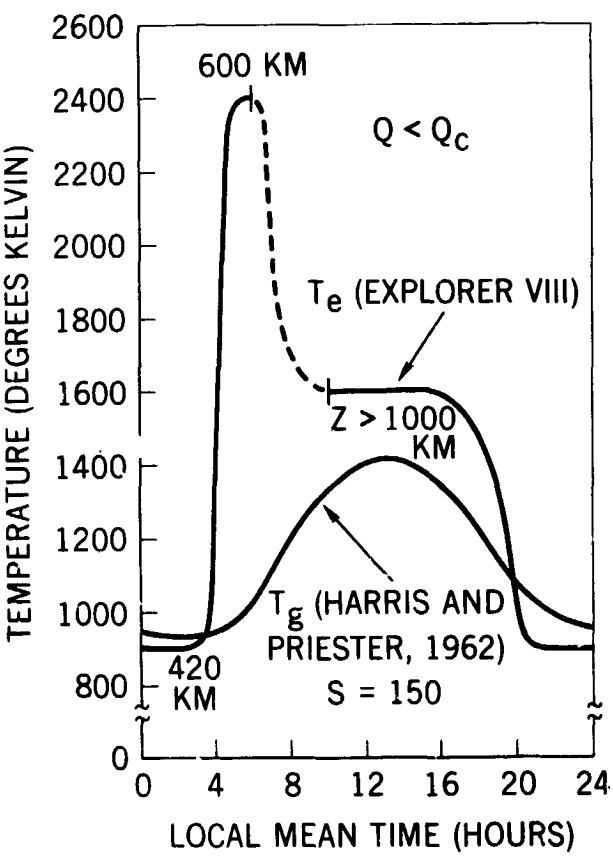

FIGURE 2.—Diurnal electron temperature variation measured during November 1960 from the Explorer VIII satellite for magnetically-quiet days at mid-latitudes assuming T_e is constant with altitude (425–2400 KM).

during November-December 1960 (Bourdeau and Donley, 1963) from the Explorer VIII Satellite for magnetically-quiet days assuming T_e is constant with altitude. Depending on which of the current reference atmospheres for the pertinent level of solar activity is used, the average midday T_e value of 1600°K taken at midday and at altitudes above 1000 km corresponds to an estimated value for T_e/T_g of about 1.15–1.33.

It is seen from Equation (1) that the ratio of the heat input to the square of the electron density (Q/N_e^2) controls the electron temperature at high altitudes. The value for Q/N_e^2 computed at 400 km from the December 1960 N_e profile in Figure 1 closely corresponds to the value used by Hanson as an upper limit in his model. We have taken into account that the heat input Q would be larger than in Hanson's case by assuming a linear change of EUV intensity with the decimetric flux index, $S_{10.7}$, and a corresponding change in the density of the ionizable constituent, $n(O)$. The higher heat input is compensated for largely by the higher electron density than that used by Hanson. Thus we should and do estimate similar values for T_e as did Hanson. Consequently, we find excellent agreement between the observed T_e/T_g of 1.15–1.33 and Hanson's theoretical upper limit of about 1.15.

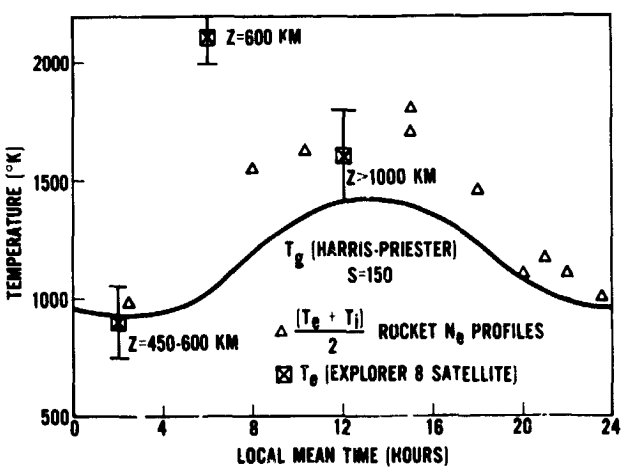

FIGURE 3.—Early charged particle temperature measurements in the upper ionosphere.

In Figure 3, the Explorer VIII data are included with measurements of $(T_e+T_i)/2$ computed from early rocket N_e profiles on the assumption of diffusive equilibrium. Of particular

interest is the ion density profile obtained by Hale (1961) at midday and at about the same time as the Explorer VIII observations. Here a value for $(T_e+_{et})/2$ of 1600°K (Hanson, 1962b) is derived for the region above 1000 km. The data are too sparse for a firm conclusion but there is a suggestion by the inter-comparison that for winter midday mid-solar cycle conditions $T_e \cong T_i$ at altitudes above 1000 km but that both the electron and ion temperatures are moderately higher than the neutral gas temperature. This would be consistent with Hanson's arguments that above 600 km (a) thermal conductivity of the electron gas could support differences between T_e and T_g which are constant with altitude and furthermore, (b) that the electrons rather than the neutral constituents could control the ion temperature so that $T_i > T_g$.

Low midday values of T_e/T_g at high altitudes also can be implied from the measurement in December 1961 of a value for $(T_e+T_i)/2$ of 1235°K (Taylor et al, 1963) from a rocket flight for which an equivalent ion temperature has been inferred (Bauer, 1964). *However*, we emphasize here Equation (1) and the extreme sensitivity of T_e to the electron density. We further emphasize that in the actual case, ratios of Q/N_e^2 which permit only moderate rather than large midday departures from temperature equilibrium as is indicated for December 1960 at high altitudes perhaps represent the exception rather than the rule at middle and high latitudes.

Let us consider now the drastic changes in charged particle temperature characteristics as one moves closer to solar minimum conditions. The average value for the index (S) of solar activity corresponding to the December 1962 profile illustrated in Figure 1 was 85. Taking into account a linear decrease in EUV intensity from the time of the rocket EUV measurements (Hall et al, 1962) and a corresponding decrease in the density of the ionizable constituents and computing Q_c directly from the observed N_e profile, the estimated ratio Q/Q_c is larger than 2. Because of the uncertainties in our knowledge of ionization cross-sections and model atmospheres, the computation of Q/Q_c is suggestive rather than quantitative. Within these uncertainties, it does appear that the EUV effect for low electron densities is sufficient to cause very large electron and possibly runaway electron temperatures.

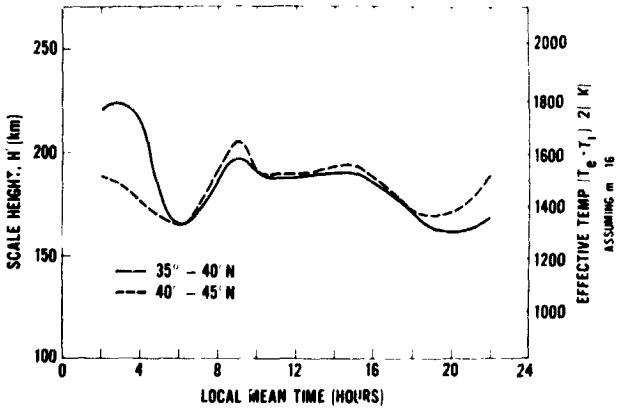

FIGURE 4.—Scale heights at 500 km from ALOUETTE satellite data (Bauer-Blumle, 1964)

In Figure 4 is plotted a mid-latitude diurnal variation of electron scale heights calculated for an altitude of 500 km from electron density profiles obtained by the use of the Alouette satellite during the period October-December 1962 (Bauer and Blumle, 1964). It is seen that on the assumption of diffusive equilibrium and O^+ as the principal ionic constituent, values for $(T_e+T_i)/2$ of 1500°K are indicated at midday. Assuming $T_i = T_g$, a value for T_e/T_g of about 2.0 is indicated (Bauer and Blumle, 1964), which is much in excess of the December 1960 value. This should not be surprising because of the large increase in the ratio Q/N_e^2 at 400 km and above from December 1960 to December 1962.

If the assumed model atmosphere and ionization cross-sections on which the computation of Q/Q_c depends are correct, the fact that runaway electron temperatures are not observed suggests that much of the heat input is not deposited locally. Also it should be emphasized that the ratio of 2.0 for T_e/T_g must be considered an upper limit since it assumes that at 500 km the ion and neutral gas temperatures are the same. Evans (1964) with radar-back-scatter experiments observes at similar latitudes and under similar conditions that $T_i > T_g$ even as low as 400 km. Thus the values for T_e implied from Figure 4 may indeed be somewhat overestimated. That the electron temperature begins to control the ion temperature at an altitude lower than that estimated by Hanson is explainable on the basis that the scale heights illustrated in Figure 4 were measured for a different

model atmosphere and electron density profile than that assumed by Hanson.

In summary, the observational evidence as expected shows a large increase in T_e/T_0 between December 1960 and December 1962 which corresponds to a change in the ratio of the heat input to the square of the electron density. In the 1962 case, there still appears to be a sufficient EUV flux to explain the high daytime electron temperatures observed at 500 km during periods of low electron density. There is indirect evidence that some of the energy is not locally deposited and direct evidence from Evans' results that the ion as well as the electron temperature is raised above the neutral gas temperature.

SEASONAL VARIATION OF T_e

Ionosonde data have shown that the electron density is much higher at the F2 peak in winter than it is in summer. For example, N_{max} measured at Washington, D.C., was on the average more than a factor of two larger in the summer than in the winter of 1962. Corresponding changes in $S_{10.7}$, which reflect changes in the heat input are not observed. These factors are in the direction of making the ratio Q/N_e^2 much higher in the summer than in the winter months. Consequently, it is possible that, at least for mid-latitudes in the Northern Hemisphere, high ratios of T_e/T_0 will persist high into the upper F region throughout a solar cycle. This could explain why some of the early rocket results taken between solar maximum and solar minimum conditions (cf Spencer et al, 1962) show different electron temperature behavior.

DIURNAL VARIATION OF ELECTRON TEMPERATURE

As illustrated in Figure 2, the Explorer VIII satellite results suggest a significant increase in T_e during the early morning hours. High values of T_e in the early morning at the F2 peak are also indicated in ground-based backscatter observations (Bowles et al, 1962) and at higher altitudes by Evans (1964).

Early morning maxima in electron temperature have been confirmed by use of the Explorer XVII satellite from which the maximum value of T_e is placed near 9h local time (Brace et al, 1964). The electron scale height results from Figure 4 also suggest a maximum T_e at approximately the same local time (Bauer and Blumle, 1964). Here the high scale heights for nighttime conditions reflect the importance of light ionic constituents. However, for daytime conditions it would be expected that m_i is relatively constant and thus that the early morning maximum represents a true T_e maximum. It should be pointed out that the nature and existence of an early morning peak in T_e has not been emphasized in the Ariel satellite results (Willmore et al, 1963).

It is possible to show from ionosonde data and Equation (1) on the assumption of no EUV absorption above 300 km that the ratio Q/N_e^2 which controls T_e near the F2 peak maximizes at dawn. However, at high solar zenith angles there could be enough absorption above 300 km to shift the T_e maximum to later in the morning. This reasoning would insert a latitude and altitude dependence on the time of the diurnal T_e maximum. It would be expected that the effect becomes more diffuse at higher altitudes because here the diurnal amplitude of the ionizable constituent has increased relative to the amplitude of the diurnal N_e variation (Bourdeau and Donley, 1963).

LATITUDE VARIATION OF ELECTRON TEMPERATURE

Early ionosonde data showed that the daytime electron density at the F2 maximum increases drastically as one goes from mid-latitudes toward the geomagnetic equator. More recently, results from the satellite Alouette has extended the observation that the geomagnetic field plays an important role in governing the electron density distribution to altitudes well above the F2 peak. In Figure 5 is presented an idealized representation of the latitudinal behavior of N_e prepared by Jackson (private communication) by combining topside sounder (Lockwood and Nelms, 1963) and ionosonde (Wright, 1962) results. Other Alouette data (King et al, 1963) show that the equatorial anomaly builds up earlier in the day at the eastern longitudes. It should be clear from the illustration and Equation (1), that in the daytime T_e should increase with increasing latitude on the basis of the electron density behavior alone, if we assume no EUV absorption above 300 km and no latitude dependence of the neutral gas character-

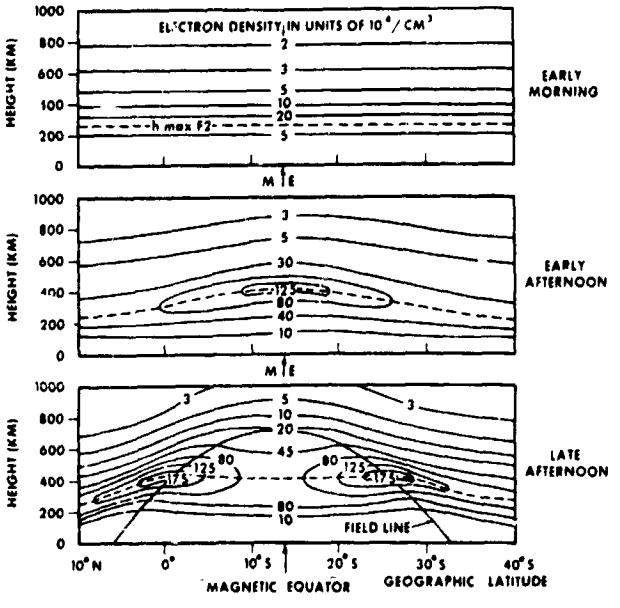

FIGURE 5.—Idealized representation of equatorial anomaly along 75° W meridian based upon data by Lockwood and Nelms (Topside) and J. W. Wright (Bottomside).

istics. An increase of daytime electron temperatures with latitude is indicated by all three methods of charged particle temperature investigation for altitudes below about 800 km. Alouette satellite data suggest constant electron scale heights above 800 km (King et al, 1963).

The ground-based incoherent backscatter results at the geomagnetic equator (Bowles, 1963) show that in the region 200–350 km T_e/T_i is close to 2 during the daytime hours, maximizing at about 275 km. Above about 400 km in the daytime the results show that T_e/T_i is unity. Daytime ion temperatures (Bowles, private communication) for March 1964, in the vicinity of 1000°K are observed Depending on the adequacy of the Harris-Priester reference atmosphere, this would put an upper limit on T_e/T_0 of 1.2 even during solar minimum conditions. Low values for T_e/T_0 at high altitudes would be expected near the geomagnetic equator because of the generally higher values of N_e and because near this location diffusion of photoelectrons vertically tends to be inhibited. This supposes heating only by EUV radiation.

The incoherent backscatter results of Evans (1962, 1964) taken near 50° north magnetic latitude show drastically different behavior of charged particle temperatures. This would be expected because of (a) the generally lower value of N_e than would exist at the equator, and the higher probability of (b) the photoelectron diffusion effect and (c) additional sources of ionization. The earlier results of Evans' taken in March-April 1962, show daytime ratios of T_e/T_i of up to 1.6 in the 300–400 km and that T_e increases with altitude up to 700 km (Evans, 1962). In more recent results taken during July 1963, Evans (1964) offers two possible interpretations for his daytime data obtained for altitudes up to 700 km: (a) if the ionic constituent is all O^+, T_e and T_i continually increase with altitude to values of 2320°K and 2040°K at approximately 700 km or (b) assuming a mixture of 80 percent O^+ and 20 percent He^+ at 700 km, T_e maximizes at about 450 km then decreases to 1960°K at 700 km while T_i increases to a value of 1410°K at 700 km. The trend of ion composition results (Hanson, 1962; Bourdeau et al, 1962; Bowen et al, 1963; Gringauz et al, 1963; Taylor et al, 1963) would imply that the latter alternative is the more likely. If so, it would be consistent with high values of Q/N_e^2 permitting high values of T_e especially below 450 km, and the possibility that cooling to light ionic constituents is becoming effective above 450 km. It should be noted that Equation (1) applies only for O^+ and that the cooling efficiency to ions should be inversely proportional to the ionic mass, m_i.

Direct electron temperature measurements measured with the use of the Ariel satellite also show that T_e significantly increases with latitude (Willmore et al, 1963) the steepest gradient centered at a geomagnetic latitude of about 20°. The midday T_e value given at the geomagnetic equator for an altitude of 400 km is about 900°K which compares favorably with T_0 given by Harris-Priester for the pertinent level of solar activity and with the T_i measurements of Bowles. The trend of the latitude variation at 400 km from the Ariel satellite is generally consistent with the latitude variation N_e and thus both the ground-based results of Bowles and of Evans (Willmore et al, 1963).

However, the situation above 400 km is more complicated. The Ariel results show T_e increasing with altitude up to maximum height of the observations at all latitudes. The continuing increase with altitude of T_e from Ariel at higher latitudes would be consistent with the 1962 results of Evans but not for the likely possibility which Evans offers that T_e decreases above 450 km for

his 1963 results. We suffer here in the comparison from a lack of simultaneity in the observations. An increase of T_e at all altitudes in 1962 is perhaps reconcilable with a possible decrease in T_e above 450 km in 1963 on the base of a lowering with solar activity of the O^+-He^+ transition altitude.

The fate of the photoelectrons which apparently escape from the altitude of their formation is not yet clear. We have made a case that for the December 1962 mid-latitude profile the ratio of Q/Q_e possibly is large enough that the high values of T_e observed up to 500 km at mid-latitudes could be explained on the basis of the EUV effect and heat conduction in the electron gas. In his interpretation of the daytime altitude behavior of T_e from the Ariel satellite, Willmore (1963) finds that for altitudes up to 600 km, the altitude dependence of the heat input computed from the observed T_e and N_e (cf Equation 1) follows the scale height of atomic oxygen and thus also concludes that the main energy input below 600 km is by the photoionization of atomic oxygen. He additionally finds that the increase of T_e above 800 km can be explained by additional energy input from the photoelectrons diffusing from below together with the main energy loss mechanism being thermal conduction in the electron gas rather than collisions with positive ions. His conclusions assume that the photoionization of helium is unimportant and additionally depend on an assumed model atmosphere.

NIGHTTIME CHARGED PARTICLE TEMPERATURE MEASUREMENTS

The charged particle temperature measurements of Figures 2 and 3 are too sparse and the dependency on the assumed reference atmosphere too critical to draw firm conclusions about departures from temperature equilibrium at night for mid-solar cycle conditions. Bowles et al (1962) observe that T_e/T_i is unity at night at the geomagnetic equator with $T_i \cong 600°K$, the latter value being in fair agreement with the Harris-Priester reference atmosphere. Remembering the different altitudes and times of the observations, Willmore et al (1963) report that at 1000 km midnight values of T_e increases from about 800°K at the equator to 1400°K at 60° magnetic latitude. Evans (1964) indicates a small but significant departure from temperature equilibrium in the F region at 50° north magnetic latitude. The definite evidence from the Ariel satellite for quite significant departures from temperature equilibrium at night at medium latitudes have been confirmed by rocket measurements (Brace et al, 1963). The Ariel results show that the nighttime departure from equilibrium becomes more pronounced at the higher latitudes. The nighttime source required to explain the Ariel observations has been estimated to be less than 30 percent of the daytime EUV heat input (Willmore, 1963).

As an example of the sensitivity of nighttime electron temperatures to small sources of heat input, consider Equation (1) and the fact that for solar minimum conditions, N_e varies by a factor of 4 from day to night at 400 km (Bauer and Blumle, 1964). From these considerations, it can be shown that less than 10 percent of the daytime EUV heat input would be required at night to maintain the same temperature difference (T_e-T_p) throughout the day.

SUMMARY AND CONCLUSIONS

For all temporal conditions and latitudes, large departures from temperature equilibrium $(T_e/T_p \geqq 2)$ are observed in the daytime lower F region at the altitude of maximum rate of electron productions. Moderate but significant daytime values for T_e/T_p are maintained to very high altitudes in winter at mid-latitudes in the middle of the solar cycle. Daytime mid-latitude data taken for summer and/or solar minimum conditions when electron densities generally are much lower reveal much larger values of T_e/T_p persisting to altitudes well above the F2 maximum. There is considerable evidence at least for altitudes below 600 km that the diurnal electron temperature maximum occurs in the early morning. Observed increases of daytime electron temperature with latitude follows the observed electron density which is under geomagnetic control. All of these temporal and latitudinal trends in the observed electron temperature are consistent with EUV as the predominant daytime source of electron heating. The uncertainties in calculating the EUV effect make it difficult to infer other possible daytime heat sources at the present time. The charged particle temperature observa-

tions strongly suggest the possibility that not all of the EUV energy is locally deposited, an important factor to be considered in the theories of formation of the ionosphere. There is some evidence principally from backscatter experiments that the ion temperature is controlled by electrons at very high altitudes.

Significant departures from temperature equilibrium at night have been observed especially for conditions close to solar minimum. The estimated intensity of this additional heat source increases with latitude but at all latitudes is only a fraction of the daytime EUV effect.

ACKNOWLEDGEMENT

The author is grateful to S. J. Bauer, L. J. Blumle, J. V. Evans and K. Bowles, for early access to the results of their charged particle temperature observations.

POSITIVE ION TEMPERATURES ABOVE THE F-LAYER MAXIMUM*

N66 37958

R. L. F. BOYD AND W. J. RAITT†

The ion mass analyser on the UK–US satellite Ariel was a spherically symmetric energy spectrometer. The spectral lines may thus be interpreted not only in terms of ionic mass and concentration but also in terms of ion temperature.

Analysis of the data obtained has made available a picture of ion temperature variation with latitude above 400 km. The results show considerable scatter from day to day together with a marked rise in oxygen ion temperature with latitude.

INTRODUCTION

The determination of ion energy (and hence mass) spectrum by the ion probe on the satellite Ariel I (1962 –) provided good data on ion temperatures from 26 April, 1962 to 5 June, 1962. Some data of reduced quality is available until 26 September, 1962. Temperature is obtained from the width of the energy spectrum line for particles arriving at the probe. In principle the lines of hydrogen, helium or oxygen may all yield temperatures. The data presented in this paper all come from a study of the oxygen line which requires a concentration of oxygen greater than about 10^5 cm^{-3}. This implies that for the present study only altitudes below 600 Km. were useful and orbit orientation was such that in the period of this study (Days 117 to 140) this altitude range corresponds to values of local solar time within two hours of noon.

OUTLINE OF THE EXPERIMENT

The probe consisted of a 9 cm. diameter sphere mounted on the spin axis of the satellite. A fine grid 10 cm. in diameter was biassed negatively so as to keep ambient electrons from reaching the sphere, which was subjected to a positive voltage sweep. By constructing the system so that the angular momentum distribution of ions approaching the inner sphere was negligibly distorted by the presence of the grid it becomes valid to obtain the energy distribution of the ions by Druyvesteyn's[1] analysis. The required second derivative of the current voltage curve was obtained electronically and so telemetered.

If R is the kinetic energy of an ion moving with a velocity equal to that of the satellite and K is the energy corresponding to the most probable ion thermal velocity then for R≫K the form of the energy spectrum line is

$$f(E) = [2\pi^{\frac{1}{2}}(\text{K.R.})^{\frac{1}{2}}]^{-1} \exp \frac{-(E-R)^2}{4\,\text{K.R.}}$$

Thus the breadth of the energy spectrum line depends not only on the thermal energy of the ions but also on the velocity of the satellite. It is roughly Gaussian in form with a width at the $\frac{1}{e}$ points of $4(\text{K.R.})^{\frac{1}{2}}$. For monatomic oxygen R is about 5eV and K about 0.1eV so the line width is over 2 volts. While this broadening reduces the mass resolution it greatly eases the problem of determining the ion temperature.

Medicus[2] has obtained a more exact expression for the energy distribution of ions with a Maxwellian distribution arriving at a moving vehicle shown plotted in Fig. 1.

Analysis of the Ariel data has been carried out by fitting values computed from the approximate expression to the observed data.

*This paper was contributed to *Goddard Space Flight Center* under the joint United Kingdom–United States program which developed and launched the satellite Ariel I.

†Both authors are affiliated with the Department of Physics, University College, London, England.

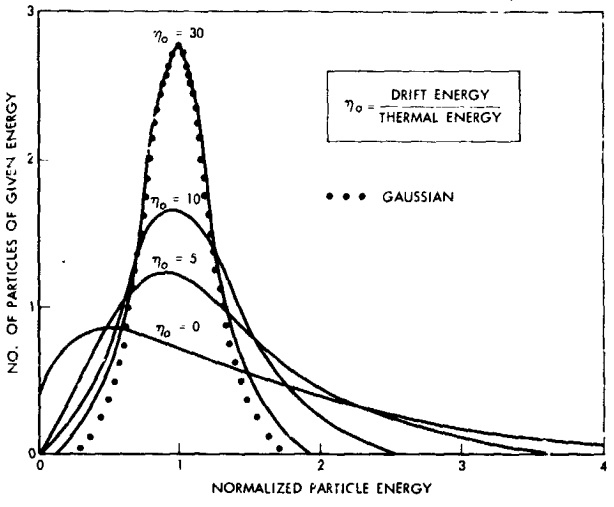

FIGURE 1.—Energy distribution of particles with Maxwellian distribution arriving at a moving vehicle.

EXPERIMENTAL RESULTS

The oxygen ion temperatures between 10 and 12 hours Local Solar Time measured in the longitude range −50° to 150° during the early northern summer of 1962 are plotted as a function of latitude in Fig. 2. The quantity of data is inadequate to make possible a complete decoupling of the effect of altitude from the effect of latitude. During the period selected, however, perigee was a little south of the equator so that the range of altitudes covered is not large. The approximate altitude corresponding to a given latitude is shown by the scale at the top of the figure.

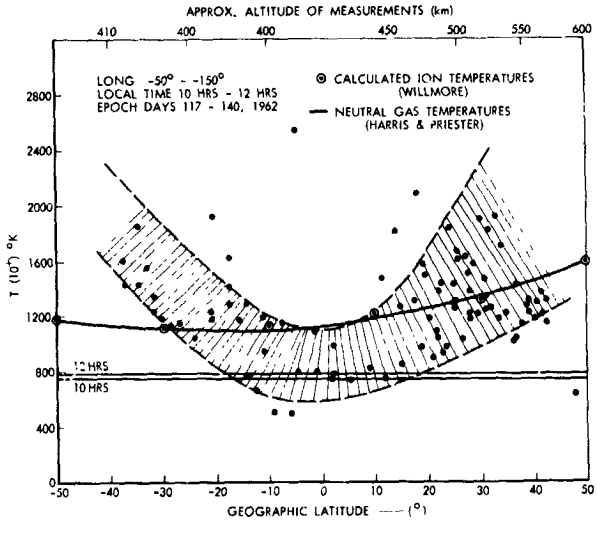

FIGURE 2.—Oxygen ion temperatures as a function of latitude.

Comparison of successive values of ion temperature obtained on a single pass suggest that instrumental consistency is at least as good as ±200 deg. K and possibly a good deal better. Most of the scatter of the points must therefore be taken to reflect real differences in ion temperature from one occasion to another.

Part of the scatter may be attributable to the range of local solar times, to the seasonal change and to the motion of the line of apsides. There may also be some dependence on magnetic activity and on longitude. However, it is not possible to account for most of the scatter in any of the above ways. The main conclusions are therefore that there is a variation in oxygen ion temperatures from one day to another amounting to several hundred degrees and that there is also a marked tendency of the oxygen ion temperatures to increase with latitude.

DISCUSSION OF RESULTS

Fig. 2 shows the neutral gas temperature based on the data of Harris and Priester[3] and a curve of ion temperature computed by A. P. Willmore[4] from the electron temperature data obtained on the same satellite (Willmore et al)[5] on the consideration that the heat flow from the electrons reaches the neutral gas by way of coulomb interaction with the ions. Willmore finds a rise of ion temperature with both latitude and altitude and appropriate weight has been given to both factors in plotting the curve from his data.

Except near the geomagnetic equator where the small dip angle would inhibit upward diffusion of photoelectrons, the energy input to the ionospheric electrons and hence to the ions due to solar radiation will vary as the cosine of the zenith angle.

Since the average fractional energy loss per collision of ions of mass M_i with gas atoms of mass M_g is

$$\frac{\Delta E}{3/2kT_i}=\frac{8}{3}\frac{M_iM_g}{(M_i+M_g)^2}\left(1-\frac{T_g}{T_i}\right)$$ where T_i and T_g refer to the ion and gas temperature.

We can write the energy flux

$$Q=4k\cdot n_i\cdot n_g\cdot S\cdot\left(\frac{3k}{2}\right)^{\frac{1}{2}}\left(\frac{T_i}{M_i}+\frac{T_g}{M_g}\right)^{\frac{1}{2}}\frac{M_iM_g}{(M_i+M_g)^2}(T_i-T_g)$$

where k is Boltzman's constant, n_i and n_g refer to the number densities of ions and gas atoms and S is the appropriate ion-atom energy exchange cross-section.

To a first approximation Q and n_i both vary as the cosine of the zenith $<$, n_g and T_g are constant and $(T_i - T_g) \ll T_g$. Thus writing $Q = Q \cos \chi$ and $n_i = n_0 \cos \chi$ we have

$$T_i - T_g \doteq Q_0 \left[4(3/2kT_g)^{\frac{1}{2}} \cdot n_0 \cdot n_g \cdot S \cdot k \cdot \left(\frac{1}{M_i} + \frac{1}{M_g} \right) \frac{M_i M_g}{(M_i + M_g)^2} \right]^{-1}$$

which shows that the factors most likely to influence the ion temperature in the topside ionosphere are ionic and neutral composition—affecting M_i, M_g and S—and ionic concentrations reduced to zero zenith angle, quantities which are also interrelated by the hydrostatic equation.

N_0 at the layer peak does in fact, fall with increasing latitude so the difference between the gas and ion temperature is to be expected to increase with latitude. The wide scatter in the data may well be related to variations not only in n_g but in ionic and possibly even in neutral particle composition. A preliminary consideration of the rate of energy exchange suggests that for the same flux the temperature difference between oxygen ions and helium atoms must be several times larger than when the ions are helium. The small amount of helium ion temperature data analysed so far supports this view. The possibility of the electric fields having an appreciable effect on the ion temperature would seem to be ruled out by the far larger effect they would have on the electrons.

One important factor must not be overlooked. It is the fact that by selecting only passes giving a high enough density of oxygen to enable oxygen ion temperature to be obtained at the higher altitudes (which correspond to higher latitudes) a premium is put on passes for which the ion temperature is high enough to give an adequate oxygen ion concentration.

GEOMAGNETIC CONTROL OF DIFFUSION IN THE UPPER ATMOSPHERE*

S. CHANDRA AND R. A. GOLDBERG

N64-28071

In many recent papers concerned with providing an explanation for the geomagnetic anomaly, agreement with measured data has been obtained from the equations of motion for electrons and ions when used with an empirical boundary condition, whereas poor agreement has resulted from attempts to numerically integrate the commonly employed form of the continuity equation. We have been able to explain this discrepancy by demonstrating that the assumptions used to derive this form of the continuity equations do not agree with observation.

Since the equations of motion do provide a favorable description for the geomagnetic anomaly, we have studied the possible physical models leading to the form of the equations used, and found that although field aligned diffusive equilibrium provides the correct form, a more reasonable assumption concerning electron and ion collisions with neutrals also leads to the same result. We have then been able to provide a more realistic theoretical description of the geomagnetic anomaly by employing an analytic form for the boundary condition which is in better agreement with measurement than those previously used.

Finally, by combining the equations of motion for neutrals, electrons and ions, we have been able to indicate geomagnetic control for the neutral atmosphere in the lower F region of the ionosphere, although the exact shape of this distribution is unknown.

INTRODUCTION

In recent months, it has become increasingly evident that some confusion exists in the understanding of the basic physical mechanisms governing diffusion and the existence of the geomagnetic anomaly in the ionosphere. This apparent confusion arises by comparison of the work of Chandra (1964), (to be referred to as C–1), in which it is shown that the assumption of ambipolar diffusion along a field line cannot lead to geomagnetic control of the charged particles, and such papers as Goldberg and Schmerling (1962, 1963), (to be referred to as GS–I and GS–II), and Goldberg, Kendall, and Schmerling (1964), (to be referred to as GKS), in which this process does appear to produce geomagnetic control of the charged particle density in the ionosphere.

The purpose of this paper is to describe and resolve the confusion which exists in the field at this moment, and then to point out the new problems with which we must contend in order to derive and apply the diffusion equation to ionospheric problems correctly. In addition, a section will be devoted to an improved theoretical description of the geomagnetic anomaly by using an analytic expression for the vertical electron density distribution at the equator which is more in accordance with measurement than the simple Chapman type distribution employed in GKS.

FUNDAMENTAL EQUATIONS AND DEFINITIONS

The major cause of confusion appears to lie in the application of two phrases, viz. *ambipolar diffusion* and *diffusive equilibrium*. Let us investigate and discuss each of these terms to determine how loose usage of them has led to some of the current problems of misunderstanding.

In the normal sense, ambipolar diffusion refers to a plasma in which the negative (electrons) and positive (ions) charges do not move independently due to the influence of the electric field caused by their Coulomb interactions. In this medium, the electrons and ions drift in pairs and this motion of electron-ion pairs is referred to as ambipolar diffusion. The condition for ambipolar diffusion in a neutral plasma is thereby

$$\vec{v}_e = \vec{v}_i = \vec{v} \qquad (1)$$

*Published as *Goddard Space Flight Center Document X-615-64-121*, May 1964.

where $\vec{v}$ is macroscopic velocity and the subscripts e and i refer to electrons and ions respectively. When

$$\vec{v}=0 \tag{2}$$

the condition for diffusive equilibrium is satisfied.

The implications of (1) are quite straightforward, as shown in C–I. In an isothermal atmosphere and in the presence of a magnetic field, this requires $\nabla x(\vec{v}x\vec{B})=0$. In particular, the assumption of field aligned plasma diffusion ($\vec{v}x\vec{B}=0$) can only be satisfied for the trivial case, $\vec{v}=0$, resulting in a hydrostatic distribution of electron density independent of geomagnetic latitude.

On the other hand, favorable comparison between Alouette topside sounder measurements and theoretical calculations of the geomagnetic anomaly has been obtained in GKS by assuming conditions of ambipolar diffusion and diffusive equilibrium along field lines, thereby indicating a possible conflict with the results in C–I. The problem resolves itself once one investigates the meaning of ambipolar diffusion and diffusive equilibrium in the GKS sense.

Let us first write the general equations of motion for neutrals, electrons and ions, respectively, where the subscript n refers to neutral. Following C–I:

$$\frac{n_e m_e m_n}{m_e+m_n}\nu_{en}(\vec{v}_n-\vec{v}_e)+\frac{n_i m_i m_n}{m_i+m_n}\nu_{in}(\vec{v}_n-\vec{v}_i) = -\nabla p_n+n_n m_n\vec{g} \tag{3}$$

$$\frac{n_i m_e m_i}{m_e+m_i}\nu_{ei}(\vec{v}_e-\vec{v}_i)+\frac{n_e m_e m_n}{m_e+m_n}\nu_{en}(\vec{v}_e-\vec{v}_n) = -\nabla p_e+n_e m_e\vec{g}-e\,n_e(\vec{E}+\vec{v}_e\times\vec{B}) \tag{4}$$

$$\frac{n_i m_i m_e}{m_e+m_i}\nu_{ei}(\vec{v}_i-\vec{v}_e)+\frac{n_i m_i m_n}{m_i+m_n}\nu_{in}(\vec{v}_i-\vec{v}_n) = -\nabla p_i+n_i m_i\vec{g}+e\,n_i(\vec{E}+\vec{v}_i\times\vec{B}) \tag{5}$$

where n is number density, ν_{kl} is the collision frequency between the k^{th} and l^{th} particle, m is mass, p is pressure, $\vec{g}$ is gravitational acceleration, e is the absolute value of electron charge, $\vec{E}$ is electric field, and $\vec{B}$ is magnetic field. In writing equations (3)—(5) it is assumed that $\frac{\nu_{lk}}{n_k}=\frac{\nu_{kl}}{n_l}$

In the following we assume that the plasma is in a quasineutral state

$$n_e\approx n_i=N \tag{6}$$

and that the electrons, ions and neutrals obey the ideal gas law in the ionosphere,

$$p_j=n_j kT_j \tag{7}$$

when k is Boltzmann's constant and T is temperature. Furthermore, we assume thermal equilibrium, i.e.

$$T_e=T_i=T \tag{8}$$

Then,

$$p_e=p_i=p \tag{9}$$

In addition, we assume for simplicity that

$$\vec{v}_n\approx 0 \tag{10}$$

Then summation of (4) and (5) provides

$$\frac{m_n m_e N}{m_e+m_n}\nu_{en}\vec{v}_e+\frac{m_n m_i N}{m_i+m_n}\nu_{in}\vec{v}_i=-2\nabla p +N(m_e+m_i)\vec{g}+\vec{J}\times\vec{B} \tag{11}$$

where $\vec{J}$ is current density, defined as

$$\vec{J}=Ne(\vec{v}_i-\vec{v}_e) \tag{12}$$

Since we are investigating ambipolar diffusion and diffusive equilibrium in the GKS sense, it is desirable to write this equation in component form along a field line as

$$\frac{m_n m_e}{m_e+m_n}\nu_{en}\vec{v}_e\cdot\vec{h}+\frac{m_n m_i}{m_i+m_n}\nu_{in}\vec{v}_i\cdot\vec{h} =\left[\frac{-2kT\nabla N}{N}+(m_e+m_i)\vec{g}\right]\cdot\vec{h} \tag{13}$$

where $\vec{h}$ is a unit vector in the direction of the magnetic field. Let us write (13) in more familiar form by using

$$m_e\ll m_i,\ m_n \tag{14}$$

and defining the scale height of the ionizable constituent as H_i, where

$$H_i=\frac{kT}{m_i g} \tag{15}$$

Also, for convenience, we make the approximation

$$m_n\approx m_i \tag{16}$$

Then

$$\frac{m_e\nu_{en}}{2}\vec{v}_e\cdot\vec{h}+\frac{m_i}{4}\nu_{in}\vec{v}_i\cdot\vec{h}=-kT\left(-\frac{\nabla N}{N}+\frac{\vec{i}_r}{2H_i}\right)\cdot\vec{h} \tag{17}$$

Finally, we write

$$\vec{h} = -(\vec{i}_r \sin I + \vec{i}_\theta \cos I) \tag{18}$$

where $\vec{i}_r$ and $\vec{i}_\theta$ are unit vectors in the r and θ directions and I is the magnetic dip angle, reckoned positive when the north seeking pole of the needle points downward. Now, if we treat ambipolar diffusion in the GKS sense, we simply imply that the electron and ion velocity components in the field direction are equal, i.e.

$$\vec{v}_e \cdot \vec{h} = \vec{v}_i \cdot \vec{h} = v_\parallel \tag{19}$$

Applying (18) and (19) in (17), we obtain

$$v_\parallel = \frac{-kT}{\mu\nu}\left[\sin I\left(\frac{1}{N}\frac{\partial N}{\partial r} + \frac{1}{2H_i}\right) + \frac{\cos I}{Nr}\frac{\partial N}{\partial \theta}\right] \tag{20}$$

where

$$\mu\nu = \frac{m_e\nu_{en}}{2} + \frac{m_i\nu_{in}}{4} \tag{21}$$

Assuming that

$$m_e\nu_{en} \ll m_i\nu_{in} \tag{22}$$

because of (14), we may write

$$\mu\nu \approx \frac{m_i\nu_{in}}{4} \tag{23}$$

Equation (20) is a familiar result derived in such papers as Kendall (1962) and GS–II. However, it is clearly not the result of ambipolar diffusion, which is given by (1), but instead, the result of a statement concerning the field line components of electron and ion velocities given by (19).

If we now demand

$$v_\parallel = 0 \tag{24}$$

which is the statement implying diffusive equilibrium along a field line in the GKS sense, we obtain the familiar equation

$$\sin I\left(\frac{1}{N}\frac{\partial N}{\partial r} + \frac{1}{2H_i}\right) + \frac{\cos I}{Nr}\frac{\partial N}{\partial \theta} = 0 \tag{25}$$

which can also be written as

$$\frac{1}{N}\frac{dN}{dr} + \frac{1}{2H_i} = 0 \tag{26}$$

provided we recognize that r and θ are not independent in (25) but related by the dipole field conditions

$$r = r_0 \sin^2\theta \tag{27}$$

and

$$\tan I = 2\cot\theta \tag{28}$$

It is evident that (26) can only be treated in total derivative form if the integration is carried out along the field line.

Statements concerning the components of vectors in a particular direction, such as (19), do not imply any conditions on the total vector. As a result, (25) has not required the assumption of any restrictions on the behavior of the velocity components normal to the field lines.

Equation (26) has been the basis of describing geomagnetic control in the upper F-region in GKS paper. Although (26) has been derived assuming diffusive equilibrium along a field line, it is undesirable to apply this concept because it is of purely hypothetical nature. We now investigate other assumptions to find a more realistic justification for (26).

Let us rewrite (17) as

$$\frac{m_e\nu_{en}}{2}v_{e_\parallel} + \frac{m_i\nu_{in}}{4}v_{i_\parallel} = -kT\left(-\frac{\nabla N}{N} + \frac{\vec{i}_r}{2H_i}\right)\cdot\vec{h} \tag{29}$$

We find two ways for the right hand side of (29) to approach zero. The first imposes a new condition on the velocities, viz:

$$\vec{v}_e = -\frac{m_i\nu_{in}\vec{v}_i}{2m_e\nu_{en}}$$

or

$$v_{e_\parallel} = -\frac{m_i\nu_{in}v_{i_\parallel}}{2m_e\nu_{en}} \tag{30}$$

a result which, although possible, would require a very special condition that the electron velocity be of the order of 10^3 times greater than and in the opposite direction of the ion velocity.

However, if we can demand that the collision frequencies between electrons and neutrals and between ions and neutrals be sufficiently small so that the drag forces arising due to collision be negligible as compared to the pressure gradient, gravity and Lorentz forces it is possible to derive equation (26) without imposing any restriction

on the velocities of electrons and ions. We believe that this assumption is more realistic in the upper F-region where the gyro-frequencies of electrons and ions are much greater than their corresponding collision frequencies.

Although the collision frequency assumption is physically more desirable, it prevents us from obtaining a simple expression for $v_{e\parallel}$ or $v_{i\parallel}$. Instead, we must return to the original equations of motion, (4) and (5), and solve for $\vec{v}_e$ and $\vec{v}_i$ explicitly, as has been carried out in the appendix in C-I. Unfortunately this introduces a very serious complication in the work because of the difficulty in eliminating electric field from the expressions of $\vec{v}_e$ and $\vec{v}_i$ without making specific assumptions about the relationship between $\vec{v}_e$ and $\vec{v}_i$. The implications of these assumptions will be discussed in the latter part of this paper. In the following section we proceed to discuss the physical implications of equation (26).

THE ELECTRON DENSITY DISTRIBUTION WITH A VARIABLE SCALE HEIGHT

Equation (26) can be integrated along a field line to provide the general solution

$$N(r,\theta)=f(r_0,\pi/2)e^{\frac{r\cot^2\theta}{2H_i}} \tag{31}$$

However, if we treat T and m_i constant but recognize that g is proportional to $1/r^2$, H_i is then proportional to r^2, and we obtain

$$N(r,\theta)=f(r_0,\pi/2)e^{\frac{r\cos^2\theta}{2H_i(r)}} \tag{32}$$

In both cases, $f(r_0, \pi/2)$ is an arbitrary function of height at the equator which cannot be determined by the equations of motion from which (31) or (32) are derived. The function $f(r_0, \pi/2)$ must therefore be given as a boundary condition in this problem and can only be determined empirically or by use of additional equations governing the physics of the problem.

Since (31) or (32) depend exclusively upon the equations of motion, it appears that an additional equation, such as the continuity equation, should lead to the desired boundary condition. Unfortunately, as we will show in the next section, the derivation and solution of the continuity equation depend upon a knowledge of $\vec{E}$. Thus, the complexity of the problem becomes quite formidable and it is difficult to anticipate a simple method of solution at this time.

Instead we depend upon an empirical type boundary condition, which may very well be the solution of the correct continuity equation, to derive the explicit form of the electron density distribution.

The incorporation of a Chapman distribution for the boundary condition in (31) leads to the results obtained in CKS. Since such a boundary condition can only be considered as a rough approximation to the shape of the actual vertical electron density distribution at the equator, it is desirable to employ an analytic boundary condition which more closely resembles the true height profiles. Chandra (1963) has proposed a modified form of the Chapman function which includes the effect of variable scale height and which is found to fit the measured vertical distribution for electron density at mid-latitudes far more accurately than the simple Chapman form. We assume here that such a function also describes the vertical electron density distribution at the equator. We can then write

$$f(r_0,\pi/2)=N_{r_{m0}}\exp\frac{1}{2}\left\{1-\frac{r_0-r_{m0}}{H_0\left[1-\alpha\exp\left(-\alpha\frac{(r_0-r_{m0})}{2H_0}\right)\right]}-\exp\left[-\frac{r_0-r_{m0}}{2H_0\left[1-\alpha\exp\left(-\frac{\alpha(r_0-r_{m0})}{2H_0}\right)\right]}\right]\right\} \tag{33}$$

where H_0 is the scale height of the ionic constituent and $N_{r_{m0}}$ is the value of electron density at the equatorial height r_{m0}. The parameter α, which is a measure of departure from the simple Chapman function, and thereby a *shape factor*, is defined as

$$\alpha=\frac{H_0-H(r_{m0})}{H_0} \tag{34}$$

where $H(r_{m0})$ is that value of (Hr_0) at $r_0=r_{m0}$. Also, r_0 is understood to be the radial height specifically at $\theta=\pi/2$.

Although it will not be shown here, (31) and (32) produce nearly identical results in the equatorial region because the small variation of r in the height region of our interest. Furthermore,

the simplified form given by (31) is more convenient for comparison with the results of the GKS paper. We therefore substitute (33) into (31) and obtain

$$N(r,\theta)=N_{r_{m0}}\exp\frac{1}{2}\left\{1-\frac{r\csc^2\theta-r_{m0}}{H_0\left[1-\alpha\exp\left(-\frac{\alpha(r\csc^2\theta-r_{m0})}{2H_0}\right)\right]}+\frac{r\cot^2\theta}{H_t}-\exp\left[-\frac{r\csc^2\theta-r_{m0}}{2H_0\left[1-\alpha\exp\left(-\frac{\alpha(r\csc^2\theta-r_{m0})}{2H_0}\right)\right]}\right]\right\} \tag{35}$$

Equation (35) then provides a general expression for the electron density at all heights and colatitudes provided that we are in a region where the effects of collision can be neglected.

The variation of $N(h,\theta)N_{h_{m0}}$ with colatitude at constant height is shown in Figures 1–4 for various values of α, h_{m0} and H_0. In these figures, we have converted radial height r to altitude h by taking the earth's radius as 6370 km. We have also assumed that $H_0=H_t$ because the effective scale height in (33) approaches H_0 at high altitudes and Chandra (1963) has indicated that H_0 becomes equal to H_t at these altitudes.

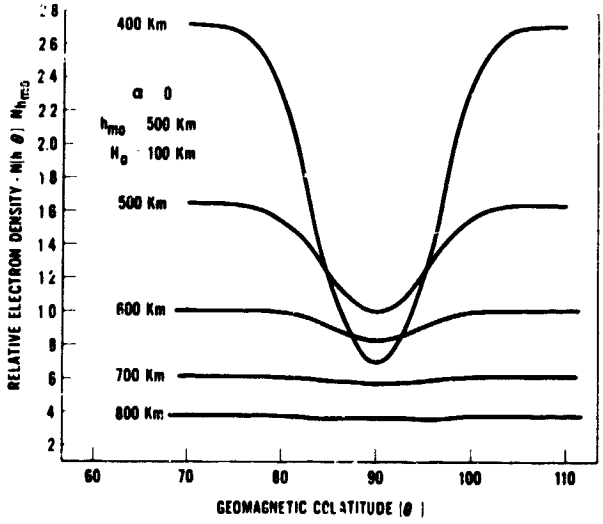

FIGURE 1.—Constant height profiles of relative electron density vs. colatitude for $\alpha=0$, $h_{m0}=500$ km, $H_0=100$ km.

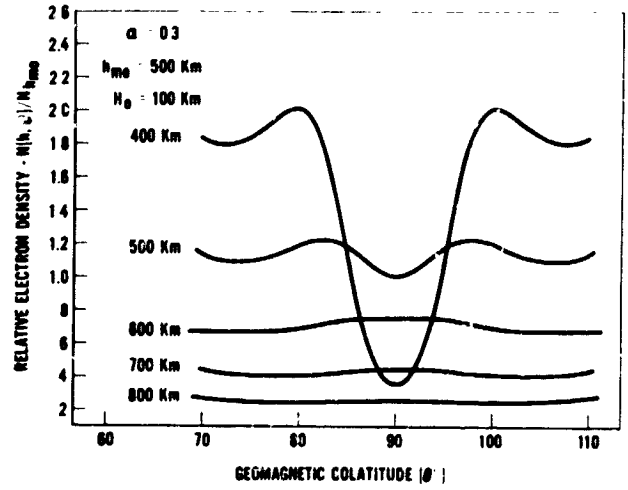

FIGURE 3.—Constant height profiles of relative electron density vs. colatitude for $\alpha=0.3$, $h_{m0}=500$ km, $H_0=100$ km.

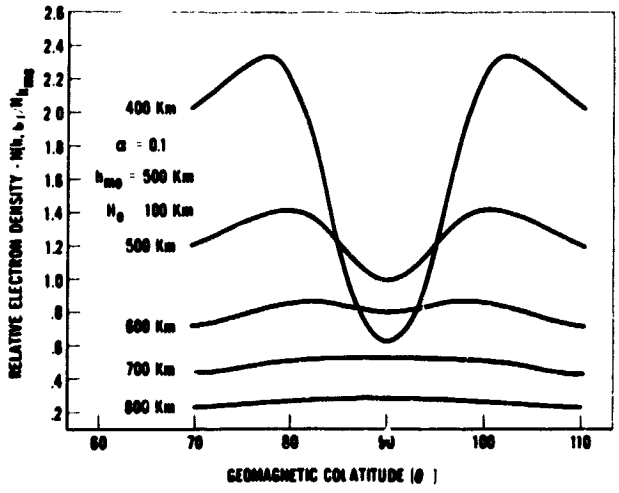

FIGURE 2.—Constant height profiles of relative electron density vs. colatitude for $\alpha=0.1$, $h_{m0}=500$ km, $H_0=100$ km.

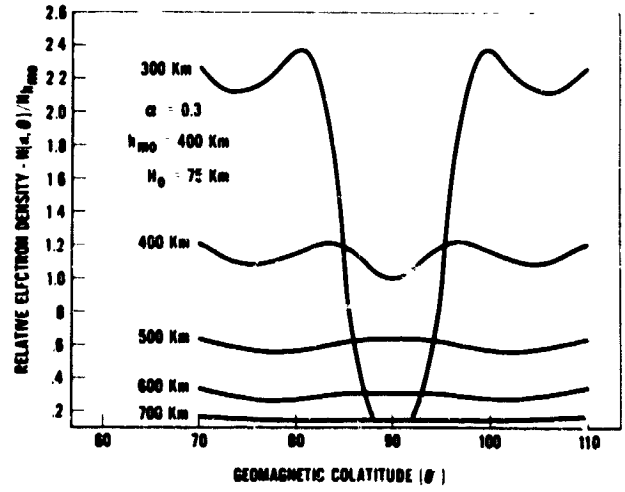

FIGURE 4.—Constant height profiles of relative electron density vs. colatitude for $\alpha=0.3$, $h_{m0}=400$ km, $H_0=75$ km.

We first note that the basic features of the theoretical electron density distribution are unaltered from those first obtained in GKS to describe the geomagnetic anomaly in the vicinity of the equator. Once again the theoretical description breaks down in the bottomside but this is precisely the region where the neglect of momentum transfer terms becomes in-valid. Furthermore, comparison of Figures 3 and 4 clearly shows the insensitivity of the topside results to the parameters h_{m0} and H_0 (except for shifting the constant height profile scale vertically). We therefore conclude the principal properties of the curves can be studied quite extensively by simply altering the shape factor α.

The changes due to variations in α are shown by comparison of Figures 1, 2 and 3. We have also provided a more detailed comparison for one particular height profile in Figure 5. Although

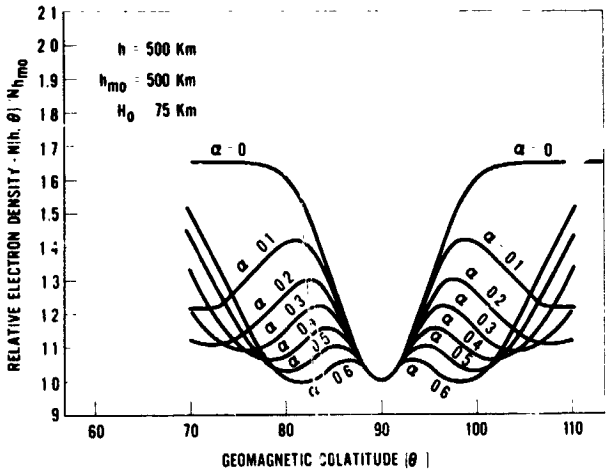

FIGURE 5.—The α dependent behavior of the 500 km profile of relative electron density vs. colatitude for $h_{m0}=500$ km, $H_0=75$ km.

we have included values up to $\alpha=0.6$ to demonstrate the trend of the curves, the highest values are extreme and not likely to be representative of ionospheric conditions. On the other hand, $\alpha=0.1$ to $\alpha=0.4$ are very reasonable values for us to expect under normal conditions representing diurnal and solar cycle variations.

Finally, in equation (35), if we identify the term $H_0[1-\alpha \exp[-\alpha(r \csc^2\theta - r_{m0})/2H_0]]$ with 1/k of the GKS paper, we see that since α is positive, $kH_t>1$ is true for all heights. In particular, if $\alpha=0$, we generate curves which are identical to those in GKS for $kH_t=1$. This explains why $kH_t>1$ provides the closest fit with experimental data in that paper.

PROBLEMS INVOLVED IN THE DERIVATION OF THE DIFFUSION EQUATION

In the previous sections we have seen how the equations of motion for electrons and ions are sufficient to obtain a theoretical description of the electron density distribution in the topside equatorial region of the ionosphere under equinox conditions. This has required us to make certain assumptions concerning collision frequencies or velocity components along field lines and also forced the application of an empirical boundary condition at the equator. In order to produce the empirical boundary condition theoretically and also obtain a solution which is valid in both the topside and bottomside equatorial F region, it is necessary to turn to the continuity equation for additional information. Using the explicit expressions for velocity which are derivable from the equations of motion, it is then possible to derive the diffusion equations associated with the ionosphere.

If we simply require total ambipolar diffusion (equation 1) to occur in the ionosphere so that $\vec{v}$ is independent of the electric field explicitly, and also demand that, in all regions concerned, the motion along field lines are much larger than the drifts normal to field lines, we must then invoke $\vec{v}\times\vec{B}=0$ which, using (4), (5) and (28), gives the constraint equation

$$\frac{1}{N}\frac{\partial N}{\partial r}+\frac{1}{2H}=\frac{2}{N}\frac{\partial N}{r\partial\theta}\cot\theta \qquad (36)$$

This leads to a hydrostatic distribution of electron density which does not agree with measured results, as has been demonstrated in C–I. A second approach (Kendall, 1962, and GS–II) is the assumption that ambipolar diffusion exists only along field lines (see equation (19)). Thus, if we assume that the parallel velocity components of electron and ion velocity are equal and much greater than either of the unequal perpendicular velocity components, we can write (20) as a good approximation for the entire velocity. In mathematical notation, we have

$$\vec{v}\cdot\vec{h}=|\vec{v}_\parallel|=v_\parallel\gg v_{e_\perp},\ v_{i_\perp} \qquad (37)$$

where $v_{e_\perp}$ and $v_{i_\perp}$ are the perpendicular components of electron and ion macroscopic velocities respectively. This implies that

$$\vec{v}_\parallel \approx \vec{v} \tag{38}$$

and provides us with a velocity expression independent of electric field. The general contention has been that (38) allows us to write the steady-state continuity equation in the following form:

$$Q-L=\nabla\cdot N\vec{v}\approx\nabla\cdot N\vec{v}_\parallel \tag{39}$$

where Q and L are production and loss respectively. The procedure has been to substitute (20) into (39) and obtain the well known form of the two dimensional diffusion equation without invoking the equation of constraint (36).

We wish to discuss this approach by first questioning the validity of (37), and then demonstrating that even if it were true, (38) cannot in general imply (39) without the additional inclusion of the constraint equation. This will demonstrate that the field line ambipolar diffusion approach with neglect of the perpendicular velocity components is identical to the total ambipolar diffusion case in which velocities are assumed to lie along field lines. Thus, the results of the two approaches are identical, leading to the conclusion that ambipolar diffusion in which the macroscopic velocity lies along a field line, cannot be the correct physical model to describe the equatorial electron density distribution in the F region of the ionosphere.

Let us first consider (37). We have already seen that the assumption of diffusive equilibrium along a field line ($v_\parallel=0$) leads to a correct description of the electron density in at least the topside region of the ionosphere. If this is the true model of the physical situation, then it is inconsistent with (37) and we cannot expect any results obtained using (37) to provide us with correct results concerning this region. If, on the other hand, the neglect of momentum transfer terms can be attributed to small collision frequencies instead of diffusive equilibrium, (37) need not be violated. This might be a further justification for validating the collision frequency assumption instead of the diffusive equilibrium model. Unfortunately, as we approach the equator, we see from (20) that $v_\parallel$ approaches zero since both sin I and $\partial N/\partial\theta$ approach zero. The latter condition is based strictly upon the empirical condition of symmetry about the equator. We therefore find that no matter how small $v_{e_\perp}$ and $v_{i_\perp}$ may be, there will always be a region about the equator in which (37) does not apply unless

$$v_{e_\perp}=v_{i_\perp}=0 \tag{40}$$

which is identical to the equation of constraint, (36).

We now return to the second question. That is, even if the parallel components of electron and ion velocities are much greater than the perpendicular component, which could still be possible provided $v_{e_\parallel}\neq v_{i_\parallel}$, is it possible to describe the electron density distributions in the entire region of the ionosphere by (39)? We note that

$$\nabla\cdot N\vec{v}=\vec{v}\cdot\nabla N+N\nabla\cdot\vec{v}=(\vec{v}_\parallel+\vec{v}_\perp)\cdot\nabla N+N\nabla\cdot(\vec{v}_\perp+\vec{v}_\parallel) \tag{41}$$

where $\vec{v}$ is now either the electron or ion velocity and

$$\vec{v}=\vec{v}_\parallel+\vec{v}_\perp \tag{42}$$

Now, in order to write (39), we must demand that

$$\vec{v}_\parallel\cdot\nabla N+N\nabla\cdot\vec{v}_\parallel\gg\vec{v}_\perp\cdot\nabla N+N\nabla\cdot\vec{v}_\perp \tag{43}$$

Although (43) could be true for certain special cases, there is not a priori guarantee that (43) will be implied by (37) in general without the additional condition that $v_\perp=0$. Thus, if we are to write (39) as a direct and general implication of (37), we are once again forced to employ the constraint equation.

We cannot state that (40) holds in a very small region about the equator so that its effect outside this region can be neglected. The geomagnetic anomaly itself is a second order effect and we cannot expect to reproduce it by neglecting second order terms which are responsible for its existence.

We therefore find that if ambipolar diffusion exists in the ionosphere, and if it is restricted to the field line direction, we cannot assume (37) without imposing an additional constraint equation. Furthermore, (37) does not generally imply (39) in the ionosphere with or without ambipolar diffusion unless the constraint equation is also employed. However, since (37), (39), and the assumption of ambipolar diffusion along a field line do not provide to the correct description of equatorial electron density, we must conclude that these

assumptions are not valid in a theory leading to a description of the electron density distribution in the equatorial ionosphere.

Kendall (1962), and Rishbeth, Lyon and Peart (1963), have attempted to numerically integrate (39) derived from (20) and (37), without invoking the equation of constraint. They have been unable to obtain the correct description of the geomagnetic anomaly and have therefore concluded that diffusion may not be a very important physical process governing the measured distribution of electron density. However, on the basis of the discussion presented in this section, it now appears that the physical assumptions used in deriving the form of the continuity equation used in their work may not be valid, which simply implies that the diffusion equation is far more complicated than originally believed. Since (19) and (37) are not longer valid, we can no longer equate electron and ion velocities to eliminate electric field. Instead, we must write separate continuity equations for electrons and ions and describe the behavior of electric field before it is possible to obtain the correct theoretical description of the geomagnetic anomaly.

It may appear that the results presented in GS–II are also not valid for the reasons discussed above. However, a closer inspection of GS–II shows that no new information was obtained from the solution of continuity equation than that already available from the equations of motion. The equation discussed in GS–II was simply

$$\nabla\cdot N\vec{v}_{\parallel}=0 \tag{44}$$

where the explicit production and loss terms were neglected in obtaining the series solution. Furthermore, as shown in GKS, the equation of motion leading to (26), whether derived assuming $\vec{v}_{\parallel}=0$, or by making assumptions concerning collision terms, has the identical solution to that obtained from (44) in GS–II. For the case $\vec{v}_{\parallel}=0$, (44) obviously cannot give any new information. This explains why the empirical boundary condition was necessary to obtain a non-arbitrary solution from (44) in GS–II. We should point out, however, that solutions of (39) making use of explicit production and loss terms should not give correct results in the equatorial regions of the ionosphere for the reasons discussed in this section.

THE DISTRIBUTION OF THE NEUTRAL ATMOSPHERE

In this section we will show that when the drag forces are not negligible, as might be the case in the lower F-region and E-region, it is possible to study the behavior of the neutral atmosphere without imposing any restrictions on the velocities of the various constitutents. To obtain the necessary starting equation, we first sum (3), (4) and (5):

$$-\nabla(p_e+p_i+p_n)+(n_nm_n+Nm_i)\vec{g}+\vec{J}\times\vec{B}=0 \tag{45}$$

where we have once again used (14). The component of (45) along the direction of magnetic field is then

$$[-\nabla(p_e+p_i+p_n)+(m_nn_n+m_iN)\vec{g}]\cdot\vec{h}=0 \tag{46}$$

Comparison of (45) and (46) shows that the net force due to pressure gradient and gravity of all particles is perpendicular to the magnetic field and balanced by a current flow force. Next, using (7), (8), (9), (18) and (28), we have

$$\frac{\partial(n_n+2N)}{\partial r}+\frac{\tan\theta}{r}\frac{\partial(n_n+2N)}{\partial\theta}+\frac{n_n}{H_n}+\frac{N}{H_i}=0 \tag{47}$$

where H_n is the scale height of the neutral atmosphere.

Since $N\ll n_n$ and $H_i\approx H_n$, we can write

$$\frac{n}{H_n}+\frac{N}{H_i}\approx\frac{n}{H_n}+\frac{N}{H_n}\approx\frac{n+2N}{H_n} \tag{48}$$

where the suffix on n has been dropped for simplicity. Then (47) becomes, in total derivative form,

$$\frac{d(n+2N)}{dr}+\frac{n+2N}{H_n}=0 \tag{49}$$

Integration of (49) along the field line gives

$$n(r,\theta)\approx n+2N=\vec{g}(r_0,\pi/2)e-\int_{r_0}^{r}\frac{dr}{H_n} \tag{50}$$

where $g(r_0,\pi/2)$ is an arbitrary function of height at the equator and r_0 is defined in (27). If we now demand that the radial distribution of the neutrals obey the normal hydrostatic law at the equator, so that

$$g(r_0,\pi/2)=n_{00}\,e-\int_{r_{00}}^{r_0}\frac{dr}{H_n} \tag{51}$$

where n_{00} is the neutral number density at height r_{00} on the equator, then

$$n(r) = n_{00}\, e - \int_{r_{00}}^{r} \frac{dr}{Hn}, \qquad (52)$$

a result which is entirely independent of θ. If, on the other hand, $g(r_0, \pi/2)$ is perturbed *in any manner* from the exact hydrostatic equilibrium case, we will obtain a distribution for n which does depend on θ. The origin of this angular dependence on the neutrals may seem somewhat surprising until we realize that in selecting a functional form for $g(r_0, \pi/2)$, any deviation in the equatorial neutral distribution from hydrostatic equilibrium must arise due to collisions between neutrals and geomagnetically controlled charged particles. Thus, if the collisions between neutrals and charged particles are sufficiently large to make the momentum transfer forces between charged and neutral particles important, the neutrals will begin to tend toward the angular distribution of the geomagnetically controlled particles. This can also be seen from (3), where it is obvious that we will not obtain the exact hydrostatic distribution in a region when the terms on the left hand side become important. On this basis, we might expect to observe angular variations of the neutral distribution in the bottomside regions of the ionosphere where charged-neutral particle interactions become important.

CONCLUSIONS

From the discussion and results of this paper, we have shown the following:

1. From the equations of motion, it is possible to derive an expression for the electron-density distribution along a field line either by assuming diffusive equilibrium along the direction of the magnetic field or by neglecting the drag forces arising from collisions. The latter assumption appears to be more realistic in the topside of the ionosphere. In either case, it is necessary to assume a radial distribution at the equator to obtain the electron density distribution.

2. We have provided a more accurate formula for the representation of the equinox geomagnetic anomaly than that produced in GKS. Since the empirical boundary condition equation used herein has been shown by Chandra (1963) to fit nearly all vertical profiles of electron density measured to date, we can safely assume that the proper selection of parameters in this formula will lead to a reasonable reproduction of the anomaly in any equatorial region of the ionosphere where interactions of neutrals with charged particles are small because of infrequent collisions.

3. The theory discussed above is semiphenomenological; i.e., it is based on effect and not cause. It does not require a knowledge of the complicated array of physical effects and mechanisms which combine to form the geomagnetic anomaly but, instead, uses an empirical boundary condition which is the accumulated effect of all these causes.

Naturally, if we are to increase our knowledge of the basis mechanisms causing the anomaly and thereby replace the empirical boundary condition by one based on more fundamental considerations than measurement, we must turn to the equations of continuity. Unfortunately, the derivation of the correct continuity equations requires knowledge concerning the electron and ion velocities and/or the electric fields acting on these particles. Currently, most derivations of the continuity equations employ simplifying assumptions, such as $v_{e\parallel} = v_{i\parallel} = v_\parallel$; $v_\parallel \gg v_{e_\perp}, v_{i_\perp}$. The equation derived in the literature under the above assumptions has been numerically integrated by several workers to obtain a theoretical electron density distribution near the equator under steady state conditions. The results obtained by these workers have been unable to account for the gross features of the geomagnetic anomaly, at least to the correct order of magnitude. This has led them to believe that diffusion is of minor importance in governing the geomagnetic anomaly.

We have been able to demonstrate that the velocity assumptions described above do not lead to the proper description of the geomagnetic anomaly. We therefore feel that the assumption about velocities used in the continuity equation rather than the ineffectiveness of motions are responsible for the unsatisfactory description of the geomagnetic anomaly obtained by others.

4. A study of the neutral atmosphere distribution has led us to the conclusion that geomagnetic control of neutrals occurs in any region of the ionosphere where interactions of neutrals with charged particles become important. Since this is most likely to occur in the lower F region of

the ionosphere we suggest that such geomagnetic control of the neutrals might be observable in this region.

ACKNOWLEDGEMENTS

We wish to thank Miss Partica A. Egan for programming the numerical computations used in this work. We also wish to thank Drs. Frank C. Jones and Arnold P. Stokes for many valuable suggestions and critical comments concerning this paper.

Both authors have carried out this research as NAS–NRC Postdoctoral Resident Research Associates.

THE EFFECT OF A VARIABLE ELECTRON TEMPERATURE ON THE EQUATORIAL ELECTRON DENSITY DISTRIBUTION IN THE UPPER IONOSPHERE

RICHARD A. GOLDBERG

By incorporating a model for the measured electron temperature distribution at the magnetic equator in the isothermal and temperature equilibrium theory of Goldberg, Kendall and Schmerling [J. Geophys. Res., *69*, 417–427, 1964], it has been possible to gain further insight into the behavior of the equatorial geomagnetic anomaly under steady state and equinoctial conditions. In particular, it is shown that the measured deviation from thermal equilibrium in the bottomside ionosphere is very influential in allowing extension of the previous theoretical description of the geomagnetic anomaly well into the bottomside ionosphere and to higher latitudes than originally applicable. For completeness, the effect of gravitational variation is now included, but it is shown that this alone contributes only minor improvements to the original results. Finally, several less common properties in the behavior of the geomagnetic anomaly are investigated, and it is shown under what conditions these secondary effects will occur.

INTRODUCTION

The theory describing the equatorial electron density distribution under conditions of thermal equilibrium, equinox, and steady state, originally presented in Goldberg and Schmerling [1963, 1964] and improved upon in Goldberg, Kendall and Schmerling [1964] (to be referred to as GKS), has provided reasonably good agreement when comparison is made to the measured results of the Alouette Topside Sounder Satellite. Furthermore, Chandra and Goldberg [1964] (to be referred to as CG) have demonstrated that the rather artificial concept of field line diffusive equilibrium need not be employed to obtain the necessary equations, but instead, the neglect of collisions between charged and neutral particles is sufficient in this aim. This has enabled us to understand why the theoretical results agree best with data in the topside ionosphere, since this is the region where such an assumption is most reasonable.

Recent theoretical considerations (Hanson and Johnson, 1961; Hanson, 1962; Dalgarno et al, 1963) and recent measurements with rocket probes (Spencer et al, 1962; Brace et al, 1963) and radar backscatter techniques (Evans, 1962 and 1964; Bowles, 1964) have now demonstrated that thermal equilibrium (electron temperature T_e = ion temperature T_i) does not occur in the lower F region ionosphere during the day including that time when the electron density is experiencing nearly steady conditions. It is the purpose of this paper to provide a simple analytical approach for including a temperature model, based on the theoretical or measured T_e distribution, in the theory discussed in GKS and CG and to demonstrate the possible effects of deviation from conditions of thermal equilibrium on the topside electron density distribution. Furthermore, it will be shown how inclusion of this T_e distribution has allowed extension of the theory into part of the bottomside F layer. Comparison with data is also made to provide a possible explanation of several features of the geomagnetic anomaly heretofore unexplained. For completeness, the effects of variable gravity are also included and the slight modifications in the results due to this effect are demonstrated.

THE FUNDAMENTAL EQUATION

From CG, combination of the equations of motion for electrons and ions provides

$$Nm_e\nu_{en}\vec{v}_e+\frac{Nm_im_n}{m_i+m_n}\nu_{in}\vec{v}_i= -\nabla p_e-\nabla p_i+Nm_i\vec{g}+ir\,\vec{J}X\vec{B} \quad (1)$$

where we have assumed

$$\begin{aligned} v_n &\ll v_e,\ v_i \\ m_e &\ll m_i,\ m_n \\ n_e &= n_i = N \end{aligned} \quad (2)$$

In (1) and (2), the subscripts e, i, and n refer to electrons, ions, and neutrals respectively; p is pressure; n is number density; ν_{jk} is collision frequency between the j^{th} and k^{th} particles; m is mass; v is velocity; g is gravitational acceleration; B is the earth's magnetic field; and J is current density defined as

$$\vec{J}=Ne(\vec{v}_i-\vec{v}_e) \quad (3)$$

where e is the absolute value of electron charge.

If now, we assume that ν_{en} and ν_{in} are sufficiently small to allow neglect of the drag forces, then

$$-\nabla p_e-\nabla p_i+N\,m_i\vec{g}+\vec{J}X\vec{B}=0 \quad (4)$$

Assuming the electrons and ions behave as ideal gases and taking the field line component of (4), we obtain

$$[-Nk\nabla(T_e+T_i)-(T_e+T_i)k\nabla N+Nm_i\vec{g}]\cdot\vec{h}=0 \quad (5)$$

where T_j is the temperature of the j^{th} type particle, k is Boltzmann's constant, and $\vec{h}$ is a unit vector in the direction of the earth's magnetic field.

Let us define

$$\tau=\frac{T_e+T_i}{2} \quad (6)$$

$$H_\tau=\frac{k\tau}{m_ig} \quad (7)$$

Then

$$\left(\frac{\nabla\tau}{\tau}+\frac{\nabla N}{N}+\frac{\vec{i}_r}{2H_\tau}\right)\cdot\vec{h}=0 \quad (8)$$

where $\vec{i}_r$ is a unit vector in the radial direction. If we assume that the earth's magnetic field is a dipole lying in the r, θ plane, we obtain

$$\frac{1}{\tau}\left(\frac{\partial\tau}{\partial r}\sin I+\frac{1}{r}\frac{\partial\tau}{\partial\theta}\cos I\right)+\frac{1}{N}\left(\frac{\partial N}{\partial r}\sin I+\frac{1}{r}\frac{\partial N}{\partial\theta}\cos I\right)+\frac{\sin I}{2H_\tau}=0 \quad (9)$$

where I is the magnetic dip angle defined by

$$\tan I = 2\cot\theta \tag{10}$$

and θ is geomagnetic colatitude. (In the following discussion, all coordinates given are geomagnetic.) As pointed out in CG, (9) can be written in total derivative form as

$$\frac{d\tau}{\tau}+\frac{dN}{N}+\frac{dr}{2H_\tau}=0 \tag{11}$$

provided the integration is carried out along a field line. The solution of (11) is

$$N(r,\theta)=N(r_0)\frac{\tau(r_0)}{\tau(r,\theta)}e^{-\int_{r_0}^{r}\frac{dr}{2H_\tau}}$$

where r_0 is the equatorial height of the field line of integration, i.e.

$$r_0 = r\csc^2\theta \tag{13}$$

and $N(r_0)$, $\tau(r_0)$ represent the vertical distributions of N and τ at the equator.

THE BOUNDARY CONDITIONS

From (12), it is clear that the complete temperature distribution, given by $\tau(r,\theta)$, must be known in addition to the radial distribution of N at the equator, $N(r_0)$, before $N(r,\theta)$ can be determined uniquely. In previous work, $\tau(r,\theta)$ has simply been specified as a constant everywhere. We now investigate the properties of the theoretical electron density distribution when we include a simple radial model for τ based on measurement and theory.

Recent rocket probe measurements (Spencer, et al, 1962 and Brace, et al, 1963) at Wallops Island, Virginia, show a vertical electron temperature profile under quiet day conditions which departs from the ion temperature at 150 km, peaks between 200 and 250 km with a value of $T_e \approx 2T_i$, and then returns to the $T_i = T_e$ value at about 350 km. Evans [1962] obtains a similar type behavior and later [1964] shows improved results which indicate a peak at 300 km and a return to $T_e/T_i = 1$ above 700 km for radar backscatter measurements in the midlatitude region of Boston, Mass. The only measurements available in the equatorial region are those of Bowles [1964] using the backscatter technique and he reports a T_e/T_i peak value of 2 occurring at about 275 km. Furthermore, he never finds $T_e/T_i > 1$ above 400 km.

Hanson and Johnson [1961], Hanson [1962] and Dalgarno et al [1963] have presented theoretical models for T_e/T_i based on local EUV heating which result in similar type profiles to those measured, viz. $T_e/T_i = 2$ at the peak with the peak occurring between 200 and 250 km. The theoretical models are probably most representative of the equatorial regions where EUV heating is most likely to predominate. The theoretical peak height is somewhat lower than that reported by Bowles [1964] but Dalgarno et al [1963] explain that their lower value for the peak can be attributed to an underestimate of the cooling rate by neglect of the contribution from vibrational excitations. They also state that one should expect a more rapid cooling rate in a warmer atmosphere and this appears to indicate a higher altitude for the T_e/T_i peak at times of higher sunspot number. These are important considerations in selecting the numerical values for the height of the electron temperature peak (r_p) in the next section.

The results discussed above clearly demonstrate the absence of thermal equilibrium in the lower F region of the ionosphere. Unfortunately, the data and theoretical models available are rather limited and the exact behavior and distributional shape is currently rather uncertain. As a reasonable first guess, we therefore choose a simple analytic distribution for T_e which is representative of any of the above profiles but which does not fit any of them in an exact sense. We also consider the temperature behavior to be independent of latitude in the equatorial region under consideration (i.e. from 20°N to 20°S).

An expression which possesses these qualifications is

$$T_e = T_i\left[1+\frac{K-1}{1+\frac{(r-r_p)^2}{H_T^2}}\right] \tag{14}$$

where K is the ratio T_e/T_i at the peak height (r_p) of the T_e distribution and H_T is a scaling factor which governs the thickness of the T_e distribution and which will be referred to as the thermal scale height. A typical plot of (14) is shown in Figure

1 for various values of H_T and for $r_p = 6650$ km. From (14), we obtain

$$\tau(r, \theta) = \tau(r) = \frac{T_i}{2}\left[2 + \frac{K-1}{1+\frac{(r-r_p)^2}{H_T^2}}\right] \quad (15)$$

Although the effect of the gravitational height dependence is small, we include it for completeness in the work which follows. The scale height of the ionizable constituent is given by

$$H_i = \frac{kT_i}{m_i g} \quad (16)$$

If we define H_p as that value of H_i at the height r_p, i.e. the matching point, and we treat T_i as constant in the region under consideration, then

$$H_i = \frac{r^2}{r_p^2} H_p \quad (17)$$

With these definitions, we have

$$H_\tau = \frac{H_p}{2}\frac{r^2}{r_p^2}\left[2 + \frac{K-1}{1+\frac{(r-r_p)^2}{H_T^2}}\right] \quad (18)$$

The form of H_τ given by (18) allows explicit integration of the integral in (12). We obtain

$$-\int_{r_0}^{r} \frac{dr}{2H_\tau} = \frac{r_p^2[F_1+F_2+F_3+F_4]}{2H_p\left[r_p^2 + \frac{H_T^2(K+1)}{2}\right]^2} \quad (19a)$$

where

$$F_1 = \left[r_p^2 - H_T^2\frac{(K+1)}{2}\right]\left[\frac{H_T(K-1)}{2\left(\frac{K+1}{2}\right)^{\frac{1}{2}}}\right]\left[\tan^{-1}\left(\frac{r-r_p}{H_T\left(\frac{K+1}{2}\right)^{\frac{1}{2}}}\right) - \tan^{-1}\left(\frac{r_0-r_p}{H_T\left(\frac{K+1}{2}\right)^{\frac{1}{2}}}\right)\right] \quad (19b)$$

$$F_2 = r_p H_T^2\left(\frac{K-1}{2}\right)\ln\left[\frac{(r_0-r_p)^2 + H_T^2\left(\frac{K+1}{2}\right)}{(r-r_p)^2 + H_T^2\left(\frac{K+1}{2}\right)}\right] \quad (19c)$$

$$F_3 = 2r_p\left[\frac{K-1}{2}H_T^2 \ln r/r_0\right] \quad (19d)$$

and

$$F_4 = \frac{r_0 - r}{r\, r_0}\left[\left(r_p^2 + \frac{H_T^2(K+1)}{2}\right)(H_T^2 + r_p^2)\right] \quad (19e)$$

Finally, we must apply an analytic form for $N(r_0)$. Although Chandra (1962) formulated an improved functional form for $N(r)$ than that described by the simple Chapman function and this has been incorporated in the results of CG, it is necessary to return to the simple Chapman function in the work that follows in order to make direct comparison with Goldberg, Kendall and Schmerling (1964). Hence, we let

$$N(r_0) = N(r_{m0})e^{\frac{1}{2}\left[1 - \frac{r_0 - r_{m0}}{H_e} - e^{-\frac{r_0 - r_{m0}}{H_e}}\right]} \quad (20)$$

where H_e is the electron density scale height at the equator and N_{m0} is the value of electron density at the vertical peak height r_{m0}.

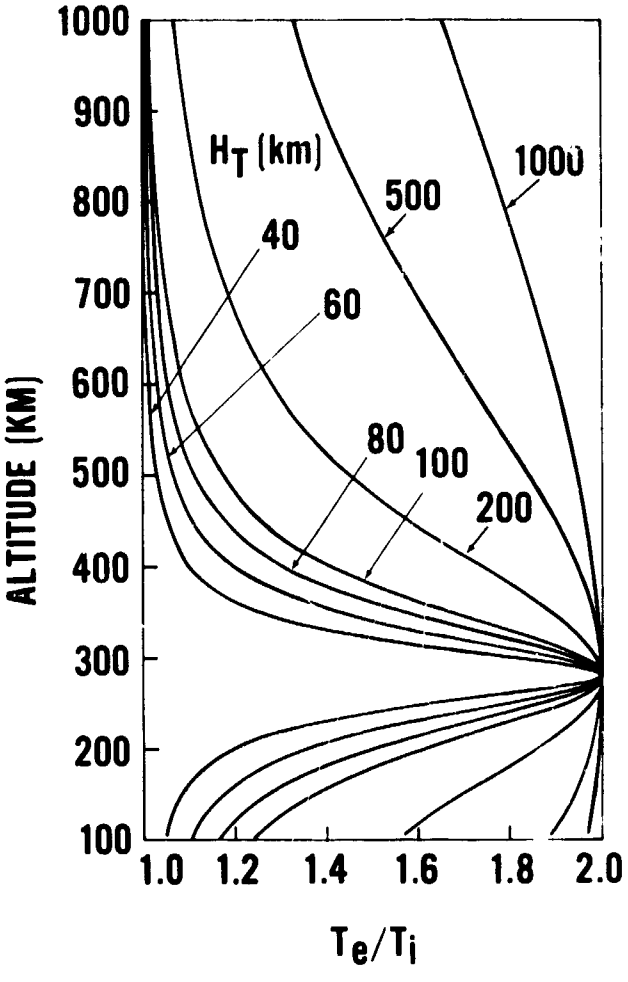

FIGURE 1.—The vertical electron temperature model.

NUMERICAL ANALYSIS AND DISCUSSION

A. The Effect of Gravity

The expressions given by (15), (19) and (20) have been incorporated in (12) to provide an analytic expression for the electron density near the geomagnetic equator above and below the electron density peak under conditions of steady state and equinox. This expression has then been programmed on an IBM 7094 to allow extensive study of its behavior under wide variations in the temperature parameters. The discussion which follows demonstrates how adjustment of the parameters governing the temperature distribution leads to variations in the properties of the geomagnetic anomaly.

Before investigating the actual effect of a variable T_e, let us first study the change induced by simply adding the gravity variation. This is obtained by replacing H_r with H_i and treating $\tau(r,\theta)$ as a constant in (12). Then

$$N(r,\theta)=N(r_0)e^{\frac{r\cos^2\theta}{2H_i}} \tag{21}$$

where H_i possesses the functional dependence on height given by (17). This can be compared to the constant H_i result employed in GKS, viz.

$$N(r,\theta)=N(r_0)e^{\frac{r\cot^2\theta}{2H_p}} \tag{22}$$

where H_2 of GKS is now H_p. (In the discussion and results which follow, the scale height of the electron density distribution H_e has also replaced $1/k$ in GKS notation).

Comparison of (21) and (22) shows that very little change in results should be expected in that region of latitude where $\cot\theta$ and $\cos\theta$ are comparable in magnitude. This encompasses nearly the entire region of our interest. This conclusion is borne out by numerical comparison of (21) and (22) for cases in which $H_p/H_e>1$. A more important result is obtained for cases presented in GKS for $H_p/H_e\leq 1$. In that paper it was shown that angular peaks could not be obtained for this range of selection in parameters, although the initial rise with latitude behaved in equivalent manner to the geomagnetic anomaly. The simple inclusion of gravity now rectifies this situation by allowing angular peaks to form for these cases.

A comparison of the 380 km and 480 km electron density profiles with and without gravity variation for $H_p/H_e=1$ is shown in Figure 2 using the numerical parameters given in Table 1 (The altitude z is related to radial distance r by $r=z+6370$ km). Curve a represents the constant g case given by (22). Curves b and c represent variable $g(r)$ cases in which the matching of H_i with H_p is taken to be at two different heights, viz. 6650 and 6850 km, respectively. We first note that the effect of varying the matching point is rather small and has little if any influence on the features we wish to discuss. We also find that regardless of matching point height, the curves stay relatively close even at high latitudes. The generation of an angular peak for $r_p=6650$ km is not surprising since $H_i/H_p>1$ everywhere above r_p. However, it is surprising to find this result for the 380 km (6750 km) profile when $r_p=6850$, since $H_i/H_e<1$ at this height. This result occurs for all cases investigated and we must conclude that although gravity is a small effect in altering the slope of the curves, as comparison of curves 2b and 2c demonstrate, it is a strong effect in providing a more realistic description of the geomagnetic anomaly should it occur under conditions where $H_p/H_e\leq 1$.

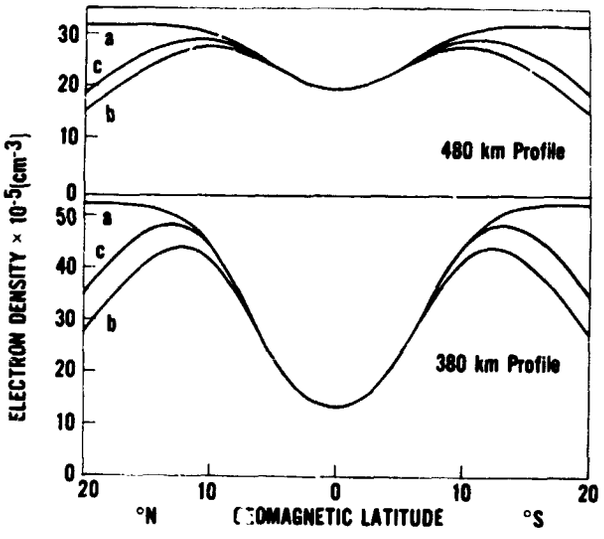

FIGURE 2.—The influence of the gravity variation on a horizontal electron density profile for $H_p/H_e=1$; a) constant g, b) and c) variable g.

B. The Effect of Temperature

Although inclusion of height dependent gravity, $g(r)$, appears to resolve the problem of theoretically describing the geomagnetic anomaly

when $H_i/H_e \leq 1$, it has been shown in CG that this condition is a rather unlikely situation to occur on both empirical and physical grounds. We therefore restrict ourselves in the discussion which follows to $H_i/H_e > 1$.

There are seven parameters to be varied in this problem on the basis of empirical conditions, viz. N_{m0}, r_{m0}, H_e, H_p, H_T, r_p and K. In GKS, it was shown that variation of the first four parameters leads to a description of the equinoctial noontime geomagnetic anomaly during various phases of the solar cycle. Furthermore, although differences in the magnitude and height range of the anomaly occur between high and low sunspot number, no changes in the basic features ascribed to this effect are expected. We will, therefore, limit ourselves to an analysis of the high sunspot case with the knowledge that the results obtained are similar but less pronounced for the intermediate and low sunspot cases. The choice of values for the first four parameters listed above have been made to coincide with GKS by selecting

$$N_{m0} = 19.25 \times 10^5 \text{ electrons/cm}^3,$$

$$H_e = 100 \text{ km}, \; r_{m0} = 6850 \text{ km},$$

and $$H_p = 112.5 \text{ km}.$$

Selection of H_p at the given value insures $H_i/H_e > 1$ in the entire region of interest. The values of the other numerical parameters used are given in Table 1. (These values are selected to coincide as accurately as possible with the temperature profile discussed earlier).

TABLE 1.

Figure	Curve	r_p (km)	H_T (km)	K
1	----------	6650	Variable	2
2	a	----------	0	1
	b	6650	0	1
	c	6850	0	1
3	----------	6650	40	2
4	----------	6650	40	2
5	----------	6650	40	2
6A	----------	Variable	40	2
6B	----------	6850	40	Variable
6C	----------	6850	Variable	2
8	----------	6850	40	2
9	----------	6850	40	2
10	----------	6775	40	2

We can therefore reduce the problem to a three parameter study; H_T and K which determine the thickness and magnitude of the T_e peak respectively; and r_p, which determines the relative distance between the electron temperature and density maxima.

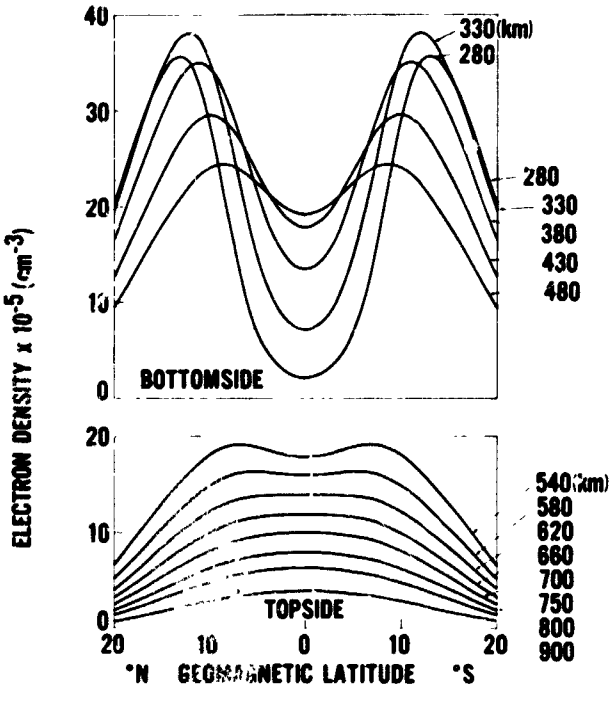

FIGURE 3.—Horizontal profiles of electron density under conditions of variable electron temperature.

Figure 3 represents a sequence of electron density constant height profiles under the effects of T_e variation. Figure 4 represents an equivalent set of vertical profiles. The temperature profile used is illustrated in Figure 1 with parametric values selected for reasons discussed in a previous section.

Comparison of Figure 3 to the thermal equilibrium, constant gravity results given in GKS shows very little modification of the curves out to the angular peak. On the high latitude side of the peak, however, we find a more rapid decrease of electron density in better agreement with measured profiles. This effect is due primarily to the inclusion of the gravitational variation and not the variation in T_e.

A more important result, and one which is entirely due to a variable T_e, is evident in Figure

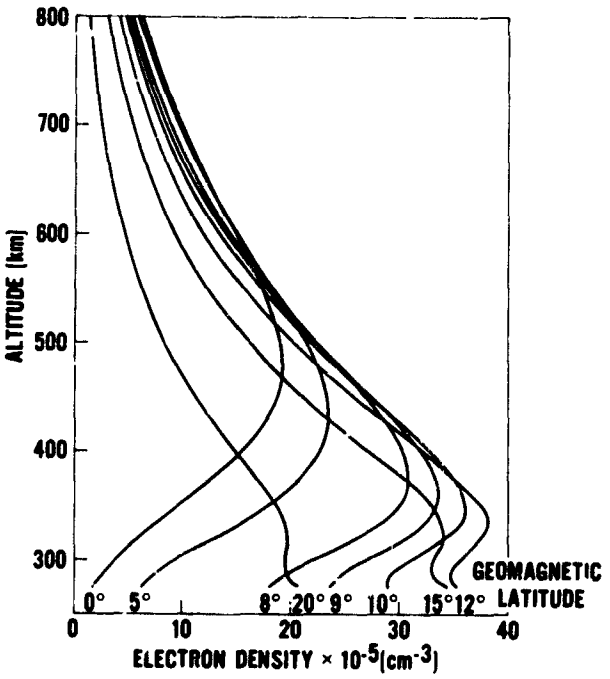

FIGURE 4.—Vertical profiles of electron density under conditions of variable electron temperature.

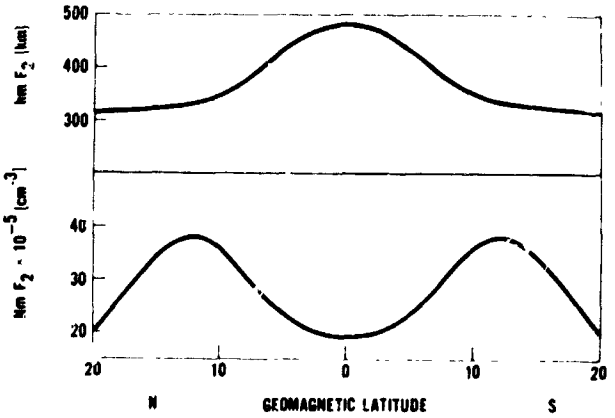

FIGURE 5.—Behavior of N_mF2 and h_mF2 with latitude under conditions of variable electron temperature.

4. We now find qualitative results which match measured data to a height nearly two electron scale heights (H_e) below the equatorial $F2$ peak before discrepancies begin to occur. Since the vertical profiles show a departure from measurement below this height, it appears that the neglect of friction terms in the equations of motion is no longer valid below this region. Nevertheless, it is a valuable extension of the theory to find that the effect of collisions can be neglected to heights well below the equatorial $F2$ peak, especially since it appeared by the results of GKS that collisions were important everywhere below this peak, i.e. in GKS results obtained below the peak do not agree with data and the vertical peaks shown in Figure 4 of this work could not be produced.

The variation of the peak electron density N_mF2 with latitude is given in Figure 5. We observe that a variable T_e produces angular peaks in N_mF2 in accord with measurement, (cf. Croom et al, 1959) whereas in GKS, it was shown that thermal equilibrium is incapable of producing the angular "turnover." Furthermore, this result must be attributed to a variable T_e, since inclusion of variable gravity alone does not alter the results for this parameter given in GKS. The variation of the height of the $F2$ peak, h_mF2, is also given in Figure 5. We observe a leveling out of this height at higher latitudes in accord with measurement (cf. Thomas, 1962), a result which also is not available under thermal equilibrium considerations. A study of these quantities show that their magnitude and shape are very stable to wide variations in K, H_T and $r_{m0}-r_p$, except when K and H_T become very small, i.e. $H_T \leq 29$, $K \leq 1.2$. At these and smaller values we find a rapid transition into the forms published in GKS for thermal equilibrium, in which h_mF2 drops steadily with latitude and N_mF2 rises with latitude without showing any angular peaks.

Figure 6A demonstrates the variation of a typical constant height profile with r_{m0}, viz. 380 km, holding K and H_T fixed. We note that as r_p approaches r_{m0}, the original angular peak converts into a sharper peak adjacent to a relatively flat "ledge." Further study has shown that this effect is not dependent on the absolute value of r_{m0} or the relative distance between the actual constant height profile and r_{m0}. Instead, this behavior is exclusively dependent on $r_{m0}-r_p$.

Because the results which follow depend only on the relative separation $r_{m0}-r_p$ and not on the absolute values of r_p and r_{m0}, and because of the discussion in an earlier section explaining how r_p can actually be larger in a warmer (high sunspot number) ionosphere, we have selected the relatively high value of $r_p \approx r_{m0} = 6850$ km. If the condition $r_p = r_{m0}$ occurs at a lower height, the same results will occur simply shifted this distance in altitude. From Figure 6A we find that the new effect is not present until r_p is very nearly

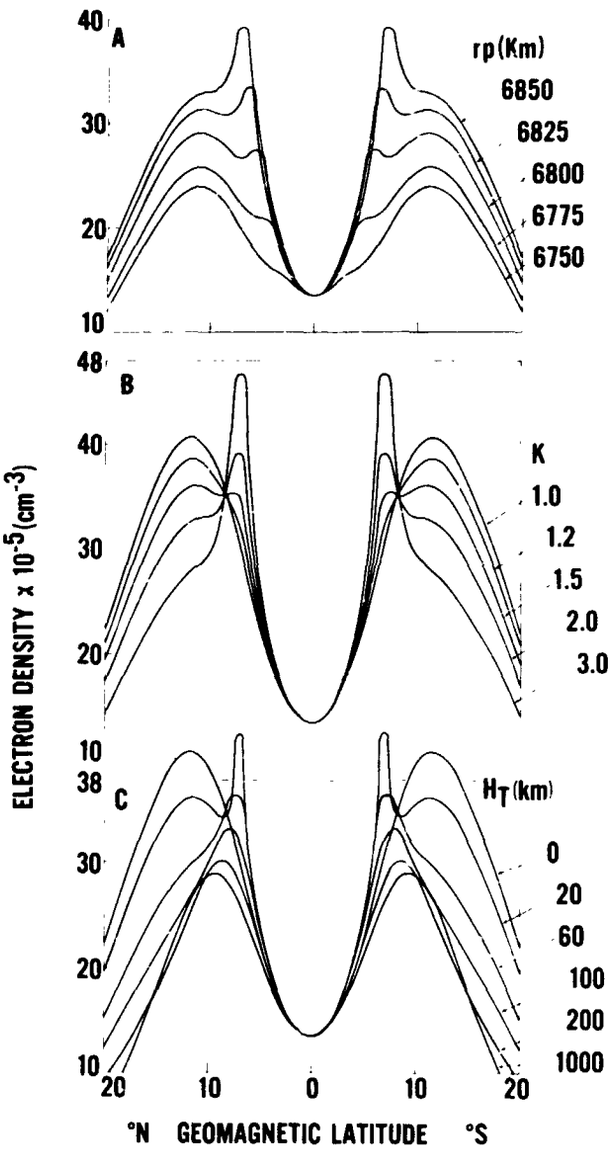

FIGURE 6.—Behavior of a constant height electron density profile (6750 km) with *A*) relative distance between electron temperature and density peaks, *B*) magnitude of temperature peak, *C*) thickness of temperature peak.

equal to r_{m0}, and becomes more pronounced as r_p increases (or r_{m0} decreases).

Although the above effect is not always present, it has appeared in measurements of King et al (1963), an example of which is shown in Figure 7. No attempt has been made to accurately fit this particular profile, however, since there are many combinations of the seven parameters available for such a fit and the profiles showing this property best in the published literature do not always represent noon equinox conditions. Nev-

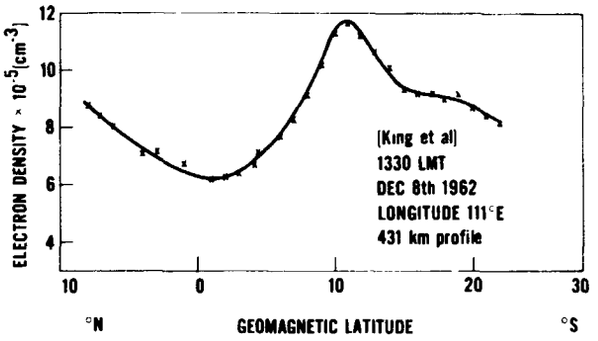

FIGURE 7.—The 431 km electron density profile (King et al, 1963) for December 8, 1962, 1330 LMT, using ALOUETTE data.

ertheless, the effect does occur, and this indicates that the electron temperature and density peaks do lie relatively close together at certain times. During such an occurrence, we would expect the geomagnetic anomaly to appear in a form similar to the result given in Figure 8, where we notice a

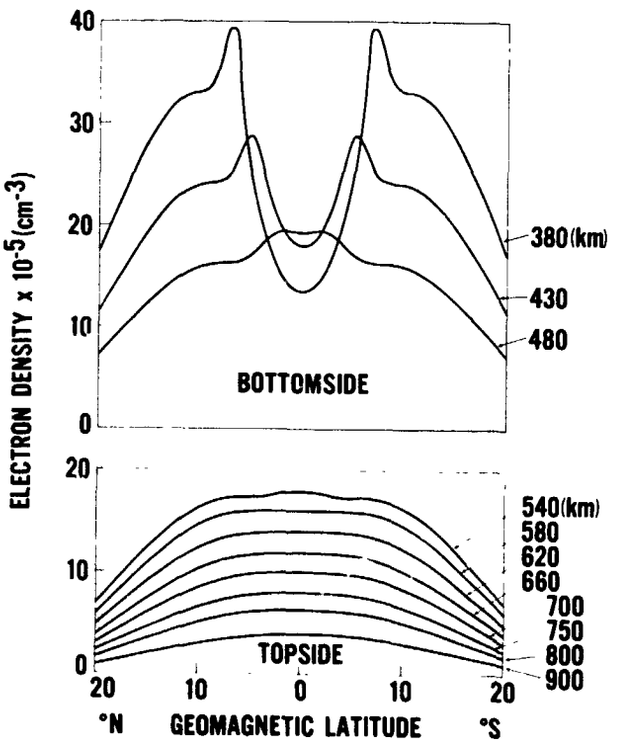

FIGURE 8.—Horizontal profiles of electron density under conditions of variable electron temperature for $r_p = r_{m0}$.

low latitude "ledge" replacing the low latitude "trough" at higher altitudes. We also note a reduction in the height above which the anomaly disappears.

The sequence of vertical profiles corresponding to Figure 8 ($r_p = r_{m0}$) are shown in Figure 9. We

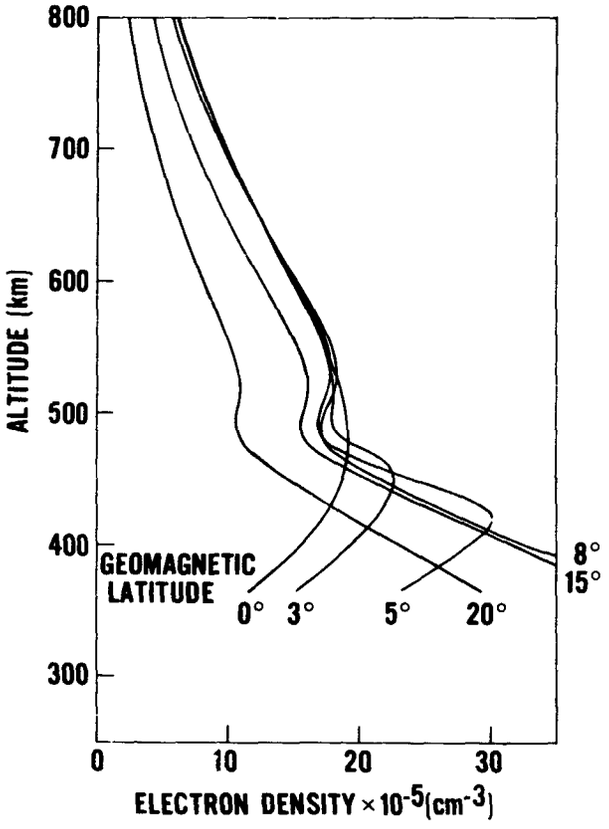

FIGURE 9.—Vertical profiles of electron density under conditions of variable electron temperature for $r_p = r_{m0}$.

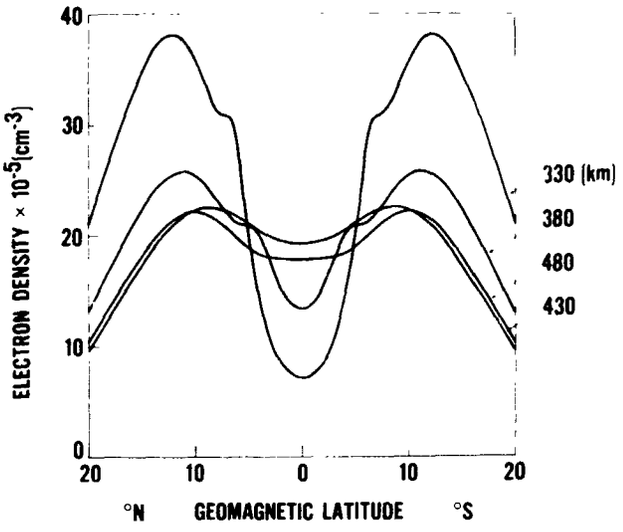

FIGURE 10.—Horizontal profiles of electron density showing the "inner ledge" effect.

find that this extreme lowering of the electron density peak (or raising of the temperature peak) leads to an additional small "bump" in the topside region.

Other smaller effects are also seen upon more detailed study of the results. For example, if $r_{m0} - r_p$ is of the order $.75H_e$ (see Figure 6A), we find the sequence of horizontal profiles illustrated in Figure 10, demonstrating a much smaller ledge occurring on the low latitude side of the angular peaks with no ledge present on the high latitude side. The topside results in this case are identical to those of Figure 3. The determination of this behavior from measurement is difficult, however, because of the small magnitude of the effect.

As partially shown in Figures 6B and 6C, a study of the variations of both K (temperature peak magnitude) and H_T (temperature peak thickness) do not lead to any new conclusions but form a consistent picture, i.e. as K decreases, the ledge gradually disappears leaving the normal horizontal profile for the variable gravity case. As H_T decreases, the effect first sharpens before disappearing for $H_T \leq 15$ km. Similarly, as K and H_T decrease, the topside "bump" in the vertical profile (cf. Figure 9) gradually lowers and blends with the single peak obtained under variable gravity conditions alone. Increasing H_T and K improves the results on the bottomside by reducing the magnitude of the electron density profiles to more reasonable values in this region. Increasing H_T also sharpens the angular peak slightly. Finally, if we consider cases of very large H_T, such as $H_T = 1000$ km, we find a behavior very similar to the $H_T = 0$ situation. This demonstrates that it is the gradient of T_e/T_i, and not its magnitude, which is mostly responsible for the results involving the effect illustrated in Figure 7.

SUMMARY AND CONCLUSIONS

The theory presented in GKS has been extended to include the effects of the variation in gravity and an electron temperature profile based upon empirical and theoretical results. This extension in the theory has led to distinct improvements in the theoretical description of the geomagnetic anomaly when comparison with data is made.

The inclusion of gravitational variation alone has led to an increased gradient on the high latitude side of the theoretical constant height profiles representing the geomagnetic anomaly, this being in better accord with measurement. Furthermore, for the cases in which $H_i/H_e \leq 1$, we now

find angular peaks occurring in the constant height profiles, something which was not available under constant gravity considerations.

The inclusion of an electron temperature vertical profile creates results which are far more remarkable, however. We now obtain a description of the geomagnetic anomaly to heights as low as $2H_e$ below the F2 peak at the equator, thereby indicating that the neglect of friction or collision terms in the equation of motion is allowable down to these heights. The theoretical behavior of N_mF2 and h_mF2 are also found to agree with measurement out to midlatitudes and an angular peaking of N_mF2 is seen to occur. These are results which could not be obtained in GKS under isothermal conditions and thermal equilibrium.

Although T_i has been treated as a constant in the derivation of the expression used to obtain these results, this is not considered to be a serious limitation in the theory since the major gradients in T_i currently appear to be considerably smaller than those in T_e and occur in the very lowest sector of the region under consideration.

Further study with a variable T_e shows that as the height of the electron temperature and density peaks approach one another, we can expect to find an interesting change in the shape of the horizontal electron profiles describing the geomagnetic anomaly. Experimental evidence is presented to show that this behavior does occur at certain times. We also find that the slope of the electron temperature peak rather than its magnitude is more responsible for this effect. In addition, the vertical profiles undergo a slight modification with the appearance of a small "bump" in the topside above h_mF2 during its occurrence. It should be noted, however, that the evidence given in Figure 7 is a topside result and the theoretical results of Figure 8 do not show this effect extending into the topside. Assuming that 431 km was slightly above r_{m0} in Figure 7, we must conclude that either r_p was slightly higher than r_{m0} or that $r_p = r_{m0}$ with the temperature peak exhibiting a sharp gradient (large K, small H_T) on that day, since these are the only possible methods for theoretically obtaining this effect in the topside with the temperature profile assumed. (Naturally, a different electron temperature profile, such as one which possesses a secondary peak in the topside, should not be ruled out as a possible cause of observing this effect in the topside). Since r_{m0} decreases rapidly with sunspot number, we would expect the above behavior to be most frequent during the low sunspot number period of the solar cycle.

Finally, several secondary features originating from the theory due to the magnitude of the separation between N and T_e peaks ($r_{m0} - r_p$) are discussed, but this type of "fine structure" is considered too small to be seen at this time.

ACKNOWLEDGEMENTS

I am grateful for the valuable assistance given to me in the programming and numerical analysis of this work by Christopher E. Bock and William M. Litman. I also offer my deepest thanks to Dr. S. J. Bauer for critically reading the manuscript and making several helpful suggestions.

A SYNOPTIC VIEW OF IONIC CONSTITUTION ABOVE THE F-LAYER MAXIMUM*

N66 37959

W. J. RAITT, SUSAN LAFLIN AND R. L. F. BOYD†

The UK-US satellite Ariel carried an ion mass spectrometer operating on the principle of analysis of arrival energy of the ions. A very large amount of data has been gathered and it is now possible to obtain a picture of the variation of the ionic composition above 400 km with latitude and longitude.

A strong diurnal effect is evident together with marked geomagnetic control. There is evidence also for a seasonal variation.

INTRODUCTION

The international satellite Ariel I (1962 –) provided an opportunity for a synoptic study of the composition of the topside ionosphere over a prolonged period.[1] Data on ionic constitution was received at stations of the Minitrack network from 26 April, 1962 until 26 September, 1962—a period of 151 days during summer in the northern hemisphere. The relative concentration of oxygen in the topside ionosphere is found to increase with latitude during the day. A marked diurnal variation in composition is also evident. This paper presents some of these data and draws special attention to the evidence for a geomagnetic control of the composition from a set of satellite passes with apogee over the equator and another set with apogee at northern apex.

The apparatus consisted of a gridded probe 10 cm. in diameter. The probe was mounted on the axis of the satellite and being spherically symmetrical was insensitive to the spin of the vehicle.

An ion retarding (positive sawtooth) voltage enabled a Dryvesteyn analysis of the energy distribution of the ions arriving to be obtained, the necessary double differentiation of the current-voltage characteristic being carried out electronically.

The energy of arrival of an ion depends principally on its mass so that the energy spectrum consists of a number of peaks corresponding to ions of mass 16 (oxygen), 4 (helium) or 1 (hydrogen) a.m.u. The integration of these peaks leads to the concentration of each type of ion. Since the first derivative of the current voltage curve which corresponds to this integral of the energy distribution was one of the telemetered quantities, typical raw data of the kind shown in figure 1 was obtained. The sizes of the steps in these

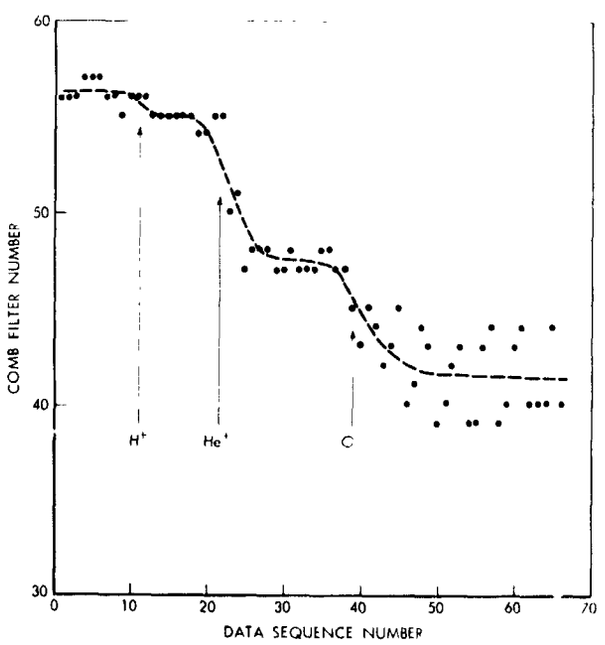

FIGURE 1.—Example of raw telemetered data showing presence of 3 ion types.

curves lead directly to the concentrations of the various ion species.

THE DAILY VARIATION OF IONIC CONSTITUTION

A number of satellite passes over the equatorial region 10°S. to 10°N. and over the latitude band 35°N. to 45°S. covering a period of 125 days in the northern summer have been analysed, to obtain the diurnal variation in the ion transition altitudes (i.e. where O^+ and He^+ concentrations are equal and where He^+ and H^+ concentrations are equal). Inevitably some seasonal and secular variations are also involved. To reduce the former the altitudes are plotted as a function of solar zenith angle before and after mid-day. In addition, since the basic data gives composition at the actual altitude and local solar time given by the orbital parameters some processing of the data is necessary in order to obtain a single parameter (such as transition altitude) to characterise the state of ionic composition. For this purpose it has been assumed that ion temperature is equal to gas temperature and that the composition at one height may be obtained from that at another height from the hydrostatic equation. The gas temperature function employed was based on the data of Harris and Priester[2] corrected to the mean solar 10 cm. emission for the period covered by the data.

It is certain that this operation introduces some error in scale but it cannot seriously affect the general form of the results.

The diurnal variation of transition altitudes is plotted for the two latitude ranges in figure 2. (The latitude variation will be considered in more detail in the next section). It shows a flat maximum at solar zenith angles corresponding to about 17.00 hours.

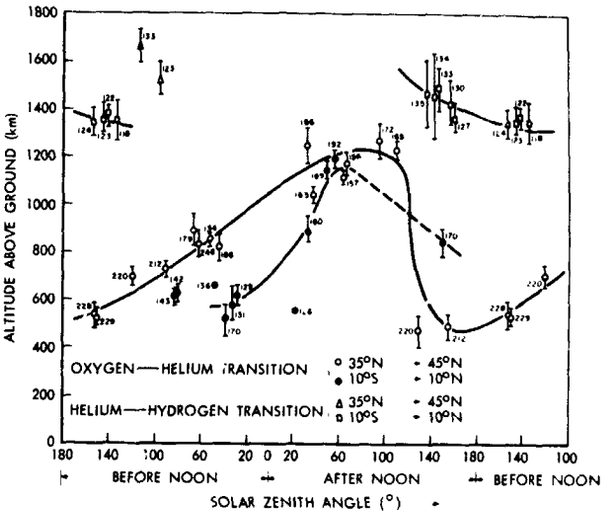

FIGURE 2.—Diurnal variation of transition altitudes.

LATITUDE VARIATION OF IONIC CONSTITUTION

In seeking to establish the variation of composition with latitude it is difficult to eliminate the effects of changing altitude and local solar time. By selecting a short period (four days) during which apogee was nearly over the equator and the descending equatorial passage occurred at about 1500 hours local solar time it is possible to study the region between 45°N. and 45°S. during the period 12.00 to 18.00 hours over which as the previous section shows, the diurnal variation is slowest. At the same time, the altitude range does not change by more than 200 Km. Figure 3 shows contours of percentage oxygen ion concentration betweeen days 189 to 193 in 1962.

There is evidence for a pronounced latitude variation in composition showing higher concentrations of oxygen ions at high latitudes. (The change of composition from 10 percent

$$O^+\left(\frac{[O^+]}{[He^+]}=\frac{1}{9}\right) \text{ to 80 percent } O^+\left(\frac{[O^+]}{[He^+]}=4\right)$$

exceeds the composition change that might be attributed to the 100 Km change in altitude by a factor of 10). The altitude and local solar time are plotted at the side of the figure.

In addition to the evident geomagnetic control of the composition there seems also to be a displacement of the centre of symmetry towards the winter (southern) hemisphere.

LONGITUDE VARIATION OF IONIC CONSTITUTION

A variation of composition with longitude is likely to be due to the asymmetry of the geomagnetic field. This fact is confirmed by the way the contours on figure 3 follow the geomagnetic equator.

Figure 4 shows similar data obtained over the period from day 150 to day 155 in 1962. In this

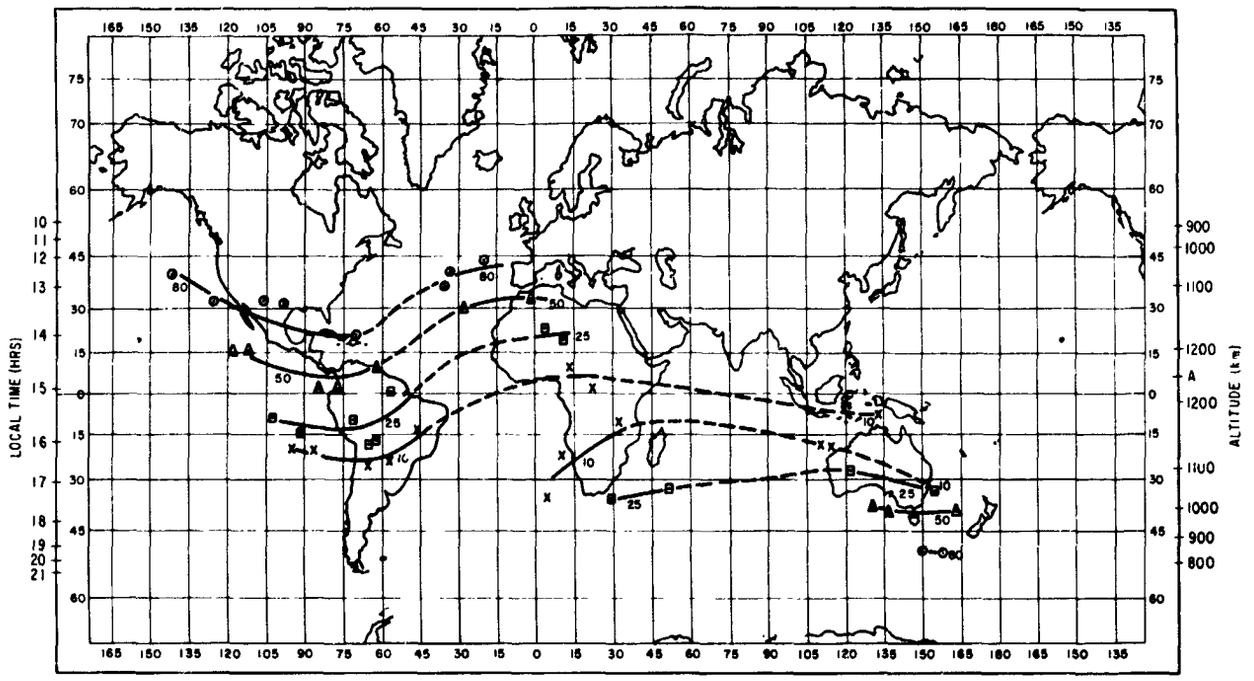

FIGURE 3.—Ion composition contours days 189–193, 1962.

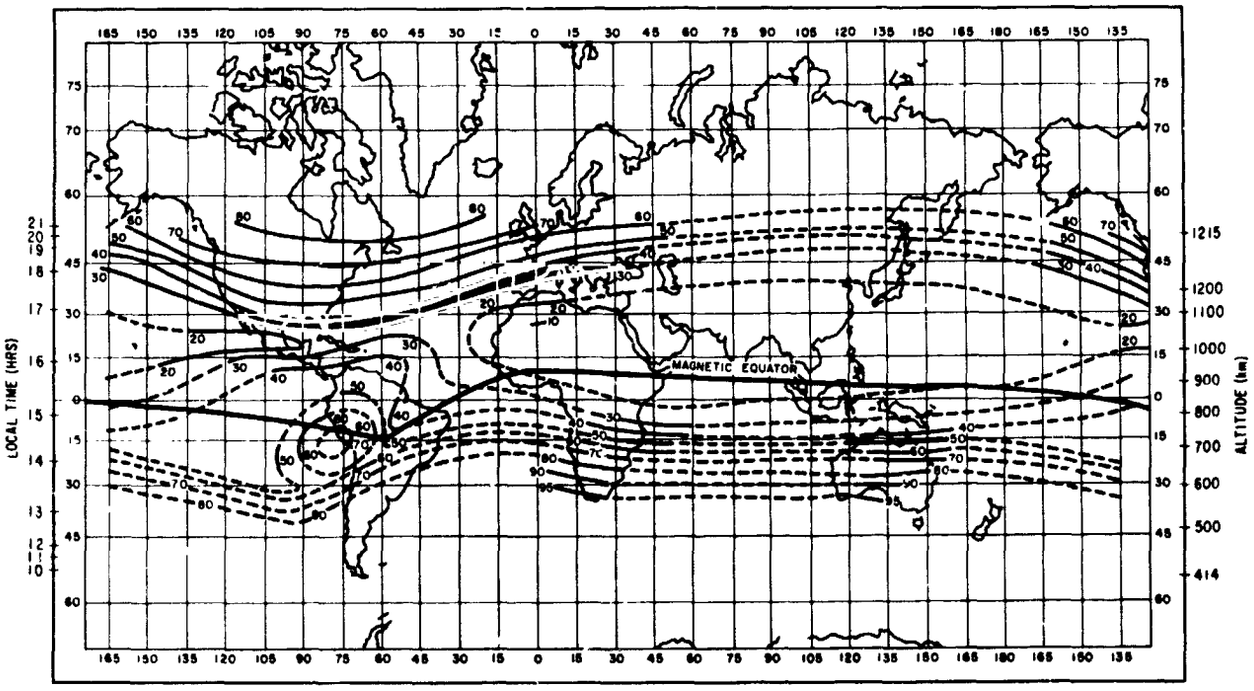

FIGURE 4.—Ion composition contours days 151–155, 1962.

case, the effects of altitude and local solar time on the latitude variation are too great to enable useful conclusions about latitude variation to be drawn. However, variation along any single line of latitude does not suffer from this source of uncertainty and it is again evident that there is a strong geomagnetic control with an extremely complex situation over the South American anomaly. This area of increased oxygen was not detected on the earlier results (days 189–193)

possibly because less data was analysed then and also the altitude and local time is this region were such that the percentage oxygen was only of the order of 10 percent which is near the limit of detection of the probe. On the other hand, there may be a real seasonal or secular difference.

It seems likely that many of the features may be attributed to the dependence of ion temperature on electron concentration[3] while near the equator the horizontal magnetic field (and possibly electric fields) probably make the hydrostatic equation inapplicable. It is worth noting that where the ionic composition ratio is determined by the hydrostatic equation it is the ion temperatures, not the electron temperatures that are relevant. Effects of the magnitude of those illustrated could be produced by an ion temperature change of about 20 percent.

MAGNETIC SHELL ENHANCEMENTS DURING MAGNETIC DISTURBANCES*

A. P. WILLMORE AND C. L. HENDERSON†

Langmuir probe observations of electron density on the satellite Ariel I for May–July 1962 show that even on magnetically quiet days longitudinal irregularities appear, particularly near the South Atlantic anomaly. The region of locally depressed density near the shell L=4 shows a diurnal variation of intensity, and in the southern hemisphere it inverts to an increase in density during the late morning. A minimum has been observed at the magnetic equator in the evening hours, about 500 km above the peak of the equatorial anomaly.

For disturbed periods enhancements have been observed with a structure resembling magnetic shells, which tend to merge and to approach lower L values as the disturbance increases. For one disturbed period strong enhancements were noted at night near the South Atlantic anomaly. These phenomena imply the influence of energetic particles on topside irregularities.

INTRODUCTION

Langmuir probe measurements of electron density recorded on the satellite Ariel I during the period May to July 1962 (Willmore et al.) have been used to study the quiet-day distribution, and variations due to magnetic disturbances. No major disturbance occurred in this period, but there were several isolated, moderate storms for which definite enhancements could be identified.

Table 1 lists the magnetic data for these disturbances. Unfortunately there were no probe data for most of the peak disturbance period on May 6 and 31. We have therefore presented results for the three other periods.

METHOD OF ANALYSIS

Since the observations were magnetically recorded on the satellite, data for complete orbits were available.

These were separated into northbound and southbound passes, each covering the full latitude range of 54°N. and S. From 14 successive passes a complete scan of latitude and longitude could be mapped. Because of the slow motion of perigee in the orbit, and the slow rotation of the orbital plane, a line of constant latitude on such a

map is also a line of constant height to within ± 10 km, and of constant local time to ± 10 minutes. This form of presentation was used to show the longitude and magnetic latitude variations of electron density on quiet days. (figs. 1–4).

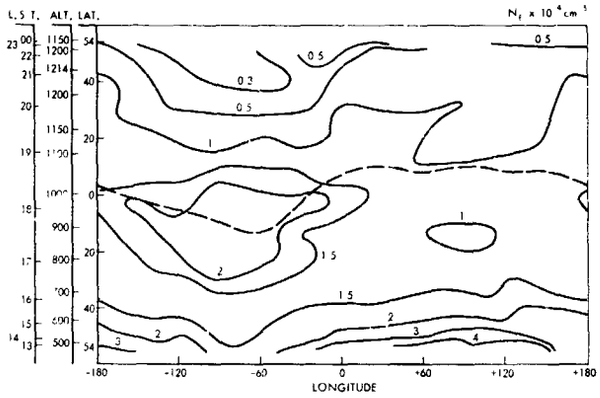

FIGURE 1.—Contours of electron density for northbound passes on May 24, 1962. The dashed line is the magnetic equator.

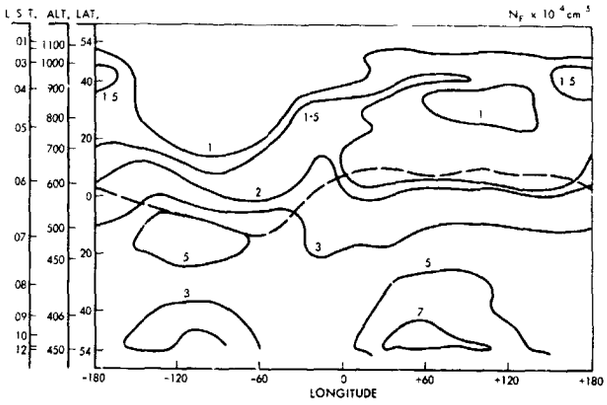

FIGURE 2.—Contours of electron density for southbound passes on May 24, 1962.

For determining disturbance effects, plots of electron density versus latitude for "corresponding" passes on successive days were superimposed. The days included, but were not confined to, those listed in Table 1. The passes were at intervals of 14 orbits, and for corresponding latitudes there was a daily shift of 2° longitude eastwards, a change of less than 20 km in height, and a decrease of 20 minutes in local time. Variations of electron density at a given latitude due to these orbital shifts are in general linear, and can therefore be distinguished from variations which correlate with Kp. A region was classed as showing a disturbance effect only when the electron density for a given latitude differed significantly on the disturbance day from that on the neighboring quieter days.

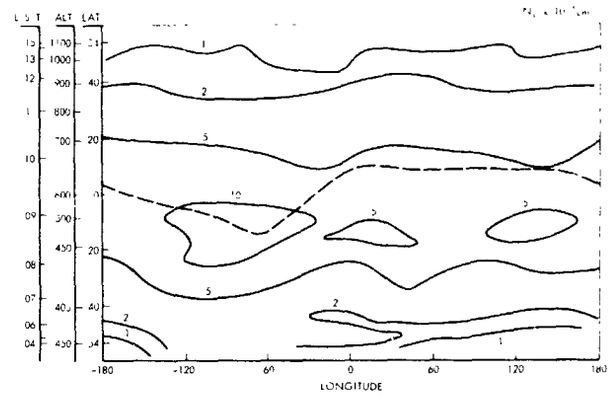

FIGURE 3.—Contours of electron density for northbound passes on June 20, 1962.

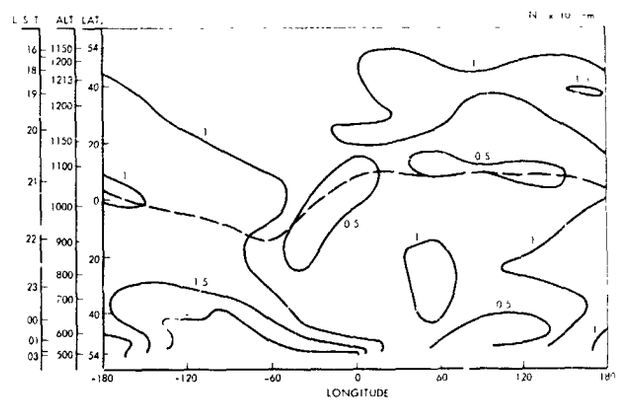

FIGURE 4.—Contours of electron density for southbound passes on June 20, 1962.

No decrease in electron density was unambiguously associated with magnetic activity. Nelms and Warren (this conference) observed a decrease over a wide range of latitudes when Kp reached very high values, up to 9–. However, this referred to altitudes near the maximum of the F layer and so was lower than our observations.

Several regions of increased electron density were observed, and are depicted in figs. 5–8. Bold lines indicated enhancements, fine lines no significant disturbance effect, and blank spaces an absence of data. In some places where there

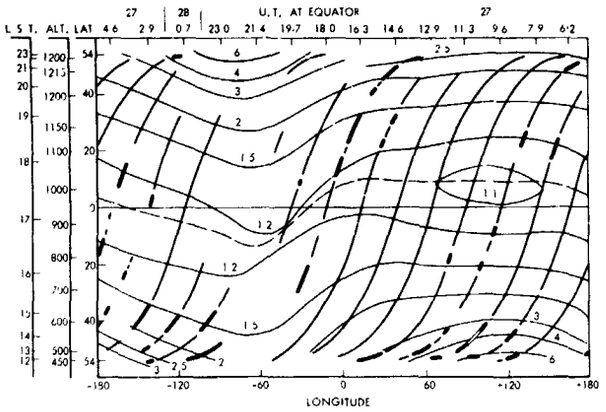

FIGURE 5.—Enhancements for May 27–28, northbound passes. The contours are intersections of L shells with the satellite orbit.

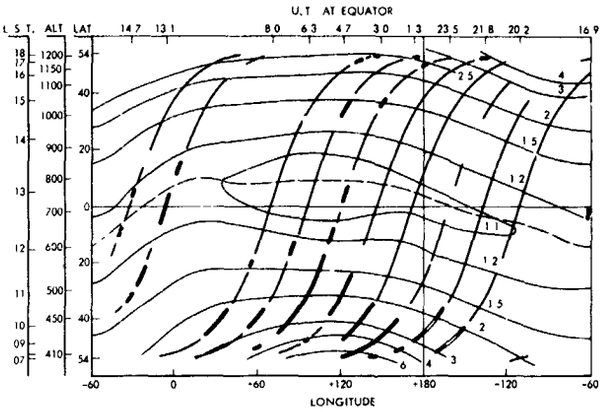

FIGURE 7.—Enhancements for June 9–10, northbound passes.

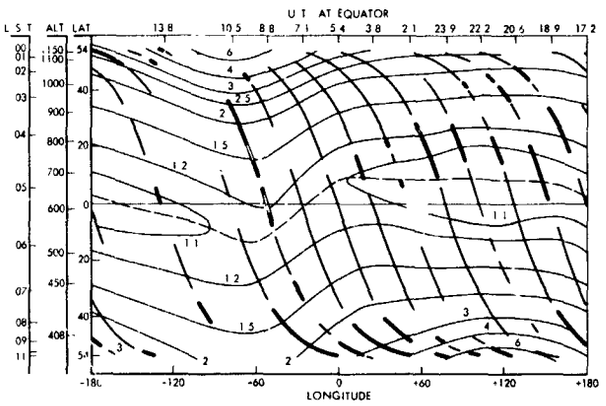

FIGURE 6.—Enhancements for May 27, southbound passes.

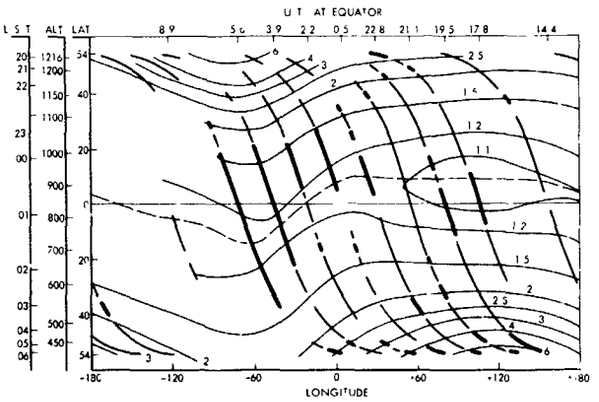

FIGURE 8.—Enhancements for June 9–10, southbound passes.

was a small gap but the sourrounding data suggested a high probability of enhancement, the gap has been bridged by double fine lines. The magnetic equator has been shown as a dashed line, and contours of L values have been drawn. Each pass has been identified by the universal time when the geographic equator was crossed.

QUIET DAY VARIATIONS

Figures 1 and 2 show the contours of electron density for northbound and southbound passes on May 24th, a very quiet day (K sum = 3+). Figures 3 and 4 give the contours for June 20th, when K sum = 8o.

Several interesting regions can be seen:

1. There is a strong maximum on the magnetic equator, centered at longitude —90° This is well-defined on figures 1, 2 and 3, but is absent on figure 4. It is near the South Atlantic anomaly, but displaced about 45° westward. This maximum persists for se eral days at a time, and on other occasions disappears completely. The presence of the maximum is not inconsistent with the model of the diurnal variation of the equatorial anomaly described by King et al (1963a), since the anomaly would not have formed at the local times of figs. 2 and 3, and for fig. 1 the peak would be below the altitude of Ariel. The absence of a maximum in fig. 4 is more puzzling.
2. The regions of high magnetic latitude centered in the northern hemisphere at longitude −90°, and in the southern at

+90°. Muldrew (1963) and others have noted a minimum in electron density extending for about 3° in latitude in the vicinity of the magnetic shell $L=3$ to 4. Figures 1, 2, and 4 show this minimum in the northern hemisphere. It is not present on figure 3. The southern hemisphere region shows a minimum only on figure 4. There is no evidence of it on 1 and 3, and there is a strong maximum on 2. From these and other contour maps it is evident that there is a diurnal variation of this feature. For the southern (winter) hemisphere the electron density (relative to that of neighbouring latitudes) is a minimum during the local night hours, and a maximum in the late morning. For the northern (summer) hemisphere, the local time variations are similar, except that the minimum is deeper and more persistent, and just disappears near noon. It is interesting to note in the high southern latitudes near longitued −100° that the diurnal variation of relative electron density is opposite to that at longitude +90°.

3. On figure 4 a pronounced minimum is evident along the magnetic equator. In the original data this minimum could be for every pass over the equator. It appears to be a feature of the evening ionosphere. It also deviates south of the magnetic equator into the region of the South Atlantic anomaly. The altitude and local time for the minimum as seen in figure 4 are such as to place it some 500 km above the peak of the equatorial anomaly. It is therefore a new and apparently independent phenomenon.

DISTURBANCE EFFECTS

For details of the magnetic conditions for the different disturbance periods, refer back to Table 1. The general impression from the curves of figs. 5–8, and other similar plots, is a tendency for enhancements to occur along magnetic shells, which merge as the disturbance increases. The patterns do not show complete shell formation except in the region of $L>3$. This may be linked with the comparative weakness of the disturbances, and the fluctuations of magnetic activity. Favoured L values would appear to be 1.2 ± 0.1, 1.5 ± 0.1, 2.0 ± 0.2, 2.5, and generally for $L>3$. Other disturbance features seem to vary from storm to storm.

Figures 5 and 6 show enhancements for the minor disturbance of May 27th. From the scale of universal time it will be seen that the passes have been folded to accommodate them all on one scan of longitude. For example on fig. 5 the pass for 0.7 hours on May 28th is next to that for 2.9 hours on May 27th, and the upper portions of passes for 6.2 and 7.9 hours appear on the left of the diagram. A comparison of the enhancements in the high southern latitudes reveals differences in distribution which are due partly to differences in storm time, in that a clear progression to lower L values occurs, particularly in fig. 6. This is probably masked by local time effects to some extent in fig. 5, in that the higher level of undisturbed electron density reduces the relative size of an increase. In fig. 6 it is notable that the enhancements near the magnetic equator are confined almost entirely to the northern hemisphere.

The effects due to a more significant disturbance on June 9th-10th are shown in figs. 7 and 9. Rothwell et al (1963) have reported on the enhancements in the high southern latitudes for this disturbance. Note the shift in the origin of the longitude scale in fig. 7 in order to include the more marked enhancements on the one graph. The major feature of this plot is the broad region of enhancement in the southern hemisphere, which moves toward the equator as the storm intensifies. This storm-time effect receives further support from the coincidence that the disturbance lasted 36 hours, and so a direct comparison of enhancements for the same latitude, longitude, height and local time could be made for successive days. Passes at 1.8, 3.5 and 5.1 hours on June 9th (not shown in the figure) show enhancements in high southern L regions for $L>3$. This compares with L down to 2, 1.5 and 1.3 for the corresponding passes on June 10th. The equatorial enhancements for this figure are similar to those noted by King et al (1963b) in the equatorial anomaly region for the major disturbance of September 22nd, 1963. Figure 8 is

remarkable for the strong night-time enhancement near the magnetic equator, which was most pronounced in the vicinity of the South Atlantic anomaly. Passes for 2.7 and 4.3 hours on June 9th also show this strong equatorial enhancement. The northern hemisphere part of the Sayers shell for $L=1.27$ was very prominent in the longitude region $-70°$ to $+40°$ for the whole of the period June 8th-13th.

The disturbance on June 21st-22nd, the graphs for which are not reproduced, showed enhancements confined almost entirely to the high latitude regions.

CONCLUSIONS

1. Longitudinal irregularities exist even in magnetically very quiet periods. However, the pattern changes to some extent between successive quiet periods.
2. The enhancements show a structure resembling magnetic shell forms, which suggests a particle origin. The tendency of L values to decrease as magnetic activity increases also resembles precipitation zones of the outer Van Allen belt; also the occurrence of a maximum over the South Atlantic anomaly.
3. Therefore it appears that particle effects are at least partly responsible for the ionization irregularities. In this case, the changes in the pattern cannot reflect variations in flux associated with local geomagnetic field changes in the vicinity of the measurements. They must therefore be mapping in some way the geomagnetic field at high L values, where the particles must either be produced or accelerated.

V. FIELDS AND PARTICLES

MEASUREMENT OF PRIMARY COSMIC RAY CHARGE AND ENERGY SPECTRA DURING 1963*

V. K. BALASUBRAHMANYAN† AND F. B. McDONALD

The differential energy spectra of *H* and *He* nuclei in the interval 100–800 Mev/nuc, the integral *H* and *He* flux >800 Mev/nuc and the cosmic ray charge spectra in the range $Z=1-8$ have been measured using a three element telescope consisting of two thin scintillation counters and a Cerenkov Counter. The measurements were made from Fort Churchill, Canada on a Skyhook balloon flight during June, 1963. The ratio of $Li+Be+B/C+N+O$ appears to be constant in the two regions 400–800 Mev/nuc and >800 Mev/nuc. This ratio extrapolated to the top of the atmosphere is $0.28\pm.08$. A marked difference is observed in the form of the low rigidity differential spectra of *H* and *He*. These measurements are compared with the results available from the last solar cycle.

INTRODUCTION

The objectives of the experiment reported here are two fold:

(a) To develop an improved detector system with adequate charge and energy resolution so that individual charges, their absolute intensities, energy spectra and time variation could be studied with the long range aim of using the detector in a satellite borne experiment.

EXPERIMENTAL SET-UP

A schematic drawing of the detector system is shown in Fig. 1. The system is similar in principle to that reported by McDonald and Webber[1] except for some technical improvements to achieve better charge and energy resolution. For each particle traversing the telescope, the pulse height from all three detectors are recorded. For each detector there is a 512 channel pulse height analyzer and the data is recorded on a balloon borne tape recorder. The total weight of the complete system including batteries and pressure can is 65 lbs.

The results of a balloon flight on 24 June 1963 are reported here. During this flight the balloon remained for 12 hours at a ceiling altitude of 5 gms/cm². The equipment performed reliably throughout the flight and the pre-flight and post-flight calibrations were in agreement with each other. The period during the flights was characterized by a quiet sun, with no abnormal activity.

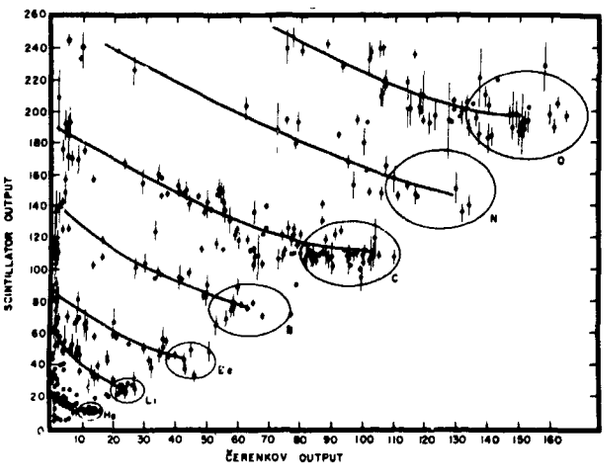

FIGURE 2.—Plot of Cerenkov output vs. ionization loss in telescope.

RESULTS

Fig. 2 shows the charge resolution obtained in the region $Z=2-8$. In the region 350 Mev/nuc (>5 Cerenkov Pulse height) there is excellent resolution between all components. The L/M ratio at the observation level of 5 gm/cm^2 for the energy range 400–800 Mev/nucleon, $=.36\pm.07$ where as for the energy >800 Mev/nucleon the ratio is $.36\pm.09$. The ratio extrapolated to the top of the atmosphere using fragmentation parameters of Friedlander et al.[2] is $0.28\pm.08$ in agreement with the results at Texas 41°N.[3]

A summary of the results on the charge distribution obtained in this experiment is shown in Table 1. Also shown there, are results from previous measurements from other experiments.

MODULATION

Fig. 3 shows the integral intensity of *He* nuclei, the medium and heavy nuclei as a function of neutron count. For rigidity >1.5 BV the agreement between the curve obtained by Webber and McDonald during the last solar minimum, shows that at medium rigidities the sea level neutron count correlates well with the direct measurements. This gives a measure of confidence regarding the accuracy of the measurements.

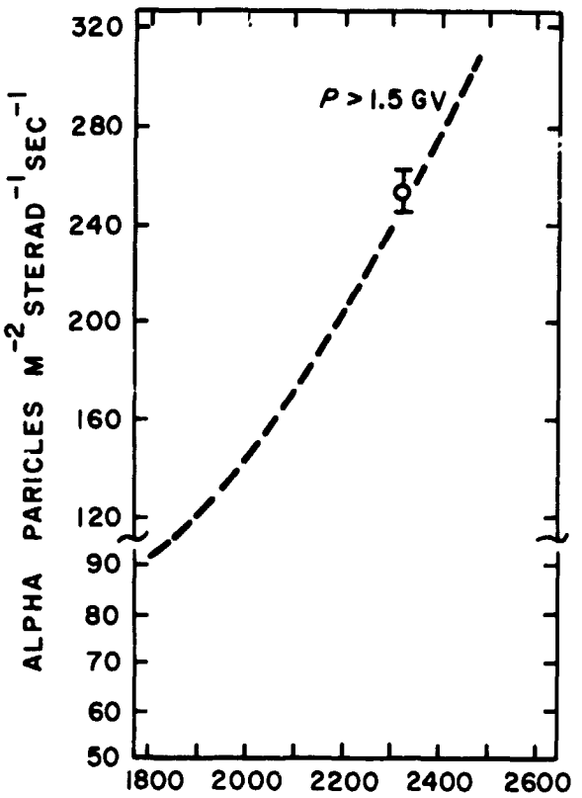

FIGURE 3.—Mt. Washington neutron rate.

Fig. 4 shows the differential rigidity spectra of protons and *He* nuclei. There are some interesting

TABLE 1.—*Comparison of Charge Distributions Obtained at the Top of the Atmosphere Charge Distribution (Percent)*

Charge	Balasubrahmanyan & McDonald	Waddington[3]	Aizu[4] et al	Tamai[5]	Fichtel[6]	O'Dell[7] et al

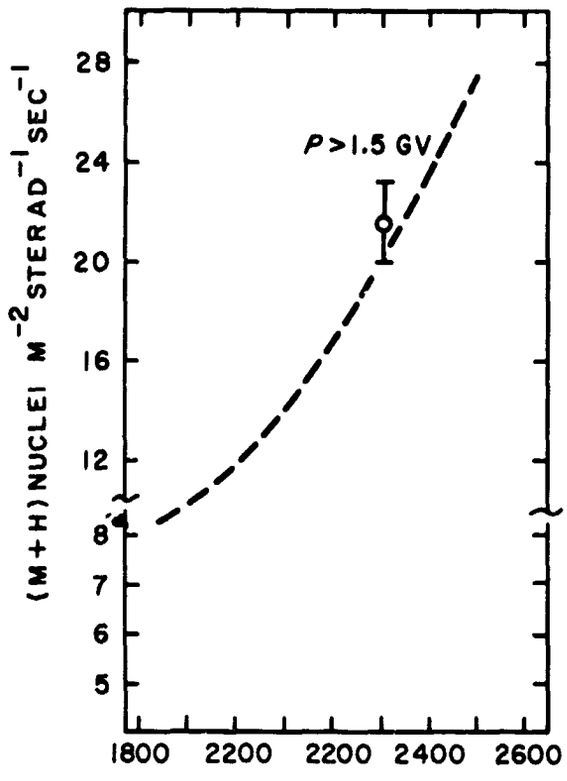

FIGURE 4.—Mt. Washington neutron rate.

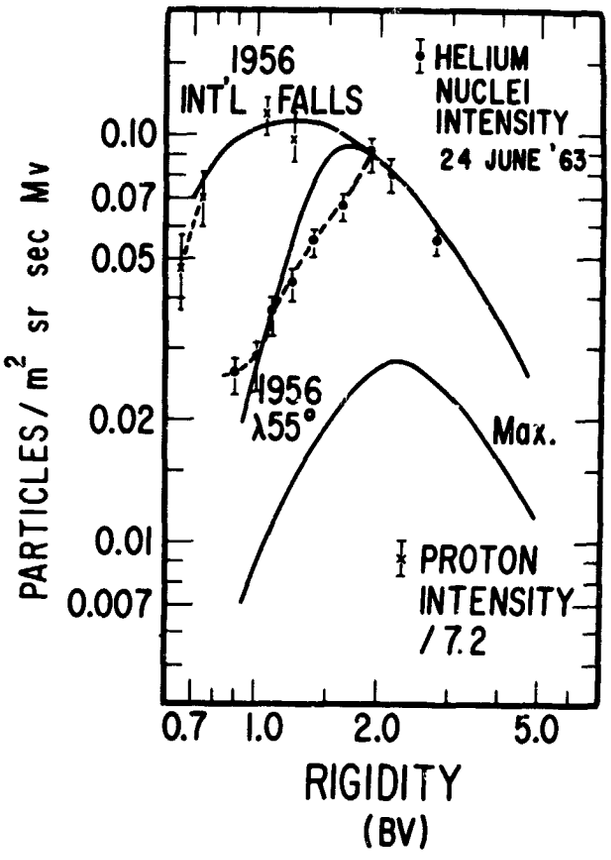

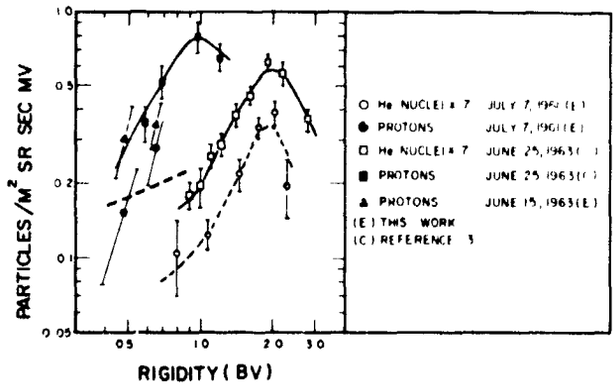

FIGURE 5.—Alpha and Proton Rigidity Spectra

features which this figure reveals. First the differential intensity of Helium nuclei of rigidity >2BV appears to have recovered to the previous solar minimum period. On the low energy side, the previous measurement at International Falls, Minnesota is higher than both the proton and *He* curves of the present experiment. So, on the low rigidity side the recovery is still not complete.

Another interesting feature is the difference in rigidity spectra between the proton and *He* nuclei curves. The recovery for protons has been faster than for *He* nuclei for the same rigidity. In Fig. 5 the results of the counter measurements and that of Nuclear Emulsion measurements by Fichtel et al.[8] are shown. The good agreement between the results of these two entirely different experiments, particularly in the field of intensity measurements of low energy protons, where the secondary corrections etc. are applied on an entirely different and independent basis, gives one a measure of confidence in the interpretation of these results and their bearing on the modulation process.

Parker[9,10] has proposed a diffusion model, wherein the solar wind is responsible for the modulation. In this model, the modulation at a given rigidity is different for particles with different charge to mass ratios because of the velocity dependence of the diffusion mechanism. This model predicts that the differential spectra of the helium nuclei and protons should be different, with the *He* nuclei being suppressed more than

protons. The observations reported here are at least in qualitative agreement with Parker's theory.

MAGNETOHYDRODYNAMIC SHOCK STRUCTURE IN A MOVING MAGNETIC FIELD*

DAVID B. BEARD†

The shock structure around a cylinder immersed in a cold collisionless plasma stream containing a weak magnetic field has been investigated in two dimensions. The stream pressure on the boundary of the sheath is proportional to $\cos^2\psi$ where ψ is the angle between the stream velocity and the normal to the sheath. The thickness of the sheath and particle density in the sheath on the upstream side of the cylinder have been found to be nearly constant. A tear drop shaped vacuum is formed downstream from the cylinder. The plasma electrons have essentially all the ion stream kinetic energy in the transition sheath upstream of the cylinder but the ion stream energy is regained downstream from the cylinder. The importance of this shock structure when applied to the earth's magnetosphere and the generation of Type I comet tails is discussed briefly.

1. INTRODUCTION

The solar wind, consisting of a cold plasma flowing constantly at high velocity away from the sun, is now known to contain a weak magnetic field [1,2] oriented somewhat perpendicular to the stream velocity vector. Though the magnetic field carried along in and moving with the stream velocity is so weak that the magnetic field pressure is only one percent of the stream pressure, the field prevents the particles from moving independently of one another. The result is that any object larger than a few ion gyroradii will create a magnetohydrodynamic shock when immersed in the solar wind.[3-9]

The distinctive features of shocks generated in the solar wind are caused by the shape of the object creating the shock and the effect of arresting the velocity of the magnetic field lines which initially must move with the wind velocity since the stream pressure is overwhelmingly greater than the magnetic pressure. The plasma and its field are compressed on the upstream surface of the obstacle and much of the stream kinetic energy is diverted to gyromotion perpendicular to the compressed magnetic field. A simple extension of ordinary M theory of the magnetic pinch effect shows that on entering the compressed field region through the charge separation electric field on the surface, the plasma electrons will acquire essentially all of the kinetic energy of the ion stream in the solar wind. This energy is returned to the ion stream after the plasma in the compressed field region moves around to the downstream side of the obstacle.

In the work presented here a simple model is discussed in which a cylinder of intense magnetic field parallel to its axis presents an obstacle to a cold plasma stream containing a weak magnetic field parallel to the cylinder axis. Besides the inherent interest of the model in understanding magnetohydrodynamic shock structure under such unusual conditions, the model illuminates some gross aspects to be expected in astrophysical problems which occur, for example, in the boundary of the earth's magnetic field and in the tail rays of comets.

2. PHYSICAL CHARACTERISTICS OF THE TRANSITION SHEATH SURROUNDING A CYLINDER IN A MAGNETIZED PLASMA STREAM

The simple idealized model considered here is illustrated in Fig. 1. A proton-electron plasma, collisionless and with no thermal motion, is streaming parallel to the polar axis with velocity v_0, and encounters a cylinder of radius R containing an arbitrarily intense magnetic field sufficient

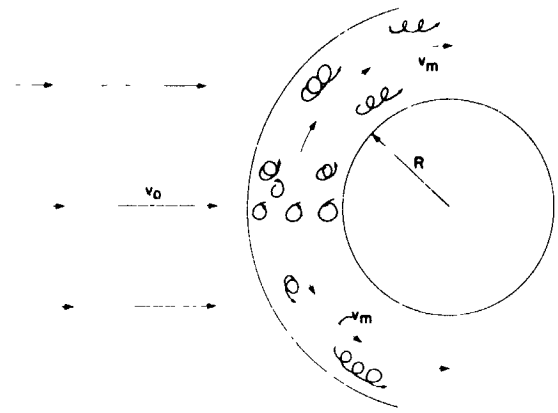

FIGURE 1.—Illustration of solar wind containing a weak magnetic field perpendicular to the plane of the figure incident on a cylinder of radius R. The arrows represent the velocity of the field lines (particle guiding centers) in the free stream v_0, and in the transition sheath, v_m. The circles and loops represent partial trajectories of the particles while in the sheath.

to exclude the incident plasma stream. (In general the obstacle need furnish only a spatially varying magnetic field pressure, $H_g^2/8\pi$, but a cylindrical shape has been introduced at the start to simplify the discussion of the paramount physical features resulting from the analysis.) Finally, the incident plasma stream is assumed to contain a weak magnetic field, parallel to the cylinder axis, which is carried along with the plasma. The stream magnetic field exerts a pressure of only one percent of the stream pressure and the field traveling with the stream velocity v_0 is maintained by the small gyromotion of the plasma in the moving velocity frame of the plasma stream. In this connection it might be noted that the preliminary analysis by Dr. M. Neugebauer of the Mariner R plasma data yielded an effective plasma thermal energy of the order of 10–30 electron volts in a stream energy of the order of a kilovolt. Dr. Neugebauer's analysis was made by examining the energy spread parallel to the stream motion, but the presence of a magnetic field and the gyromotion it causes guarantees that the result is valid for the particle energy component perpendicular to the stream motion as well.

The particle pressure on the outer boundary of the transition sheath is given by

$$p_p = (n_0 v_0 \cos\psi)(m_p v_0 \cos\psi) = n_0 m_p v_0^2 \cos^2\psi \qquad (1)$$

where n_0 is the proton density in the stream m_p is the proton mass and ψ is the angle between the normal to the outer boundary surface of the transition sheath and the stream velocity vector. The second paranthetical factor represents the momentum change of the incident particles at the boundary as they enter the sheath. The external pressure confining the particle and enhanced magnetic field pressure in the sheath acts perpendicularly to the surface. Hence there is no change in particle center of motion momentum component parallel to the boundary which would result in a momentum change factor not linearly dependent on $\cos\psi$.

There is, of course, a very important change in the particle motion on crossing the boundary of the sheath and that is that near the stagnation point, in particular, much of the stream motion is diverted to gyromotion perpendicular to the magnetic field. Although the magnetic field is too weak to contribute effectively to the pressure near the stagnation point, it does cause the charges to rotate about the lines of force. Particle pressure, however, dominates every other consideration and the guiding center of the particles are caused to move towards decreasing pressure gradients "dragging" the magnetic field lines along with them. The particle pressure within the transition sheath is given by

$$p_p = \tfrac{1}{2} n_s m_p v_p^2 = \tfrac{1}{2} n_s m_p (v_0^2 - v_m^2) \qquad (2)$$

where n_s is the ion density within the sheath, v_p is the particle velocity component perpendicular to the field, and v_m is the velocity of the guiding center, that is, the velocity of the magnetic lines of force. The factor 1/2 arises because of the two dimensional motion of the particles within the sheath as opposed to the monodirectional motion of the stream pressure. In three dimensions, where the particle motion is also along the lines of force, the factor might be 1/3.

We thus obtain an expression for the pressure equality on the boundaries of the sheath.

$$n_0 m_p v_0^2 \cos^2\psi + H_0^2/8\pi = \tfrac{1}{2} n_s m_p (v_0^2 - v_m^2) + (n_s^2/n_0^2) H_0^2/8\pi = H_c^2/8\pi \qquad (3)$$

where H_c is the magnetic field intensity in the cylinder at the inner boundary. Since the plasma is collisionless, the magnetic field intensity is directly proportional to the particle density, and

thus the magnetic field intensity anywhere in the sheath is $(n_s/n_0)H_0$. Particle thermal pressure would be easy to include for similar reasons. Since n is proportional to H and the square of the thermal velocity, v_{pt}^2, is proportional to H if the motion is adiabatic, the particle thermal pressure is a constant multiple of the magnetic pressure and may be included by multiplying H_0^2 by an appropriate factor.

The change in the external pressure, P, as a function of the distance along the boundary of the sheath, l, results in a pressure gradient which accelerates the plasma within the sheath.

$$n_s m_p \frac{dv_m}{dt} = n_s m_p v_m \frac{dv_m}{dl} = -\frac{dP}{dl} + \frac{d}{dl}\left(\frac{n_s^2}{n_0^2}\frac{H_0^2}{8\pi}\right) + \frac{m_p}{2}(v_0^2 - v_m^2)\frac{dn_s}{dl} \quad (4)$$

which may also be obtained by differentiating Eq. 3 with respect to l. Throughout most of the upstream side of the cylinder H^2_0 is negligible compared with the particle pressure and Eq. 3 may be approximated by

$$n_s = 2P/m_p(v_0^2 - v_m^2)$$

which satisfies Eq. 4 since the last two terms in Eq. 4 are negligible in these circumstances. Thus, $v_m \sim v_0 \sin\psi$ throughout the transition sheath on the upstream side and n_s is nearly constant and equal to $2n_0$. As ψ approaches $\pi/2$, however, the magnetic pressure becomes significant and n_s decreases with l depending on ψ as

$$n_s \sim n_0[1 + \tfrac{1}{4}(8\pi n_0 m_p v_0^2/H_0^2)\cos^2\psi - (3/32)(8\pi n_0 m_p v_0^2/H_0^2)^2\cos^4\psi] \quad (5)$$

Using the approximations valid on the upstream side of the cylinder the position of the outer boundary to the transition sheath is easily obtained by requiring particle conservation. The number of particles arriving per second per unit cylinder length within a distance, y_2, from the polar axis is $n_0 y_2 v_0$; the number leaving the transition region per second per unit cylinder length is $n_s(r_2 - r_1)v_0 \sin\psi$ (see Fig. 2).

$$r_2 - r_1 \sim r_2 \sin\theta_2/2 \sin\psi \quad (6)$$

For a cylindrical obstacle for which r_1 is constant, $\theta_2 = \psi$, and

$$r_2 = 2r_1 \quad (7)$$

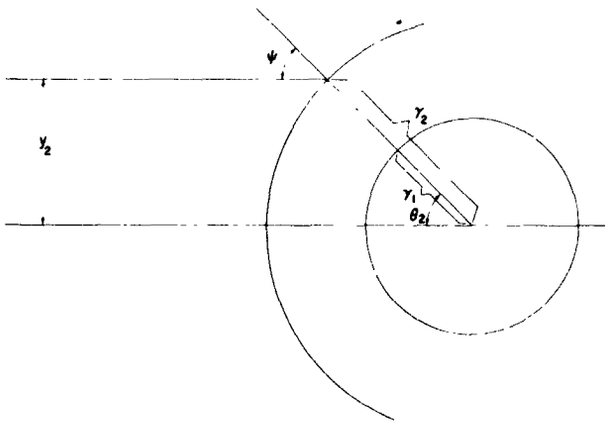

FIGURE 2.—Diagram of use of constant flux condition in determining the sheath thickness, $r_2 - r_1$, by which particles leave a volume of unit height after entering the volume within the length y_2.

If the obstacle were not cylindrical a differential form of the constant flux condition, Eq. 6, would be required

$$n_0 v_0 d\,l \cos\psi = n_s(r_2 - r_1)v_0 d(\sin\psi)$$

$$\frac{d\psi}{dl} = \frac{n_0}{n_s}\frac{1}{r_2 - r_1} = \frac{1}{r_2}\frac{d\psi}{d\theta} \quad (8)$$

which yields Eq. 7 in the region where $n_s = 2n_0$ if r_1 and r_2 are now regarded as functions of ∂. If n_s is a decreasing function of θ, as it is near $\theta \sim \psi \sim \pi/2$, $r_2 - r_1$ increases faster than r_2 and $\frac{d\psi}{d\theta}$ is less than unity. In this region, the parametric equations 5 (or rather 3) and 8 must be solved numerically.

The magnetic pressure cannot be neglected in the region

$$\theta \sim \psi \gtrsim \cos^{-1}[H_0/(8\pi n_0 m_p v_0)^{1/2}] \sim 84° \quad (9)$$

where the stream velocity is

$$v_m \sim v_0 \sin\psi \sim 0.99 v_0 \quad (10)$$

and

$$(v_0^2 - v_m^2)^{1/2} \sim 0.10\, v_0$$

Therefore, on the downstream side of the cylinder, the guiding center of stream velocity in the transition sheath is again approximately v_0, and the velocity perpendicular to the field lines and v_0 is less than $0.10\, v_0$. The stream expands freely into the vacuum behind the cylinder so as to form a diffuse triangle shaped tail, based on

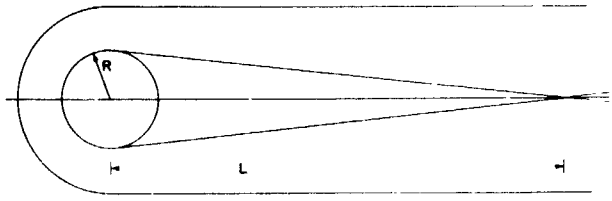

FIGURE 3.—The shock structure behind a cylinder of radius R. The length of the vacuum downstream from the cylinder $L \sim RV_0/(v_0^2 - v_m^2)^{\frac{1}{2}}$.

simple kinematics, which closes more than ten cylinder radii downstream and leaves a turbulent wake as illustrated in Fig. 3.

3. THE SHOCK PRODUCED ENERGETIC ELECTRONS IN THE TRANSITION SHEATH

The preceding section has given us a general description of our simple two dimensional model problem as illustrated in Figs. 1–3. A weakly magnetized plasma moving with velocity v_0 enters a transition sheath where the velocity of the particle's guiding centers, that is, the velocity of the magnetic lines of force, changes abruptly at the outer boundary of the transition sheath to a lower velocity, v_m. Ferraro[10] and especially Dungey[11] and Rosenbluth[12] have shown how a charge separation layer will be created at any boundary where the magnetic field is suddenly increased on the side away from the plasma. Beard,[13] Grad,[14] and Sestero[15] have further developed the theory of the electric field on the boundary which serves to energize the electrons at the expense of the positive ions. The electric field arises due to the difference in momentum between the electrons and the positive ions, and thus there is no field in any region where the momenta of the opposite charges are equal.

In the simple two-dimensional problem discussed in this paper, it might be anticipated that when the plasma enters and passes through the transition sheath the charges will have gained or lost potential energy (depending on the sign of their charge) as though they had passed through permeable condenser plates at the boundary. Hence, if there is no reverse electric field, the electrons will have acquired essentially all of the initial stream kinetic energy of the positive ions.

Following Rosenbluth's [12,13] analysis in which the plasma did not enter the region of increased field intensity, we write, for the changed conditions of this problem, the equations of motion of a charge initially moving parallel to the x axis

$$\ddot{x} = \frac{q}{m}E(x) + \frac{q}{mc}H\dot{y} \tag{11}$$

$$\ddot{y} = -\frac{q}{mc}H(\dot{x} - v_m) \tag{12}$$

where the coordinate system is illustrated in Fig. 4, q and m are the charge and mass of the charged

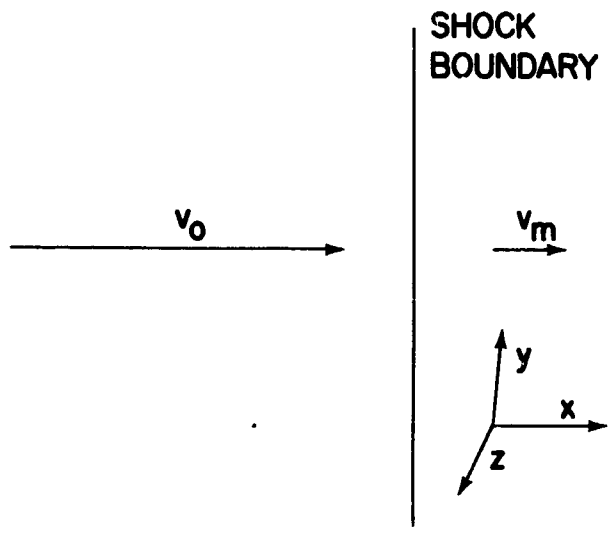

FIGURE 4.—The coordinate system used in analyzing particle motion in a magnetic field parallel to the z axis whose field lines travel with a velocity v_0 to the left of the shock boundary and with velocity v_m to the right of the shock boundary.

particle, E is the electric field perpendicular to the boundary which is tangent to the y, z plane, H is the magnetic field and is parallel to the Z axis, and v_m is the velocity of the guiding centers (i.e. the magnetic lines of force) which are assumed to be moving entirely parallel to the x axis for this part of the analysis. Eq. 12 is easily integrated and yields the y component of the particle velocities.

$$\dot{y} = \frac{-q}{mc}x / \int_{-\infty}^{t} H\,(x' - v_m)dt' \tag{13}$$

Hence the y component of the particle momenta is the same for both electrons and protons.

The particle densities are inversely proportional to the x component of the average velocity of the particles. To avoid the impossibly large electric

fields resulting from excessive charge separation the x component of the average velocities of the particles must be kept equal everywhere. This requires that in being slowed from an initial velocity v_0 to the final guiding center velocity of V_m, the x-component of the deceleration of the electrons must be equal to the deceleration of the ions. Thus Eq. 11 and 13 yield the equality

$$\frac{e}{m_e}E(x)-\left(\frac{e}{m_e c}\right)^2 H\int_{-\infty}^{t} H\,(x'-v_m)dt'=-\frac{e}{m_i}E\,(x)$$

$$-\left(\frac{e}{m_i c}\right)^2\int_{-\infty}^{t} H\,(x'-v_m)dt'$$

where the subscripts e and i refer to electron and positive ion and $q_e=-e$, $q_i=e$. Neglecting the right hand side of this equation as being of order m_e/m_i smaller than the left hand side we obtain the familiar M theory result

$$E(x)=\frac{e}{m_e c^2}H\int_{-\infty}^{t} H\,(x'-v_m)dt' \qquad (14)$$

If Eq. 13 and 14 are inserted into Eq. 11, then the integral of Eq. 11 after multiplication by x is to zero order in m_e/m_i

$$x_i^2=v_0^2-\frac{2e}{m_i}\int_{-\infty}^{x} E\,(x')dx'$$

Let X_M represent the position at which the incident proton first reaches the final guiding center velocity, V_m, (i.e. the position beyond which the compressed field is constant.) then,

$$\tfrac{1}{2}m_i(v_0^2-V_m^2)=e\int_{-\infty}^{X_M} E\,(x')dx' \qquad (15)$$

Eq. 15 has the very obvious physical interpretation that the total potential drop for $-\infty<x<x_M$ is equal to the change in the ion stream kinetic energy divided by the ion charge. For $x>x_M$ charge neutrality does not require $\dot{x}_e/x'_i$; only their averages, V_m, must be equal.

Since the momenta of the electrons and protons are equal, no further charge separation takes place; the gyroradii of the particles are equal. The momentum of an ion in the stream $m_i v_0$ has been reduced to $(m_e/m_i)^{1/2}m_i v_0$ in exerting the pressure on the boundary needed to confine the enhanced magnetic field interior to the boundary. The kinetic energy of the ions has been reduced, however, from $\frac{1}{2}m_i v_0^2$ to $\frac{1}{2}m_e v_0^2+\frac{1}{2}m_i v_M^2$. The considerations of the previous section are still valid since the total particle pressure in the transition layer is not affected by the electrical potential at the boundary since the electron energy in the transition layer is $\frac{1}{2}m_i v_0^2-\frac{1}{2}m_i v_M^2$.

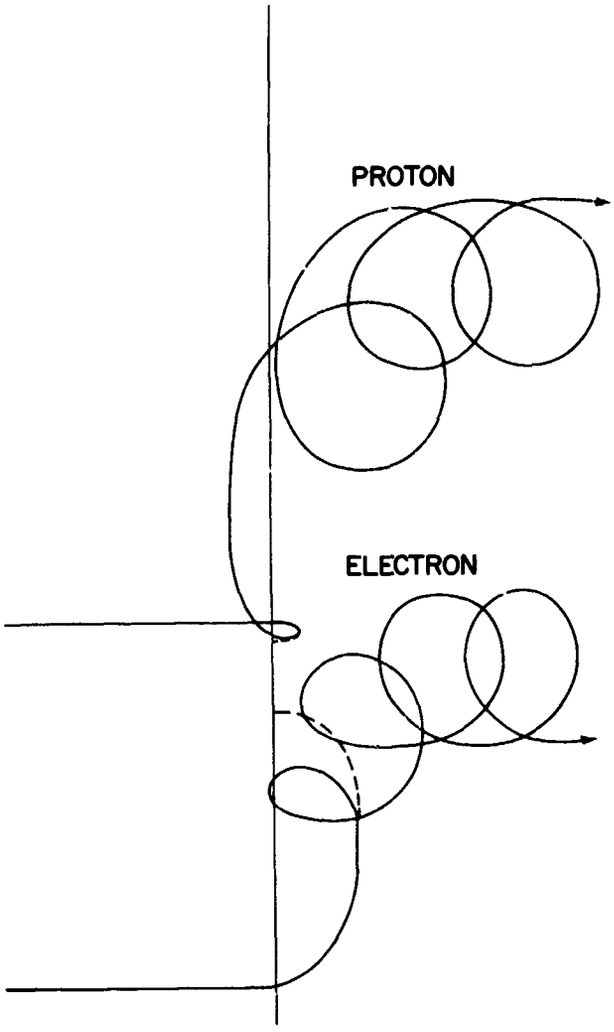

FIGURE 5.—Electron and proton trajectories initially traveling with a moving magnetic field which is slowed down and compressed, downstream from the shock boundary.

A free hand drawing of the particle motion as it crosses the boundary is shown in Fig. 5 for conditions near the stagnation point. The conclusions are essentially unchanged at other points on the boundary as illustrated in Fig. 6 if one considers only the component of the guiding center

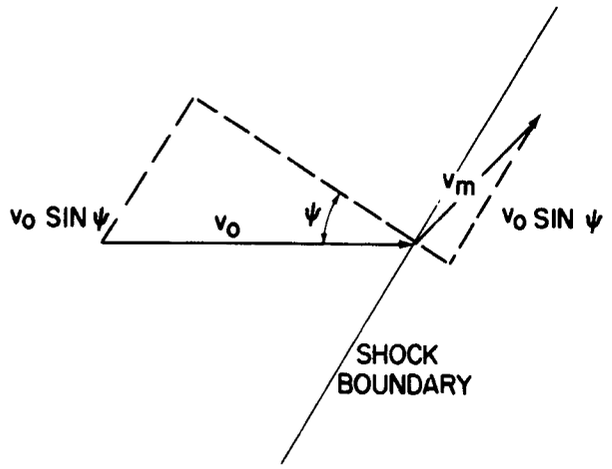

FIGURE 6.—The geometry of the guiding center or field line motion on both sides of the shock boundary for oblique incidence.

motion perpendicular to the boundary. The component of the stream velocity parallel to the boundary is the same on both sides of the boundary and therefore the problem reduces to the stagnation point case in a coordinate frame which moves with the velocity $v_0 \sin\psi$ parallel to the boundary and $v_0 \cos\psi$ supplants v_0 in the stagnation point considerations. In accelerating to nearly the free stream velocity again in its motion away from the stagnation point, the motion of the plasma in the transition sheath causes the initial ion kinetic energy to be recovered at the expense of the electron energy.

CONCLUSIONS

A cold plasma stream containing a weak magnetic field (field pressure much less than particle stream pressure) will be compressed on the upstream surface of a cylindrical obstacle whose axis is parallel to the magnetic field. The particle density and magnetic field intensity within the transition sheath on the upstream side are double their free stream value. The thickness of the sheath is equal to the cylinder radius over almost all of the upstream surface and thickens slightly near the joining of the upstream and downstream surfaces due to the additional magnetic pressure, however small, in the transition sheath. The enhanced magnetic pressure in the transition sheath, however slight, prevents the ions from returning completely to their initial free stream motion on the downstream side of the cylinder. As a result, a plasma stream, even though the particles initially have a unique velocity, will expand into the vacuum behind the cylinder. In the case of a plasma with some thermal velocity $(kT/2\pi m)^{1/2}$ the vacuum downstream would be a diffuse isoceles triangle whose height would be $v_0 (2\pi m/kT)^{1/2} R$ where v_0 is the initial stream velocity and R is the cylinder radius (1/2 the triangle base.)

The enhanced magnetic field in the transition sheath creates a charge separation layer at the boundary of the undisturbed plasma stream. The total change in electrical potential across this layer is equal to half the stream pressure on the transition sheath. The plasma stream moves through the charge separation layer, and, on entering the transition sheath, the electrons acquire all the kinetic energy the ions would have had perpendicular to the magnetic field in the absence of the charge separation layer. At the stagnation point the electron kinetic energy in the transition sheath equals the initial ion kinetic energy in the free stream, but elsewhere in the transition sheath the electron kinetic energy equals the difference between the ion free stream kinetic energy and the ion stream energy in the transition layer.

ASTROPHYSICAL APPLICATIONS

The application of this work to Type I comet tails is straightforward and will be reported elsewhere. The slight ionization of massive cometary molecules through charge transfer with protons in the solar wind cause the interplanetary magnetic field lines to slow down drastically in overcoming the inertia of the massive cometary ions initially at rest. The energetic electrons in the transition sheath which forms on the surface of the "slowed" field lines then rapidly and efficiently ionizes hundreds of cometary molecules per cc. The energetic electrons will further rapidly diffuse out along the field lines (as suggested by Axford in private conversion) and pull the ions out along the field lines so as to form the striking ray structure known as Type I comet tail rays.

The simple model examined in this paper also yields a good qualitative understanding of the phenomena observed at the edge of the earth's magnetic field and enables predictions about the

energy of the charges in the magneto-sheath to be made. The sphericity of the earth's magnetosphere introduces a new physical dimension. In the plane containing the stagnation point and the magnetic field lines the particle pressure both inside and outside the outer boundary of the transition sheath (A. J. Dessler has suggested the name magneto-sheath) is still proportional to $\cos^2\psi$. The particles are decoupled, however, from the magnetic field in the direction of the field, and conservation of magnetic flux requires that the magnetic field intensity be approximately independent of distance from the stagnation point or $\cos\psi$ in the case of a cylinder and to *increase* away from the stagnation point in the case of a sphere. Therefore, in this plane the shock boundary around a circular surface would expand faster than in the plane at right angles to the interplanetary magnetic field. The particle density in this plane away from the stagnation point is less than in the plane perpendicular to the magnetic field.

The particle pressure in this plane is *not* communicated along the field lines and this introduces a complication in the analysis depending on the isotropy of the particle velocity discussed below. Free hand drawings of the field lines are illustrated in Figs. 7 and 8.

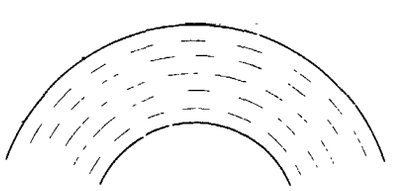

FIGURE 7.—Magnetic field lines indicated by dashed lines in free interplanetary space and in the transition sheath in the plane containing the field direction.

Another aspect of the magnetosphere problem is that turbulence on the surface or the sharp kinks produced in magnetic field lines where the interplanetary field lines are joined to the lines in the magnetosheath will invalidate the simple two dimensional analysis presented in this work. The particle motion in the magnetosheath will be more nearly isotropic in three dimensions

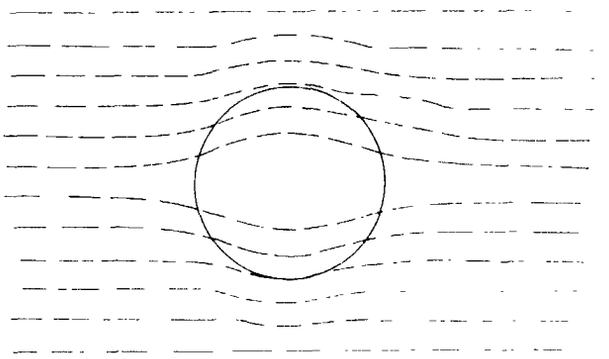

FIGURE 8.—Magnetic field lines, indicated by dashed lines, viewed in projection from the upstream side as they diverge and slide around a spherical obstruction bowing out most pronouncedly in the equatorial plane.

instead of being isotropic in twod imensions. This causes the particle density and field intensity to be three times the interplanetary values and the thickness of the sheath near the stagnation point to be more nearly one-half of the radius of curvature of the magnetosphere.

Independent of these considerations the sudden increase of the magnetic field intensity from the interplanetary field value to the magnetosheath value will cause the magnetosheath electrons to have the same momentum perpendicular to the field lines as the protons do. Thus the particle energy and pressure perpendicular to the field lines will be monopolized by the electrons. The particle energy and pressure parallel to the field lines will be monopolized by the protons, however, since charge separation effects will cause the electron and proton velocities to equalize.

ACKNOWLEDGEMENT

I would like to thank Dr. John Banister of Sandia Corporation for a helpful discussion of this problem. I would also like to thank both the Sandia Corporation and the Goddard Space Flight Center for their hospitality and support of this work.

SOLAR CYCLE CHANGES IN INNER ZONE PROTONS

ROBERT C. BLANCHARD† AND WILMOT N. HESS

N65-29503

Time dependent calculations of the inner Van Allen belt proton population show that large changes of the population up to a factor of 50 will take place during the solar cycle. The effect is most pronounced for the region of B–L space corresponding to minimum altitudes of 300–700 km. Because different energy protons respond to the changing solar cycle at different rates the proton energy spectra will change with time also.

The purpose of this paper is to calculate the expected changes in inner zone proton populations with time in the solar cycle.

Freden and White [1959] identified the penetrating component of the inner zone of the Van Allen belt as due to energetic protons and measured the energy spectrum of the protons of $E>75$ Mev. This and subsequent experimental work on Atlas rockets [Freden and White, 1960; Freden and White, 1962; Armstrong, Harrison, Heckman and Rosen, 1961] has confirmed and extended this finding and we now have a well-established proton energy spectrum at $L\sim1.4$, $B\sim.20$, which is about apogee for these flights, for near solar maximum (see Fig. 1). The analysis of this spectrum [Freden and White, 1960] has shown conclusively that the protons are produced by neutron decay.

One of the features of this component of the radiation belt is the time constancy. Measurements after a solar flare [Freden and White, 1962] gave essentially the same fluxes of protons as before the flare. For $L>1.6$ changes in proton spectra are seen [Naugle and Kniffen, 1961] associated with solar proton events [Pizzella, 1961]. These may be explainable in terms of neutrons produced in the polar regions by solar protons [Lenchek, 1962; Lingenfelter, to be published]. For $L<1.6$ only gradual changes in the proton populations have been observed on Explorer VII [Pizzella, 1961]. It was originally suggested [Pizzella, 1961] that such changes implied that neutrons could not produce all inner zone protons but this does not seem to be the case. Hess [1962] showed that slow changes in proton population were expected due to changes in the galactic cosmic ray flux during the solar cycle and more

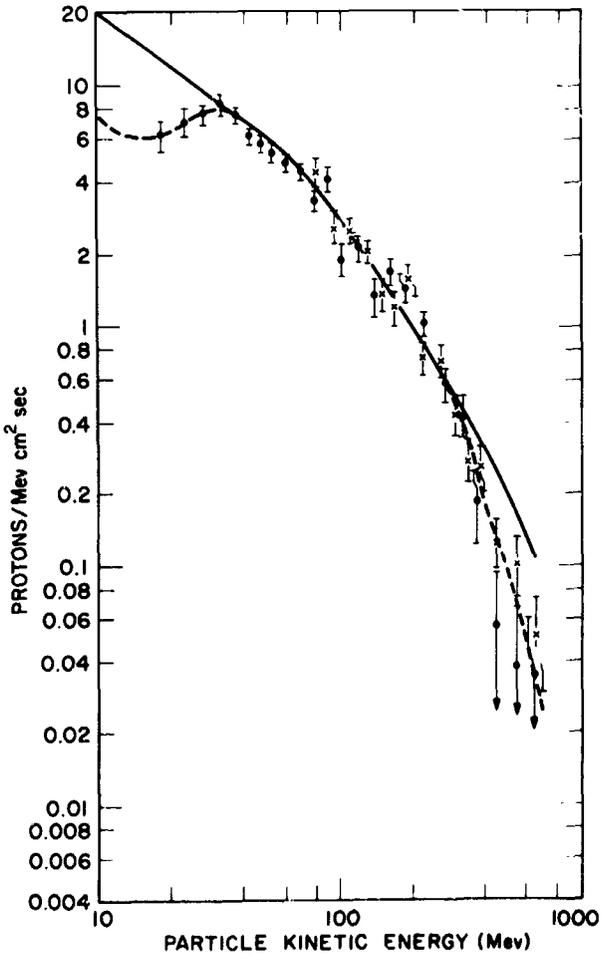

FIGURE 1.—The experimentally measured inner zone proton energy spectrum (Freden and White 1962) for $L\sim1.4B\sim.20$.

†This work was done as part of the requirements for a Master's Degree from the College of William and Mary.

importantly due to changes in the upper atmospheric density during the solar cycle. We will now make a quantitative discussion of the expected changes in proton populations for $L<1.6$.

The continuity equations for protons is usually written [Singer, 1958; Hess, 1959; Freden and White, 1960]

$$\frac{dN(E)}{dt}=+S(E)-L(E)+\frac{d}{dE}\left[N(E)\frac{dE}{dx}v\right]=0 \quad (1)$$

and the steady state population of protons $N(E)$ solved for. We are now interested in time variations so we will write the time dependent form of this equation

$$\frac{dN(E,t)}{dt}=+S(E,t)-L(E,t)+\frac{d}{dE}\left[N(E,t)\frac{dE}{dx}(t)v\right] \quad (2)$$

The source term $S(E, t)$ will use the neutron decay source strength of Hess for solar maximum $S(E)$ multiplied by a function of time $f(t)$ to consider the solar cycle variation in galactic cosmic ray flux as determined by McDonald and Webber [1961]

$$S(Et)=S(E)f(t)=\frac{0.8E^{-2\cdot0}}{\nu\gamma T_n}\frac{re^3}{r}F(t) \quad (3)$$

where $f(t)$ varies from 1.0 at solar max to 1.25 at solar min in a similar way to Fig. 2.

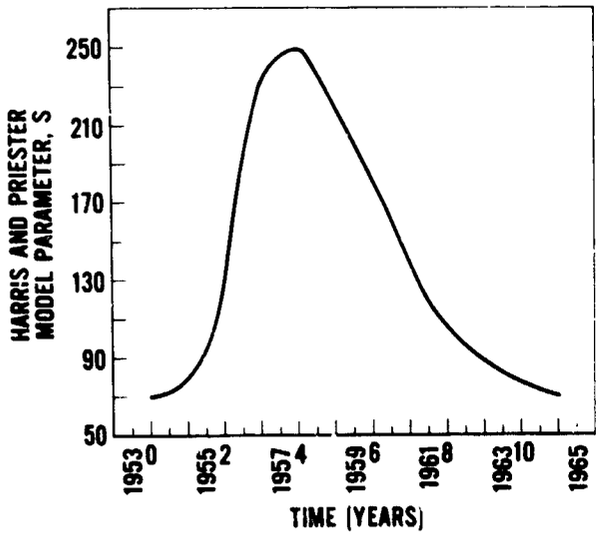

FIGURE 2.—Solar cycle used in these calculations S is the Harris and Priester (1962) model parameter which is related to but not the same as the 10 cm flux intensity.

For the loss term $L(E, t)$ following Freden and White [1960] we consider nuclear collisions

$$L(E,t)=N(E,t)v\Sigma_i\sigma_i\bar{\rho}_i(t) \quad (4)$$

where $\bar{\rho}_i(t')$ is the average atmospheric density of atmospheric component i (O_2, O, N_2 or He) and σ_i is the inelastic cross section for collisions (assumed geometric).

The last term in equation 2, the change in proton population due to slowing down, varies with the solar cycle due to the atmospheric density change

$$\frac{dE}{dx}=\left[\frac{\rho(t)}{2.69\times10^{19}}\right]\times\frac{dE}{dx}\Big|_{NTP} \quad (5)$$

where $\bar{\rho}$ (t) is the average atmospheric density of equivalent oxygen atoms. The variation of $\bar{\rho}_i(t)$ and $\bar{\rho}(t)$ with time in the solar cycle is the major reason for the change in proton population.

AVERAGE ATMOSPHERIC DENSITIES

A major part of this problem was to determine the average atmospheric densities used in calculating the loss rate of trapped protons by coulomb scattering. To do this the theoretical model of the upper atmosphere developed by Harris and Priester [1962] was used. This model gives the time dependences of the atmosphere for both solar cycle and diurnal variations. It agrees well with several measurements of density by satellite drag (King-Hele, 1963; Bryant, to be published) and recently has been checked by preliminary data of densities from the Explorer XVII satellite. Spencer et al [1963] This model atmosphere is the most complete description of the time dependence of atmospheric densities available and agrees well with the current experimental data. We must perform several operations on the H and P model data to get it in form to use for this problem. Harris and Priester give the atom densities n_i of the several atmospheric constituents i in the form of.

$$n_i(h, t, S)$$

where h is altitude above the earth, t is local time, and S is a model parameter related to, but not the same as, the intensity of the average 10 cm solar flux, F, in watts/m^2-cps$\times10^{-22}$. Recent studies of atmospheric densities [Harris and

Priester, 1963] show that the model number S is the same as $\bar{F}$ near solar max but near solar min $S<\bar{F}$. For example, $\bar{F}=70$ corresponds to the model $S=100$. Fig. 2 shows the solar cycle variation of S we have used based on the last solar cycle.

The first operation on the H and P atmosphere is to average over local time. The protons we will consider live long enough so that they will encounter the midday density bulge and the nighttime minimum many times and will average them out.

Secondly, we perform a longitude average. As the particles drift around the earth their mirror points do not stay at constant altitude but rather follow a certain path in B–L space. Several such constant B–L rings are shown in altitude-longitude coordinates in Fig. 3. The particles dip

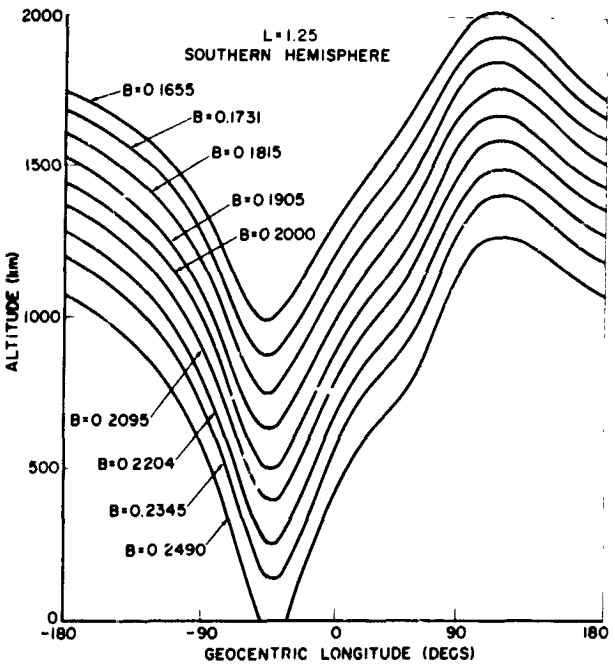

FIGURE 3.—Variation of the altitude of B-L rings with longitude.

lowest in the South Atlantic due to the nature of the earth's magnetic field. A B–L map of minimum altitudes is shown in Fig. 4. Due to the variation in altitude of the protons' mirror point, longitude averages were made using the B–L rings every ten degrees in both northern and southern hemispheres. This step gives the average mirror point density for a proton's motion. Walt has recently shown that the protons do not

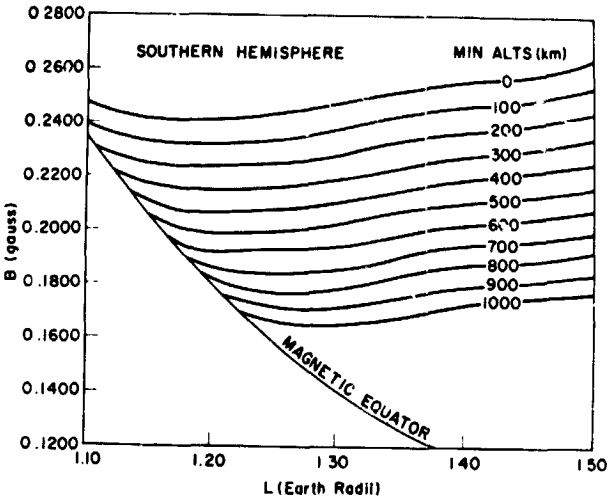

FIGURE 4.—B–L map of minimum altitudes.

drift in longitude at a constant rate because of the variation of the magnetic field gradient and field line curvature. This effect is ignored here. It probably amounts to about a 20 percent correction on average densities. Values of atmospheric densities are not known that well now anyway.

The third operation on the H and P atmosphere is to average over a bounce from one mirror point to the conjugate mirror point. Since the protons live much longer than a bounce period, and since no change in direction of the proton is considered during slowing, it is permissible to average the density in this fashion. A dipole field is assumed in carrying out this step.

Ray [1960] gave the bounce averaging process as

$$\rho=\frac{\int\rho(\lambda)ds}{\int ds} \tag{6}$$

where the element of length along the particle's orbit is

$$ds=\frac{vdt}{\cos\alpha}=\frac{d\ell}{\cos\alpha} \tag{7}$$

where $d\ell$ is the element of length along the field line. Using

$$d\ell^2=dr^2+r^2d\lambda^2 \tag{8}$$

and

$$r=L\cos^2\lambda \tag{9}$$

with the mirror equation and the expression for the magnetic field variation along a field line

combining and substituting in equation 6 gives

$$\bar{\rho}_i = \frac{\int \rho_i(\lambda) A(\lambda) d\lambda}{\int A(\lambda) d\lambda} \tag{10}$$

where

$$A(\lambda) = \frac{\cos^4 \lambda 1 + 3 \sin^2 \lambda}{[\cos^6 \lambda (1+3 \sin^2 \lambda_m)^{\frac{1}{2}} - \cos^6 \lambda_m (1+3 \sin^2 \lambda)^{\frac{1}{2}}]^{\frac{1}{2}}} \tag{11}$$

The subscript m here corresponds to the particles' mirror point. This bounce averaged density has been integrated on a computer.

The last step is to combine the five i constituents N_2, O_2, O, He and H to give the averaged number of equivalent oxygen atoms

$$8\bar{\rho} = 14\bar{\rho}(N_2) + \bar{\rho}(O) + 16\bar{\rho}(O_2) + 2\bar{\rho}(He) + \bar{\rho}(H) \tag{12}$$

Values of $\bar{\rho}$ at different times in the solar cycle for $L = 1.25$ are shown in Figure 5.

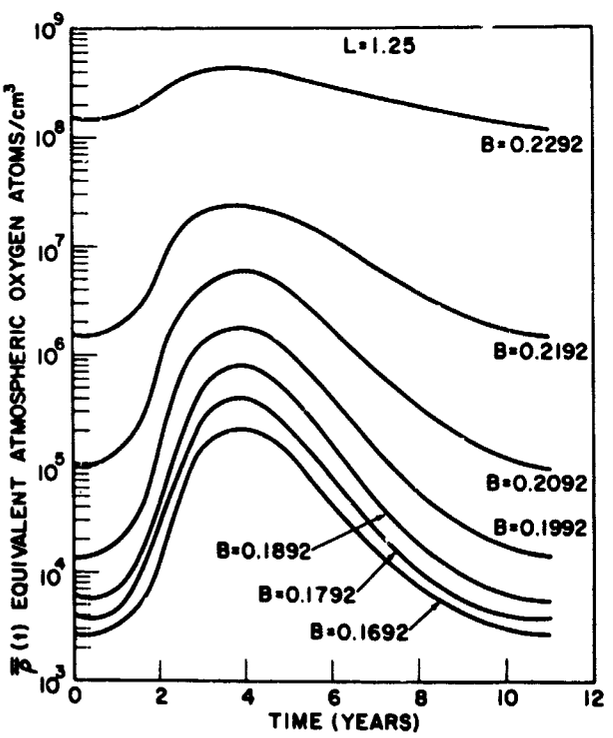

FIGURE 5.—Average atmospheric densities at different times of the solar cycle at different B–L points.

We can use the data on the rate of energy loss dE/dx for oxygen at NTP [Aaron, Hoffman and Williams, 1949] in equation 5 with this averaged density $\bar{\rho}$ to calculate the loss rate.

RESULTS

Equation (2) is integrated stepwise starting with $N(E) = O$ at $t = O$ to build up to an oscillating proton population which is the same from one

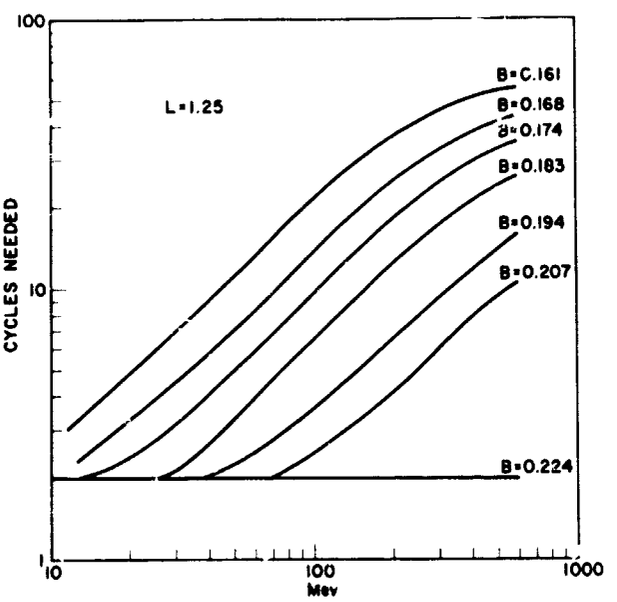

FIGURE 6.—The number of solar cycles needed for a group of protons to come within 1% of its final oscillating population for $L = 1.25$ starting with $N(E) = O$ at $t = O$.

solar cycle to the next. In Figure 6 is shown the number of solar cycles after which the population change per cycle is less than 1 percent for $L = 1.25$. After achieving this final condition the proton energy spectrum varies during one solar cycle as shown in Figures 7–11. The dotted curves top and bottom in these figures are what the proton spectrum would be if steady state conditions were achieved at solar max and solar min. Steady state clearly is not achieved for high energy protons or for high altitudes.

It is also interesting that this calculation predicts a spectral peak above 100 Mev for certain conditions (Figure 7, year 3) due to the time lag

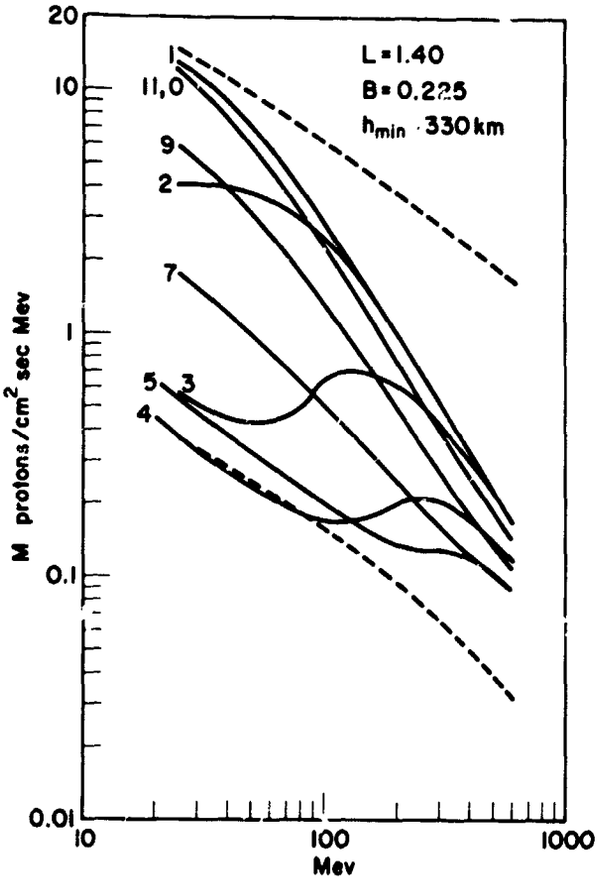

FIGURE 7.—Proton energy spectra at different times in the solar cycle for $L=1.40$, $B=.225$. The curves are labeled by the time in years from solar min.

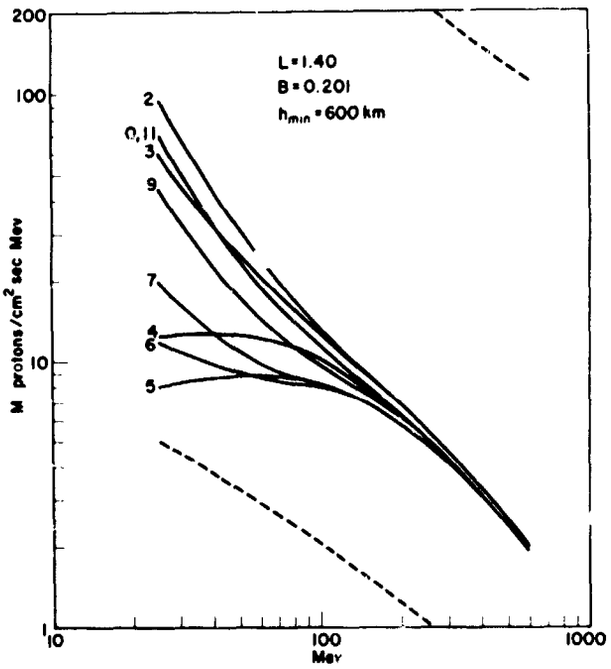

FIGURE 8.—Proton energy spectra at different times in the solar cycle for $L=1.40$, $B=.201$. The curves are labeled by the time in years from solar min.

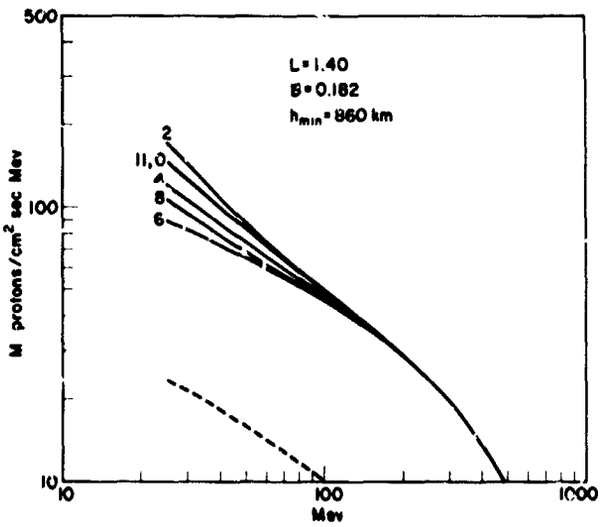

FIGURE 9.—Proton energy spectra at different times in the solar cycle for $L=1.40$ $B=.181$. The curves are labeled by the time in years from solar min.

in different energy protons adjusting to solar cycle changes.

Figures 12 and 13 show time histories for various conditions. Large variations from solar max to solar min populations are seen in these figures. The amplitude of these changes for $L=1.25$ and 1.40 are shown in Figures 14 and 15.

A comparison of past experimental results and the calculations of this paper is shown in Table I. In discussing these experiments we can consider three types of information.

In comparing time changes of the proton fluxes two situations occur:

1. Some individual experiments run long enough (a year or more) so that they should see proton flux changes directly. From Table I, experiments (*c*) and (*d*) are of this time. Although in experiment (*d*) it is not one experiment on one satellite, it is many identical experiments on essentially identical satellites, and therefore this experiment falls in this category.

2. Different experiments on different satellites can be compared to provide data on proton flux changes. Data of this type is given in experiments (*a*), (*e*) and (*f*) in Table I.

The third type of data is given by:

3. Direct measurement of the proton energy

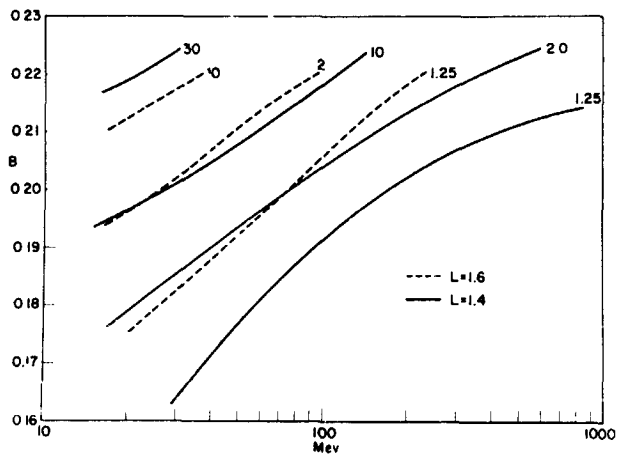

FIGURE 15.—The amplitude of the proton population change during the solar cycle for $L=1.4$ and 1.6.

spectrum in one experiment. Experiments (*a*), (*b*), (*e*), (*f*) and (*g*) are of this type.

In comparing flux time change experiments of type (1) with the calculations, the agreement is good. Two experiments covering the period 1959 to 1962 give results consistent with the calculations.

Comparing with type (2) data does not work as well. The observed changes of flux with time agree qualitatively with those predicted but not quantitatively. The experimental flux ratios are smaller than the calculated ones. Two remarks are in order here. First, type (2) data usually has larger errors attached to it than type (1) because it involves the systematic errors of two experiments while type (1) data involves no systematic errors—only statistical errors are involved in the time variations in the flux. Because of this the experimental flux ratios using type (2) data are probably not as accurate as those using type (1) data. Secondly all the comparisons of type (2) data involve Explorer IV data so there is no independent check of experimental consistency.

We may have over-estimated the amplitude of the change of proton populations in this present calculation by as much as a factor of two because our solar cycle model uses $S=70$ at solar minimum while recent data of Harris and Priester (1963) shows that $S=100$ is probably more appropriate. Changing the shape of the model solar cycle (Figure 2) will also affect the results of the calculation. The solar cycle must rise more rapidly towards solar max. than it falls to solar min. in order to produce the changes in spectrum calculated here. Solar cycle 16 was quite symmetrical and should not give the calculated results.

Of the five experiments of type (3) that help understand the proton energy spectrum the first two (*a*) and (*b*) in 1960 showed a modest sized peak at about $E=40$ Mev. The more recent experiment (*g*) of Rowland et al in 1962 shown in Figure 16 does not show such a peak. The solid curve on Figure 16 compared with the data of Rowland is the results of the present calculations normalized. The agreement is fairly good. Recent experiments (*f*) (*g*) show a large low energy proton population but cannot be compared with early experiments because the early ones did not go down to such low energies. Figures 7–11 show that the calculated spectral shape should not change much during the period of these measurements—from 6 to 9 years solar cycle time The proton fluxes should increase but the shape of the spectrum stays nearly the same. Striking changes in spectral shape should occur on the upswing of the solar cycle. The agreement with spectral shape in Figure 16 is not bad but the peaks in experiments (*a*) and (*b*) should not occur at $t=6$. It may be that a neutron absorption as suggested

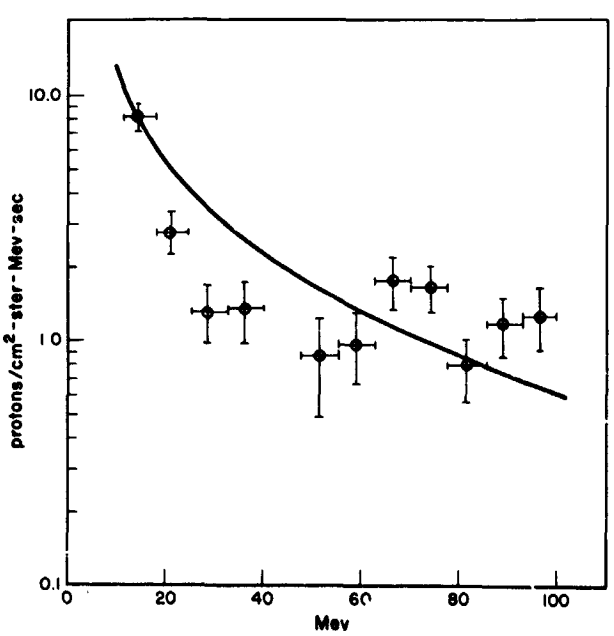

FIGURE 16.—The energy spectrum of inner zone protons measured by Rowland et al, 1963, on an Atlas pod at $L=1.27$, $B=.216$ shown for comparison is the spectrum calculated in this paper for $L=1.27$, $B=.207$, $t=9$.

by Freden and White (1962) is required to explain the peak.

All of the information presented so far on Figures 6 through 15 are mirror point fluxes M, that is, the flux of protons mirroring per unit volume at one particular B and L. For low altitudes where the atmosphere changes rapidly with altitude it is nearly correct to compare this flux with measured omnidirectional flux values. For these low altitudes the omnidirectional flux is very nearly the same as the mirror point flux. To show a more complete picture of the solar cycle proton changes we have converted to omnidirectional fluxes using equations (24) of Hess and

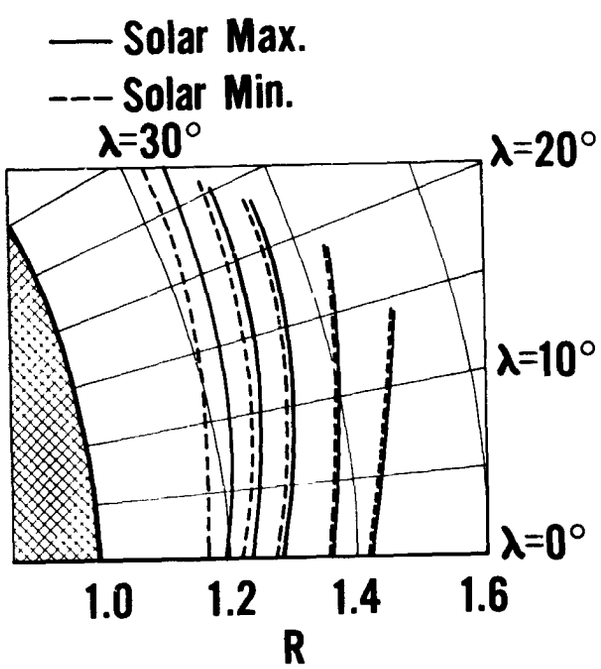

FIGURE 17.—An $R-\lambda$ map of the omnidirectional flux of $E=25$ Mev protons at solar max and solar min.

Killeen (1961). Figure 17 shows a calculated R–λ map of the 25 Mev proton omnidirectional fluxes J at solar max and solar min. An isoflux contour is clearly at lower R for solar minimum.

In conclusion we have shown that large changes in proton fluxes will take place during the solar cycle for those regions of B–L space corresponding roughly to minimum altitudes of about 300–700 km. Changes in proton spectra will occur also. Comparison of the calculations with available experimental information are not conclusive. Some kinds of experimental data agree quantitatively with the calculations. Other data agrees qualitatively but not quantitatively. The crucial tests of the calculations will involve measuring changes in the proton flux and spectrum as we approach solar maximum during 1966–68. We know experimentally (King-Hele 1963) that the atmospheric density changes used in the calculation are reasonable These calculated effects must take place with about the magnitudes shown here unless there are features of the inner belt protons which we do not now understand.

A NEUTRAL-POINT EXPANSION OF THE IDEAL MAGNETOSPHERE*

RONALD BLUM†

The idealized model of the geomagnetic field–solar wind interaction yields a singular (neutral) point on the magnetopause at which the magnetic field vanishes. If we expand the fields in a power series around this point, including quadratic terms, we can derive an approximate equation of the magnetopause in a small neighborhood of the neutral point which is consistent with the idealized boundary conditions to fourth order. We then consider the additional pressure due to multiple reflections of particles in this neighborhood and show that less than a 4 per cent correction to the single-reflection pressure condition is necessary.

INTRODUCTION

In the idealized model of the geomagnetic field–solar wind interaction [*Beard*, 1960] we assume the field to be excluded from the plasma and contained in a cavity called the magnetosphere. The boundary of the cavity, or magnetopause, is unknown, but we stipulate the dynamic condition that the magnetic pressure just inside the magnetopause be exactly balanced by the kinetic pressure of solar wind particles elastically reflected from the surface (thermal effects are neglected). Figure 1 is a schematic drawing of the magnetosphere with the dipole located at the origin of coordinates and perpendicular to the direction of the plasma stream.

Mathematically, this situation is described by the field

$$\mathbf{H} = -\text{grad}\ \Omega \qquad \nabla^2\Omega = 0 \qquad (1)$$

inside the magnetosphere, and the boundary conditions

$$\mathbf{H}\cdot\text{grad}\ F = 0 \quad \text{(confinement)} \qquad (2)$$

$$\mathbf{H}\cdot\mathbf{H} = \beta^2 \cos^2\chi \quad \text{(pressure)}$$

which hold on the surface, $F(x', y', z') = 0$, where χ is the angle of incidence of the incoming plasma (Figure 1), and $\beta^2 = 8\pi(2nm_iV^2)$. V, n, and m are the plasma drift velocity, ion number density, and ion mass, respectively.

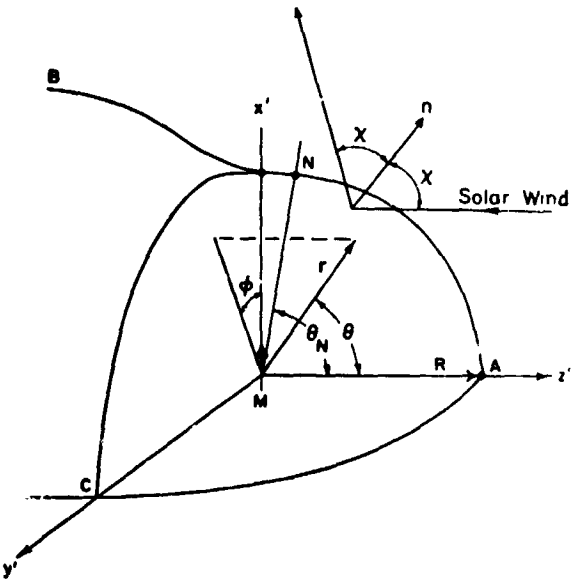

FIGURE 1.—Schematic drawing of the magnetosphere.

A singular point on this unknown surface is N, the neutral point, where the magnetic field lines 'split,' the field vanishes, $\chi = \pi/2$, and the gradient is in the x' direction. Although the problem is unsolved as yet, there are some good approximations to the general shape [*Mead and Beard*, 1963; *Spreiter and Briggs*, 1962; *Midgley and Davis*, 1963]. However, these approximations generally fail in the region of the neutral point, a region of interest since, if it does exist, it is likely to be

*Published in *Journal of Geophysical Research*, 69(9): 1765–1768, May 1, 1964.

†National Academy of Sciences—National Research Council Postdoctoral Research Associate with NASA.

unstable, and a possible point of entry for high-energy particles into the magnetosphere.

The neutral point considered here is an X-type neutral point [*Dungey*, 1958, pp. 39–41, 51–52, 98–102]; however, it lies *on* a bounding surface, which must run parallel to one of the limiting

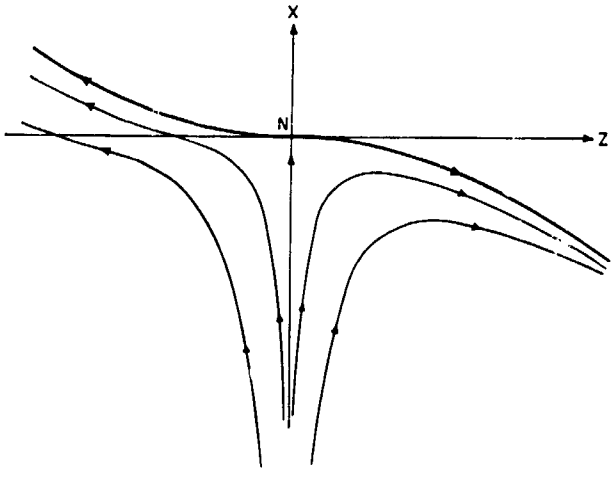

FIGURE 2.—Fields near the neutral point in the noon meridian plane.

field lines (Figure 2). We must assume that surface currents can be made to account for the disappearance of the field outside the surface (magnetopause).

SERIES REPRESENTATION

We can represent the field $\mathbf{H}=\beta\mathbf{h}$ by means of its scalar potential Ω. We first transform to the (x, y, z) coordinate system with origin at N such that

$$R(dx, dy, dz)=(dx', dy', dz') \tag{3}$$

In a region small compared to the apex radius R, we have $x^2+y^2+z^2\ll 1$. The scalar potential is expanded in the form

$$-\Omega/\beta=ax^2+by^2+cz^2+dx^3+ey^3+fz^3 +mxy^2+nxz^2+rzx^2+szy^2 \tag{4}$$

We must include cubic terms in the potential, since we expect the limiting field lines to be curvilinear in the xz plane. There are no linear terms, because the field must vanish at N; terms in y to the first power are deleted, because symmetry requires $H_y=0$ in the xz plane. The dependence on xz has also been omitted, since for $y=0=z$ there should only be an x component of H on the x axis (Figure 2).

The gradient of (4) yields the normalized field:

$$\begin{aligned} h_x&=2ax+3dx^2+my^2+nz^2+2rxz \\ h_y&=2by+3ey^2+2mxy+2szy \\ h_z&=2cz+3fz^2+2nxz+rx^2+sy^2 \end{aligned} \tag{5}$$

and the requirement $\nabla\cdot\mathbf{H}=0$ yields

$$\begin{aligned} &a+b+c=0 \quad 3d+m+n=0 \\ &3f+r+\cdots\ e=0 \end{aligned} \tag{6}$$

Furthermore, as Figure 2 shows, we expect $a<0$, $c>0$.

NOON MERIDIAN CONTOUR

In the xz plane the boundary conditions (equation 2) on the noon meridian contour become $(dx/dz=x')$:

$$h_x/h=-F_z/F_x=x' \tag{7}$$

$$h_x^2+h_z^2=x'^2/(1+x'^2) \tag{8}$$

If we substitute for x' in (7) and (8), then

$$h_x^4+h_x^2(2h_z^2-1)+h_z^4=0 \tag{9}$$

and, since both components must vanish at N,

$$h_x^2=(1-2h_z^2-(1-4h_z^2)^{1/2})/2\to h_z^4\to N \tag{10}$$

From Figure 2 we see that h_x is opposed in sign to the coordinate z on the noon meridian countour. Thus, sufficiently close to N,

$$h_x=\pm h_z^2 \text{ for } z\lesssim 0 \tag{11}$$

If we substitute into (7) and differentiate,

$$x''=\pm dh_z/dz \quad z\lesssim 0 \tag{12}$$

which leaves two alternatives: either x'' is discontinuous at N or $x''=0$ at N. The latter implies $c=0$, which is inconsistent with the geometry of the limiting field line in the xz plane. Thus the curve, $\{x=x(z),\ y=0\}$, must be represented as two separate power series for $z\lesssim 0$. Since (11) must be satisfied on the noon meridian contour, it gives an implicit representation of that contour near N. This must agree with $x=\int dz h_z/h_z$ of

(7) and with Figure 2. The leading term of (11) is

$$2ax+nz^2=\pm 4c^2z^2 \qquad (13)$$

If $n=0$, equation 13 implies that a is of positive sign, which contradicts Figure 2. Therefore we must assume that n has two different values, according to the sign of z. This is permissible as long as $\mathbf{h}$ remains continuous at $z=0$, and $\nabla\cdot\mathbf{h}=0$ everywhere. If we compare (13) with the leading term of (7), we find

$$x'=\pm h_z\lesssim 0 \qquad x=\pm cz^2 \qquad (14)$$

near N. Thus, (13) becomes

$$n=\pm 2c(2c-a) \text{ for } z\lesssim 0 \qquad (15)$$

SURFACE REPRESENTATION

Since the gradient is in the x direction at N, we can represent the surface by two second-order expansions in (y, z):

$$F(x,y,z)=x-A^{\pm}z^2-B^{\pm}y^2-C^{\pm}yz=0 \qquad (16)$$

for $z\lesssim 0$. By symmetry, $B^+=B^-=B$; (14) requires $A^+=-A^-=c$. If we form the dot product $H\cdot\nabla F=0$ and substitute for x form (16) we find the confinement condition satisfied to second order in z^2, y^2, and yz when

$$m=2B(2b-a) \qquad (17)$$

$$C^{\pm}(1-b/a-c/a)=0 \qquad (18)$$

The divergence conditions (equations 6) require that d also be discontinuous, since $3d+m+n=0$, although m is continuous. Therefore, from (17) and (15),

$$3d=\pm 2c(a-2c)+2B(a-2b)z\lesssim 0 \qquad (19)$$

Equation 18 is incompatible with $a+b+c=0$ unless $C^{\pm}=0$. Although (19) forces h_z to be discontinuous at $z=0$ ($a\neq 2c$), the 3 dx^2 term is negligibly small compared to the ax term in (5).

Third-order terms in $\mathbf{H}\cdot\nabla F=0$ are eliminated by simply setting $f=0=s$. Then, by the divergence condition, $r=0$ also. Thus in the power series representation, the confinement condition of (2) is satisfied up to fourth-order errors, on the postulated surface of (16). If we substitute the expansions for $\mathbf{h}$ and $F(x, y, z)$ into the pressure condition of (2), we find

$$h_x^2+h_y^2+h_z^2=\cos^2\chi$$
$$\doteq(\partial F/\partial z)^2(1-\text{2nd-order terms}) \qquad (20)$$

and expanding $\mathbf{b}$ yields

$$4c^2z^2+4b^2y^2+\text{4th-order terms}$$
$$=4c^2z^2(1-\text{2nd-order terms}) \qquad (21)$$

By setting $b=0$ we can reduce the error in the second boundary condition to fourth order. Our final expansion for the field in the neighborhood of N is given by:

$$-\Omega/\beta=cz^2-cx^2-(m\pm 6c^2)x^3/3$$
$$+mxy^2\pm 6c^2xz^2 \qquad (22)$$

and the surface of the magnetosphere near N is given by

$$F(x,y,z)=x-(\pm)cz^2-my^2/2c \qquad (23)$$

for $z\gtrsim 0$.

MULTIPLE REFLECTIONS AT N

Midgley and Davis [1963] have observed that the effect of multiple reflections of particles near N might seriously alter the pressure condition (equation 2) near the neutral point. In the second-order approximation, we can show that the shape of the surface is consistent with the pressure condition to within 4 per cent. This effect would be most pronounced in the xz plane; we shall calculate the added pressure δp at a point (x, z) on the noon meridian contour due to multiple reflections.

Figure 3 represents a particle incident on the point (x_0, z_0) on the contour $x=cz^2$, $z\lesssim 0$, $y=0$, with an angle of incidence χ_0. This particle, on first reflection, strikes the magnetopause again at (x, z) where

$$(x-x_0)/(z-z_0)=c(z+z_0)=\tan 2\chi_0 \qquad (24)$$

and

$$\cot\chi_0=-x'(z_0)=-2cz_0 \qquad (25)$$

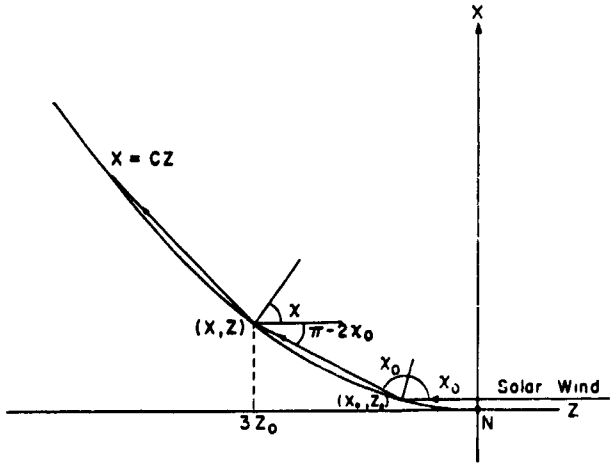

FIGURE 3.—Multiple reflections near the neutral point.

therefore,

$$z = 4cz_0/(1-4c^2z_0^2) - z_0 \doteq 3z_0 \qquad (26)$$

as indicated in Figure 3. We note that the angle of incidence is $\pi - 2\chi_0 + \chi$ at (x, z), and the change in the normal component of momentum will be correspondingly smaller. If we pursue the particle to the third point of reflection we find

$$c(z+3z_0) = \tan 2(\chi - \chi_0) \quad z \doteq 5z_0 \qquad (27)$$

However, the effect of the particle, by this time, is negligible.

We now consider the additional pressure δp at (x, z) due to particles reflected from (x_0, z) and compare it with the pressure $p = 2nmV^2 \cos^2 \chi$ of the incident plasma stream (ignoring the y coordinate). If $nV\, dx_0$ particles/sec are incident on an area of $ds_0 = (dx_0^3 + dz_0^2)^{1/2}$ at (x_0, z_0), they are reflected onto an area $ds = (dx^2 + dz^2)^{1/2}$ at (x, z), where their momentum changes by $2mV \cos(\pi - 2\chi_0 + \chi)$ per particle. Therefore, since $dx = 9dx_0$,

$$\delta p = -2mnV^2 \cos(\chi - 2\chi_0)(dx/ds)/9 \qquad (28)$$

If we substitute for χ, χ_0 from (25) and note that $dx/ds = \cos\chi$, then we find

$$\delta p/p = 1/27 \ll 1 \qquad (29)$$

We can conclude that the effect of multiple reflections near the neutral point is negligible and that the pressure condition is valid over the entire magnetosphere in this idealized representation.

POSSIBLE SOURCE MECHANISM FOR LOW-ENERGY GALACTIC ELECTRONS

KARL A. BRUNSTEIN*

A calculation is made of the expected secondary electron flux resulting from the knock-on collisions of the primary nuclear beam with the interstellar gas. The model includes ionization losses and a statistical Fermi-mechanism energy gain. Comparison is made with recent satellite experimental data.

INTRODUCTION

Recent interest in cosmic-ray electrons has been confined largely to higher energies. Specifically, experimental results [1–3] in the energy region of the order of 100 MeV to several BeV have been of interest because of their bearing on the problem of galactic radio emission. The study of lower energy electrons, although probably not of direct importance to the radio emission question, is of importance because of its relationship to the higher energy electron spectrum, and because of its bearing upon the questions of solar modulation and energetic electron production.

Several workers in the field have arrived at the conclusion that the primary cosmic-ray beam must traverse several g/cm^2 of interstellar material prior to being sampled at or near the earth.[4–6] This necessarily implies a flux of low-energy electrons in equilibrium with the primary beam due to the knock-on process in the interstellar gas. This problem has been extensively studied for knock-on electrons due to muons in various substances.[7–9] The equilibrium problem in the interstellar gas is somewhat different from the laboratory experiments described in Refs. 7 and 8 because of the absence of the cascading process in the interstellar gas and the enhanced ionization loss rate in the partially ionized hydrogen.[10] In addition, there is the possibility of further acceleration of the secondary electrons in the inter-stellar material.[11]

It is not clear that these galactic electrons of low rigidity could penetrate into the solar cavity; however, recent work by Palmeira and Balasubrahmanyan [12] suggests that, at least during solar minimum, they can. This question is not considered here. The question of solar modulation is a separate one. By considering the knock-on flux as expected in the absence of solar influence and comparing with experimental data obtained outside the magnetosphere, new information concerning solar influence may be inferred.

PROCEDURE

A model is adopted in which the knock-on electrons, once produced, lose energy due to the ionization effect and gain energy due to a statistical Fermi mechanism. It is further assumed that the electrons tend to remain in the somewhat localized regions in which they are produced and that the losses due to diffusion out of the galaxy are negligible at these low rigidities. In addition, synchrotron losses are neglected at the energies in question here. Then, assuming a source of knock-on electrons and the predominance of the ionization loss and statistical gain mechanisms, a calculation of the low-energy electron spectrum is made.

Assuming a primary proton beam not varying appreciably with time, one can write the equation for the density of knock-on electrons as

$$\partial N(E,t)/\partial t+\alpha N(E,t)-(k-\alpha E)[\partial N(E,t)/\partial E] = Q(E)$$

*National Aeronautics and Space Agency—National Academy of Sciences—National Research Council Regular Post-Doctoral Resident Research Associate.

with $N(E,0)\equiv 0$, where

$N(E,t)$ = electron density at energy E and time t in electrons/m³-MeV,

$(dE/dt)_{\text{Fermi}}=\alpha(E+M_e c^2)$ defines α,

$k=|dE/ds|\rho c-\alpha M_e c^2$, dE/ds being the ionization loss rate, and

$Q(E)$ = production rate in electrons/m³-MeV-sec.

It is possible to solve the differential equation for arbitrary production rate $Q(E)$. The solution is found to be

$$N(E,t)=\sum_{n=0}^{\infty}\frac{(k-\alpha E)^n(1-e^{-\alpha t})^{n+1}}{(n+1)!\alpha^{n+1}}\frac{d^n}{dE^n}Q(E).$$

Adopting the Bhabha[9] cross section for knock-on production and the rigidity spectrum of McDonald and Webber [13] for the galactic proton beam, we may write for the production rate

$$Q(E)=\varphi(E)/E^2-\gamma(E)/E,$$

where

$$\varphi(E)=8\pi CM_e c^2 a\left(\frac{Mc^2}{Ze}\right)^{-1.25}\times\int_{(1-2M_e c^2/E)^{1/2}}^{\beta_{\max}}\beta^{-4.25}(1-\beta^2)^{-0.375}d\beta$$

$$\gamma(E)=4\pi Ca\left(\frac{Mc^2}{Ze}\right)^{-1.25}\times\int_{(1-2M_e c^2/E)^{1/2}}^{\beta_{\max}}\beta^{4.25}(1-\beta^2)^{0.625}d\beta,$$

$C=0.150$ cm²/g,

and

$a(Mc^2/Ze)^{-1.25}=5420$ (m²-sr-sec)$^{-1}$.

The dependence of φ and γ upon E makes this rigorous approach impractical. Instead, by use of the mean value theorem, one finds that $Q(E)$ may be approximated by

$$Q(E)\cong AE^{\delta},$$

where A and δ are readily evaluated. Substitution of $Q(E)=AE^{\delta}$ into the differential equation for $N(E,t)$ enables one to use the method of characteristics to solve the equation to yield

$$N(E,t)=\frac{1}{k-\alpha E}\left(\frac{A}{\delta+1}\right)\left[\frac{1}{\alpha^{\delta+1}}\left(k-\frac{k-\alpha E}{e^{\alpha t}}\right)^{\delta+1}-E^{\delta-1}\right].$$

Taking $\rho=2\times10^{-26}$ g/cm² [14] and letting $t\to\infty$, we get, setting $dJ/dE=(C/4\pi)N(E)$

$$\frac{dJ}{dE}=\frac{2.48\times10^{-13}}{1.625\alpha}\,\frac{E^{-1.625}-(k/\alpha)^{-1.625}}{(k/\alpha)-E}.$$

In addition to this flux calculated for the primary proton on hydrogen interaction, there will be a significant contribution from the heavier nuclei in the cosmic-ray beam. The knock-on production rate at a given primary velocity is very nearly a function of Z^2.[15] We then write the relation for the contribution of nuclei of change Z_i as

$$\left(\frac{dJ}{dE}\right)_i=Z_i{}^2\frac{J_i(>\beta)}{J_p(>\beta)}\left(\frac{dJ}{dE}\right)_p.$$

Using relative fluxes as given in the review by Ginzburg and Syrovatsky,[14] we arrive at the conclusion that the knock-on contribution from primaries of charge $Z\geq 2$ will be approximately 0.75 times the proton contribution. The total expected knock-on flux is then approximately 1.75 times the proton contribution.

The ionization loss rate for electrons of 3 to 15 MeV is nearly independent of energy for materials of low Z. In the interstellar hydrogen gas, however, it is fairly strongly a function of the degree of ionization. A degree of ionization of 10 per cent with a corresponding dE/ds value of 5 MeV/g/cm² has been taken.[10]

The calculated electron fluxes for different values of α are plotted in Figs. 1 and 2.[16] It is seen that the resultant intensity is a strong function of α, the parameter in the statistical acceleration mechanism. Typical electron fluxes as measured with IMP-A are also shown in the figures. It is seen that the range of α values selected, $1/\alpha=3\times10^{14}$ sec to $1/\alpha=3\times10^{15}$ sec, allows a fairly good matching of the theoretical and experimental fluxes. The value $\alpha\sim10^{-15}$ sec^{-1} does not appear unreasonable.[17,18]

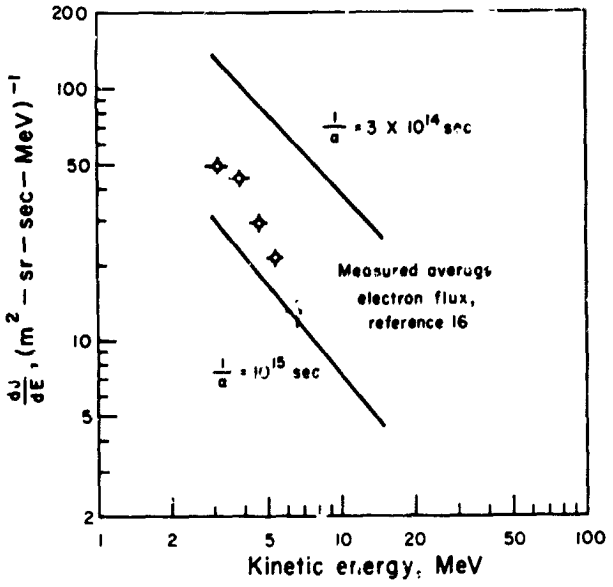

FIGURE 1.—Calculated spectra for values of α indicated. Circles: average electron flux from Ref. 16.

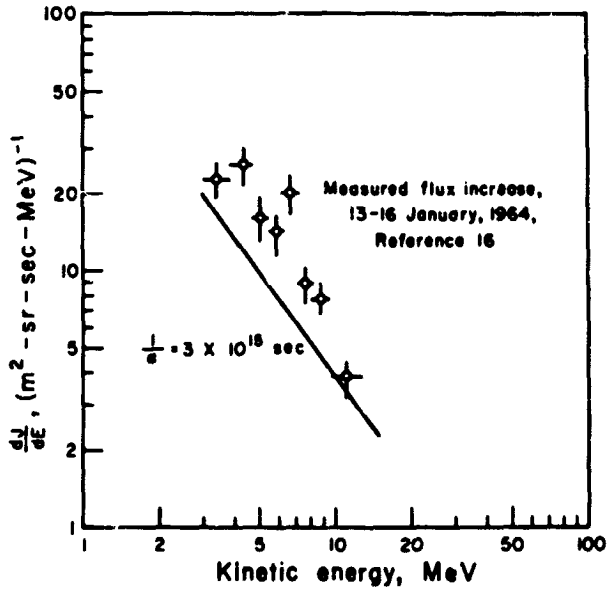

FIGURE 2.—Calculated spectrum for $1/\alpha = 3 \times 10^{15}$ sec. Circles: a typical flux increase, taken from Ref. 16.

It is not clear at this time whether the measured flux increase or the entire measured flux can be attributed to the knock-on process. Both possibilities are suggested by the reasonableness of the α values required.

CONCLUSION

The electron-positron flux resulting from the proton-proton interactions in the interstellar material has been discussed by several authors.[19,20] DeShong, Hildebrand, and Meyer[3] conclude, based on electron-positron ratios, that a substantial portion of the electron flux above 50 MeV must have an origin other than proton-proton collisions. It is speculated that a substantial portion of the lower energy electron flux seen in space may be attributed to knock-on electrons acted upon primarily by ionization losses in the interstellar gas and a Fermi type acceleration process. This, of course, requires that the low-energy electron flux should be composed largely of negative electrons. In addition, any long term solar modulation should be of an inverse activity dependence, similar to the primary nuclear beam. Both of these expectations will be subjected to experimental test by proposed experiments during the next solar half-cycle.

The knock-on process should produce secondary electrons in the BeV energy range also. The theoretical cross section in this case contains spin-dependent terms, and one does not feel as trusting of it as in the low-energy case where the interaction is one of Coulomb force only. In addition, these higher energy electrons may diffuse out of the galactic disk more readily and will also be subject to synchrotron losses. It is nevertheless interesting to plot the low-energy electron

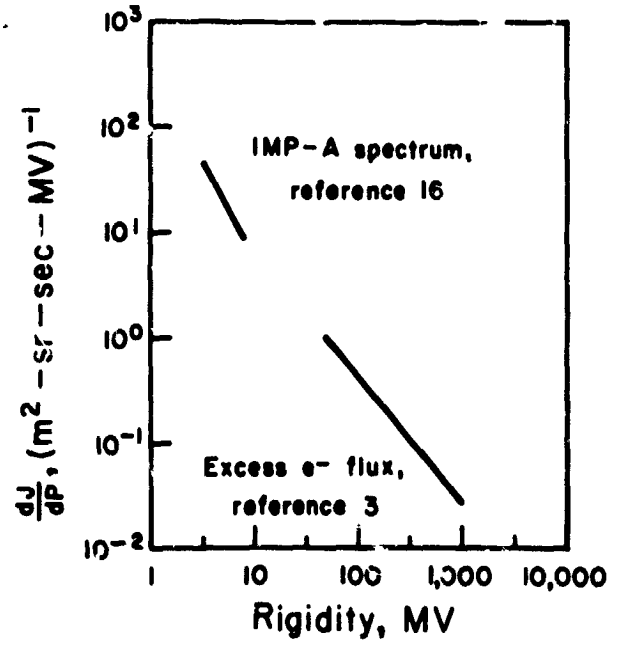

FIGURE 3.—The average electron flux from Ref. 16 shown along with the excess electron flux arrived at in Ref. 3.

flux along with the higher energy flux as has been done in Fig. 3. It is suggested by Fig. 3 that the knock-on process at higher energies may also be of significance.

Adopting for the moment the conclusion that the low-energy electrons as seen by IMP-A are due to the knock-on process, leads to the conclusion that the Fermi mechanism must be moderately effective for these low-energy electrons and that the parameter α has the value $\alpha \sim 10^{-15}$ sec^{-1}.

ACKNOWLEDGEMENT

I would like to express my appreciation for help given by Dr. Phillip Abraham in overcoming mathematical complexities. Dr. Thomas L. Cline kindly made his data available prior to publication.

STUDIES OF SOLAR PROTONS WITH EXPLORERS XII AND XIV*

D. A. BRYANT†, T. L. CLINE, U. D. DESAI‡ AND F. B. McDONALD

Four solar proton events observed by Explorers XII and XIV in 1961 and 1962 are discussed. These events are directly associated with solar activity, and in three cases, are followed either by secondary events delayed about 2 days or by recurrent events on succeeding solar rotations. It is shown that the rate of propagation of solar protons in some of these primary events is linearly dependent on particle velocity and that this dependence makes it possible to separate the source characteristics from the propagation effects. In each event which shows this velocity dependence the propagation curves of all observed energies agree and reach maximum intensity at a time much greater than the rectilinear travel time. These results lead immediately to the conclusions that propagation involves an important degree of scattering and that the degree of scattering is independent of energy over the observed range of 1.4 to 500 mev. The energy spectrum at the time of escape from the sun, the "source spectrum," is determined in each event which shows this velocity dependence and is described by a power law in kinetic energy from a few mev to several hundreds of mev. A striking feature of all events is the existence of periodic fluctuations in intensity, which are simultaneous at all energies, having a period from 1. to 1.5 hours depending on the event. This result indicates a local origin, and it is suggested that the fluctuations reflect processes occurring in the region between the magnetosphere and the earth's shock front.

I. INTRODUCTION

During the last solar cycle it has become apparent that large solar flares are often accompanied by the acceleration of protons and other nuclei to energies sometimes exceeding tens of bev. Over a five-year period centered around the last solar maximum about sixty of these events were observed. Solar-proton events have been studied by many techniques. Ionization chambers, mu-meson telescopes, and neutron monitors at sea level provide indirect information at energies above a few bev. With high-altitude balloons, measurements down to about 80 mev are possible. Rocket measurements have no inherent low-energy threshold but are limited to brief samples of an event. Studies by radio techniques of the ionization produced in the D layer are sensitive to energies down to about 10 mev but have little energy resolution. Satellite studies can combine the advantages of the other techniques: they can provide almost continuous coverage with good energy and time resolution and with no inherent energy threshold, yielding a higher probability of detection of solar-proton events than can be provided by the other methods. Finally, a satellite with a sufficiently eccentric orbit can provide measurements of solar protons free of interaction with the earth's magnetic field and free of disturbances by the earth's trapped radiation.

The satellites Explorer XII and Explorer XIV carried cosmic-ray instruments with response for solar protons of energy as low as 1.4 mev. They were active from 16 August to 5 December 1961 and from 2 October 1962 to 1 August 1963, respectively. We discuss here several findings resulting from the study of the major solar proton events observed with these satellites during 1961 and 1962. Anomalous features of certain other events will be treated in later papers.

II. THE APPARATUS

Explorers XII and XIV were essentially identical satellites with similar orbits. The apogee of

*Published as *Goddard Space Flight Center Document X-611-64-217*, July 1964.

†Goddard Space Flight Center and D.S.I.R. Radio Research Station, Slough, Bucks, England.

‡Goddard Space Flight Center and Physical Research Laboratory, Navrangpura, Ahmedabad, India.

Explorer XII was about 13 earth radii and that of Explorer XIV about 16 earth radii; thus, for more than half the time in each orbit they were beyond the outer edge of the magnetosphere which varied from about 7 to over 12 earth radii. Gaps about 8 hours wide appear in the data as a result of discarding the observations made during the passes of the satellite through the magnetosphere. Various characteristics of the satellites are listed in Table I.

The detectors used for solar proton measurements in Explorers XII and XIV provided differential energy measurements from 1.4 mev to 500 mev and an integral measurement at about 600 mev. There were three detectors: a scintillation-counter telescope, a geiger-counter telescope and a single scintillation counter. The scintillation-counter telescope with a 32-channel pulse-height analyzer provided the differential-energy measurements for energies above 50 mev and the integral measurement at 600 mev. The geiger-counter telescope used in the single mode and in the coincidence mode gave integral measurements at 30 mev and 100 mev. Low-energy measurements were made with the single scintillation counter and an 8-channel integral pulse-height analyzer. The axis of the geiger-counter telescope was oriented parallel to the satellite's spin axis and the other detectors were normal to it. A summary of the dynamic range and resolution of each of the detectors is given in Table II. Corrections were applied to all the data for particles penetrating the detector shielding and for particles clipping the edges of the scintillators; only when these corrections were small were the data used for analysis. The detectors are described more fully in a previous publication (Bryant *et al.*, 1962).

III. THE EVENTS

In this paper we confine our attention to the solar proton events following the flares of 10 September, 28 September, and 10 November 1961 and the flare of 23 October 1962. Some details of these flares and the plage regions producing them are given in Table III. The table also contains comments on the flares (H. Prince and R. Hedeman, private communication, 1963) and on the accompanying type IV radio emission (A. Maxwell, J. Warwick, private communications, 1963). Some of the flares were followed by delayed effects and these are also listed. Effects delayed by the prompt 2-day sun-to-earth transit of enhanced plasma and effects delayed by the rotation of the sun (27-day recurrent events) are listed separately.

A calendar of all the solar particle events observed during the intervals discussed here is shown in Figure 1, in which the occurrence of

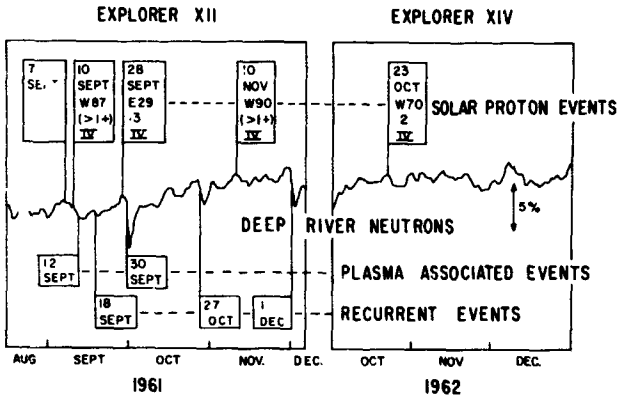

FIGURE 1.—Solar particle events observed with Explorers XII and XIV during 1961 and 1962. The occurrence of each primary solar proton event is indicated above the cosmic-ray neutron intensity plots with a flag which displays the solar longitude and classification of the parent flare and the existence of associated type IV radio bursts. Occurrences of both varieties of delayed proton events are also indicated; a plasma-associated event occurs with a delay of two days and a recurrent event takes place when a long-lived solar streamer passes central meridian on a succeeding solar rotation.

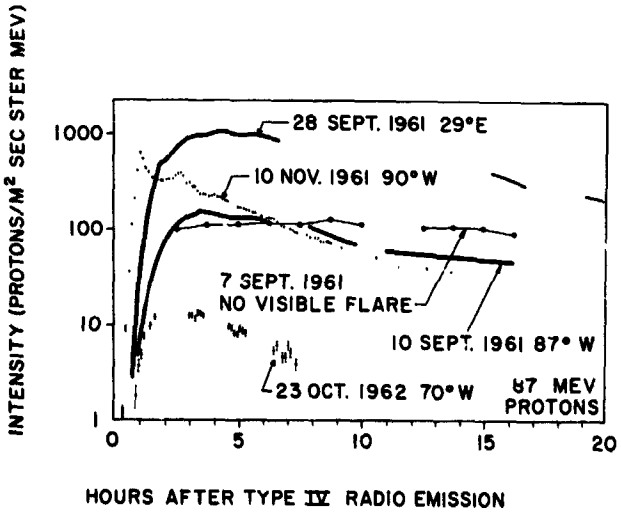

FIGURE 2.—The intensities of 87-mev protons vs time after the type IV emissions during the five primary solar proton events. The shapes of only two events, those of 28 September 1961 and 23 October 1962, are seen to be quantitatively similar, as monitored in this manner.

primary events and delayed effects are plotted against the cosmic-ray intensity measured by a sea-level neutron monitor (courtesy of H. Carmichael, private communication, 1962). Examination of the data showed no evidence either for any other smaller discrete events or for any separate, continuous increases over the general background level. The intensity of one energy interval of protons, centered at 87 mev, is plotted for all five primary events in Figure 2, indicating the widely varying behavior of the events. The event of 7 September 1961, which does not lend itself to obvious correlation to any known flare, will be discussed in a later paper.

IV. THE EVENT OF 28 SEPTEMBER 1961

The solar proton event of 28 September 1961 was initiated by a class 3 flare 29° east of central

meridian. Table III shows the pertinent solar and geophysical data. Some aspects of the event were considered in an earlier paper (Bryant *et al.*, 1962).

Intensity vs. time profiles of various energy components of the event are shown in Figure 3. Time is measured in hours from 2208 UT, the time of emission at the sun of a brief x-ray burst observed by Anderson and Winckler (1962) from 2216 to 2217 UT. For the first few hours points are plotted at intervals of about 7 minutes, and later points are hourly averages. The energy parameter is the mean energy of each interval as outlined in Table II. It is clear that the time taken to reach maximum intensity increases with decreasing energy. The data are less complete at the lower energies because at first the correction due to high-energy particles which penetrate the shielding of the low-energy particle detector is large, and because the satellite entered the trapped-radiation zone soon after the first effect became small.

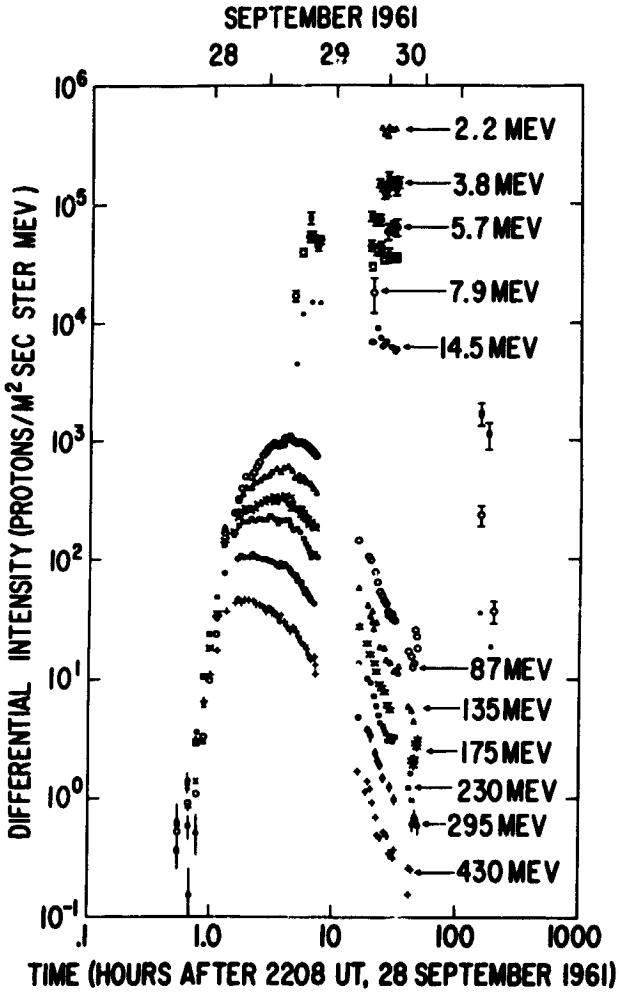

FIGURE 3.—The differential intensities of solar protons during the 28 September 1961 event plotted against time after the x-ray burst at the sun. The data are interrupted when the satellite passed through the magnetosphere and when the delayed increase occurred on 30 September 1961.

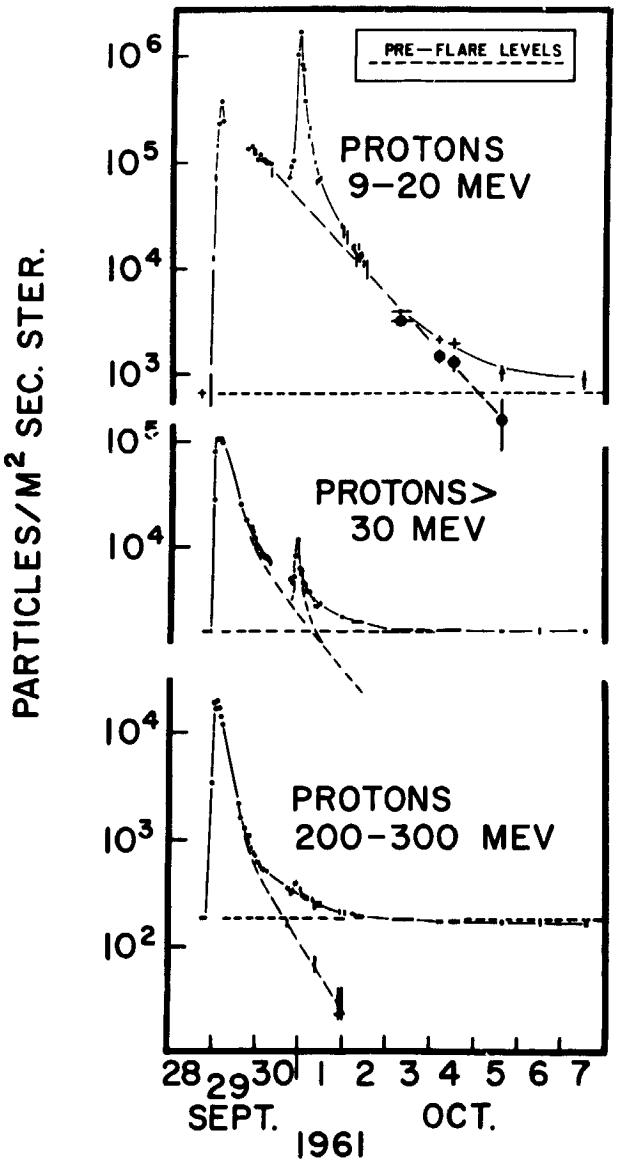

FIGURE 4.—Representative proton intensities between 28 September and 7 October, showing the delayed intensity increase of predominately lower-energy protons on 30 September 1961. The energy spectra of these particles are relatively constant with time, unlike those of the velocity-ordered primary solar proton event, and their arrival times are essentially constant with energy, occurring at the time of arrival of the enhanced solar plasma, two days after the flare.

There is a departure from a smooth decay at about 48 hours. At that time an increase took place in the intensity of low-energy particles which was associated with the arrival of a solar plasma stream that produced a sudden-commencement geomagnetic storm and a Forbush decrease. This occurrence is described in detail in the earlier paper, but for the sake of completeness it is briefly described here. The details of this increase, omitted in Figure 3, are shown for some energy intervals in Figure 4 on a linear time scale. Late on 30 September there is a sudden increase in intensity which is more marked at lower energies. The increase starts at about 1930 UT just before the sudden commencement of a magnetic storm at 2108 UT. The maximum intensity of particles of energy above 3 mev during the increase is more than ten times that attained during the main solar-proton event. Axford and Reid (1962) reported riometer observations of this burst of low-energy protons and had previously observed a similar event on 10 February 1958 (Reid and Axford, 1962). Other events of this kind have been reported by Charakhchyan *et al.* (1963).

After a full rotation of the sun, when the plage region responsible for the flare of 28 September was again close to central meridian, there was another burst of low-energy protons. This time the increase was much smaller. Figure 5, which is a plot of the total intensity above 3 mev on a further-compressed linear time scale, shows the full sequence of events. This recurrent event was also associated with enhanced solar plasma responsible for a recurrent geomagnetic storm and a recurrent Forbush decrease. We have put forward this event and a similar one following the 10 November 1961 flare as new evidence for the existence of long-lived solar streams (Bryant *et al.*, 1963).

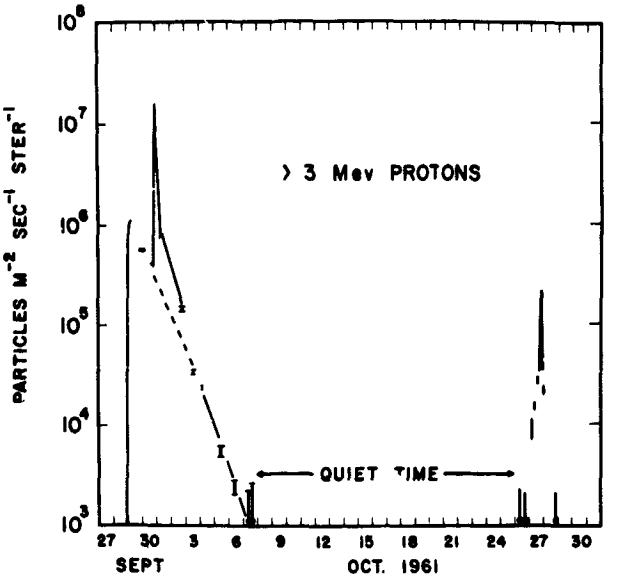

FIGURE 5.—The intensity of protons of energy above 3 mev between 30 September and 28 October 1961. The delayed increase on 30 September is superposed on the primary solar-proton intensity decay and the recurrent event on 27 October follows the completely event-free intervening period.

a) Velocity Dependence

The energy dependence of the rate of rise of intensity suggests that the propagation of the particles is a velocity-dependent process. A striking linear dependence on velocity is revealed by the following analysis.

We assume that all particles were accelerated at the same time or, more strictly, that they were all accelerated within a time interval short compared with the interval between acceleration and observation. We may then determine the distance a particle has traveled between acceleration and observation by taking the product of particle velocity and time from the beginning of the event. The time used here for the beginning of the event is 2208 UT, the time of the x-ray burst at the sun. We then convert the intensity vs. time profile to an intensity vs. distance profile. The intensity vs. distance profile is effectively a distribution in distance traveled. This distribution is a property of the medium through which the particles have traveled. Figure 6 shows the result of this treatment in which the distance traveled is measured in astronomical units. In constructing this figure the intensities of each component have been scaled to give the best fit to a common curve. The physical meaning of this normalization will be examined further below.

We note from Figure 6 that all components lie very closely on a common curve, apart from small-scale deviations to be discussed later as a separate topic. The fact that we have essentially a common curve shows that particles of all energies have traveled a given path length with equal probability; this is true for all path lengths to the extent that the various components of Figure 6 do

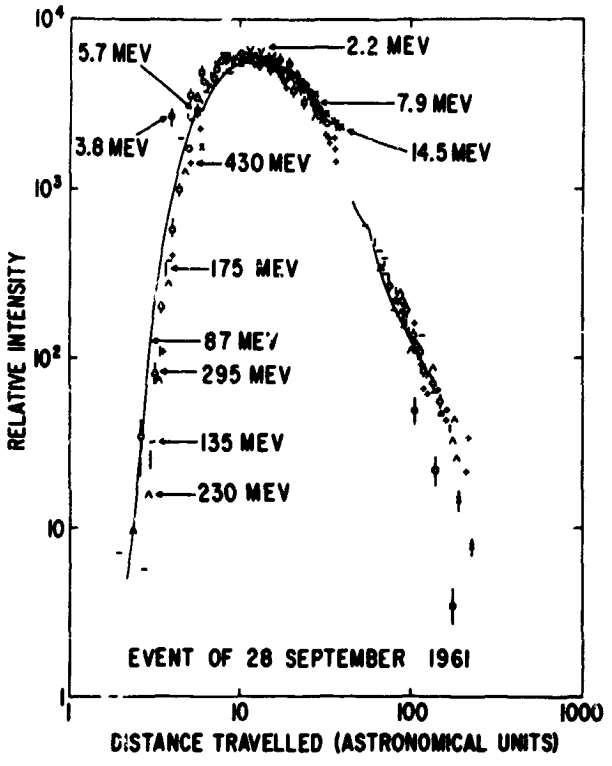

FIGURE 6.—The intensity vs time plots of Figure 3 converted to relative intensity vs distance plots. The distance is computed for each energy component by taking the product of the corresponding particle velocity and time from the event; the intensities are scaled to give the best fit to a common propagation curve. This fit occurs over a dynamic range in energy of a few hundred and a velocity range of 14, and over a time duration of several days.

lie on a common curve. We note that the distance traveled by most particles is many astronomical units, which indicates that propagation involved an important degree of scattering. Further, the degree of scattering is not a function of energy over the observed range. This suggests that the mode of propagation is a diffusion-like process and that energy-dependent processes, such as drift across magnetic field lines, play a minor role. In fact, it has been shown that the equation for simple diffusion describes the propagation curve of this particular event through its maximum (Bryant *et al.*, 1962). It fails to do so, though, during both the early anisotropic phase and the later stages where boundary conditions are important.

b) Source Spectrum

We now discuss the physical meaning of the scaling factors used to construct Figure 6. Consider the relative intensity of any two components of the event. We have recorded the intensities not as a function of time but as a function of distance traveled, and found that the relative intensity is essentially constant over a range from 2 to more than 100 astronomical units. There is nothing to suggest that an extrapolation back to zero distance in invalid. The relative intensity of two components at zero distance is, by definition, a measure of the shape of the source spectrum.

The scaling factors used to produce Figure 6 provide these relative intensities and Figure 7 shows the source spectrum obtained directly from them. The source spectra of two other events analyzed in a similar way are also shown. The ordinate of Figure 7 is arbitrarily chosen to show the maximum intensity reached at the earth. The differential intensities shown are proportional to the absolute differential intensities of protons produced at the sun and retain, therefore, the same spectral form, but the constant of proportionality which depends on the geometry of propagation is unknown. The spectrum is well represented by a power law in kinetic energy with a slope of about -1.7.

We note that, apart from small-scale fluctuations, this event is completely described by two graphs: the source spectrum of Figure 7 and the distribution of path length during propagation of Figure 6.

V. THE EVENT OF 23 OCTOBER 1962

The event of 23 October 1962 is the smallest discussed here and probably the lowest-intensity primary solar-proton event studied to date. It was initiated by a class 2 flare occurring 70° west of central meridian; further details of the flare and associated phenomena are listed in Table III. The event was also observed by the cosmic-ray equipment on Mariner II (H. Anderson and V. Neher, J. Van Allen, private communications, 1963).

Figure 8 shows the intensity vs. time profiles of various components of the event. We see that again the higher-energy components reach a maximum earlier than the lower-energy components. The intensity vs. time profiles, corrected for particle velocity and superimposed in the same way as for the event of 28 September 1961, are shown

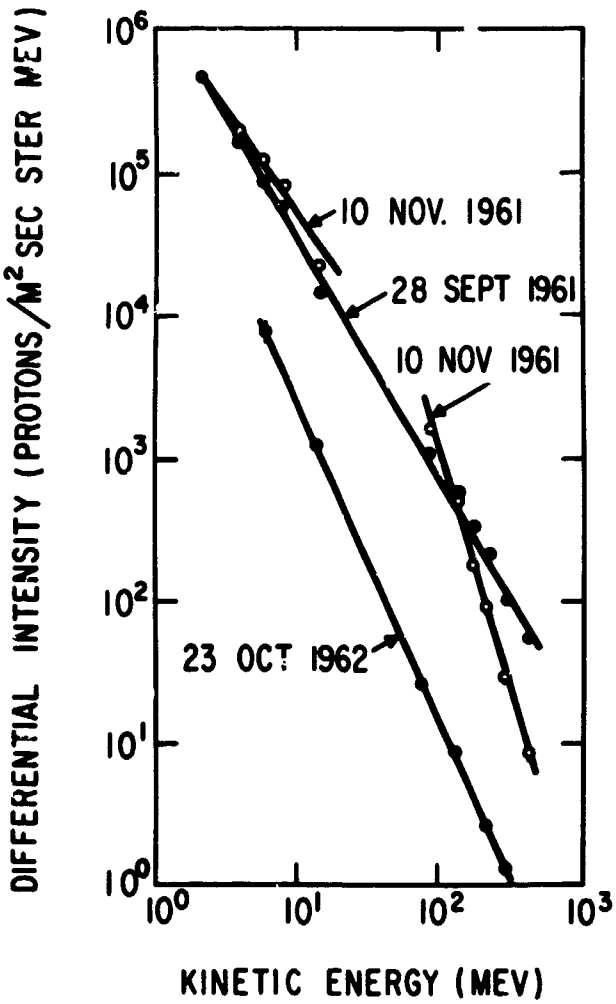

FIGURE 7.—The source spectra of three solar proton events. The intensities plotted are arbitrarily chosen to show the maximum intensities reached at the earth; as explained in the text the relative scaling of the two sections of the spectrum of 10 November is not necessarily meaningful. In the case of the solar proton events which totally conform to a velocity-dependent behavior, such as those of 28 September 1961 and 23 October 1962, the source spectrum is the unique differential energy spectrum of the protons at the time of their escape from the sun; in each event the source spectrum is proportional to that shown here with a constant which depends in an unknown way on the geometry of propagation.

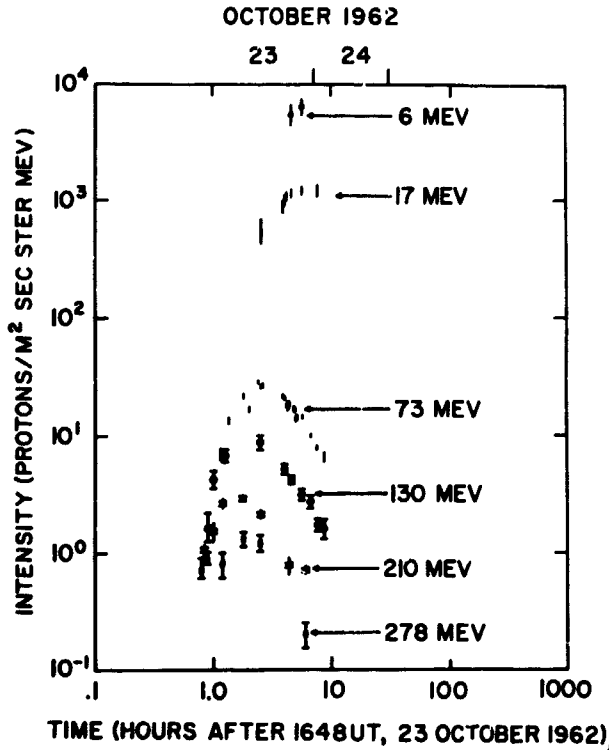

FIGURE 8.—The differential intensities of solar protons during the 23 October 1962 event plotted against time after the onset at the sun of type IV radiation. The behavior of this event is qualitatively similar to that of the early portion of the 28 September 1961 event. Due to the relatively low intensity of the event, the differential intensities of protons of energy above 300 mev could not be measured, the protons of energy below 5 mev did not arrive until after the satellite entered the magnetosphere.

in Figure 9. We find a good fit to a common curve so again the observation that higher-energy particles arrive earlier is explained quantitatively as a dispersion effect. The source spectrum obtained from the relative normalization used to construct Figure 9 is shown in Figure 7. We note that again it is well represented by a power law in kinetic energy. The slope of the spectrum in this case is about -2.3.

VI. THE EVENT OF 10 NOVEMBER 1961

The solar proton event of 10 November 1961 was one of two events observed by Explorer XII resulting from flares on the West limb of the sun (Table III). A long-lived solar stream emanating from the flare region produced a recurrent event 21 days later on 1 December (Bryant *et al.*, 1963).

Intensity vs. time profiles for this event are shown in Figure 10. A feature of these curves is a sudden drop in intensity at 1.3 hours (1546 UT). It occurs in all components that show a measurable intensity at this time. A second drop occurs at 3 hours (1730 UT). As we shall mention again in Section VII, these fluctuations are very likely unusually large cases of a feature common to all

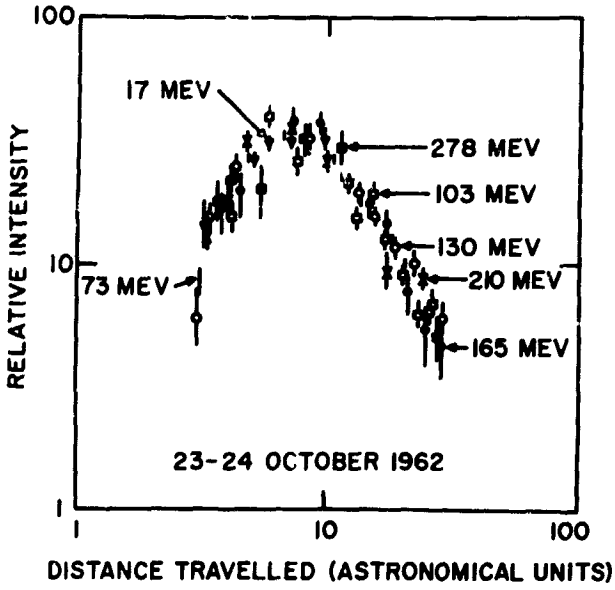

FIGURE 9.—The intensity vs time plots of Figure 8 converted to a relative intensity vs distance plots, scaled to give the best fit to a common propagation curve.

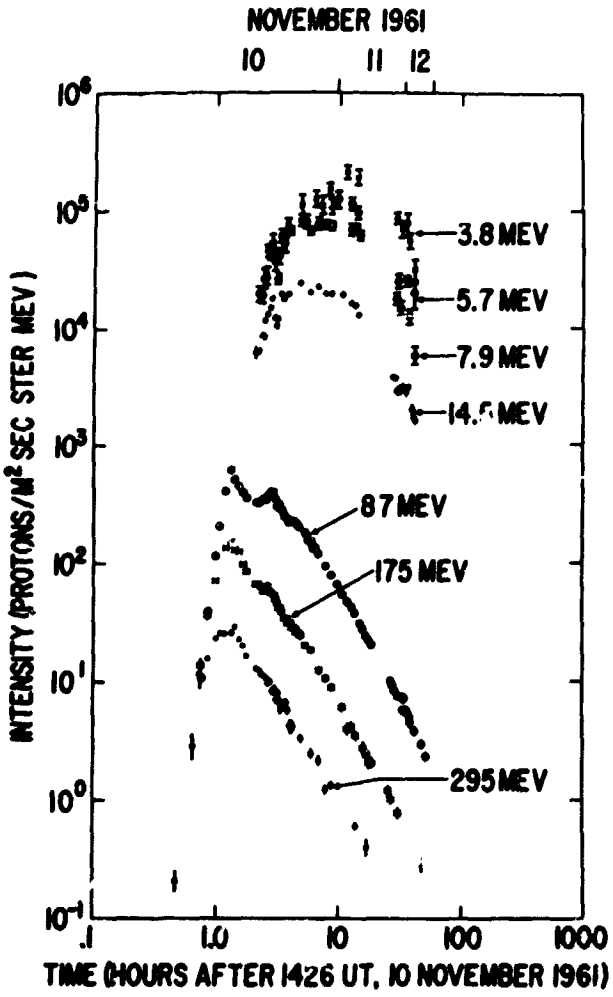

FIGURE 10.—The differential intensities of solar protons during the 10 November 1961 event plotted against time after the flare. A sudden drop in the intensities of the higher-energy protons occurs at 1.3 hours; this discontinuity in the slopes of the propagation curves occurs before the arrival of most of the lower-energy protons.

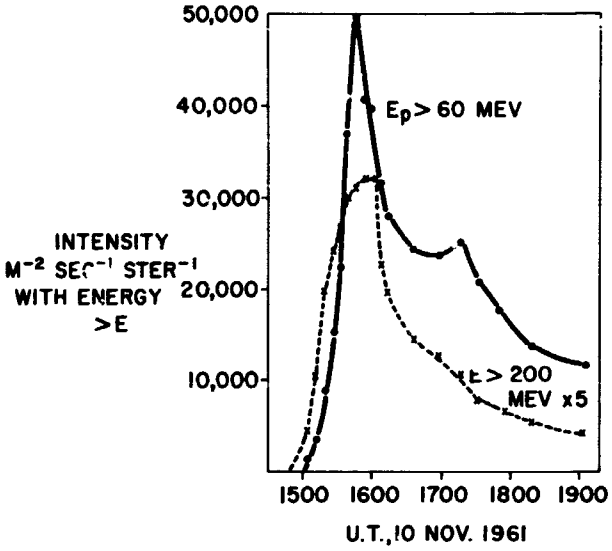
four primary events discussed here, namely a periodic intensity fluctuation with a period of about one hour. However, since these particular changes are so unusually large and sharp they may be due to some other cause. The flare producing this event was accompanied by unusual loop activity, so it may not be by chance that the solar-proton intensity exhibits unusual behavior. We are unable to link any specific happening at the sun with the changes taking place near the earth but we are able to deduce when it should occur. Figure 11 shows the integral intensities above 60 mev and above 200 mev plotted in a linear scale to show how drastically the behavior changed. The data are consistent with the breakdown having occurred simultaneously at all energies, but the time resolution of the measurements would permit a 15 minute dispersion and so is consistent with the dispersion to be expected from the velocity difference acting over a distance of 1 astronomical unit. The breakdown occurs in the 87 mev component somewhere between 1546 and 1556 hours. Since 87 mev particles take 20 minutes to travel 1 a.u., the first ones to bring information of a change would have left the sun between 1526 and 1536 if they traveled in a straight line, but (more likely) between 1521 and 1531 if they traveled along a curved path defined by the interplanetary magnetic field. Optical or radio information would reach the earth 8 minutes later, somewhere between 1529 and 1539. Though the flare showed great activity (see Table III for comments) we have found no evidence for any drastic change of conditions in this period.

a) Velocity Dependence and Source Spectra

The complicated structure of this event defies a description in terms of velocity dependence alone. As will be shown below, there are occasions on which a velocity dependence is revealed. Figures 12a and 12b show velocity-compensated intensity-distance profiles for the higher and lower energies taken separately. The higher-energy



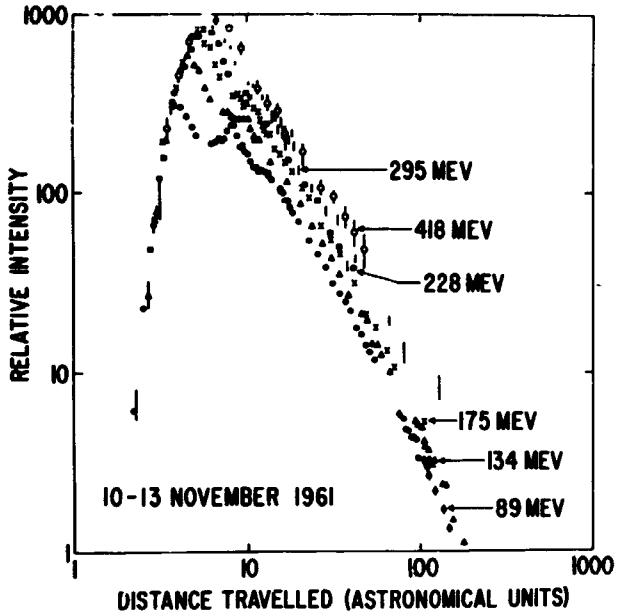


FIGURE 11.—The integral intensities of protons above 60 mev and above 200 mev during the first few hours of the 10 November 1961 event, plotted on a linear scale. These components are chosen so as to display the maximum dispersion of the times of peak intensity; since measurements were made every 7 minutes, the data are consistent with the peak intensities having occurred simultaneously.

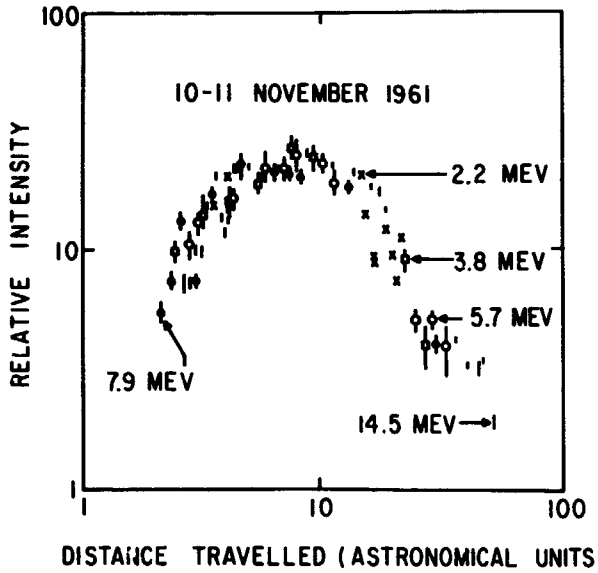

components are velocity dependent before the sudden drop in intensity at 1.3 hours, and the lower-energy components are velocity dependent throughout the event. The fact that the lower-energy components do not show a measurable intensity until after the breakdown of velocity dependence at higher energy introduces a further uncertainty in interpretation.

Two source spectra are shown for this event in Figure 7, one for the higher and one for the lower energies. Since the velocity-compensated intensity vs. time profiles are different, the relative normalization of the two sections of the spectrum is not meaningful. The normalization for each section of the spectrum is arbitrarily chosen to be the maximum intensity reached at the earth. It may be that the common fit of the low-energy intensity curves is not significant, since the deviation from a common propagation envelope increases as energy decreases among the high-energy groups.

b) Time Dependence

Although this event shows a velocity dependence that holds very well at certain times, it cannot be completely described by a single source

FIGURES 12a and 12b.—The intensity vs time plots of Figure 10 converted to relative intensity vs distance plots. Two groups are separately scaled to give the best fit to a common high-energy curve before the 1.3-hour peak, and to a common low-energy curve after it. A unique high-energy propagation curve does not exist throughout the event, but appears to be approached asymptotically with increasing energy. A common low-energy curve is apparent, but it may relate more directly to a local modulation than to interplanetary propagation.

spectrum and single propagation curve. Further, there are two sudden intensity drops that occur over a wide energy range with no dispersion. They almost certainly result from sudden changes

in the propagation medium which probably take place near the earth but, from the above discussion, which may also take place at the sun. Other effects of this kind are described in the next section and discussed more fully in section VIII.

VII. THE EVENT OF 10 SEPTEMBER 1961

The event of 10 September 1961 was initiated by a flare on the west limb of the sun. The intensity vs. time profiles of Figure 13 show that the event was dominated by intensity changes occurring simultaneously at all energies. Only gross features, such as the fact that the lower-energy components reach maximum intensity later than the higher-energy components, can be attributed to dispersion. There are no systematic changes of behavior with energy and consequently no quantitative fit to velocity dependence. A linear plot of three sample components (Figure 14) typifies the irregular behavior of the event. The high intensity reached by this and lower-energy components early on 12 September, about 1 day after the flare, is probably due to the arrival of enhanced solar plasma that produced a small cosmic-ray decrease at about that time following geomagnetic activity at 1106 UT on 11 September. This increase is like the delayed arrival of low-energy particles seen about 48 hours after the 28 September 1961 event, but in this case there is a much slower onset no doubt having to do with the west limb location of the flare.

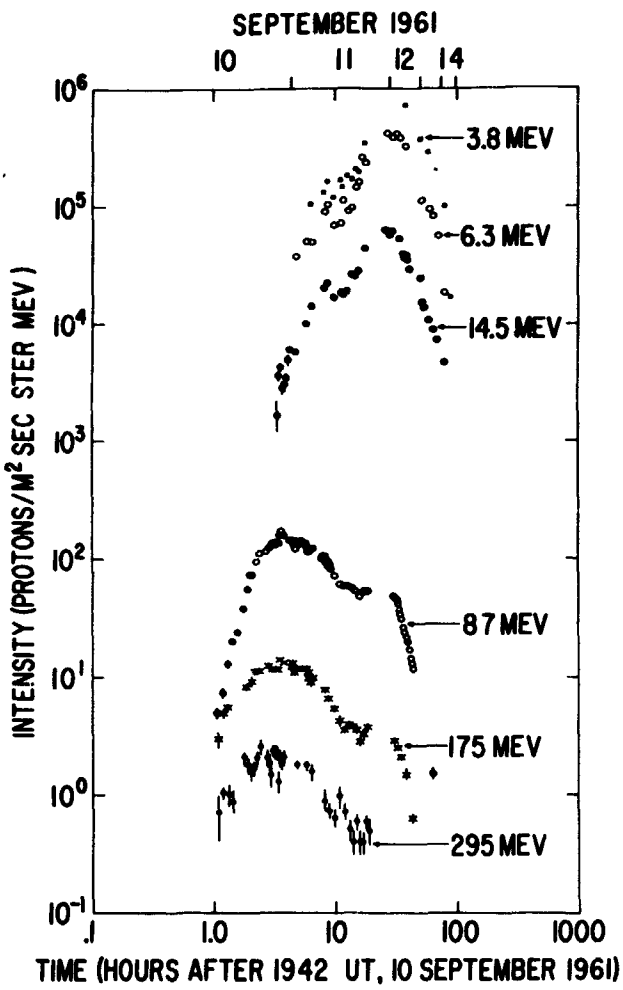

FIGURE 13.—The differential intensities of solar protons during the 10 September 1961 event plotted against time after the flare. There is a qualitative velocity ordering for the first 10 hours; during this time the higher-energy protons tend to increase in intensity before the lower-energy protons do, but there is no quantitative fit to a velocity dependence. Later in this event the intensities of protons of all energies increase together in a manner qualitatively similar to that of 30 September; this occurrence is also accompanied by cosmic-ray and geomagnetic fluctuations associated with the arrival of enhanced solar plasma.

a) Fluctuations

Superimposed on the large-scale features of the intensity vs. time profiles are a series of fluctuations which are nearly periodic, with the same frequency and phase at all energies. They take place in all these events, but are most clearly marked in the event of 10 September 1961. Figure 15, which shows the integral intensity vs. time profiles on a linear scale for the 5.7-mev and the 30-mev components of this event, illustrates these

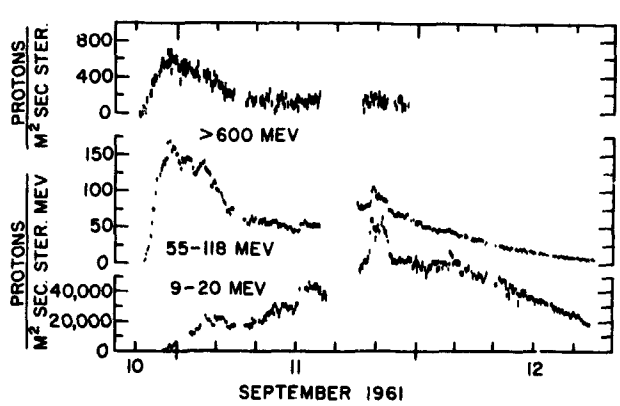

FIGURE 14.—A linear plot of the intensity of minimum-ionizing protons and of two lower-energy groups during the 10 September event, displaying both the irregular behavior of the intensity early in the event and the delayed increased on 11 September. These intensity variations dominate the pattern of this event.

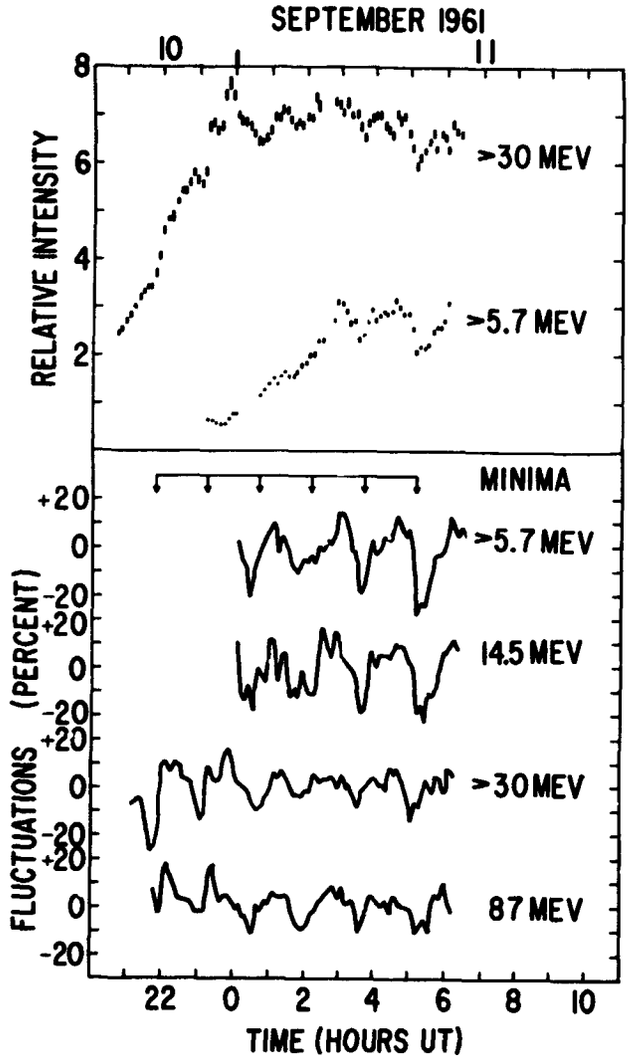

FIGURE 15.—Linear plots vs time of two integral proton intensities during the 10 September event; the deviations from the running means of intensity of these and two differential intensities are also shown in order to illustrate the relative fluctuations. A regular modulation appears having period and phase that are constant with energy; the times of minimum relative intensity are indicated to illustrate the approximate periodicity. Since there is no discernible velocity dispersion of this modulation within an event, these fluctuations are believed to have a local origin.

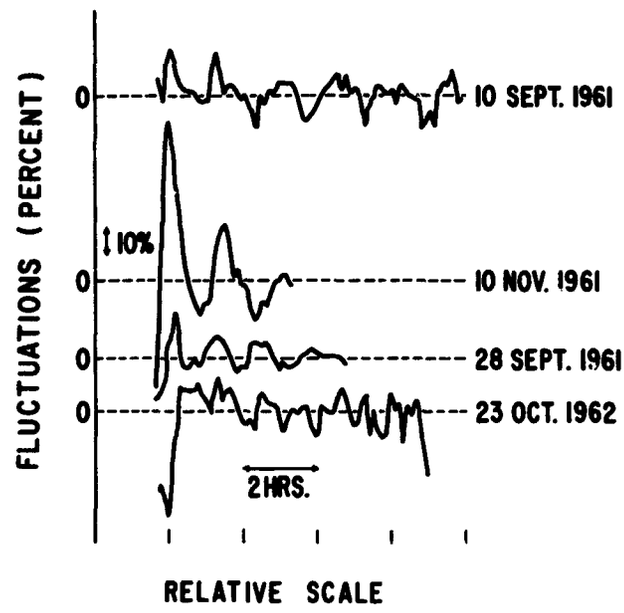

FIGURE 16.—The fluctuations of the 87-mev component of the solar proton intensities of four solar proton events. The period of the fluctuation is constant within an event but varies from 1. to 1.5 hours with the event.

fluctuations. To show the periodic fluctuations more clearly, the lower-frequency components have been removed by subtracting the running mean of one period length; the result for several energy components is shown in the lower half of the figures. Fluctuations of this kind occur to some extent in all events: Figure 16, in which the relative time scale is in units of hours, shows the fluctuation of the 87-mev component for all events. The sudden drops in intensity near the beginning of the 10 November 1961 event have the same frequency and phase as the other fluctuations, so it appears that they may not be isolated happenings caused directly by activity at the sun but the first two members of a series of fluctuations, although they were unusually large and very sharp. The amplitude of the fluctuations depends little on energy in any of the events. Table IV summarizes the periods and amplitudes of the fluctuations.

VIII. DISCUSSION

The following general statements can be made summarizing the results presented above.

(1) Solar proton events observed in the 2- to 600-mev energy region fall into at least three categories: the primary events have maximum intensity soon after the parent flare; these are sometimes followed about two days later by secondary events that occur with the arrival of the solar plasma; they also are occasionally followed by recurrent events that do not immediately follow solar activity but occur when the parent plage region passes central meridian on successive 27-day intervals.

TABLE IV.—*Solar-Proton Event Characteristics*

Event	10 Sept. 1961	28 Sept. 1961	10 Nov. 1961 Low Energy	10 Nov. 1961 High Energy	23 Oct. 1962
Energy Range of Velocity Dependence (mev)	(none detected)	1.4 to 500	1.4 to 22	55 to 500	4 to 330
Exponent of Source Spectrum		−1.7	−1.5	−3.5	−2.3
Scale of Source Spectrum at Max. Intens. $(cm^2\ sec\ ster\ mev)^{-1}$		1.6×10^6	1.4×10^6	$7.\times10^9$	$4.\times10^5$
Most Probable Distance (a.u.)		12	8	9	8
M.F.P. (a.u.) from Diffsuion Theory		0.04	0.06	0.055	0.06
Fluctuation Period (hours)	1.4	1.3	(none detected)	1.5	1.0

(2) The intensity vs. time profiles often show a linear velocity dependence. In two of the events under discussion (28 September 1961 and 23 October 1962) this velocity dependence lasts throughout the events. Exceptions occur in the event of 10 November 1961, which shows some early departure from this behavior and in the event of 10 September 1961, which shows no quantitative agreement with velocity dependence.

(3) All events show a series of periodic intensity fluctuations with a period of from 1. to 1.5 hours. These occur without dispersion.

If we convert those intensity vs. time profiles which show a quantitative, linear velocity dependence to probability vs. distance profiles, we are led directly to the following conclusions:

(4) Properties of the propagation medium and properties of the source can be studied separately and, in particular, the shape of the energy spectrum at the source can be obtained.

(5) Propagation involves an important degree of scattering (since the most likely distance traveled is about 10 astronomical units).

(6) The degree of scattering is independent of particle rigidity in the region below 1.5 bv (since all the propagation curves are the same).

a) Velocity Dependence

The analysis described in section IV, showing the velocity dependence of these events, has constituted a necessary but insufficient test. For example, we might have found an even closer fit had we compensated the intensity vs. time profiles by velocity raised to the power n, where n is close to but not equal to 1. We now show that the best value of n is indeed 1. To find the best value of n, the various intensity vs. time profiles were shifted horizontally and vertically to give the best fit to a chosen reference curve. No account was taken of particle velocity at this stage. The factors by which the curves were horizontally shifted were then plotted against particle velocity. The result is shown in Figure 17a in which, for comparison, lines of slope unity have been drawn through the points. The normalizations are arbitrary and depend on the curves chosen for reference. We find that the slopes of all lines are close to unity, the mean value being 1.0 ± 0.1. The energy intervals over which this test could be performed are implied by the figure and are indicated in Table IV. The various parts of Figure 17a have been superimposed in Figure 17b, where, as in 17a, a line of slope unity has been drawn through the points for comparison. (The energy range studied here does not extend sufficiently far into the relativistic region to permit a test of rigidity dependence as opposed to simple velocity dependence.)

Further evidence of velocity-dependent propagation in solar-proton events was provided by a comparison of alpha-particle and proton intensities during the events of 12 November 1960 and

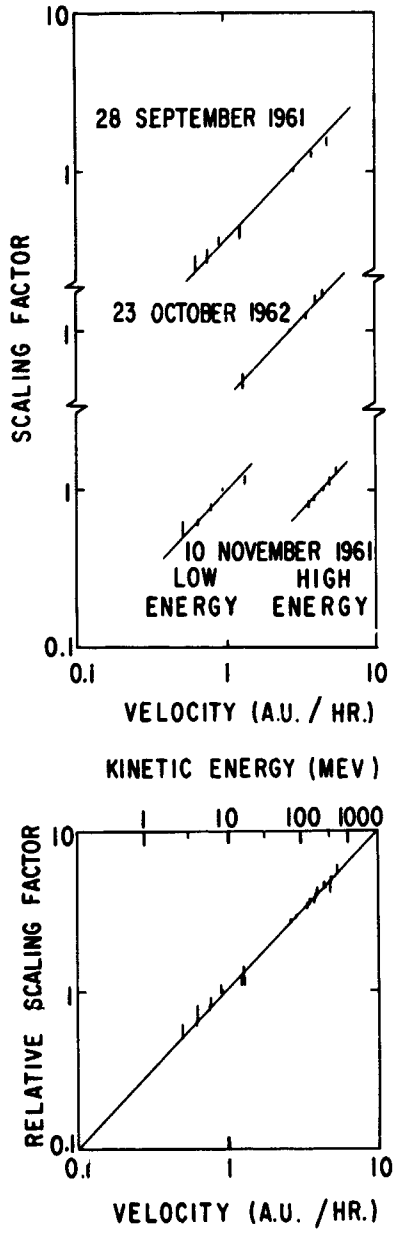

FIGURE 17a and 17b.—The scaling factors by which the differential intensity vs time plots of each event were shifted horizontally to give the optimum fit to a common curve. This effort was made to determine the nature of the dependency on velocity; comparison lines of slope 1 are used to indicate the closeness of fit to a linear velocity dependence.

15 November 1960 by Biswas *et al.* (1962, 1963). Several rockets carrying nuclear emulsions were fired into these events, and the relative intensity of alpha particles and protons having the same velocity was found to be the same at certain times even though the energy spectra of protons and alpha particles were changing with time.

b) The Source Spectrum

We note from Figure 7 that a given source spectrum is well represented by a power law in kinetic energy, although the event of 10 November 1961 is an exception in that two power-law spectra are required. The 28 September 1961 spectrum is remarkable in that it fits a power law over a dynamic range of nearly three decades in energy. The fact that there is no deviation from this smooth, simple spectral representation, even at the low-energy portion of this source spectrum, prompts us to put forward the argument, based purely on aesthetic grounds, that the amount of matter traversed by the solar protons after acceleration was less than the range of 1 mev proton, that is, about 1 milligram cm^{-2}. If we consider a beam of particles penetrating an absorber, we find the emerging spectrum very much depleted in particles with energies near that required to just penetrate the absorber. There is consequently a rapid change of slope at low energies. It seems unlikely, therefore, that an excess production of lower-energy protons would occur in such a manner as to exactly compensate their absorption in an amount of material greater than their range resulting in so simple a form of source spectrum.

We can draw no conclusions here about the solar-proton acceleration process from the shape of the source spectra, since there probably are a number of processes that would produce the observed spectra. Table IV gives the slopes of the spectra observed in the events under discussion.

c) The Propagation Medium

For the purpose of this discussion we define the propagation medium to be the medium through which solar protons travel after acceleration and escape from the acceleration mechanism. Let us now consider where the scattering takes place.

Meyer, Parker and Simpson (1956) suggested that during the 23 February 1956 event scattering took place in interplanetary space beyond the earth's orbit. Parker (1963) has discussed a mechanism of simple diffusion throughout interplanetary space; E. Roelof (private communication, 1963) has found that scattering by magnetic fields in interplanetary space that are irregular in space and/or time would produce a degree of scattering that is a function of particle rigidity.

McCracken (1962) introduced the idea of small-angle scattering caused by irregularities in an otherwise quasi-radial interplanetary field to account for the onset of isotropy in several solar-proton events. Anderson *et al.* (1959) and Gold (1962) have suggested that the processes of scattering and drift in the strong magnetic fields near the sun must play an important part in solar-proton propagation. Bryant *et al.* (1962) and Hoffman and Winckler (1963) found that the intensity vs. time profiles of several solar-proton events are well represented by those to be expected from a process of simple diffusion in interplanetary space.

The propagation curves of the three velocity-dependent events are compared in Figure 18.

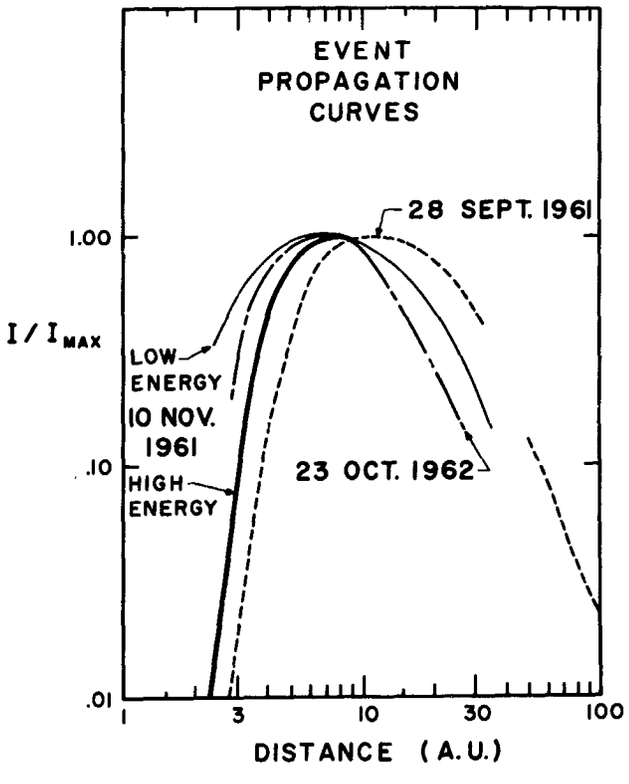

FIGURE 18.—The propagation curves of the three velocity-dependent events. These curves represent distributions in the distance travelled by solar protons from release into the propagation medium to the point of observation.

Apart from that of the low-energy component of 10 November 1961, the curves are geometrically similar to a remarkable degree. It is meaningful, therefore, to associate with each of the curves a parameter describing the rate of propagation of the event. A convenient parameter, though somewhat poorly defined, is the most probable distance traveled—that is, the distance traveled by the particles arriving at maximum intensity. These distances are listed in Table IV. We notice that the ordering of the propagation geometry in the three events correlates either with the phase of the solar cycle or with the displacement in longitude of the flare from about 70 degrees west, the origin of the earth-intercepting garden-hose line. For example, the slowest event is that from a flare at 29 degrees east; it is also the first in time. No significance is claimed for either correlation on the basis of such a small number of events.

We have mentioned that the intensity curves which fit a common propagation curve in a given event also fit the equation for simple diffusion. The resulting effective mean free paths and other parameters are listed in Table IV. In spite of this fit, it is difficult to see how solar protons could undergo a process of simple diffusion in interplanetary space especially since the garden-hose magnetic field has been observed to play an important part in guiding solar protons away from the sun. Another difficulty is that the observed velocity independence of the scattering implies that the scattering takes place at discrete scattering centers, rather than as a continuous process, as would otherwise seem more reasonable. The finding that the degree of scattering is independent of rigidity, combined with Roelof's result for continuous scattering in irregular magnetic fields, rules out such a mechanism at least for the events under discussion.

In order to reconcile a diffusive propagation with the previously observed guiding by the garden-hose interplanetary field, we consider a model in which scattering occurs near the sun and the particles escape to the earth after diffusing from the flare to the foot of a line of force providing direct access to the earth (Gold, 1959). We meet at once with two difficulties. Firstly, particle drift produced by gradients and curvatures in any general field near the sun would lead to a rigidity-dependent propagation. Secondly, there must be a certain amount of scattering in interplanetary space to account for the onset of isotropy (McCracken, 1962). Since any pitch-angle scattering would in general be accompanied by a change of guiding center there would be some

motion across the lines of force. The question then arises of the relative importance of motion along the lines of force and motion across them. We have then reached a process of anisotropic diffusion in interplanetary space instead of one of simple isotropic diffusion. Anisotropic diffusion conceivably could account for the observations, but there is no present theoretical treatment against which to test the data.

d) The Stability of the Propagation Medium

One important consequence of a velocity-dependent propagation is that low-energy protons travel through the propagation medium later than the high-energy protons and yet suffer the same degree of scattering. The average properties of the propagation medium can, therefore, remain constant for at least two days. It is important to remember, though, that changes must have been occurring in the magnetic field structure during the period of propagation. During the event of 28 September 1961, for example, there was an enhanced solar plasma moving out from the sun. Where the solar protons are isotropic in interplanetary space, even gross changes in magnetic field structure can produce only small effects if they take place many mean free paths from the point of observation. Only changes in magnetic field structure occurring near the satellite could strongly influence the measured intensity. We suggest that the character of the 10 September 1961 event was largely determined by such effects, dominating the intensity vs. time character more than the dispersion that otherwise should have been present. One can only speculate at this stage on the details of the mechanism producing time-dependent effects.

e) Local Disturbances of the Propagation Medium

As was mentioned above, the periodic intensity fluctuations are almost certainly a result of magnetic field structure in the region of interplanetary space near the earth. The fluctuations could result from, for example, adjacent regions of strong field and weak field constituting a trapping region or "magnetic bottle." Such regions would exclude some incident particles, thereby lowering the particle density in the region of the weaker field. Such regions might eventually become filled as a result of scattering from magnetic irregularities and, in fact, the magnitude of the fluctuation does decrease with time. This mechanism does not account for the regularity of the fluctuation unless there is postulated a characteristic wave motion of interplanetary plasma. The wave motion is not a property of all interplanetary plasma but is confined to the region between the magnetosphere and the quasi-stationary bow wave postulated by Axford (1963) and others. They pointed out that interaction between the solar wind and the magnetosphere should create a bow wave standing several radii from the magnetosphere on the sunlit side of the earth; this phenomenon was recently observed with a plasma detector (Bridge *et al.*, 1964) and a magnetometer (Ness *et al.*, 1964) on Explorer XVIII. All solar-proton measurements reported here were made outside the magnetosphere but behind this bow wave. It is possible, therefore, that the modulation of solar-proton intensity was confined to this region alone: regular structure in this region may be due directly to regular structure in the solar wind or it may be a natural frequency of the region.

Fluctuations with a period of approximately one hour were noted in the Explorer X magnetic field and plasma data (Heppner *et al.*, 1963; Bonetti *et al.*, 1963) where they were interpreted as a result of the passage of the space probe in and out of the pulsating boundary of the magnetosphere. Mathews *et al.* (1961) noted fluctuations with a period of 1.25 hours in neutron monitor records of the event of 12 November 1960. They suggested that these fluctuations were a direct result of pulsating decreases in the horizontal component of the earth's field measured at the equator. Winckler *et al.* (1961) also observed similar fluctuations in balloon measurements of solar-proton intensity. All of these forms of fluctuation may have been due to the same cause, namely, either a regular structure in the interplanetary plasma density or a natural frequency of the region between the bow wave and the magnetosphere.

VELOCITY DEPENDENCE AND SOURCE SPECTRA OF SOLAR PROTON EVENTS*

D. A. BRYANT†, T. L. CLINE, U. D. DESAI‡ AND F. B. McDONALD

It has become clear from recent satellite measurements[1,2] that solar protons can be transported from the sun to the earth in three distinct ways in addition to the direct way sometimes observed with cosmic-ray monitors at sea level.[3] We wish to describe these four modes of propagation and then show how the velocity dependence of one of these modes makes it possible to determine the energy spectrum of the particles at the time of release from the sun.

We classify solar particle events consisting of radiation with energy above 1 Mev into four distinct classes. The distinction between the classes depends upon the way in which the particles are transported from the sun to the region of the earth. The first two classes consist of particles that arrive at the earth in a manner determined by particle velocity; the first class consists of predominantly higher-energy anisotropic particles that arrive after nearly a direct transit and the second class consists of those that arrive after a diffusive propagation; the third class consists of those that arrive in a manner determined by the motion of enhanced solar plasma; the fourth class consists of those that depend upon the rotation of the sun. Typical delays between the occurrence of a solar flare and the arrival at the earth of particles in these four classes are different. The delay of the first class event is close to the rectilinear transit time for highly relativistic particles and is therefore only a few minutes. The arrival-time delay of the second class depends upon the rate at which particles propagate through interplanetary space and so varies with energy up to a number of hours. The typical delay for particles in the third class is not a function of energy since particles of all energies arrive with the enhanced solar plasma responsible for Forbush decreases and geomagnetic storms; it is the transit time of solar plasma across one astronomical unit, that is, about two days. The fourth class event takes place near the time of central-meridian passage of a plage region responsible for a flare and solar particle events of the other classes during the previous solar rotation. This fourth class is closely associated with long-lived solar streams. The delay between the parent flare and the arrival of these particles is not a function of energy since particles of all energy arrive with the plasma stream. The delay depends upon the solar longitude of the parent flare and may therefore be as long as one solar rotation, or 27 days. Figure 1 shows the times of occurrence of events of the latter three classes seen by Explorers XII and XIV during parts of 1961 and 1962. Four sequences of events are evident.

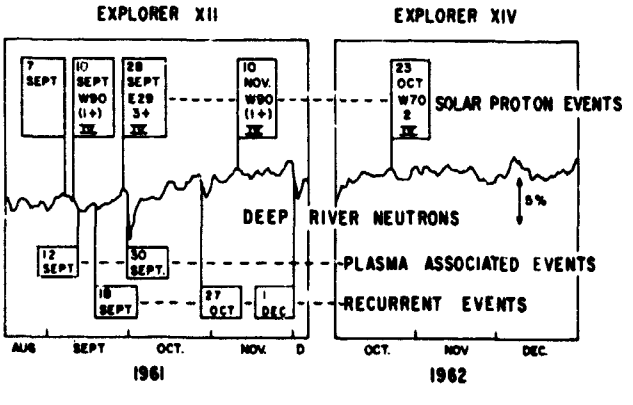

FIGURE 1.

†Goddard Space Flight Center and D.S.I.R. Radio Research Station, Slough, Bucks, England.

‡Goddard Space Flight Center and Physical Research Laboratory, Narrangpura, Ahmedabad, India.

No events of the first class were seen with sea-level monitors during these time intervals. Figure 2 shows the variation in intensity of interplanetary protons of energy greater than 3 Mev during a sequence involving all the three classes of events seen. Superimposed on the intensity decay of the velocity-ordered event of 28 September is the plasma-associated event of 30 September, followed in turn after 27 event-free days by a recurrent event on 27 October.

We now confine our attention to several velocity-ordered events observed on Explorers XII and XIV. We show how it has been possible in these events to determine separately the influence of the propagation medium and the form of the energy spectrum of particles released from the sun, that is, the source spectrum. These deductions were made possible by the fact that differential energy measurements could be made outside the magnetosphere with the equipment carried by these satellites.

A striking velocity dependence was shown by the solar proton event of 28 September 1961. This is shown by Figures 3 and 4. Figure 3 shows intensity vs. time profiles for various differential energy components. The abscissa is in units of hours from the time of the flare. Figure 4 shows the behavior of the intensities of the same differential components of the event but this time plotted not as a function of time but as a function of distance traveled. The distance traveled is simply the product of particle velocity and time from the flare. The intensity curves of the various components have been vertically scaled to give the best fit to a common curve. The physical meaning of this normalization will be examined further below. We note from Figure 4 that all components lie very closely on a common curve. We may interpret Figure 4 as a measure of the probability that a particle should travel a given distance before reaching the earth from the sun. The fact that we have essentially a common curve shows that particles of all energies traveled a given path length with equal probability. This is true for all path lengths to the extent that the various components of Figure 4 lie on a common curve. The statistical distribution of path length traveled is clearly a property of the propagation medium of interplanetary space. We note that the distance traveled by most particles is an order of

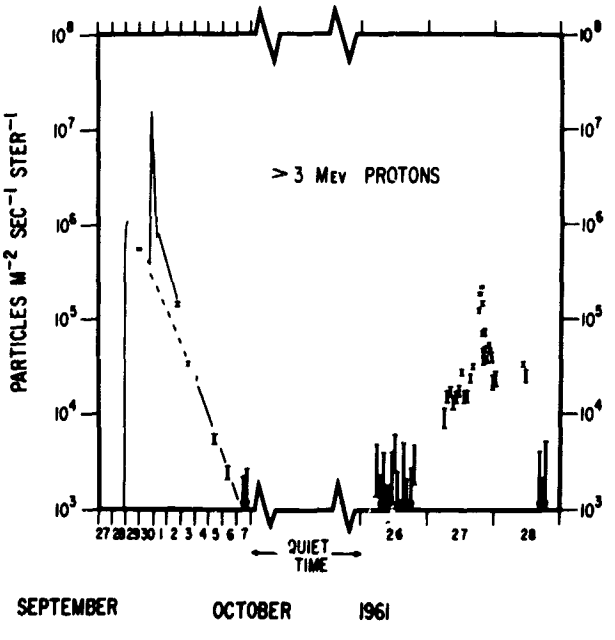

FIGURE 2.

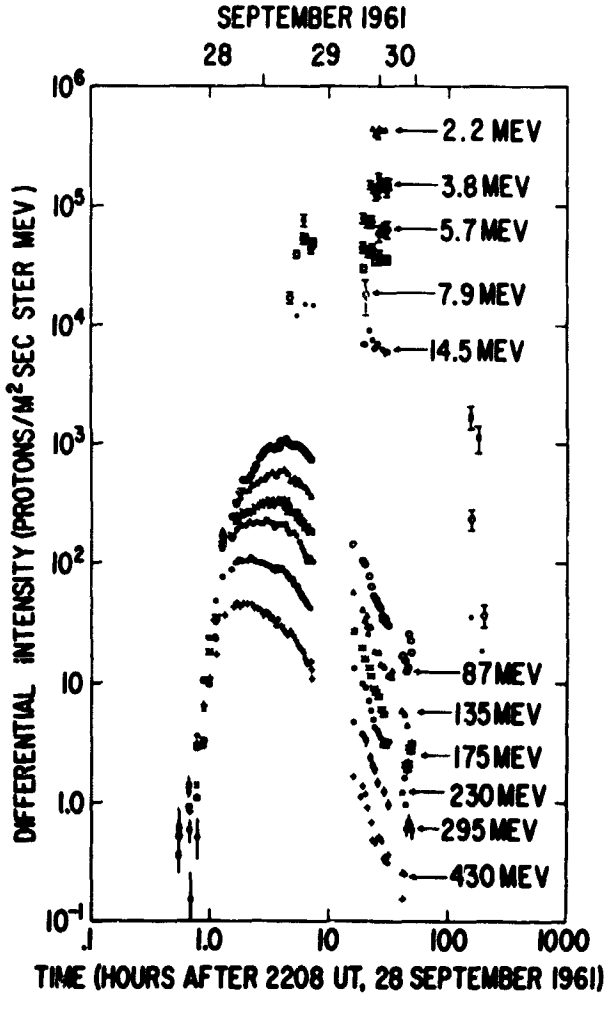

FIGURE 3.

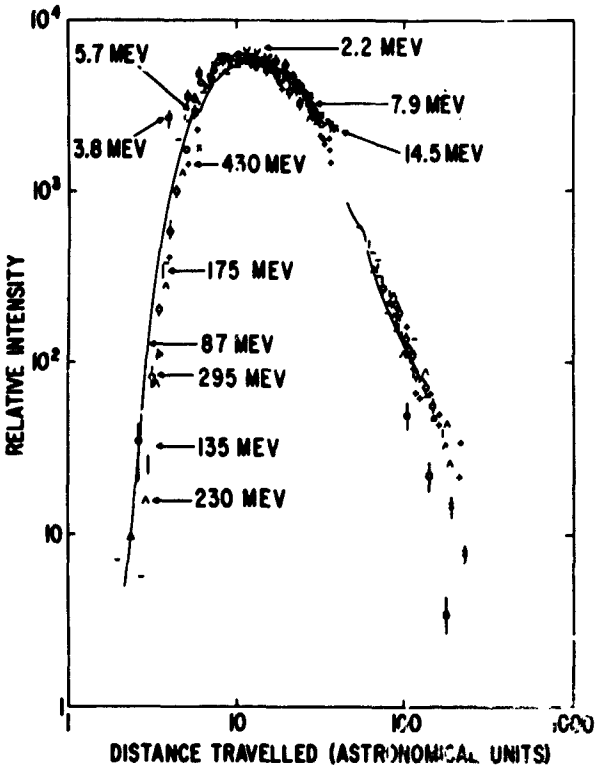

FIGURE 4.

magnitude larger than one astronomical unit. This indicates that propagation involved an important degree of scattering. Further, the degree of scattering is not a function of energy over the range examined. This suggests that the mode of propagation is a diffusion-like process and that energy-dependent processes, such as drift across magnetic field lines, do not play a dominant role. In fact, the equation for simple diffusion fits the propagation curve of this particular event through its maximum. It does not fit, though, at the beginning where anisotropy is dominant and at the end where boundary conditions must be taken into account.

Some of the other solar proton events we have observed with Explorers XII and XIV show the same degree of good fit to common, velocity-compensated, intensity vs. distance curves, but a few contrast by not fitting at all. We believe that these exceptions do not weaken our argument for velocity dependence but strengthen it by illustrating that there are times when the properties of the propagation medium cannot, by this technique, be sorted from the source characteristics because, for example, the medium could be changing as the particles are propagating through it. In fact, some solar events may thereby be combinations of events of our first three categories. Although our observations indicate that solar proton intensities in some cases depend very closely upon the first power of velocity, a choice between velocity and rigidity dependence cannot be made from these data alone. There are indications from earlier emulsion measurements of solar proton and alpha intensities,[4] however, that velocity dependence is preferable.

We discuss now the physical meaning of the scaling factors used to construct Figure 4. Let us consider the relative intensity of two components of the event. We have recorded the intensities not as a function of time but as a function of distance traveled and found that the ratio of intensities is essentially constant over a range from 2 astronomical units to more than 100 astronomical units. There is nothing to suggest that an extrapolation back to zero distance is invalid.

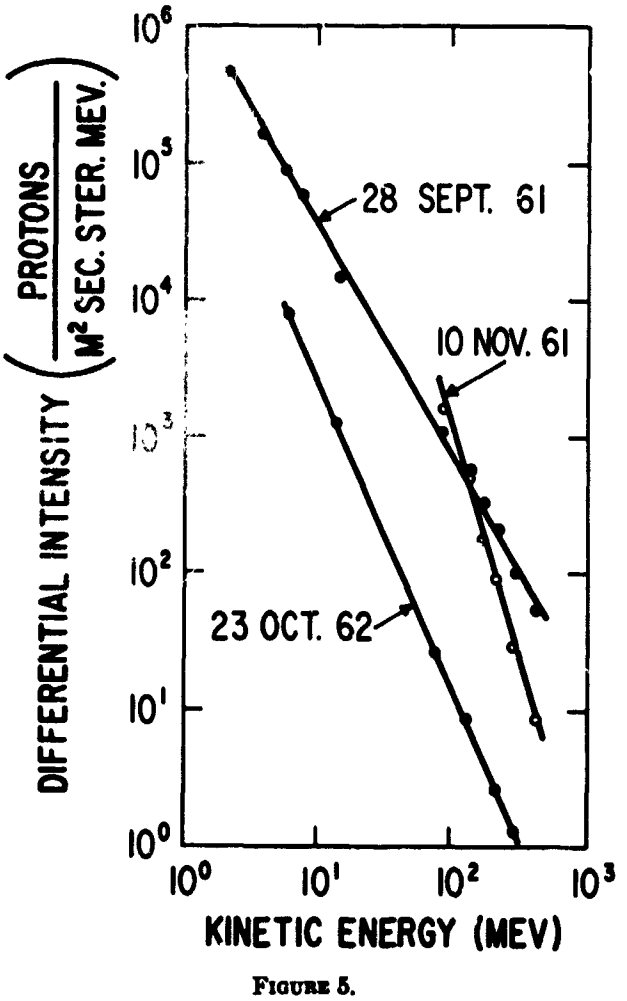

FIGURE 5.

The ratio of the intensities of two components at zero distance is, by definition, a measure of the shape of the source spectrum. Figure 5 shows the source spectrum obtained directly from the scaling factors used to produce Figure 4. The source spectra of two other events analyzed in a similar way are also shown. The ordinate of Figure 5 is arbitrarily chosen to be the maximum intensity reached at the earth. The differential intensities shown are proportional to the absolute differential intensities of protons produced at the sun and retain, therefore, the same spectral form, but the constant of proportionality depends on the geometry of propagation, which is unknown. (For example, since simple diffusion theory fits this propagation curve through maximum intensity, the numerical solution it gives for the source intensity is of the same spectral form, but that solution is for diffusion in an infinite, isotropic sphere, and is probably not a meaningful one.)

We note from Figure 5 that the source spectra are commonly very well represented by power laws in kinetic energy. This fact prompts us to put forward the argument, based purely on aesthetic grounds, that the amount of matter traversed by the solar protons after acceleration was less than the range of 1 Mev proton, that is, about 1 milligram cm^{-2}. It seems highly unlikely that an excess production of lower-energy protons would so exactly compensate their absorption in an amount of material greater than their range such as to produce so simple a form of source spectrum.

An interesting feature of these events is the existence of small-scale deviations from a common curve. Superimposed on the generally velocity-dependent intensity-time profiles are fluctuations which are nearly periodic with the same frequency and phase over the entire energy range studied. These fluctuations are evident in the velocity-ordered events discussed above, but are more striking in the 10 September 1961 event which showed no velocity dependence and was no doubt influenced by greater interplanetary disorder. Figure 6 shows plots of some sample intensities and indicates the periodic fluctuations. In this event the period is about 1.5 hours; in other events the period is slightly different. Since the transit-time dispersion over the energy range studied is significant, the fact that, in any given

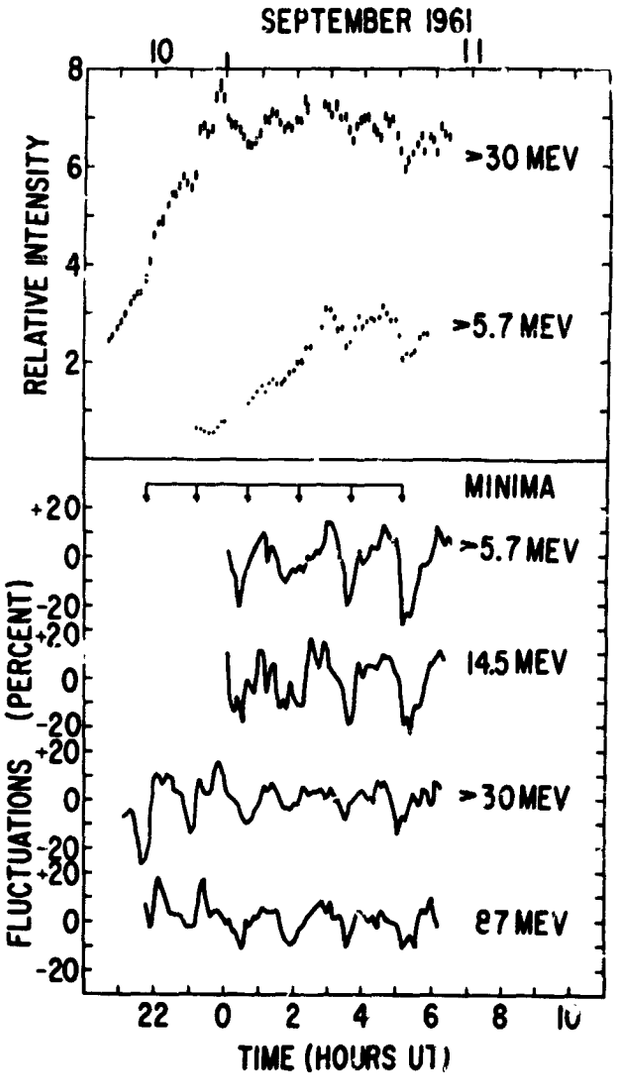

FIGURE 6.

event, the fluctuations have the same period and are in phase at all energies shows that their origin is local. We suggest, therefore, that they reflect the magnetic field structure in local interplanetary space, but we as yet have no explanation for their periodicity.

COMMENTS ON THE VANGUARD 3 MAGNETIC FIELD DATA AND ANALYSIS*

JOSEPH C. CAIN AND SHIRLEY HENDRICKS

The principal results of the Vanguard 3 magnetic field experiment are summarized in a report and a paper [*Cain et al.*, 1962 *a*, *b*]. Since some of the material presented in these documents has been used by several authors, it is worth while to clarify a few points and to report a modification indicated by a later analysis.

The Vanguard 3 report gives a series of 63 spherical harmonic coefficients fitted to the data themselves by the iterative procedure of *Jensen and Cain* [1960] (reviewed by *Heppner* [1964]). This field, designated Vanga, used g_n^m and h_n^m to $n=m=7$ and gave an rms deviation from the data of 21 γ. The data selected for this fit were the 2797 observations given by *Cain et al.* [1962*a*] as $L=0$(=best data), excluding four such observations with residuals (measured F−computed F) over 100 γ. These observations were those recorded at Blossom Point, Maryland, on October 4, 1959, at 0h 47m 23s, 0h 47m 37s, 19h 50m 11s and 19h 50m 29s. In the Vanguard 3 report we said 'The Vanga field should be construed only as a smooth curve through these data and not necessarily as a physically meaningful description of the geomagnetic field in regions remote from the Vanguard measurements.' We should note here that there is also no claim that the Vanga coefficients provide a description of other than the *total scalar field* $|\bar{F}|$ within the spacetime volume over which the data are taken. The validity of these statements is amply illustrated by *Leonard* [1963] in connection with the Johnson Island tests. In his paper he shows that the observed auroral emission seen at a point conjugate to the bomb explosions could best be predicted by the set of 48 coefficients derived by *Jensen and Cain* [1962] and that the worst agreement resulted from using the Vanga coefficients. This disagreement is not surprising, since the field line tracing requires a knowledge of the vector field and since the nearest Vanguard 3 observation was made more than 3000 miles away!

One feature of the Vanguard 3 data relative to the Vanga fit was the systematic variation of the residuals with altitude. This fact was illustrated in Figure 2 of *Cain et al.* [1962*b*] and led to the conclusion that 'A smaller systematic variation of the field was noted that appeared to require external sources. . . .' Subsequent analysis of the data using a slightly modified technique has changed this conjecture. This improvement was to solve the whole set of equations simultaneously in the linear expansion of potential rather than using the previously adopted technique of solving for small sets (up to 16) of coefficients at once, holding the rest constant, and iterating so as to correct all coefficients for a given n at a time. These methods were used, since difficulties were originally found in finding stable solutions to the Vanguard 3 data, and it was thought that the problem was one of losing accuracy in the solution involving large determinants.

The results of using the improved techniques are shown in Table 1, where we give the smallest

TABLE 1.—*rms Residuals between Vanguard 3 Data and Sets of Spherical Harmonics using Different Numbers of Coefficients*

Maximum $n=m$	No. of Coefficients	rms Residuals, γ
3	15	83.2
4	24	25.6
5	35	17.6
6	48	16.9 Vangb
7	63	16.7

*Published in *Journal of Geophysical Research*, 69(19):4187–4188, October 1, 11964.

rms residual to the Vanguard 3 data that could be determined with the specified number of coefficients. As can be seen in this table, it was possible to obtain a fit to a rms of 17.6 γ with only 35 coefficients, whereas the previous best fit of 21 γ required 63 coefficients. Only spatial terms are used here owing to the short period of 84 days over which the data are taken. However, an inspection of the isoporic charts in F over the regions of measurement show changes in the earth's surface up to 15 γ in a quarter year. It is thus likely that a somewhat better fit to the Vanguard 3 data will be made possible by the inclusion of secular change terms even over this short an interval.

The 48-term set designated 'Vangb' in Table 1 was used to re-evaluate the conclusions drawn in the Vanguard 3 paper. The only change is illustrated in Figure 1, which gives the average deviation with altitude of the observations from this new field. The systematic shift with altitude illustrated in Figure 2 of the original paper [*Cain et al.*, 1962*b*] vanishes. Thus there are no longer any detectable local sources in the volume of the Vanguard 3 measurements that contribute systematically to the field at the level $\sim 6\gamma$. The major conclusion of the Vanguard 3 paper that the sources of the D_{st} field must lie above altitudes of the order of 2500 km remains unaltered. The positive correlations previously obtained between D_{st} at the earth's surface and the residuals to the new fit are not lessened. Instead, the correlations shown in Figure 9 of the Vanguard 3 paper are slightly more positive.

Although the Vangb field gives comparable results in serving as a tool for analysis of the Vanguard 3 magnetic field data, its validity outside the regions of the data is even less than for Vanga. This fact was well illustrated when we attempted to find the Vangb conjugate point for Johnson Island to compare with those computed and observed by *Leonard* [1963]. The result is that for Vangb the magnetic equator passes nearly *through* Johnson Island and thus the conjugate point starting with an altitude of zero falls within 100 km!

Further analyses of the main geomagnetic field have been done which include the use of the Vanguard 3 data as a valuable addition to the total data set. The results of this work were reported recently [*Daniels and Cain*, 1964] and will form the basis of a publication in which a realistic field will be presented. It is hoped that workers in the field of geomagnetism will meanwhile confine the use of the Vanga set of coefficients to interpolations of the scalar field $|\bar{F}|$ in the spacetime volumes enclosed by the Vanguard 3 data and not attempt extrapolations to other regions where the result is likely to be fictitious.

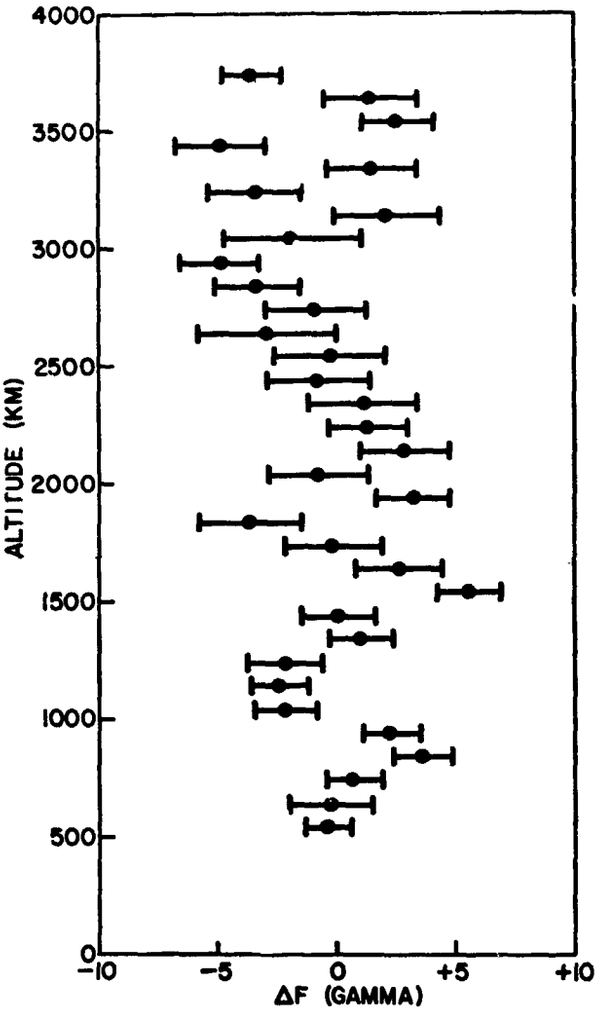

FIGURE 1.—Average deviation of the Vanguard 3 magnetic data from the 48 coefficient Vangb field plotted as a function of altitude. These average residuals are given with error bars signifying the standard error of each mean.

PARTICLE ACCELERATION IN CISLUNAR SPACE*

A. G. W. CAMERON

The recent discovery[1] of a characteristic red luminescence when enstatite achondrites are bombarded by 40-keV protons led Kopal and Rackham[2, 3] to observe the Moon in order to determine whether a similar luminescence might be excited in lunar materials by solar wind bombardment. On the night of November 1–2, 1963, Kopal and Rackham observed an enhanced red emission from the vicinity of the crater Kepler. The duration of the red glow was of the order of 10 min or longer, and it appeared twice within a 2-h period. No repetition of this phenomenon was observed on the following night or at the next lunation.

Among the circumstances which may be relevant to an explanation of this phenomenon are the following: the enhanced emission occurred within one day of Full Moon. There had been a class 3 solar flare on October 28 and two class 1 flares on November 1, and the Earth was in a magnetically disturbed region of space. Cosmic-ray neutron counts indicated that recovery from a Forbush decrease was occurring at the time of the luminescence.

Kopal and Rackham [2] noted that the red glow from the Kepler region approximately doubled the brightness of the lunar surface there, so that the amount of energy emitted in the red was approximately 10^4 ergs/cm^2 sec. They further concluded [2] that since the highest luminescent efficiency (in the Bustee meteorite) had been found to be 20 percent,[1] it was likely that the incoming energy responsible for the luminescence was at least 5×10^4 ergs/cm^2 sec. The other two enstatite achondrites examined by Derham and Geake [1] had a luminous efficiency lower by a factor of three, so it is not unlikely that the incident energy exceeded 10^5 ergs/cm^2 sec. Because approximately the same luminous efficiency is found during bombardment of the meteorite powder by photons of several MeV as by protons of 40 keV[4], it appears likely that the above conclusions ear not sensitive to the energy of the particles bombarding the lunar surface.

Kopal and Rackham [2] have discussed a possible interpretation that the above events resulted from bombardment of the lunar surface by an enhanced flow of solar plasma initiated by the preceding solar activity. They noted that the energy flux required was five orders of magnitude greater than that normally available in the solar wind, which must be considered a difficulty. Kopal [4] has suggested that an alternative mechanism might be required in which the lunar bombardment would involve particles, of energy greater than those of the solar wind, which had been accelerated in the preceding class 3 flare and trapped by the chaotic magnetic field configuration then existing in interplanetary space. It is the purpose of this communication to suggest a further alternative.

The region of interaction between the solar wind and the Earth's magnetosphere is very complex; but the following general picture has emerged (see, for example, Hines [5]). In the solar direction the pressure of the solar wind compresses the magnetosphere, but the solar wind must then flow around the magnetosphere, so that in the antisolar direction a long cavity is formed into which the terrestrial magnetic field can expand. Quite large energetic particle fluxes are observed near the magnetosphere boundary in the antisolar direction, and it has been suggested that the region of trapped radiation may extend to a distance comparable with that of the Moon.[6] A recent analysis of terrestrial magnetic activity has shown that the general level of activity is slightly changed for several days on either side of Full Moon, suggesting that the antisolar magnetic cavity may extend to the lunar distance.[7] Since the solar wind

*Published in *Nature* 202(4934):785, May 23, 1964.

exhibits supersonic flow with respect to the Earth, it is necessary that a standing shock wave must be formed beyond the magnetopause. The highly turbulent magnetic fields between the shock front and the magnetopause have been observed.[8]

It seems to be the case that wherever turbulent fluid motions and chaotic magnetic fields exist in Nature, the acceleration of charged particles to energies much exceeding thermal energies takes place. This is inferred to be the case in strong extragalactic radio sources, in supernova remnants, in solar flares, and in the magnetosphere itself. One acceleration mechanism which can be very efficient in certain circumstances is the second-order acceleration of charged particles traversing time-varying fluctuations in a magnetic field system.[9] This is probably responsible for the acceleration of particles in the outer part of the magnetosphere which are then dumped directly into the atmosphere to produce aurorae. The process will be enhanced at times of greater magnetic activity when the solar wind is exerting varying pressure on the magnetopause.

It is a logical extension of these considerations to expect that extensive particle acceleration will take place in the shock zone beyond the magnetopause. The particles thus accelerated will be discharged down the magnetic field lines in the antisolar direction. By analogy with the auroral discharges, it is possible that the particle beams in the antisolar direction may carry an energy flux large compared to that in the solar wind. However, since the energy going into the charged particle beams must be derived from that of the solar wind, it is evident that such particle streams will be isolated in local regions of space, and that the integrated energy flux of plasma and particles together cannot exceed the initial energy flux of the plasma flow.

The luminescence near the crater Kepler observed by Kopal and Rackham may have been produced by these energetic particle streams. It may also have been produced by trapped radiation in the distant tail of the magnetosphere. Many more observations will be needed to evaluate the plausibility of these two possibilities. In either case, such luminescence can be expected to occur principally at times near Full Moon and during unusually large magnetic activity on the Earth. Because of the localized nature of the incident particle streams, lunar luminescence excited in this way is likely to be observed only in small regions of the Moon at any one time and to exhibit variations with periods of a few minutes.

Because of the complex character of the phenomena suggested here, it is not possible to suggest the range of energies to which particles are likely to be accelerated in the shock zone, and hence it is not clear whether such particle streams will constitute a radiation hazard to a manned lunar landing or to manned spaceflight in the antisolar direction.

I wish to thank Prof. Z. Kopal for a stimulating discussion of his observations.

DETECTION OF INTERPLANETARY 3- TO 12-MEV ELECTRONS*

T. L. CLINE, G. H. LUDWIG, AND F. B. McDONALD

In this Letter we report the direct observation of interplanetary electrons of energy above 3 MeV with the IMP-1 satellite (Explorer 18).

Electrons observed in the primary interplanetary radiation in the BeV energy region by Earl[1] and in the 200-MeV energy region by Meyer and Vogt[2] are believed to be of galactic origin because their energies are as high as those assumed to be necessary for their penetration into the inner solar system and because their measured intensity agrees with that which was anticipated to account for galactic radio emission. Support was lent to this hypothesis when the modulation characteristics of these particles were observed[3] to be similar to those of cosmic-ray protons and their positron-to-electron ratio was found[4] to be compatible with an origin of at least half of them in meson-producing cosmic-ray interactions in the interstellar medium. We feel that the existence of an interplanetary flux of electrons lower in energy by orders of magnitude is interesting because of the possibility that these too may have a cosmic origin. If so, their study should yield entirely new information about the galactic electron sources and modulation characteristics. If they are of solar origin, there are analogous implications. We wish to demonstrate here that the flux of lower-energy electrons we observe is indeed a primary component of the interplanetary radiation, and to discuss its properties in terms of its possible origin, either galactic or solar.

The observations reported here were made with a scintillator telescope on Explorer 18, a satellite placed in an elliptic orbit with an apogee height of 193,000 kilometers. Data were taken from the launch, on 27 November 1963, until 6 May 1964 when the satellite passed into a long period in the earth's shadow, causing failure of the detector. During this time interval the apogee moved from the sunlit side of the earth beyond the magnetosphere (terminating at about 70,000 km) and beyond the earth's shock front (observed with a magnetometer[5] and plasma sensor[6] at about 100,000 km) to the region behind the earth and inside the shock front. Electron data taken only when the satellite was beyond 125,000 kilometers are reported here; throughout the life of the instrument these data continued to be free from effects due to the trapped radiation.

The detector was developed[7] to study low-energy cosmic-ray protons, electrons and light nuclei. It is composed of three scintillators: two in coincidence, measuring energy loss and total energy, and a guard counter in anti-coincidence. When a table of intensity vs. measured energy loss vs. measured total energy is constructed from data taken at apogee, there is seen a distinct counting rate component of minimum-ionizing energy loss and of low apparent energy. An analysis of the topology of distributions in energy loss and in total energy through this minimum-ionizing component indicates that indeed it is composed of three distinct particle groups: On group with total energies corresponding to electrons that stop within the detector, a much smaller group with a high apparent total energy equal to or exceeding the energy loss of a minimum-ionizing cosmic ray traversing the detector, and a third group with very low total energies. We believe that the latter two components are surely secondary radiations composed of, respectively, cosmic rays that avoid detection by the guard counter (for example, by turning into neutrals through reactions within the detector) and gamma rays made locally in the spacecraft, producing random and coherent coincidences between the energy loss and total energy detectors.

*Published as *Goddard Space Flight Center Document X-611-64-368*, November 1964

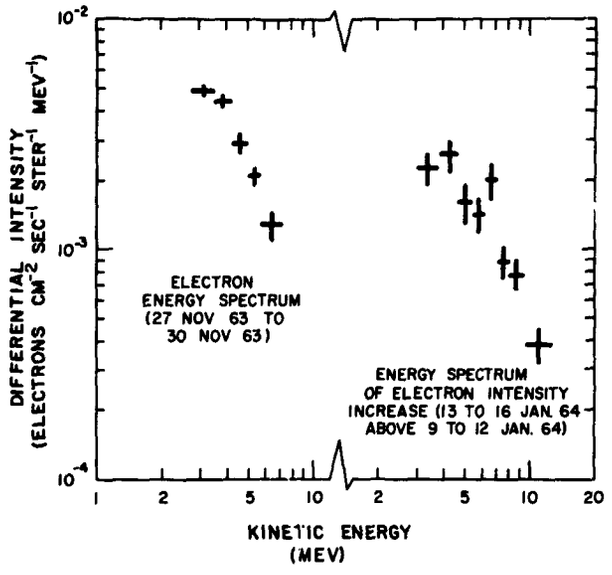

FIGURE 1.—Differential energy spectra of electrons observed beyond 125,000 kilometers from the earth. The first spectrum is from the apogee of the first orbit; the second is the difference between measurements from the 13th and 12th orbits and indicates the first significant increase in intensity.

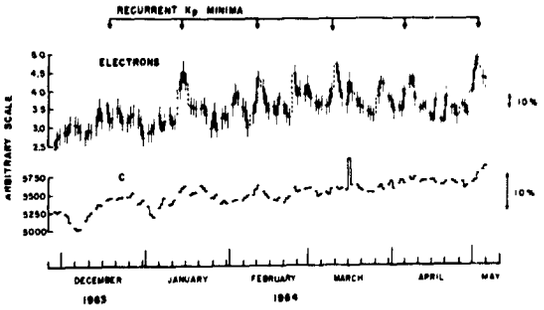

FIGURE 2.—Integral counting rate of electrons throughout the active life of the instrument plotted in quarter-orbit averages. The counting rate "C" of cosmic rays into a thinly shielded scintillator and the times of one recurrent minimum of the interplanetary index K_p are also shown. Recurrent Forbush decreases are seen in the cosmic rays in early December and January and a small solar proton event occurs in March; other increases can be largely attributed to the electron mixture in the cosmic rays.

These secondary effects were eliminated to produce Figure 1a, which shows the energy spectrum of electrons obtained during the first orbit (27 to 30 November 1963) at a time when the observed electron intensity was at a typical minimum and when there were no measurable time variations. Figure 1b shows, for comparison, a spectrum of the difference between the first statistically significant intensity increase (13 to 16 January 1964) and the immediately preceding intensity (9 to 12 January). No background corrections were necessary to produce the latter distribution since the electron intensity increase was unaccompanied by an increase of either secondary gamma rays or spurious cosmic rays; it was therefore possible to determine the intensity to higher energies. The nearly identical shapes of the two corrected spectra suggest that the electrons seen daily may have the same origin as the extra ones seen on days of increased electron flux. The integral intensity of electrons of energy between 2.7 and 7.5 MeV is $210. \pm 10.$ electrons/m²sec.ster., and that of the increase between 3. and 12.5 MeV an additional $100. \pm 10.$ electrons/m²sec.ster.

To demonstrate that most of the observed electrons are not of local or secondary origin at the satellite (e.g., such as knock-on or cascade-shower electrons produced in or near the detector) we consider their time variations. Figure 2 shows the counting rate of these electrons, partially corrected for slow gain drifts in the detector, plotted in the form of one-quarter-orbit averages throughout the active life of the instrument. (The gaps in the data occur at times when the satellite is within 125,000 kilometers; the other three points per orbit are plotted so that each center one represents data taken from beyond 185,000 kilometers.) Also shown are a comparison plot "C" of the integrated cosmic-ray flux into a scintillator with about 0.3 gram cm^{-2} shielding, and the times of a recurrent minimum in the interplanetary magnetic activity index K_p with a period of one solar rotation.

A dominant feature of the electron rate is the appearance of many statistically meaningful intensity increases, including one series apparently coincident with the recurrent K_p minimum. These electron intensity increases were not accompanied by comparable increases in the integral cosmic-ray intensity above 15 MeV: the magnitude of the electron modulation is 50 per cent on occasions, while the cosmic rays undergo modulations of less than 5 per cent. Further, following the flare of 16 March 1964 there was a solar-proton event, accompanied by Type IV solar radio emission,[8] during which the flux of protons of energy between 15 and 75 MeV briefly increased by

several orders of magnitude, while the 3- to 8-MeV electron flux rose less than 50 ± 25 per cent. (Figure 2 shows the quarter-orbit average of the total integrated cosmic ray flux increasing at that time by about 10 per cent.) These comparisons demonstrate that, at most, an insignificant fraction of the electron modulation results from modulations of cosmic rays of energy above 15 MeV.

Modulations of protons with energies below 15 MeV, such as 27-day recurrent solar proton events similar to those observed[9] with Explorer 12, were not monitored with our apparatus; but these would be expected at the times of recurrent Forbush decreases and geomagnetic activity, rather than at the time of our repeating electron increases. Several such 1- to 10-MeV proton intensity increases were observed early in the life of the satellite by Fan, Gloeckler and Simpson[10] but these were about two weeks out of phase with our electron enhancements and appear to be accompanied by, if anything, decreases in the electron intensity and in the galactic cosmic rays.

Finally, a study of 3-hour averages of the observed intensity of these electrons indicates no variations with distance from the earth, either during orbits of minimum intensity or during times of increased intensity; the electron rate is constant through the shock front to a distance of up to 50 per cent beyond it. Further, the satellite's passage through the wake of the moon[5] was unaccompanied by an electron intensity variation. Thus, these electrons are not secondary to cosmic rays or solar protons or due to geophysical processes.

We feel that the question of whether these primary electrons originate at the sun or in the galaxy cannot be difinitely answered on the basis of the available data; however, the following properties of these electrons are consistent with their being galactic. First, the differential energy spectrum of this 3- to 12-MeV component fits smoothly onto a spectral plot of the cosmic-ray electron intensities [1, 2, 4] at much higher energies. Second, the time variations of the electrons can be compared to those of cosmic rays in that there is a strong correlation between the electronint ensity increases and quiet interplanetary conditions, evidenced by K_p minima and very small sea-level cosmic-ray intensity increases. Third, there appears to be a long-term increase of electron intensity after a correction of the same order is applied for a slow, monitored drift in detector gain; if this increase is real, it is similar to the 11-year modulation of cosmic rays as solar minimum is approached. However, the fact that the differential cosmic-ray proton intensity is peaked at about 1 BV/c rigidity and negligible below 150 MV/c markedly contrasts with the fact that electrons of rigidity $\gtrsim 3.5$ MV/c are more abundant than those of greater rigidity. Parker has recently pointed out[11] that particles with gyroradius close to the idealized irregularity scale of the modulating medium should be deflected more than those of either extreme; thus these electrons of low rigidity might originate in the galaxy and penetrate the solar system as easily as those of great rigidity.

In spite of the foregoing arguments for galactic origin, it is not impossible that the electrons came instead from the sun. Several possibilities present themselves. For example, relativistic electrons might be generated over most of the upper surface of the solar atmosphere, in which case regions of enhanced and expanded plasma (which contain recurrent proton fluxes) would tend to contain fewer electrons while regions of quiet-time streaming would contain more, as we have observed. Further, the deceleration of the electrons in the enhanced plasma might be much greater than that in the quiet-time streaming. Alternatively, the electrons might be associated with the development of new sunspot regions, which is a characteristic of this phase of the solar cycle and appears to correlate weakly with the observed pattern of intensity increases.[12] We have not, however, found a correlation with any solar radio or optical activity.

The results we quote here are preliminary: an evaluation of the detector response, providing a more exact spectrum, and a detailed investigation of the time variations will be given elsewhere. We are happy to acknowledge the efforts of the many people who made the IMP-1 a success.

TELEVISION CINEMAPHOTOGRAPHY OF AURORAS AND PRELIMINARY MEASUREMENTS OF AURORAL VELOCITIES

T. N. DAVIS† AND G. T. HICKS‡

During October 1963 a series of tests were performed at Fort Churchill, Manitoba on the usefulness of an image orthicon closed-circuit television system for indirect auroral photography. The system used was similar to one described in a paper by Hicks (1963). It was equipped with an f/0.75 lens providing an effective field of view of 16°. Recording was accomplished by photographing the television monitor with a 16 mm cinema camera.

Operated at maximum sensitivity, the system enabled direct viewing of 8th and 9th magnitude stars on the television monitor. At this sensitivity level, the system was somewhat better than the unaided, dark-adapted human eye in the detection of weak auroral structures. No difficulty was found in obtaining: auroral photographs of even the weakest structures, with exposures of 1/60 sec at the normal sound cinema rate of 24 frames per second. For brighter forms it was necessary to electronically reduce the system sensitivity. Examples of some of the photographs are presented in Figure 1.

Most of the photographs were recorded on Eastman Plus-X black and white film. In addition, color photographs on Eastman High-Speed Ektachrome film were obtained by sequential insertion of broad-band color filters into the optical system. A color cycle consisting of the placement of red, green and blue filters into the system, was completed in 1/8 sec. The result was a cinema film strip showing a frame with a red image, then a frame with green image, and finally a frame of blue image; the cycle was then repeated. Projected at normal sound speed, the color film shows

FIGURE 1.—From top to bottom, four consecutive photographs of a rayed arc with evenly-spaced and relatively stable ray structures. The exposure of each photograph is 1/60 second; the interval between adjacent photographs is 1/24 sec. The spacing between the ray structures is near 1.8 Km. Note the subtle temporal changes in the aurora that are evident by comparing adjacent photographs.

much flicker but the eye integrates sufficiently so that the colors are additive. Since the spectral response of the system is broader in wavelength than the eye, the color films show more red (due to OIλ6300–6364 and N_2 First Positive bands) and blue (due mainly to N_2^+ First Negative bands near λ4278 and λ4652) than one normally sees by direct visual observation. The filters used in the preliminary tests are very wide, near 800Å at half peak transmission. In the future much narrower filters will be employed in order to isolate specific auroral emissions.

Both the color and black and white television cinema-photography techniques provide data for the study of a variety of morphological aspects of auroral structures. These aspects include auroral motions, auroral pulsations, and the growth, decay and configurations of individual structures. The technique may allow the examination of the relative spatial distributions of the principal auroral emissions in more detail than has been possible previously.

Preliminary analysis of the data has been aimed at the measurement of apparent horizontal velocities with emphasis on the faster motions. These fast motions are of folds within auroral structures, of ray bundles or of well defined regions of enhanced luminosity (streaming). In some cases it is not clear which type of motion is being observed. A summary of 49 velocity measurements is presented in Figure 2. The values presented there are obtained by assuming an auroral lower border height of 100 Km. This assumption and the limited precision of angular calibration of the television system as used in October 1963 lead to uncertainties in the velocity magnitudes which are estimated at 10 percent. The measurements were performed on moving structures visible on consecutive film frames ranging in number from 6 to 125 (time duration 0.2 to 5 secs.).

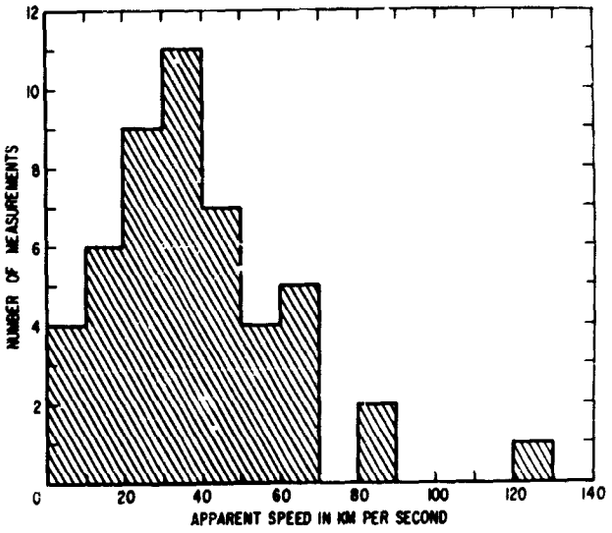

FIGURE 2.—Range of 49 measurements of horizontal speeds of auroral rays and regions of enhanced luminosity. The speed spectrum between 0 and 130 Km per/sec is divided into 13 equal blocks and the number of measurements falling within each block is shown.

AN EXPERIMENTAL EXAMINATION OF LOW-ENERGY COSMIC RAY HEAVY NUCLEI*

C. E. FICHTEL, D. E. GUSS, AND K. A. NEELAKANTAN†

In a sounding rocket experiment flown from Fort Churchill on September 4, 1963, a finite flux of cosmic ray nuclei with charges greater than that of helium was detected at energies below the experimental energy cutoff of balloon-borne experiments. The particles were examined by extending large sheets of nuclear emulsions from the sides of the rocket during its period outside the atmosphere. The flux of medium nuclei ($6 \leq Z \leq 9$; Z = nuclear charge) in the energy range from 30 to 150 MeV/nucleon was measured as $0.67 \pm .13$ particles/($m^2 sr$ sec), and the flux of ($10 \leq Z \leq 19$) nuclei in the energy range from 40 to 190 MeV/nucleon was $0.31 \pm .09$ particles/($m^2 sr$ sec). A finite flux of light nuclei ($3 \leq Z \leq 5$) was also seen in the 30 to 110 MeV/nucleon region. The abundances of medium and ($10 \leq Z \leq 19$) nuclei relative to helium nuclei in the same energy intervals were found to be significantly less than the relative abundances previously determined at high energies. However, within the statistical uncertainty, the relative differential flux values observed in the vicintiy of the earth are consistent with the helium, medium, and ($10 \leq Z \leq 19$) nuclei having the same source spectrum at least above about 0.2 BeV/nucleon for a wide range of source spectral shapes and an interstellar path length of the order of those normally assumed (i.e., 2.5 g/cm^2 or slightly larger). Other possible interpretations also are considered.

INTRODUCTION

Over the last decade the study of cosmic radiation has progressed considerably and has reached the point where the fundamental properties are becoming reasonably well established.[1–3] The proton energy spectrum now is being measured from 0.01 BeV/nucleon to approximately 10^{10} BeV/nucleon, and the composition of the cosmic radiation has been measured numerous times in the energy region above approximately 0.2 BeV/nucleon. In this region, the composition appears to be independent of energy, at least up to about 10^6 BeV/nucleon, with the possible exception of a small relative increase of the light nuclei in the 0.2 to 0.5 BeV/nucleon interval.[4–8] In particular, the helium to medium nuclei and the helium to heavy nuclei ratios are known to be the same to within about a 15 percent experimental uncertainty in tne region from 0.3 to 7.5 BeV/nucleon. The data also have revealed that there is a strong modulation of the cosmic radiation which is fairly certainly associated with the solar cycle. In the measured energy interval, the variation of cosmic ray intensity is greatest at the lowest energies.[9]

In an effort to increase our general experimental knowledge of the cosmic radiation and at the same time obtain some new insight into some of these questions, an experiment was undertaken to examine the intensity of the heavier nuclei in the cosmic radiation in the region below about 0.2 BeV/nucleon. The first question to be answered was whether or not there are any medium or heavy nuclei in this low-energy region. A cosmic ray source with a very high energy threshold for acceleration of the high charges could create a near absence of these particles, since only some particles which have been degraded in energy in their interstellar travels would be present. However, if particles are present, the measurement of their properties can provide some restraints on the combined questions of the interstellar travel of cosmic rays and the spectra at the origin.

The local solar modulation has the same effect on all the particles of primary concern in this experiment—namely, *He*, *C*, *N*, *O*, *Ne*, etc.—

because these nuclei all have the same charge to mass ratio and hence the same velocity for a given charge.

To measure the intensity of low-energy heavy nuclei, nuclear emulsions, which are detectors particularly suited for this purpose, were exposed to the cosmic radiation above the earth's atmosphere on a sounding rocket at Fort Churchill, Canada. The use of a sounding rocket rather than a polar orbiting recoverable satellite has several advantages. First, several sounding rocket shots can be spaced at desired intervals, whereas—at least until now—it has not been possible to obtain a single emulsion exposure on a recoverable satellite under less than about 2 g/cm^2 of material in a region of space where low-energy particles are not excluded by the earth's magnetic field. Also, satellite exposures are very expensive because of the cost of the necessary modifications to an existing system and the cost of testing to meet the rigid design specifications. The design of a satellite system is complicated by the requirement that the emulsions must be protected from high temperatures and still be exposed under very little matter. Further, the fact that the geomagnetic cutoffs are uncertain demands that a time resolution device be included in a satellite experiment to obtain absolute fluxes, since emulsions themselves integrate over time. Finally, the high Van Allen belt radiation background arising from the South Atlantic anomaly is an additional disadvantage associated with a satellite exposure.

To overcome the principal difficulty associated with the sounding rocket exposure—namely, having only a short exposure time available, a large area of emulsion was extended from the side of the payload during the portion of the flight when the rocket was above the atmosphere. The rocket was fired from Fort Churchill, Canada, so that the particles of interest could reach the extended detector at full intensity without having been excluded by the earth's magnetic field.

EXPERIMENTAL PROCEDURE

The nuclear emulsion detectors used in this experiment were 600-micron-thick Ilford G–5 emulsions which were assembled in eighteen packs consisting of eighteen emulsions, 6.5 cm by 9.9 cm, placed on top of each other and covered with Mylar and black electrical tape to give a water- and light-tight package. Six of these packs were placed in each tray and held in place by means of a small metal lip. A photograph of the emulsion section of the payload is shown in Fig. 1. The trays in turn were kept inside of the payload until 61 seconds after launch of the sounding rocket, at which time extension of the trays was begun. Before reentry and 411 seconds after launch, the retraction of the trays was begun. Extension and retraction each took about 7 seconds. These events and others are indicated in the time-altitude curve in Fig. 2.

The rocket itself was an Aerobee 150, which had the capability of carrying the 171-pound payload of this experiment to an altitude of 151 miles. In addition to the standard Aerobee nose cone, there were two extension sections; the one closest to the rocket was a recovery section, and the other was

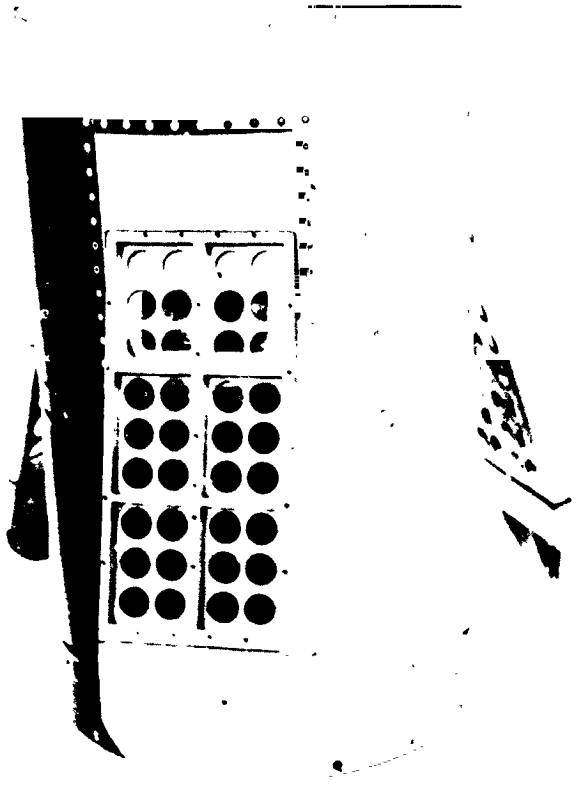

FIGURE 1.—Photograph of the rocket payload section with the emulsions removed and the emulsion trays extended. Six emulsion packs were placed in each of three symmetrically positioned trays. The angle of the trays with respect to the rocket axis was 17.5 degrees.

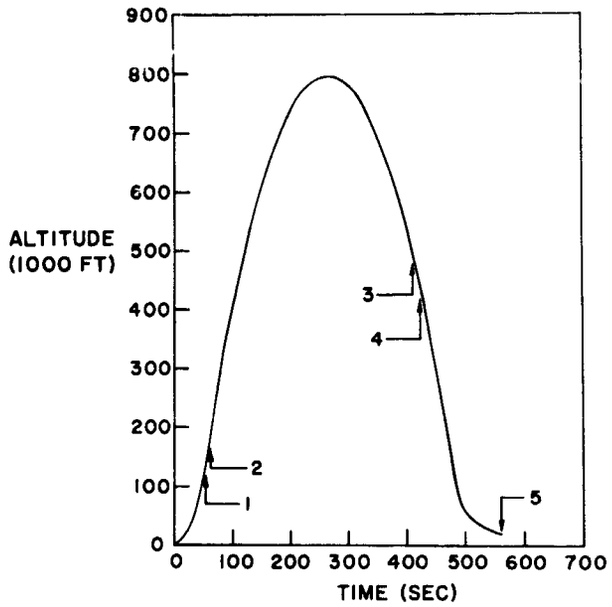

FIGURE 2.—Rocket time-altitude trajectory, showing the sequence of events: (1) rocket burnout (2) emulsion tray extension (3) emulsion tray retraction (4) payload separation (5) parachute deployment and SARAH beacon activation.

the section which housed the extension mechanisms for the emulsion trays described in the preceding paragraph. The water-tight housing for the emulsion in the retracted position extended up into the standard nose cone section. In addition, the nose cone itself contained a radar beacon, battery power for the extension and retraction motors, and a telemetry section. Magnetometer data for rocket aspect, data on the extension and retraction of the trays, and rocket parameters including acceleration and chamber pressure were telemetered.

The rocket was launched successfully at 1311 U.T. on September 4, 1963, and all parts of the payload functioned properly. It was a quiet day geophysically[10] and the Mt. Washington neutron monitor counting rate was 2318.[11] The nuclear emulsions were recovered, processed, and found to be in generally good condition. A total emulsion surface area of 821 cm^2 was available for analysis after elimination of the area held under the tray lips and the immediately adjacent area, where the clear solid angle would have been greatly reduced.

A complete area scan was made under a microscope of the top emulsion of each of the packs, as well as a complete rescan to check scanning efficiency. In the original scans, all tracks which were dark and which either had delta rays or were wider than a track formed by a single line of grains were accepted, regardless of the angle the track made in the emulsion. These tracks were then analyzed by a scientist to separate the slow proton and helium tracks from the partiles with charges greater than 2. At this point, all tracks which were within 20 degrees of the perpendicular to the emulsion were rejected. The method of charge and energy analysis is essentially the same as that used previously in other work and described in detail in a paper by Biswas, Fichtel, and Guss [12] and, therefore, will not be repeated here. Only particles which ended in the emulsion were analyzed. When this work was completed, it was found that the sample of particles, although small, was sufficiently large to permit an actual flux determination rather than simply to set an upper limit.

The calculation of the solid angle of collection involves a number of features which are indicated in Fig. 3. First, there is the restriction on the angle with respect to the plane of the emulsion (called "dip angle") mentioned above, corresponding to section A in the figure. Second, there is a very small solid angle, consisting of tracks of small dips and azimuthal angles in the emulsion which are closest to the rock t axis, which is excluded because particles would have had to pass through the rocket to enter the emulsion within this solid angle. This solid angle segment varies with position on the surface of the emulsion, but a typical segment labeled "B" is shown in Fig. 3. The final and largest portion of the solid angle which was excluded or partially excluded is made up of those angles which are forbidden to the particles by a combination of their paths along the magnetic field and the earth's atmosphere.

The method of calculating the angle of a particle with respect to the vertical for a given altitude above the earth after the particle has mirrored at a lower altitude has been discussed in an earlier paper by Biswas, Fichtel, and Guss.[12] Although the details are complicated and will not be repeated, the net effect is to increase the angle with respect to the vertical in which particles may arrive from 90 degrees to a larger angle which increases with altitude above the earth. There

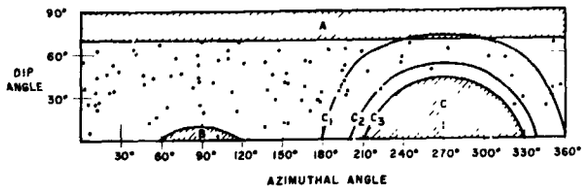

FIGURE 3.—Distribution of ending $Z \geq 6$ nuclei (indicated by black circles) in the solid angle of collection. The "dip angle" is the angle with respect to the plane of the emulsion; the "azimuthal angle" is that with respect to the perpendicular to one of the edges of the emulsion measured in the emulsion plane. The shaded area "A" was excluded from analysis because tracks in this segment had a dip too great to be analyzed. The shaded area "B" was excluded from analysis because particles at these angles had passed through the rocket material before entering the emulsion; this area varied with position in the emulsion and a typical segment is shown. The curves C_1, C_2, and C_3 are the curves for particles with space angles greater than 90°, 70°, and 60° with respect to the magnetic line of force. These curves varied somewhat as the coning angle of the rocket varied, and the ones shown are typical. The shaded area "C" is forbidden to the low-energy heavy nuclei under consideration because they would be stopped by ionization energy loss in the atmosphere between the rocket and their mirror point.

is only a very small solid angle in which particles pass through a significant amount of atmosphere, but not enough to effectively remove them from consideration. Further, the rocket was not quite vertical but had a small coning angle in addition to its spin about the principal axis; therefore, there was a small variation in the position of the set of angles in the emulsion which are at a given angle with respect to the vertical during the flight. This effect increases somewhat the solid angle in the emulsion in which primary tracks may appear but has essentially no effect on the total solid angle for collecting primary particles. Some of the curves related to this problem are shown in Fig. 3 near the area marked "C" and are labeled C_1, C_2, and C_3. The explanation of these curves is given in the figure caption. No tracks should have been observed in the shaded area C of the solid angle diagram, and none were.

The effective solid angle is then calculated from the equation

$$\Omega = \int\int (f \cdot \cos\theta) \sin\theta \, d\theta \, d\varphi,$$

where θ is the angle with respect to the perpendicular to the emulsion and φ the azimuthal angle in the emulsion: f is a weighting factor which is 0 in the shaded areas of Fig. 3 where no tracks were accepted and 1 in most of the rest of the area except around C, where it varied between 0 and 1 with position, depending on the fraction of the extended time that the primary particles could reach these angles. The cos θ factor occurs because the emulsion collecting area is a flat surface. Since the area marked "B" in Fig. 3 varies with position on the emulsion surface, Ω varies with position, but only very slightly because of the small contribution of segment B. The collection time also varies slightly with position because of the small, but finite, time required to extend the tray. With all the above factors taken into consideration, the effective primary area—collection time—solid angle factor, called "$A\,\Omega T$," was $60.7 m^2$ sr sec.

The major correction to the raw data is the one which accounts for the background tracks formed during ascent before the trays are extended and during descent after the trays are retracted. In a more recent version of this experiment flown in July 1964, this correction was eliminated by including a sliding plate mechanism which permitted separation of the tracks formed during the period that the emulsion trays were extended from those tracks made at other times. The results of this experiment will be reported later when the data reduction and analysis is complete.

The background consisted of particles of relatively large ambient energies because they had to pass through several g/cm^2 of material before reaching the emulsion, the exact amount of material depending on the angle and the height of the rocket in the atmosphere. An estimate of this background correction therefore could be made from balloon flight data because the particles composing the background had initial energies which were sufficiently great to reach balloon altitudes. For this purpose, the flux and the energy spectrum of low-energy heavy nuclei were measured in the nuclear emulsion plates carried on a balloon flight made from Fort Churchill on July 15, 1963, when the cosmic ray flux level was known to be essentially the same as on September 4, 1963, because the neutron monitor counting rates for these days differed by only 0.2 percent. The excellent

correlation between low-energy cosmic ray intensities and neutron monitor counting rates has been shown previously by McDonald and Webber.[13] In principle, the background correction could be very complex; in practice, a good approximation is obtained by simple summations because the degraded spectrum changes slowly in shape with increasing amounts of material present and, secondly, because the relative times of moving through variable amounts of residual atmosphere and remaining under a constant amount of a few g/cm² of material were about the same for the emulsions in the rocket and those on the balloon.

One final correction which had to be made to the raw data was the increase in the number of collected particles by an amount which took into account the probability that the particles might interact before ending or, in the cases of some of the higher energy particles included in the analysis, leave the stack if it entered the edge at an unfavorable angle. The upper limit to the energy was kept small in order to keep this correction small.

RESULTS AND DISCUSSION

After completion of the analysis outlined in the previous section, the results shown in Table 1

TABLE 1.—*Differential fluxes for medium nuclei and* ($10 \leq Z \leq 19$) *nuclei on September 4, 1964.*

Kinetic energy (MeV/nucleon)	$6 \leq Z \leq 9$ [p/(m² sr sec MeV/nucleon)]	$10 \leq Z \leq 19$ [p/(m² sr sec MeV/nucleon)]
50	0.0040 ± 0.0015	----------
55	----------	0.0005 ± 0.0006
90	0.0055 ± 0.0018	0.0005 ± 0.0006
130	0.0072 ± 0.0024	0.0040 ± 0.0015
170	Not measured	0.0028 ± 0.0014

were obtained. The first pointo to be made is obvious: namely, that these fluxes are quite clearly significantly different from zero. Hence, a finite flux of cosmic ray medium nuclei in an energy range as low as 30 to 70 MeV/nucleon has been observed in the vicinity of the earth. Further, there is a finite flux of heavy nuclei with energies at least as low as 110 MeV/nucleon.

In the rest of the paper, the heavy nuclei will be divided into two groups—nuclei with nuclear charges from 10 to 19, hereafter called ($10 \leq Z \leq 19$) nuclei, and very heavy nuclei ($Z \geq 20$)—because it is advantageous to keep the variation in energy loss within a charge group to within tolerable limits and because there were very few nuclei with charges of 20 or more. Comments on light nuclei ($3 \leq Z \leq 5$) will be confined to the last paragraph of this section, since they are a separate subject.

The next subject of interest is the comparison of the differential energy spectra obtained in this experiment with the differential spectra at higher energies and with the spectrum of helium nuclei. In this comparison, it is important to remember that the cosmic ray differential energy spectrum varies with the period in the solar cycle. Figure 4

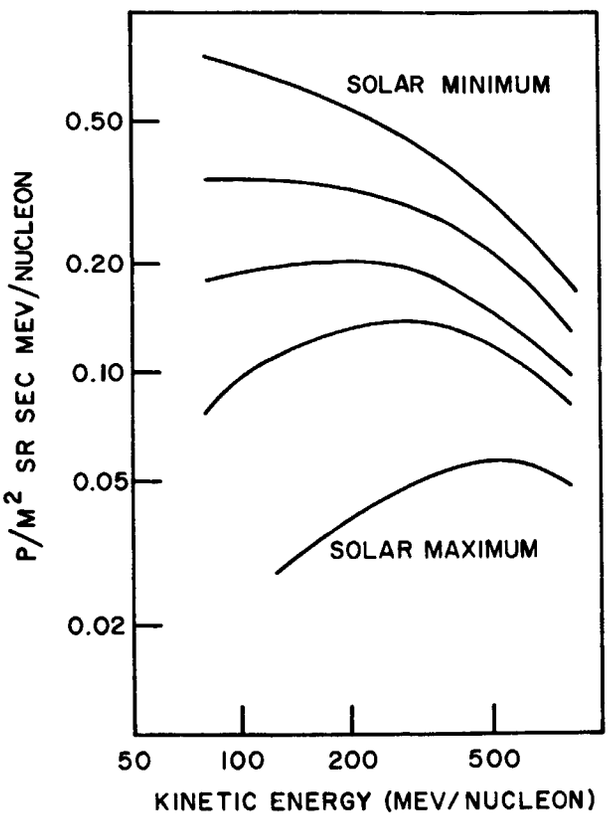

FIGURE 4.—Differential energy spectrum for helium nuclei at various times during the solar cycle. These curves were calculated from data published by Webber (see Ref. 1).

shows the differential energy spectrum for helium for various periods in the solar cycle.[1] The existing data indicate that the medium and heavy nuclei have energy spectra similar to that of the helium nuclei, only reduced in intensity.[1] The medium nuclei group, for example, is 0.063 times the helium particle intensity; and the charge group from $Z = 10$ to 19 is 0.021 times the helium particle intensity. The possibility of small differences of the order of 15 percent or less in the region from about 200 to 400 MeV/nucleon cannot be excluded; above 1.5 BeV/nucleon, they probably are correct to within 10 percent.

At the time of the firing of the sounding rocket from which the data under discussion were obtained, the cosmic ray flux had passed through the minimum value of the cycle a few years earlier and was slowly increasing. The curve in Fig. 5 shows the approximate shape of the helium particle differential spectrum at the time of the rocket shot. It has been shown[1] that the particle spectrum is a smoothly varying function of energy and that for this period in the solar cycle a 1 percent variation in the Deep River neutron monitor rate, which gives an estimate of the higher energy particle intensity, corresponds to about a 10 percent variation in the helium particle differential flux at 200 MeV/nucleon. Therefore, for purposes of correlating the measurements made here, an uncertainty of less than that will be introduced by comparing the results obtained here with helium spectra obtained when the neutron monitor was within 1 percent of the reading at the time the rocket was in the air. The authors know of four helium spectra in the energy region from about 80 to 600 MeV/nucleon that were obtained during the summer of 1963 which satisfy this condition.[14-17] An average of these spectra, which are in close agreement, was used as the basis for the curve in Fig. 5.

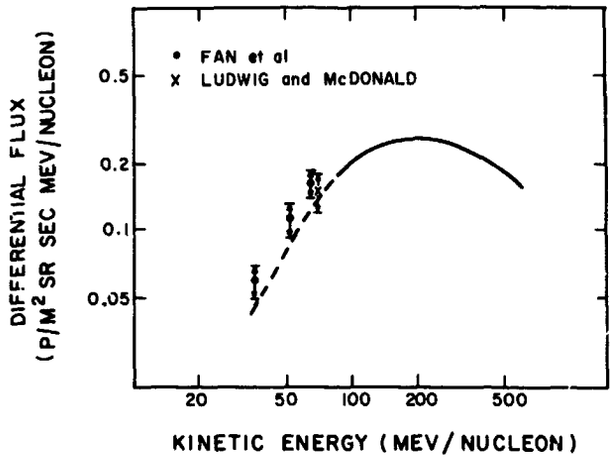

FIGURE 5.—Helium nuclei differential energy spectrum obtained as explained in the text. The low-energy points, from which the low-energy portion of the curve was deduced, are those of Fan et al, (Ref. 18) and Ludwig and McDonald (Ref. 19).

In addition, Fan et al[18] and Ludwig and McDonald[19] have obtained a helium energy spectrum in the 30 to 80 MeV/nucleon region on Explorer XVIII during the period January through March 1964, when the neutron monitor rate was typically from 1 to 2 percent higher than the rate at the time of the measurement of this experiment. To compensate for a systematic change in intensity in this region, the curve in Fig. 5 was extended below 80 MeV/nucleon by a smooth connection to data above 80 MeV/nucleon, by keeping the shape of the 30 to 80 MeV/nucleon data but reducing the intensity appropriately. This procedure could, at most, introduce a noticeable error only in the lowest medium nuclei energy interval.

Since no comparable data were available for the heavier particles at the time of writing of this paper, the helium particle curve was multiplied by the ratios mentioned above to obtain the best possible approximation of the curves for the heavier particles at higher energies.

The results displayed in Figs. 6 and 7 indicate that the low-energy spectrum of the medium nuclei observed in the vicinity of the earth falls below that of the helium nuclei multiplied by 0.063. Similarly, the $(10 \leq Z \leq 19)$ nuclei curve falls below the corresponding one for helium nuclei multiplied by 0.021. Hence, the abundance of helium nuclei relative to these higher charge groups apparently increases in the low-energy region until it is well above the fairly constant value which it has from about 400 MeV/nucleon to very high energies.

The spectra which are observed at the earth represent the source spectra after they have passed through interstellar matter and have been modulated within the solar system. Whereas

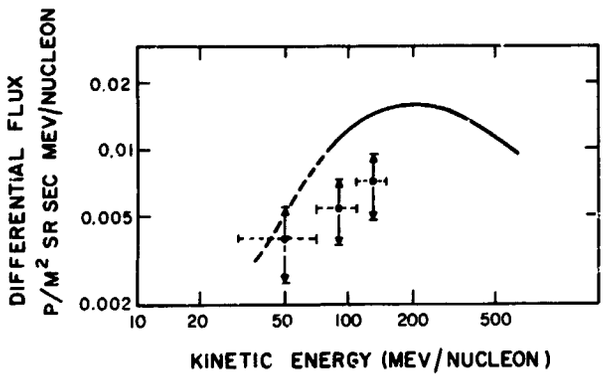

FIGURE 6.—Differential energy spectrum for medium nuclei. The curve is that for helium nuclei (Fig. 5) multiplied by 0.063.

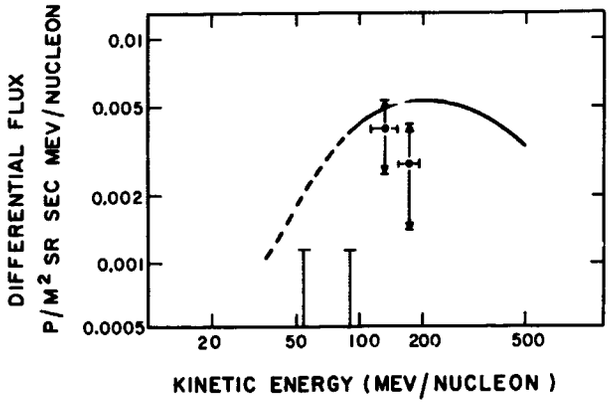

FIGURE 7.—Differential energy spectrum for $(10 \geq Z \geq 19)$ nuclei. The curve is that for helium nuclei (Fig. 5) multiplied by 0.021. For the two lowest energy points, only the upper limit corresponding to one standard deviation is shown.

the solar system modulation affects only the intensity of the increment of flux in a given energy interval, interstellar space contains enough material along the path of the particle to change appreciably the particle energy as well as the intensity. In the latter case, it normally is assumed that the intensity is changed significantly only by fragmentation in interactions and not by the complicated time-dependent magnetic effects which cause the intensity variation in the solar system. Therefore, the differential energy flux at the source for the i^{th} type of particle $j_s(i)$ is related to the differential energy flux observed in the vicinity of the earth but outside the region where the earth's magnetic field excludes, or partially excludes, particles $j_o(i)$ by the relation

$$j_o(i)[_{E=E_0} = j_s(i)]_{E=E_s(i)} \left[\frac{\Delta E_s(i)}{\Delta E_0}\right] h(v_0,R) f(i,v,\rho), \tag{1}$$

where ΔE_0 and ΔE_s represent the small energy increments containing the set of particles at the observation point and the source respectively, i is the type of particle, h the solar modulation function, f the interstellar intensity variation factor, v the particle velocity, R the rigidity (momentum/unit charge), and ρ the amount of interstellar matter traversed between the source and the earth.

The expression $f(i, v, \rho)$ is well known and is given in detail in a paper by Hayakawa.[20] However, the parameters to be substituted into the equations are not known exactly. The parameters include the mean free paths of the different elements in space, the probability of one type of particle emerging from an interaction caused by another particle and the amount of material traversed. Table 2 gives the values of the parameters used in the calculation and the references from which the parameters were obtained.[21–24] When more than one reference is given, the parameter listed in the Table is a weighted average. In Table 2, P_{ij} gives the average number of secondaries of type "j" formed in an interaction of a particle of type "i" in an interaction with a hydrogen nucleus. λ_i' is the absorption mean free path, which is given by the equation

$$\frac{1}{\lambda_i'} = \frac{1}{\lambda_i}(1 - P_{ii}), \tag{2}$$

where λ_i is the interaction mean free path.

$\lambda_H = 4.0$ g/cm²	20	$P_{MM} = 0.14 \pm 0.04$	21–24
		$P_{HM} = 0.21 \pm 0.10$	21–24
		$P_{HH} = 0.40 \pm 0.15$	21–24

The above parameters are known to vary with energy; however, their exact dependence is not well known. Above approximately 100 MeV/nucleon they are thought to be nearly constant and not to vary appreciably until the energy/nucleon is below about 30 or 60 MeV.[23 25] To reach the earth at the observed energies after passing through several g/cm² of interstellar hydrogen, the particles under consideration must spend either all or almost all of their time in interstellar space at energies above 100 MeV/nucleon. Therefore, it seems reasonable to use the parameters obtained at higher energies in view of the above considerations and the lack of sufficient information to calculate more exact values. Including the generally accepted partially tested hypothesis that the energy per nucleon does not vary significantly in an interaction leads, then, to the conclusion that f is not a function of velocity in the region of interest if ρ is not a function of energy.

The true modulation function $h(v, R)$ is not known. Many models have been presented, and each seems to have some advantages and some weaknesses.[26]: For the purposes of the present discussion, it is sufficient to note that, since all the proposed modulation mechanisms involve only magnetic or electric fields and the amount of material traversed within the solar system is negligible, particles with the same charge to mass ratio and hence the same rigidity for a given velocity will be depressed by the same amount for a given velocity.

The remaining term on the right side of Eq. (1), which multiplies $j_s(i, E)$, is $(\Delta E_s(i)/\Delta E_0)$. This term arises from the change in the width of the energy interval in which particles are contained as they lose energy. Since the rate of energy loss per nucleon varies with the nuclear species, this term will affect the different nucleon groups in different ways. Further, because of the different rates of energy loss for a given E_0, $E_s(i)$ will be different for different nuclear species; and hence $j_s(i, E)]_{E=E_{s(i)}}$ can vary for a fixed E_0 even if $j_s(i, E)$ is the same for all nuclear groups.

Consider now the ratio of the differential flux values of two different nuclear types with the same charge to mass ratio. From Eq. (1), this ratio is

$$\frac{j_0(i,E)]_{E=E_0}}{j_0(k,E)]_{E=E_0}} = \frac{j_s(i,E)]_{E=E_s(i)}}{j_s(k,E)]_{E=E_s(k)}} \frac{[\Delta E_s(i)/\Delta E_0]}{[\Delta E_s(k)/\Delta E_0]} \frac{f(i,v,\rho)}{f(k,v,\rho)} \tag{3}$$

If ρ, the fragmentation parameters, and the mean free paths are independent of velocity, $f(i, v, \rho)/f(k, v, \rho)$ becomes a constant independent of velocity. Hence,

$$\frac{j_0(i,E)]_{E=E_0}}{j_0(k,E)]_{E=E_0}} = \frac{j_s(i,E)]_{E=E_s(i)}}{j_s(k,E)]_{E=E_s(k)}} \frac{[\Delta E_s(i)/\Delta E_0]}{[\Delta E_s(k)/\Delta E_0]} [K(\rho,i,k)],\ [K \neq g(V)] \tag{4}$$

Notice also that

$$\Delta E_s(i) \lambda \Delta E_0 \xrightarrow[v \to c]{} 1 \tag{5}$$

and, for reasonable spectra,

$$\{j_s(i, E)]_{E=E_{s(i)}}\}/\{j_s(k, E)]_{E=E_{s(k)}}\} \xrightarrow[v \to c]{} \text{(Const.), for a fixed } E \tag{6}$$

The implications of the experimental results now will be examined by comparing the data with the predictions based on several suggested source spectra and interstellar mean free paths. If it is assumed first that Eq. (4) is valid, the expected ratio for $j_0(i, E)]_{E=E_0}$ and $j_0(k, E)]_{E=E_0}$ can be calculated for different values of ρ and the experimental knowledge of the limiting value for the ratio at high energies, where Eqs. (5) and (6) apply.

The most commonly assumed source spectrum is a power law in the total energy with an exponent of 2.5 as given by

$$j_1(i, W) = K_1(i)/W_N^{2.5}, \tag{7}$$

where W_N is the total energy/nucleon. In Figs. 8 and 9 the observed ratios of the differential

medium nuclei and the ($10 \leq Z \leq 19$) nuclei to the differential helium nuclei spectral points obtained in the manner described earlier are plotted and compared with the ratio expected on the basis of the observed high-energy ratio and an assumed spectral shape of the form of Eq. (7). The best recent value for the estimate of the amount of interstellar matter traversed—at least for high-energy particles—is 2.5 g/cm², which is based on a calculation by Badhwar et al[23] and Badhwar and Daniel[25] with heavy emphasis on the high-energy (>1.5 BeV/nucleon) composition data of O'Dell et al.[27] The expected ratio has been calculated for both 2.5 and 5.0 g/cm² of interstellar hydrogen. Notice that this ratio is relatively insensitive to a change of a factor of 2 in interstellar matter in this range of values. Notice also that the agreement between the experimental points and the curves for these assumed conditions is satisfactory.

As a second example, a source spectrum of the form of Eq. (7) above 300 MeV/nucleon and of the form of Eq. (8) below 300 MeV/nucleon is chosen:

$$j_2(i) = K_2(i)/(E_s)^{0.67} \qquad (8)$$

The expected ratios for this source spectrum, the observed high-energy ratios, and 2.5 and 5.0 g/cm² of interstellar matter also have been calculated and are shown in Figs. 8 and 9. Here again there is a relatively small difference in the curves for 2.5 and 5.0 g/cm², and there is satisfactory agreement with the experimental data. Smooth changes in the source spectrum in general have little effect on the resultant ratios unless the variations are very large, that is, appreciably greater than those selected here.

Hence, the following conclusion can be drawn: The experimentally observed helium to medium and helium to ($10 \leq Z \leq 19$) nuclei ratios are consistent with the assumption that the source spectra are the same and that the particles have passed through the same amount of material, which is in the range of 2.5 to 5 g/cm². This conclusion is relatively independent of the exact shape of the source spectrum. On the other hand, differences in the source spectra between helium and medium nuclei would appear relatively quickly in the form of a disagreement

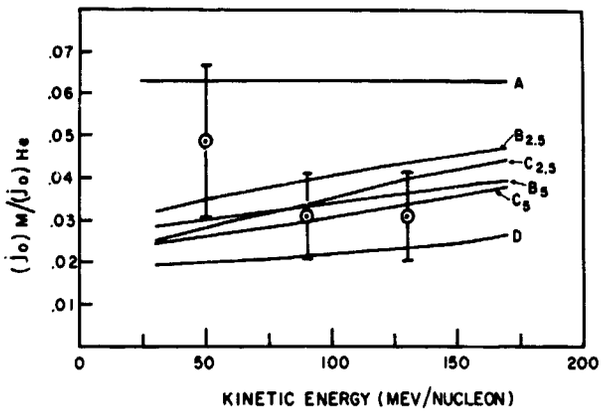

FIGURE 8. -Ratio of the differential flux of medium nuclei to helium nuclei expected after passage of the particles through various amounts of interstellar gas. Curve A: 0 g/cm² for all spectral shapes; curve $B_{2.5}$ and curve B_s: 2.5 g/cm² and 5.0 g/cm², respectively, assuming the source spectrum of Eq. (7); curve $C_{2.5}$ and curve C_s: 2.5 g/cm² and 5.0 g/cm², respectively, assuming the source spectrum of Eq. (7) for particles with kinetic energy greater than 300 Mev/nucleon and the source spectrum of Eq. (8) for particles with kinetic energy less than 300 Mev/nucleon; curve D: passage through 2.5 g/cm² for relativistic particles, 6 g/cm² for particles with kinetic energy less than 400 Mev/nucleon, assuming the source spectrum of Eq. (7).

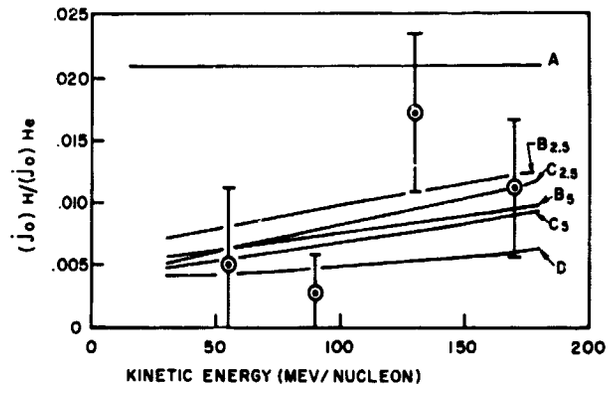

FIGURE 9.—Ratio of the differential flux of ($10 \geq Z \geq 19$) nuclei to helium nuclei expected after passage of the particles through various amounts of interstellar gas. Curve A: 0 g/cm² for all spectral shapes; curve $B_{2.5}$ and curve B_s: 2.5 g/cm² and 5.0 g/cm², respectively, assuming the source spectrum of Eq. (7); curve $C_{2.5}$ and curve C_s: 2.5 g/cm², and 5.0 g/cm², respectively, assuming the source spectrum of Eq. (7) for particles with kinetic energy greater than 300 Mev/nucleon and the source spectrum of Eq. (8) for particles with kinetic energy less than 300 Mev/nucleon; curve D: passage through 2.5 g/cm² for relativistic particles, 6 g/cm² for particles with kinetic energy less than 400 Mev/nucleon, assuming the source spectrum of Eq. (7).

between the calculated and observed helium to medium nuclei ratio as a function of energy.

The results obtained here, then, suggest there is good reason to think that above about 0.2 BeV/nucleon the source spectra of all components are at least similar. Information below this energy is not forthcoming from this approach because nuclei of the higher charges being considered must have at least this energy initially to reach the earth.

Next, assume that the particles have gone through different amounts of interstellar material depending on their energy. Dahanayake et al,[28] for example, suggest that the lower energy particles, below about 400 MeV/nucleon, have passed through more material than the high-energy ones, which are assumed to go through 2.5 g/cm^2 on the basis of the work mentioned earlier. In this case, $f(i, v, \rho)/f(j, v, \rho)$ of Eq. (3) is not a constant independent of energy. However, if the high-energy ratio of the observed fluxes is known and if the parameters of Table 2 are used, the additional expected suppression resulting from low-energy particles going through more material than high-energy ones can be calculated. The results obtained, assuming that all particles have a source spectrum of the type given by Eq. (7) and that the particles below 400 MeV/nucleon have passed through 6 g/cm^2 (as suggested by Dahanayake et al,[28]) while the high-energy ones (kinetic energy$>$1.5 BeV/nucleon) have passed through 2.5 g/cm^2, are also shown in Figs. 8 and 9. Here the agreement is poorer; further, these assumptions lead to a ratio in the 300 to 400 MeV/nucleon region which is appreciably more than one standard deviation below several measurements of the medium to heavy nuclei ratio in that region. In addition, Hildebrand and Silberberg [29] and Webber [30] now have shown that the existing experimental data on the He_3/He_4 ratio probably can be reconciled with a mean free path in the low-energy region which is the same or only slightly larger than 2.5 g/cm^2, by taking into account the properties of secondaries from interactions and the effects of the solar modulation mechanism on particles with different charge to mass ratios.

Light nuclei also were observed in the low-energy region from 30 to 110 MeV/nucleon, but no quantitative value for the differential flux will be quoted because a high scanning detection efficiency was not achieved for these particles. Since these light nuclei generally are assumed to arise from heavier nuclei, the type of theoretical analysis outlined above does not apply. There is, however, the alternate problem of interest: namely that, if the modulation effect is rigidity dependent, light nuclei might be expected to have slightly different energy spectra from the medium or heavy nuclei. If the rigidity dependence of the modulation can be determined by other means, the relative abundance of light and medium nuclei provide an independent estimate of the amount of interstellar matter traversed by the cosmic radiation at these low energies. The analysis was not pressed beyond the determination of the existence of a light nuclei flux because there was not an adequate number of particles to determine the light to medium ratio with sufficient accuracy to see a deviation from the high-energy ratio; and the additional work involved is tremendous. With an improved technique and a higher flux rate, we hope to be able to measure the relative abundance of light nuclei in the 1964 flight to be reported later.

CONCLUSIONS

The answer to the basic question of whether or not there are low-energy heavy nuclei below the energy cutoff set by material above detectors flown on balloons has been seen to be "Yes." There definitely is a finite flux of medium nuclei in an energy range as low as 30 to 70 MeV/nucleon and ($10 \leq Z \leq 19$) nuclei with energies at least as low as 110 MeV/nucleon. The abundance of medium and ($10 \leq Z \leq 19$) nuclei relative to helium nuclei in the energy regions from 30 to 150 and 30 to 190 MeV/nucleon, respectively, are less than the relative abundances at higher energies. This difference can be explained quantitatively by the higher rate of energy loss of the particles of higher charge in the interstellar matter. It also was shown that within the statistical uncertainty the resulting differential flux measurements are consistent with the helium, medium, and ($10 \leq Z \leq 19$) nuclei having the same source spectrum at least above about 0.2 BeV/nucleon for a wide range of source spectral shapes, including ones normally assumed. For a mean free path independent of energy this result also is

fairly insensitive to the values of cross sections and fragmentation parameters assumed, principally because relative values of ratios are being considered. The conclusion is independent of the solar modulation mechanism because, since all particles considered have the same charge to mass ratio, their relative abundances at a given velocity will be unaffected by the local solar modulation. No information can be obtained about the source spectrum below about 0.2 BeV/nucleon because the particles of high charge must have approximately this energy to reach the earth after passing through interstellar matter.

It has been established that there is a finite flux and that the differential flux is consistent with similar source spectra for helium, medium, and heavier nuclei and an interstellar path in hydrogen of 2.5 g/cm^2 within the relatively large uncertainties of these initial measurements. It now seems worthwhile to measure these spectra again to look for a possible variation with the period in the solar cycle and to examine the matters discussed in this paper in greater detail. This problem is being pursued.

MODULATION OF LOW ENERGY GALACTIC COSMIC RAYS*

C. E. FICHTEL, D. E. GUSS, D. A. KNIFFEN, AND K. A. NEELAKANTAN†

The exact way in which the cosmic ray energy spectrum changes with solar activity has been of particular interest because the experimental determination of this feature provides one of the most severe tests of any theory related to cosmic ray modulation. The helium and proton components in addition to being the most abundant also have the additional advantage of having charge to mass ratios which differ by a factor to two. Therefore, having a markedly different velocity for a given rigidity, these particles provide a means for separating rigidity and velocity effects.

In order to continue the study of the problem of the variation of the galactic cosmic ray proton and helium nuclei spectra, a series of balloon flights was made from Fort Churchill, Canada by Goddard beginning in 1961. It is the aim of this paper to present the results of the nuclear emulsion studies of the hydrogen and helium nuclei obtained in 1962 and 1963 and compare them to those obtained in 1961[1] and the earlier results of many experimentalists from the period of increasing solar activity.

One method of comparing the period of rising cosmic ray flux with the declining phase is to plot the integral helium nuclei flux above 250 MeV/n as a function of the neutron monitor rate which gives some measure to the higher energy cosmic rays of all charges. Figure 1 shows the smooth curve determined from many points for this period by McDonald and Webber.[2] Also shown on this figure are the points obtained by the Goddard emulsion group in 1961, 1962, and 1963. As can be seen, the points agree well with the smooth curve.

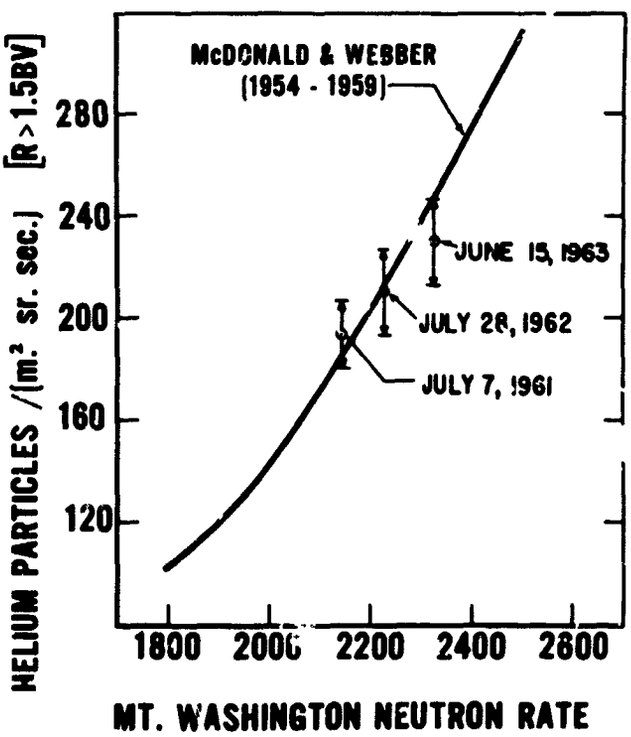

FIGURE 1.—Integral helium particle flux as a function of the Mt. Washington neutron rate.

A much more detailed and stringent comparison between the two periods is the comparison of the differential energy spectra of the helium nuclei in the present experiment with those obtained for the same neutron monitor rate during the declining phase of cosmic ray flux. Figure 2 shows the spectra for various neutron monitor counting rates during the declining phase of cosmic ray activity as given in Webber's review article.[2] These curves fit both the proton data and the helium nuclei data multiplied by seven. In general, the helium nuclei data extended down to about 1.2 BV/Nucleon and the proton data

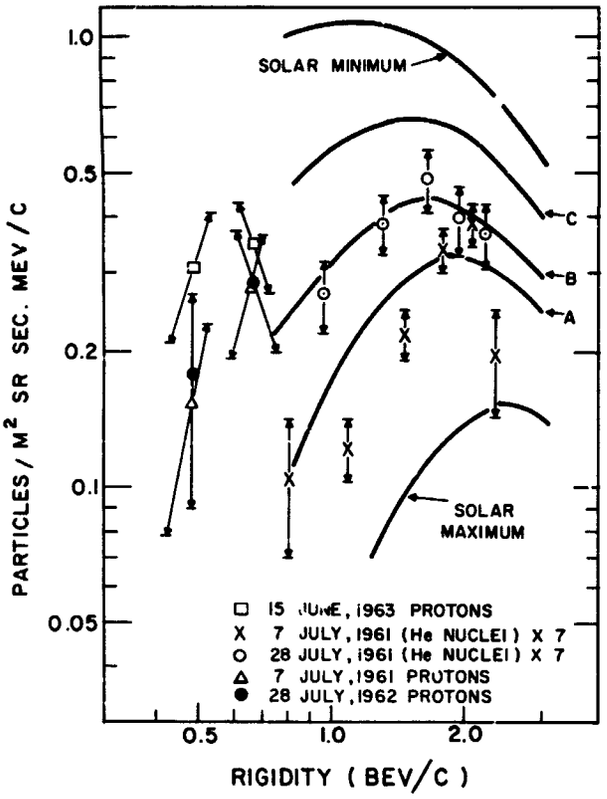

FIGURE 2.—Differential proton and helium fluxes as a function of rigidity. The solid curves are taken from figure 31a of Webber's review article and represent either the differential proton flux or the helium nuclei flux multiplied by seven for solar maximum. Curves A, B, and C correspond to times when the neutron monitor rates were the same as on July 7, 1961, July 28, 1962, and June 15, 1963, respectively.

extended from 0.8 to 1.4 BV. As can be seen, there is reasonable agreement between the helium nuclei data and the curves for the declining cosmic ray phase at the same neutron monitor rates although there is a suspicion that the helium points from this work may fall below the curve at the lowest rigidities where measurements were made. In order to obtain a more quantitative impression of the change in spectral flux from 1961 to 1962, the following numbers can be compared. The integral flux for helium nuclei with energies greater than 250 MeV/nucleon was 206 ± 13 particles/(m² sr.sec.) in 1961 and 221 ± 18 particles/(m² sr. sec.) in 1962. For the energy interval from 75 to 250 MeV/nucleon the flux was 12.7 ± 1.7 particles/(m² sr.sec.) in 1961 and 32.5 ± 4.1 particles/(m² sr.sec.) in 1962. Hence, between 1961 and 1962 there was a significant change in the helium particle flux below 250 MeV/nucleon and relatively little above.

Turning now to the protons it is known that there is a substantial secondary proton flux from interactions in the atmosphere above the detector. There is not space to describe the corrections in detail here, but the discussion of the method along with self-consistency arguments has been given in some detail in the earlier paper and will be treated further in the final publication of this work. Allowance has been made for the uncertainty in the interaction correction by drawing appropriately large errors in figure 2. This figure shows that there is a general tendency for the proton flux to increase during the period from 1961 to 1963, and that at least 1961 and 1962 the proton points lie above a reasonable extension of a smooth curve through the helium nuclei data multiplied by seven.

There is another set of data for which the analysis has just been completed which bears on this problem. Balasubraymanyan and McDonald [3] obtained a differential helium nuclei spectrum during the same period in 1963 as the proton data of this work. It agrees well with curve C above about 1.5 BV, but falls more quickly below this rigidity. These data are shown in figure 3, along with the results of this work in 1963 and

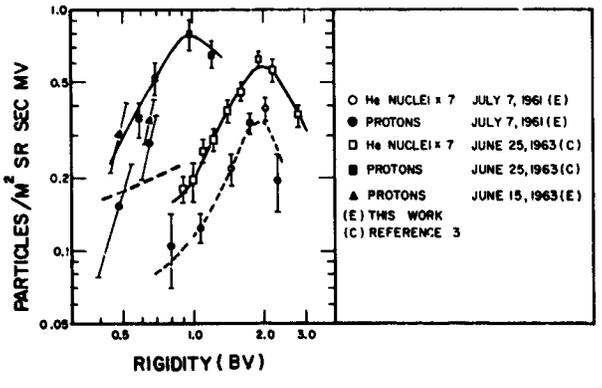

FIGURE 3.—Differential proton and helium fluxes compared to those of Balasubrahmanyan and McDonald.[3]

1961. The 1962 results lie in between those of 1961 and 1963, and were not included only to avoid unnecessarily complicating the figure. All these data are seen to be consistent with there being a difference between the proton differential

rigidity spectra and the helium one multiplied by seven below about 1.2 BV.

Hence, these combined results suggest strongly that there is a splitting of the proton differential spectrum and the helium nuclei one multiplied by seven below about 1.3 BV. This result does not contradict the earlier statements concerning the agreement in the rigidity spectra with those of the declining phase of cosmic rays because there is not sufficient helium data below 1.2 BV during this earlier period to justify a comparison in the 0.4 to 1.2 BV rigidity region. Also, although there is certainly the problem of not knowing the particle spectrum outside of the solar system, for the galactic spectra normally suggested, the splitting effect is at least qualitatively in agreement with the prediction of a modulation of the type proposed by Parker, since the protons have a higher velocity for a given rigidity than the helium nuclei and are therefore less suppressed.

MODULATION OF LOW-ENERGY GALACTIC COSMIC-RAY HYDROGEN AND HELIUM*

C. E. FICHTEL, D. E. GUSS, D. A. KNIFFEN, AND K. A. NEELAKANTAN†

A study of the energy spectrum of the cosmic-ray hydrogen and helium nuclei as a function of the period in the solar cycle provides one of the better means of gaining insight into the mechanism that modulates the galactic cosmic radiation. An examination of these nuclei in the low-energy region, where the modulation effects are greatest, has the particular merit of permitting the separation of velocity and rigidity effects, since for a given rigidity the helium nuclei have a markedly different velocity from that of the protons. Considerable information related to this problem had been obtained before 1960 for the most recent period of increasing solar activity [*Webber*, 1962].

In order to continue the study of the problem of the variation of the galactic cosmic-ray proton and helium nuclei spectrums and extend it to lower energies, a series of balloon flights, beginning in 1961, has been made from Fort Churchill, Canada. It is the aim of this letter to present the results of the nuclear emulsion studies of the hydrogen and helium nuclei obtained in 1962 and 1963 and compare them to those obtained in 1961 [*Fichtel et al.*, 1964].

The experimental data were obtained by carrying sets of nuclear emulsions aboard high-altitude skyhook balloons flown from Fort Churchill, Canada, where the earth's magnetic field allows all particles in the rigidity interval being studied to reach the top of the atmosphere. A second nuclear emulsion stack is released at the time the primary stack is rotated into the exposure position. The second stack provides the necessary information on the background particles collected during ascent and descent which must be subtracted from the particle flux measured in the primary stack, since nuclear emulsions are an integrating device.

There is not space here to describe in detail the corrections which must be applied to the data, but the discussion of the method along with self-consistency arguments has been given in some detail in an earlier paper [*Fichtel et al.*, 1964] and will be treated further in the final publication of this work. It is appropriate to mention, however, that there is a substantial secondary proton flux from interactions in the atmosphere above the detector, and allowance has been made for the uncertainty in the interaction correction in the calculation of the errors associated with the flux values that are quoted below.

In earlier work during the years 1955 through 1960, McDonald and Webber had shown that higher-energy data at higher-rigidity geomagnetic cutoffs suggested that the proton rigidity spectrum was the same as that for helium multiplied by seven [*Webber*, 1962]. Figure 1 shows that in the present data there is a general tendency for the proton points to lie above a reasonable extension of a smooth curve through the helium nuclei data multiplied by seven both in 1961 and 1962. In Figure 2 the 1963 proton data from the nuclear emulsions are plotted together with the proton and helium data of *Balasubrahmanyan and McDonald* [1964] at higher rigidity. Their data were obtained from counter experiments flown on June 24, 1963, when the high-latitude neutron monitor readings differed from those on June 15 and 16, 1963, when the emulsions were flown, by much less than 1 percent. In Figure 2 the splitting between the rigidity spectrums of the two components is quite marked. Hence, these results suggest strongly that there is

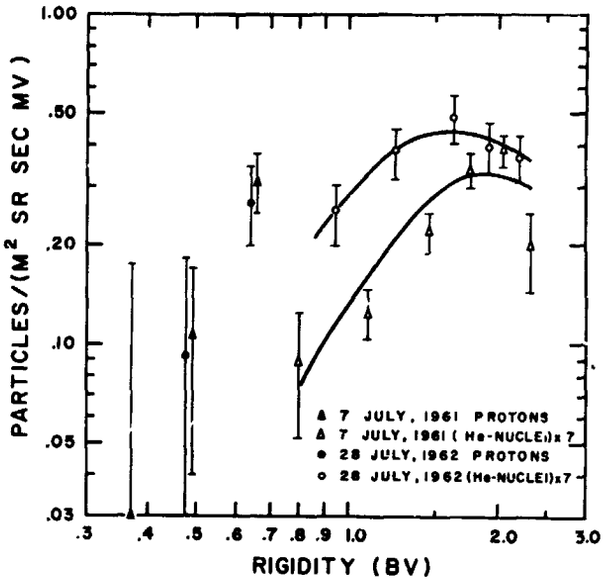

FIGURE 1.—Proton and He nuclei differential rigidity spectrums from 1961 and 1962 balloon flights at Fort Churchill.

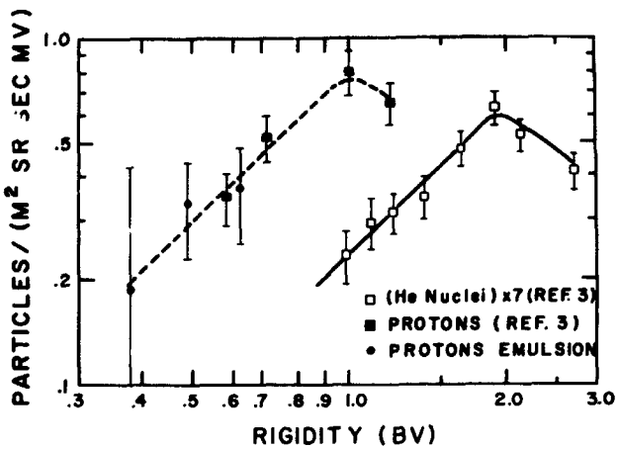

FIGURE 2.—Proton and He neclei differential rigidity spectrums from 1963 balloon flight from Fort Churchill.

a splitting below about 1.3 bv between the proton differential spectrum and that for helium nuclei multiplied by seven. This conclusion is not inconsistent with the earlier statements [*Fichtel et al.*, 1964] about the agreement in the rigidity spectrums of the proton and helium components during the declining phase of cosmic rays because there is not sufficient helium data below 1.3 bv during the earlier period to justify a comparison in the 0.4– to 1.3–bv rigidity region.

Although there is the problem of not knowing the particle spectrum outside the solar system, the splitting effect for the galactic spectrums normally suggested is at least qualitatively in agreement with the prediction of the modulation mechanisms currently proposed. Most of these models predict that protons will be less suppressed because they have a higher velocity for a given rigidity than helium nuclei. Therefore, unless the proton rigidity spectrum is very different from the helium spectrum in free space, the type of splitting in the spectrum which is observed would be predicted by these models. A more complete discussion of modulation models can be found elsewhere [*Webber*, 1962; *Fichtel et al.*, 1964].

MAGNETIC EFFECTS OF THE QUIET TIME PROTON BELT*

R. A. HOFFMAN AND P. A. BRACKEN

An analysis of the magnetic effects of the quiet time proton belt has been performed with data obtained from a proton detector aboard Explorer XII. From the measured energy spectra, intensities, and pitch angle distributions of the protons with energies above 100 kev, the current density on a magnetic meridian plane was calculated using the theory of Akasofu and Chapman, modified to eliminate several simplifying assumptions. The algebraic sum of all the currents was 0.59 million amperes, and the magnetic moment of the current loop was $0.029 M_E$. From the electric current distribution the magnetic perturbations on the meridian plane were obtained. At the magnetic equator on the earth's surface the proton belt produced a 9 γ decrease in the field in comparison with the 38 γ decrease reported by Akasofu, Cain and Chapman based on some preliminary data from the same detector. The maximum perturbation appeared at $L=3.6$ on the magnetic equator, where the field attained a value of -23 γ.

I. INTRODUCTION

The various motions which a group of charged particles exhibit when trapped in the earth's magnetic field result in electric currents. The analysis of these movements yields the observation that the net currents are parallel to lines of magnetic latitude: in some regions of space they flow eastward, and in other regions westward. If one assumes longitudinal symmetry about the earth, these motions necessarily correspond to a toroidal ring current encircling the earth.

On the basis of geomagnetic evidence it has long been postulated that some type of ring current exists. The enhancement of the current at times was thought to be one cause of magnetic activity, but even during magnetically quiet times the current was never supposed to die away completely.

Thus, since the advent of the satellite era and the discovery of the earth's trapped radiation, there has been considerable expectation that the particles which constitute the ring current would be directly observed, and their species, energies and spatial distributions determined. In addition, magneticians have sought the location of the currents by attempting to measure their magnetic effects with satellite borne magnetometers. While the trapped radiation was discovered over five years ago, the endeavor to observe any significant ring current has been unsuccessful until recently.

In an initial survey of data received from a low energy proton detector aboard Explorer XII (launched August 16, 1961), *Davis and Williamson* (1963) noticed that the energy density of the 100 kev to 4.5 Mev protons amounted to an appreciable fraction of the energy density of the earth's magnetic field during a magnetically quiet period, and from 4 out to 8 earth radii the ratio of the two energy densities was almost constant. It was of obvious interest to determine the magnitude of the magnetic field produced by this population of protons. On the basis of some preliminary data furnished by Davis, *Akasofu, Cain and Chapman* (1962) calculated the magnetic disturbance for a model proton belt which resembled the measured proton distribution. The results predicted a decrease in the surface equatorial field of about 38 γ due to the quiet time belt. *Davis and Williamson* (1963) also observed a threefold increase in proton intensities at small pitch angles during a magnetic storm. Adopting the assumptions that (1) this increase was applicable to protons of all pitch angles, and (2) the average energy of the particles equalled the quiet

*Published as *Goddard Space Flight Center Document X-611-64-*. June 1964

time energy, *Akasofu and Cain* (1962a) calculated that an additional 80 γ decrease would be observed at the equator of the earth, sufficient to account for the -60 γ main phase of the aforementioned magnetic storm.

A considerably more thorough analysis of the magnetic effects of the quiet time proton belt has now been performed from the data obtained from the proton detector aboard Explorer XII, and the results are transmitted in this paper. In addition to the fact that these protons produce the greatest magnetic disturbance of any known population of trapped particles, it is also of interest to study the effects of the ring current on phenomena related to the earth's main magnetic field. The magnetic lines of force are distorted from the shapes calculated by the spherical harmonic analysis of the field at the earth's surface. There is a stretching out or strengthening of the field at distances beyond the ring current which affects the location of the magnetospheric boundary. Of interest to cosmic ray physicists is the influence of the Störmer cut-off rigidity for solar protons approaching the earth near the polar regions. Finally, the quiet time particle distributions are established in order to acquire a basis for determining storm time variations.

Thus, in this paper the proton data are also interpreted so as to determine the extent which the magnetic perturbations of the protons effect the earth's main field.

II. PROTON LIFETIMES

The proton ring current under discussion has been described as a "quiet time" current, there being arguments against consideration that its enhancement during a magnetic storm is the cause of the main phase. If one assumes that the lifetimes of these particles are limited solely by coulomb scattering and charge exchange, the decay time of an enhanced current during a magnetic storm would be an order of magnitude larger than the one day recovery time indicated by magnetograms at ground level (*Liemohn*, 1961). To obtain agreement between the observed decay time and calculated proton lifetimes, it is necessary to postulate that protons in the energy region 1 to 100 kev (below the threshold of the Explorer XII detector) constitute the storm time ring current (*Dessler, Hanson and Parker*, 1961). In light of the fact that at magnetically quiet periods the observed proton intensities remain stable to within a factor of two over a long period of time (*Davis, Hoffman and Williamson*, 1964), the electric current resulting from them is considered to exist at all times and is described as a quiet time ring current.

However, one must recognize the fact that an enhancement of the protons within the energy range of the detector might constitute the higher energy portion of the storm time particles. Since protons trapped at a given time do have finite lifetimes, there must be a source and probably an acceleration mechanism for replenishing the population. In view of the insufficiency of our knowledge concerning such processes, it is possible that the particular acceleration mechanism, and perhaps others, may influence the lifetimes of the particles. It has also been experimentally observed that during a magnetic storm some time variations do exist. For these reasons the storm time proton observations are being carefully analyzed and will be reported in a later paper.

III. ELECTRIC CURRENTS

Since the magnetic effects of the trapped protons are due to the electric currents they establish, it is first necessary to deduce the current distribution on a magnetic meridian plane from the experimental observations of the protons. For this calculation a slightly modified version of the theory developed by *Akasofu and Chapman* (1961) is used. Essentially the same notation has also been adopted and appears for reference in the Appendix.

In Alfvén's guiding center approximation describing the motion of charged particles in a strong magnetic field, the motion is analyzed into three parts: (a) the *gyration* about and in a plane perpendicular to a magnetic field line; (b) the *oscillation* essentially along a line of force between two mirror points; and (c) the east-west *drift* motion for positively charged particles on a magnetic shell. All of these motions may contribute to the flow of an electric current, i. To calculate the current produced in a gas permeated by a magnetic field, the gas pressure and the characteristics of the magnetic field must be known at every point in the gas.

We now limit the discussion to the steady state

case with a proton distribution symmetrical about the axis of the magnetic poles. While the experimental data will be analyzed in the B/B_e (or equatorial pitch angle), L coordinate system, the computations will assume a geomagnetic dipole field. If $\hat{k}$ is the eastward unit vector normal to a magnetic meridian plane at a particular point, the volume current densities arising from the three motions are obtained from the following formulae (*Parker*, 1957):

a) The current produced by the gyration:

$$\vec{i}_L=\hat{k}\left[\frac{c}{aBh_2}\left(\frac{\partial p_n}{\partial L}-\frac{1}{2}\frac{p_n}{p_m}\frac{\partial p_m}{\partial L}\right)+\frac{c}{BR_c}p_n\right] \tag{1}$$

where

$$h_2=\frac{\cos^3\varphi}{(1+3\sin^2\varphi)^{\frac{1}{2}}}=\frac{1}{\cos^3\varphi}\left(\frac{B}{Be}\right)^{-1} \tag{2}$$

and

$$\frac{1}{R_c}=\frac{3(1+\sin^2\varphi)}{aL\cos\varphi(1+3\sin^2\varphi)^{\frac{1}{2}}}. \tag{3}$$

b) The current due to the oscillations:

$$i_0=enw_s=0, \tag{4}$$

because as many particles are passing through a unit area perpendicular to B towards one mirror point as are moving towards the other mirror point, at least over a short period of time.

c) The current produced by the drift motion:

$$\vec{i}_D=\hat{k}\left(\frac{c}{2aBh_2}\frac{p_n}{p_m}\frac{\partial p_m}{\partial L}-\frac{c}{BR_c}p_s\right) \tag{5}$$

The total current is then

$$\vec{i}=-i\hat{k} \tag{6}$$

with

$$i=\frac{c}{BR_c}(p_s-p_n)-\frac{c}{aBh_2}\frac{\partial p_n}{\partial L} \tag{7}$$

The negative sign in equation 6 signifies that a positive term in i is a westward contribution to the current density, and a negative term is an eastward contribution.

Let us briefly consider just what details in the motions of the particles give rise to the three current terms of i. The first term involving p_s is due to the westward drift motion of protons which depends upon the centrifugal force mw_s^2/R_c associated with the motion along a curved field line.

The second term also arises from the curvature of the lines of force. The circular orbits due to the gyration are more crowded together on the concave side of the line than on the convex side. This is illustrated in Figure 1a, where between two

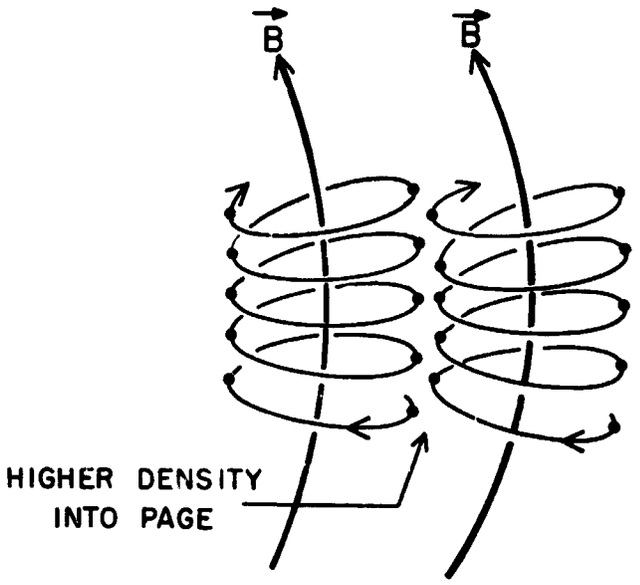

FIGURE 1a.—The source of the current due to the second term in equation 7. The eastward current between the two curved lines of force is caused by the crowding together of the circular orbits on the concave sides of the lines.

adjacent lines of force there is a higher density of particles per unit area moving into the page than out of it. For protons this results in a net eastward current at all points. Surprisingly, this term is larger than the term due to the drift motion if the pitch angle distributions are reasonably steep, as they are for the protons in the belt being discussed.

The final term is due to the fact that the radiation exists in a belt: the intensity increases with radial distance to a certain point, and then decreases. The effect in producing currents is illustrated in Figure 1b, in which the particle intensity is larger on the line of force at a greater distance from the earth, causing a more intense movement of charged particles in a direction into the page than out of it in the region between the lines of force where the two currents intersect. On the inner side of the belt the current

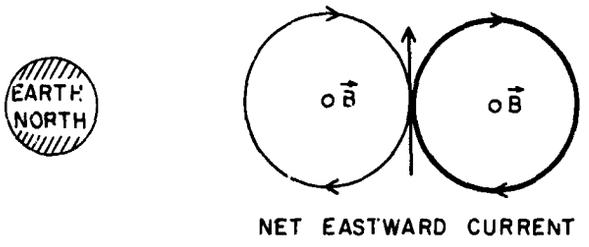

FIGURE 1b.—The source of the current arising from the last term in equation 7. If the particle intensity about the line of force further away from the earth exceeds that about the closer line, indicated by the relative weights of the gyration circles, a net eastward current results in the region between the two lines of force.

will be eastward, and on the outer side it will be westward.

The calculation of the current at all points on a meridian plane first requires the determination of the pressures p_s and p_n at each point. To simplify the equations we first consider protons of a single speed w.

The longitudinal pressure $p_s^* = Nmw_s^2$.

The lateral pressure $p_n^* = \frac{1}{2}Nmw_n^2$.

While it would be possible to calculate these pressures at each point in the magnetosphere from the experimental data, considerable simplification is obtained if they can be expressed in terms of a few parameters determined by the particle distributions. This is accomplished by first fitting the data to a special equatorial pitch angle distribution function with which the local intensities and pitch angle distributions can be obtained from the equatorial intensity and distribution by means of a single parameter depending only upon L. Then the current equation is integrated over the energy spectrum of the particles of interest at each L value; this integral turns out to be actually the total momentum flux at the equator. Hence, the local current at a given latitude depends only upon the two parameters representing the pitch angle distribution and equatorial momentum flux.

Let $F(L, s, \theta)$ denote the number density of protons at a point s on a magnetic shell L, whose speeds lie in dw at w, whose pitch angles lie in $d\theta$ at θ, and whose azimuth angle is arbitrary, since we assume symmetry in azimuth. Note that this definition of $F(L, s, \theta)$ is slightly different than that of *Akasofu and Chapman* (1961) in that it includes a differential angle in azimuth. Fortunately, we can also adopt Parker's special pitch angle distribution (*Parker*, 1957) for the functional form of the distribution in pitch angle, but with the conditions discussed in Section 4 "Proton Data" of this paper:

$$F(L,S,\vartheta, = C_\alpha\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}}\sin^\alpha\theta. \qquad (8)$$

This distribution has very useful and curious properties. It can be divided into two parts: the second part, $\sin^\alpha \vartheta$, is the local pitch angle distribution and has a form independent of B_e/B. Hence the ratio of p_n to p_s remains the same at every point on an L shell. Because the form function, $\sin^\alpha \theta$, is independent of B_e/B, the integral over all pitch angles, which would be evaluated to obtain the omnidirectional intensity at any value of B_e/B, is independent of this ratio of fields. Hence, the omnidirectional intensity varies down a line of force only as $(B_e/B)^{\frac{\alpha}{2}}$.

The constant C_α can be expressed in terms of the total density at the equator $N_e(L)$:

$$N_e(L) = C_\alpha \int_0^\pi \sin^\alpha\theta(2\pi\sin\theta)d\theta \qquad (9)$$

The integral in $N_e(L)$ will arise again in the theory and can be expressed in terms of gamma functions:

$$\int_0^\pi \sin^{\alpha+1}\theta d\theta = \sqrt{\pi}\frac{\Gamma\left(\frac{\alpha+2}{2}\right)}{\Gamma\left(\frac{\alpha+3}{2}\right)} \qquad (10)$$

Hence

$$C_\alpha = \frac{1}{2}\pi^{-3/2}\frac{\Gamma\left(\frac{\alpha+3}{2}\right)}{\Gamma\left(\frac{\alpha+2}{2}\right)}N_e(L) = A(\alpha)N_e(L) \qquad (11)$$

Therefore

$$F(L,s,\theta) = N_e(L)A(\alpha)\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}}\sin^\alpha\theta. \qquad (12)$$

Since a particle detector measures a flux rather than a density it would be well to express all equations in terms of fluxes.

$$F(L,s,\theta) = \frac{I_e(L)}{w}A(\alpha)\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}}\sin^\alpha\theta \qquad (13)$$

where $I_e(L)$ is the omnidirectional intensity at the magnetic equator as a function of L for protons of speed w. It must be noted that α is a function of L, and could also depend upon w.

Inserting this expression into the formulae for the gas pressures yields for protons with speed w:

$$p_s^* = m\int_0^{\pi} (w^2\cos^2\theta)\frac{I_e(L)}{w}A(\alpha)\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}} \sin^{\alpha}\theta(2\pi\sin\theta)d\theta \quad (14)$$

and

$$p_n^* = \frac{m}{2}\int_0^{\pi} (w^2\sin^2\theta)\frac{I_e(L)}{w}A(\alpha)\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}} \sin^{\alpha}\theta(2\pi\sin\theta)d\theta \quad (15)$$

Evaluating the integrals with the aid of equation 10, we have

$$p_n^* = \frac{1}{2}mwI_e(L)\Omega(\alpha)\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}} \quad (16)$$

where

$$\Omega(\alpha) = \frac{\alpha+2}{\alpha+3} \quad (17)$$

and

$$p_s^* = \frac{2}{\alpha+2}p_n^*, \quad (18)$$

which indicates again that the ratio of partial pressures is constant on an L shell.

The current can now be expressed in terms of $I_e(L)$ and α:

$$\begin{aligned} i^* &= \frac{c}{BR_c}\frac{\alpha}{\alpha+2}p_n^* - \frac{c}{aBh_2}\frac{\partial p_n^*}{\partial L} \\ &= -\frac{c}{BR_c}\frac{\alpha}{\alpha+3}\frac{1}{2}mwI_e(L)\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}} \\ &\quad -\frac{c}{aBh_2}\frac{1}{2}mw\left[\Omega(\alpha)\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}}\frac{\partial I_e(L)}{\partial L} + \left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}}I_e(L)\right. \\ &\quad \left. +\frac{1}{2}I(L)\Omega(\alpha)\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}}\ln\left(\frac{B_e}{B}\right)\frac{\partial\alpha}{\partial L}\right] \end{aligned} \quad (19)$$

or

$$i^* = -\frac{mwc}{aH_0}\left[D^*(\alpha,\varphi)L^2I_e(L) + E^*(\alpha,\varphi)L^3\frac{\partial I_e}{\partial L}(L) + F^*(\alpha,\varphi)L^3I_e(L)\frac{\partial\alpha}{\partial L}(L)\right] \quad (20)$$

where H_0 is the field strength on the equator at the earth's surface, and

$$D^*(\alpha,\varphi) = \frac{3}{2}\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}+4}\frac{\alpha}{\alpha+3}\frac{(1+\sin^2\varphi)}{\cos^{19}\varphi},$$

$$E^*(\alpha,\varphi) = \frac{1}{2}\frac{\alpha+2}{\alpha+3}\left(\frac{B_e}{B}\right)^{\frac{\alpha}{2}}\cos^3\varphi,$$

$$F^*(\alpha,\varphi) - E^*(\alpha,\varphi)\left[\frac{1}{(\alpha+2)(\alpha+3)} - \frac{1}{2}\ln\left(\frac{B}{B_e}\right)\right] \quad (21)$$

Equation 20 corresponds to equation 52 of *Akasofu and Chapman* (1961) with the added term depending upon α (L).

It is now necessary to integrate the current over the energy range measured by the detector. Since the scintillator has a low energy cut-off near 100 kev, the current density distribution arising from protons with energies greater than 100 kev will be calculated. This low energy limit must be kept clearly in mind in what follows.

We next make another simplifying assumption: that α is independent of energy, or the energy spectrum is a function only of L, not of pitch angle. The validity of this assumption will be discussed in Section 4, "Proton Data." This allows D^*, E^*, and F^* to be independent of energy.

The only terms remaining in the current equation 20 which depend upon energy as the velocity w and the equatorial omnidirectional flux of this velocity, $I(L)$, which is actually the omnidirectional differential energy spectrum, $\frac{dN}{dE}$. Let

$$\Psi(L) = \int_{100}^{\infty} mw\frac{dN}{dE}dE = 2m\int_{100}^{\infty}\sqrt{E}\frac{dN}{dE}dE,$$

which is a momentum flux, or twice the energy density of the protons.

Then

$$i = -\frac{c}{aH_0}\left[D(\alpha,\varphi)L^2\Psi(L) + E(\alpha,\varphi)L^3\frac{d\Psi(L)}{dL} + F(\alpha,\varphi)L^3\Psi(L)\frac{d\alpha(L)}{dL}\right] \quad (23)$$

Hence, the current at any point in space, L, φ, need be expressed only in terms of the pitch angle parameter α and the momentum profile ψ at the equator.

IV. PROTON DATA

The data relating to the low energy protons from which the current distributions have been calculated were acquired from one orbit of the satellite, pass 10A (outbound) and 10B (inbound) on August 27 and 28, 1961. At this time the major axis of the orbit was lying in the meridian plane which included the sun (see Figure 2).

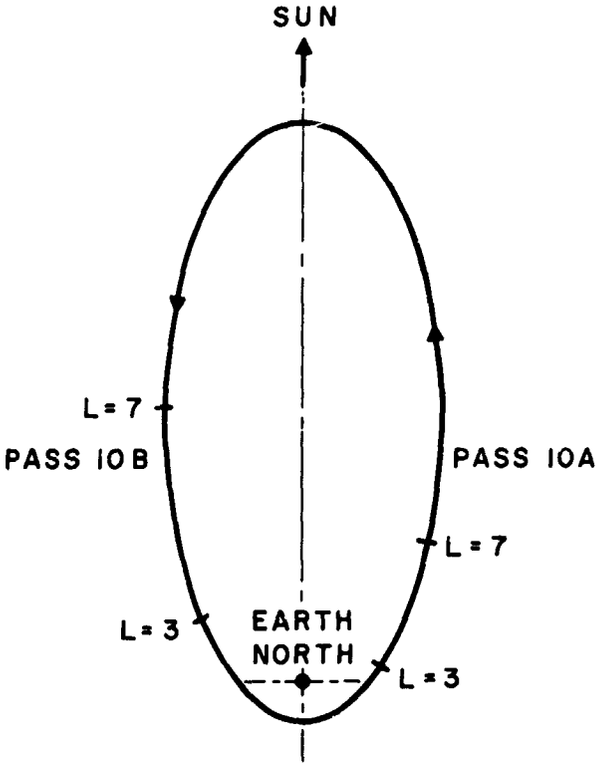

FIGURE 2.—The projection on the earth's equatorial plane of pass number 10 on August 27 and 28, 1961.

Since the heart of the proton belt ($L=3.5$) lies at a relatively low altitude in comparison with apogee ($L=13$) much of the data were collected near the twilight regions, although the outer edge of the belt was traversed on the sunlit side of the earth.

The planetary magnetic three-hour-range index K_p, plotted in Figure 3, indicated that no major disturbances were in progress. In fact the first appreciable magnetic disturbance during the lifetime of Explorer XII did not occur until pass 12.

This particular pass was chosen for thorough analysis because the orbit lay closer to the geomagnetic equator in the heart of the belt than any other orbit. Also the telemetry coverage was complete. When this study was initiated it was expected that a very typical proton distribution would be observed during the pass 10, since *Davis and Williamson* (1963) found no temporal variations larger than 30 percent during nineteen passes of Explorer VII distributed before and after this pass, but not including it. However, later comparisons with this original data indicate that the proton intensities were enhanced by as much as a factor of two at L values smaller than the maximum intensity at L of 3.5 during pass 10. The maximum was also somewhat sharper than observed on the average pass with a more rapid decrease in intensity with increasing L beyond the maximum. This means that the belt was lying at slightly smaller L values than the average belt.

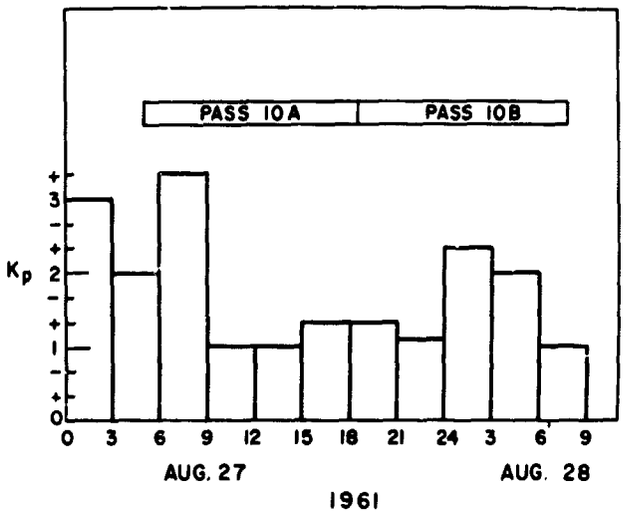

FIGURE 3.—The planetary magnetic three-hour-range index K_p for the period during which the data used in this study were acquired.

The details of the low energy proton detector have been described by *Davis and Williamson* (1963). Let it suffice here to produce a table containing the spectra employed in calculating the momentum integral (Table I), as well as some examples of pitch angle distributions. In general the energy spectrum was described as a doubly sloped exponential spectrum, illustrated in Figure 4 in the integral form which was actually measured by the detector. At L values below 2.2 the data points were best fit with power law

[1] E_1 =662 kev from 470 to 1000 kev; for $E>1000$ kev, power law with γ for integral spectrum =4.2. From 140 to 470 kev, no protons.
[2] For $E>1000$ kev, power law with γ =4.2.
[3] For $E>1650$ kev, power law with γ =4.2.
[4] Below E =255 kev, no protons.
[5] For $E>2000$ kev, power law with γ =4.2.

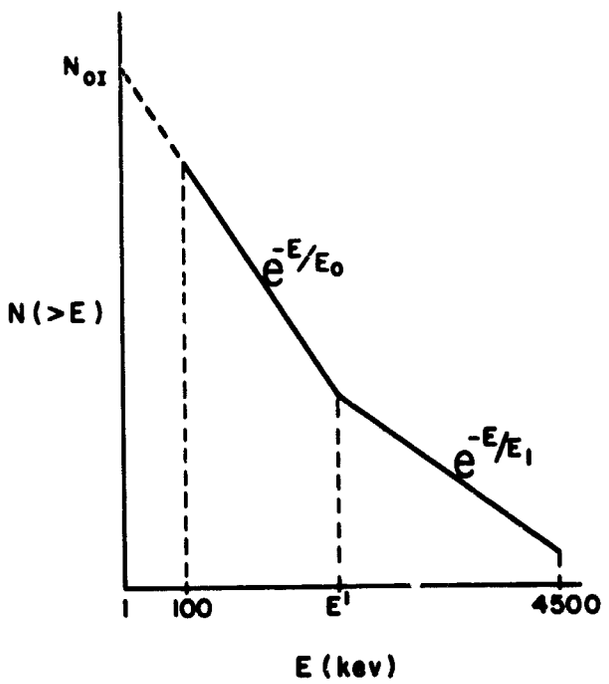

FIGURE 4.—Double sloped integral proton spectrum employed in the calculation of the momentum integral.

spectra, and up to L of 3 a steep power law spectrum was included for the higher energy protons, as suggested by the data of *Bame et al* (1963) and *Naugle and Kniffen* (1963). The spectra listed in Table I were differential before insertion into the momentum integral.

In the derivation of the formulae from which the current distributions may be computed, considerable simplification was attained by employing as the functional form of the pitch angle distribution, $\sin^{\alpha}\theta$. The measured angular distributions were found to fit this form reasonably well provided the entire range of pitch angles, 90° to 0°, was divided into two regions, 90° to 30°, and 30° to 0°, each with an independently determined value of α. Some sample fits of the data to this function appear in Figure 5.

Figure 5a illustrates the extrapolation to 90° of the distribution based on data points with pitch angles only between 30° and 56°. At low L values the orbit carried the satellite away from the magnetic equator making the measurement of protons with large pitch angles impossible. Figure 5b is an excellent example of the necessity of using the two independent values of α. An

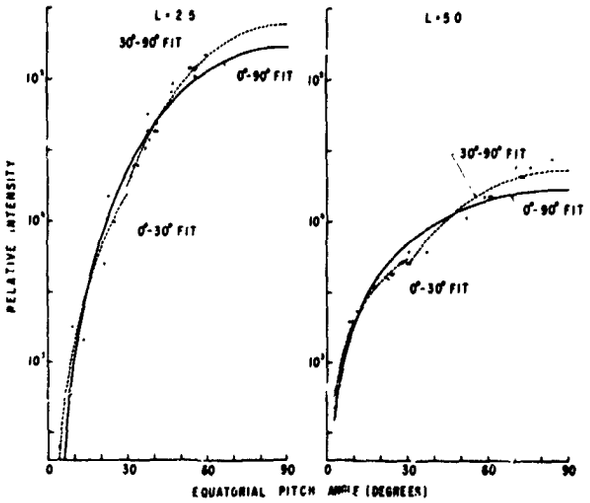

FIGURE 5.—Sample fits of the equatorial pitch angle distribution to the function sin α for the regions 90° to 30° and 30° to 0°.

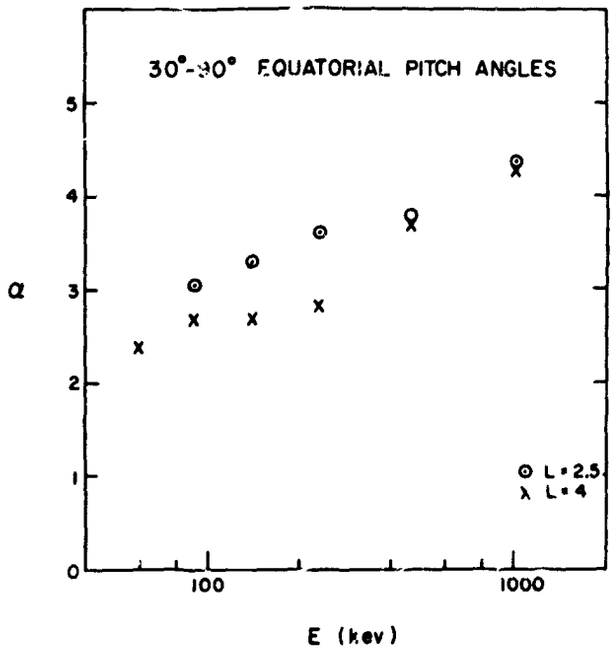

FIGURE 6.—The pitch angle parameter α as a function of energy for L values of 2 and 4.

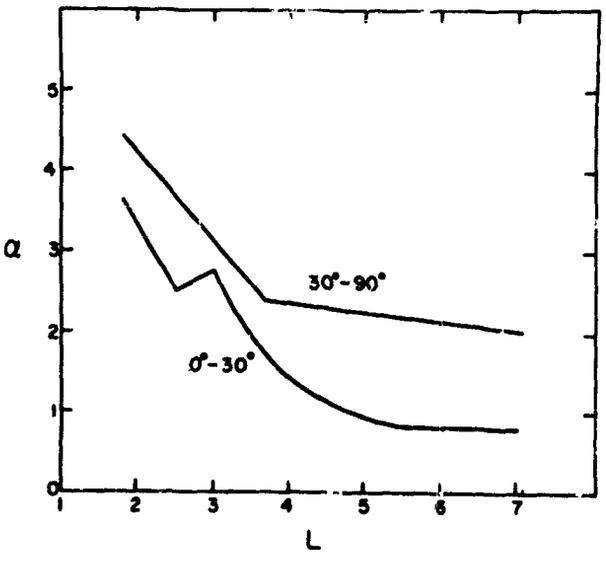

FIGURE 7.—The values of α as a function of L for the two pitch angle ranges derived for the particles having the average momentum on the given L shell.

attempt at a least squares fit of all data from 0° to 90° produced a curve (solid line) with a large hump at the middle pitch angles and a very low value at large pitch angles.

Another assumption which considerably simplified the derivation of the current distribution formulae involved the independence of α upon energy. In reality the value of α increases as a function of increasing energy, as illustrated by the data in Figure 6 for protons of equatorial pitch angles between 90° and 30°. The data in the figure were obtained from the output of the detector which measured the incident energy flux of protons rather than the particle flux. The energies at which the points are plotted are the effective low energy cut-offs for the integral energy spectrum measured at this value of L. By choosing a constant value of α for a given L, the functions D^*, E^*, and F^* (equation 21) became energy independent and could be removed from the integration over energy. Hence, the value of α (L) selected is approximately the value derived for the particles having the average momentum on the given L shell. This value of α as a function of L is plotted in Figure 7 for each of the two pitch angle ranges, 90° to 30°, and 30° to 0°.

The calculation of N_{OI}, employed in the determination of the momentum integral ψ (see Figure 4 for spectral shape of the ψ integral), required some special attention. This quantity, the integral omnidirectional intensity above zero energy, is equivalent to the directional intensities at 100 kev integrated over all pitch angles, which can be actually measured by the detector, multiplied by the factor exp $(100/E_0)$. However, the counting rates of the lowest energy channels of the detector aboard Explorer XII passed into

saturation about one earth radius on either side of the maximum intensity at 3.5 R_E, at least at large pitch angles. Hence, it was necessary to compute N_{OI} by either of two less direct methods.

If (1) a directional intensity above an energy E_c, $J(>E_c)$, is measured at a pitch angle θ_c, (2) the pitch angle distribution characterized by the parameter α is known, and (3) the energy spectrum (E_0) is measured (the latter two parameters could be determined by the current channels of the detector, which did not pass into saturation), then the value of N_{OI} can be calculated from the formulae

$$N_I(>E)=\frac{J(>E_c)}{G_0 \sin^\alpha \theta_c} 2\pi^{3/2} \frac{\Gamma\left(\frac{\alpha+2}{2}\right)}{\Gamma\left(\frac{\alpha+3}{2}\right)} \times \exp\left[(E_c-E)/E_0\right], \quad (24)$$

where G_0 is the telescope factor $=5.85\times10^{-3}$ cm^2−ster., the expression $2\pi^{3/2}$ times the gamma functions arises from integration over the pitch angles, $(\sin^\alpha \theta_c)^{-1}$ is actually an extrapolation of the directional intensity measured at θ_c to the intensity at 90° equatorial pitch angle, and $\exp[(E_c-E)/E_0]$ is an extrapolation in energy from the integral point at E_c to the energy E. The quantity N_I is then the integral omnidirection flux above the energy E, so N_{OI} would have $E=0$.

Therefore, when the counting rate channel at 100 kev was in saturation either of two extrapolations could be used to acquire N_{OI}: A higher energy channel (for example, the 880 kev step) would provide a non-saturated counting rate at a near 90° pitch angle, making $(\sin^\alpha \theta_c)^{-1}\simeq 1$ but requiring an extrapolation in energy $\exp[(E_c-E)/E_0]$, or a smaller pitch angle measurement from the 100 kev channel would provide a measurement of $J(>E_c)$ out of saturation, allowing $\exp[(E_c-E)/E_0]$ to be near one, but increasing the value of $(\sin^\alpha \theta_c)^{-1}$. Obviously the accuracy of either method depends upon how well the data can be characterized by the parameters α and E_0. The values of N_{OI} employed in the computation of ψ (L) were acquired by utilizing both methods. Table II shows a sample set of intensities calculated for an L value of 3.25 for particles with pitch angles 30° to 90°. The agreement between the various calculations of an N_{OI} at a given L value was within ±15 percent.

TABLE II

E_c(kev)	θ_c	α	E_0(kev)	N_{OI}
105	40°	2.5	222	5.01×10^8
470	30°	2.5	222	5.34×10^8
880	70°	2.5	222	4.87×10^8

From the two sets of values of α (L) necessary to describe the protons over the entire pitch angle range from 0° to 90°, a double set of N_{OI} is calculated, since this quantity is a function of α through equation 24. Hence, we obtain two independent profiles of ψ (L), one to be associated with protons having pitch angles 30° to 90°, the other with protons from 0° to 30°. These two profiles appear in Figure 8.

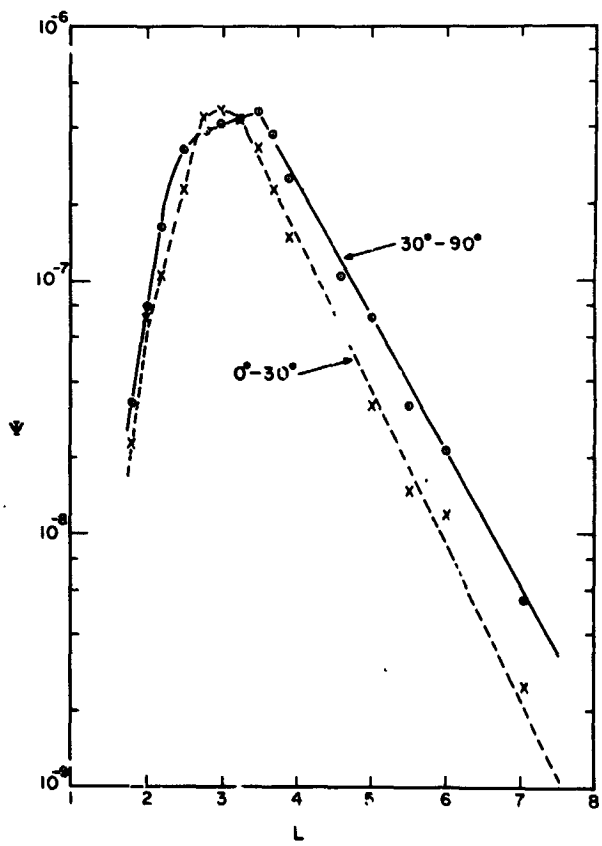

FIGURE 8.—The omnidirectional momentum flux ψ (L^3) for each of the two pitch angle ranges in units of gm/cm-sec^2 (or ergs/cm^3).

V. ELECTRIC CURRENT DISTRIBUTION

The data have now been compiled in a form sufficient for the calculation of the electric current distribution from equation 23. One must keep in mind that the current at a particular L, φ is actually a function of the local partial pressures p_s and p_n (equation 7), but we have replaced the problem of calculating them by utilizing the parameters α (L) and ψ (L). The set of these parameters which is applicable to the radiation at the point of calculation of i must be used. Since a proton with an equatorial pitch angle of 30° mirrors at a magnetic latitude of 32°, the calculation of i for latitudes less than 32° will employ the set of parameters describing protons with equatorial pitch angles from 30° to 90°, and the calculation of i for latitudes greater than 32° will utilize the parameters for protons of pitch angles 0° to 30°. There will be a discontinuity in i as a function of latitude at 32° because as this latitude is approached from the equatorial side, the parameters less accurately describe the actual radiation.

Two other discontinuities which arise in the distribution of i over a meridian plane are due to the approximation of α (L) and ψ (L) by the simple mathematical expressions listed in Table III. Except for ψ (L) in the region $L=2.25$ to 2.75 for protons with 30° to 90° pitch angles, and $L=2.75$ to 3.25 for 0° to 30° pitch angles, both α and ψ could be well approximated by either straight lines or exponentials. While the approximation curves are continuous, their derivatives contain discontinuities between the segments of the curves. Hence, since i depends upon the derivatives, it will contain discontinuities.

TABLE III

α	L Region	ψ	L Region
		30° to 90° E.P.A.	
$-1.07L+6.36$	1.5 to 3.7	$2.95\times10^{-11}\exp(L/0.256)$	1.5 to 2.4
$-0.12L+2.84$	3.7 to 10.0	$1.98\times10^{-7}\exp(L/4.12)$	2.7 to 3.5
.....	.....	$3.50\times10^{-5}\exp(-L/0.810)$	3.5 to 10.0
		0° to 30° E.P.A.	
$-1.62L+6.57$	1.5 to 2.5	$2.06\times10^{-12}\exp(5.18L)$	1.5 to 2.0
$0.52L+1.22$	2.5 to 3.0	$4.23\times10^{-10}\exp(2.52L)$	2.0 to 2.75
$27.5L^{-2.113}$	3.0 to 5.3	$5.91\times10^{-5}\exp(-1.476L)$	3.2 to 10.0
$-0.053L+1.16$	5.3 to 10.0	.....	.....

In the regions of Ψ not included by these formulae, tabulated values from the curves of Figure 8 were used.

The calculations of i in both pitch angles ranges have been performed for the region of L from 1.5 to 10 in intervals of 0.1 and latitude from the equator down an L shell to approximately 1000 km above the surface of the earth in 2° intervals by utilizing an IBM 7094 computer at Goddard Space Flight Center. Actually the calculations were terminated at a latitude within 2° of the latitude where the line of force attained a height of 1000 km. This convention was adopted so that a constant latitude increment could be used in the numerical integration involved in the magnetic field calculations. A contour plot of the current distribution on a magnetic meridian plane appears in Figure 9.

The contributions of each of the terms in equation 23 to the total current are displayed in Figure 10 for two different L shells, one on the inner side of the belt where the total current is eastward, the other on the outer side of the belt where the total current is westward. One notices from an inspection of Figures 9 and 10 that the westward portion

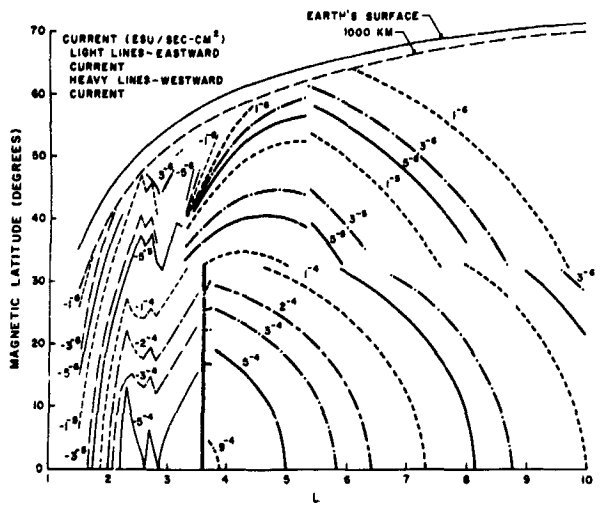

FIGURE 9.—A contour plot of the total electric current in a magnetic meridian plane derived for protons with energies above 100 kev. The currents, expressed as X^{ν} signify $X \cdot 10^{\nu}$. To convert currents from esu/cm²-sec to amps/km², multiply by three.

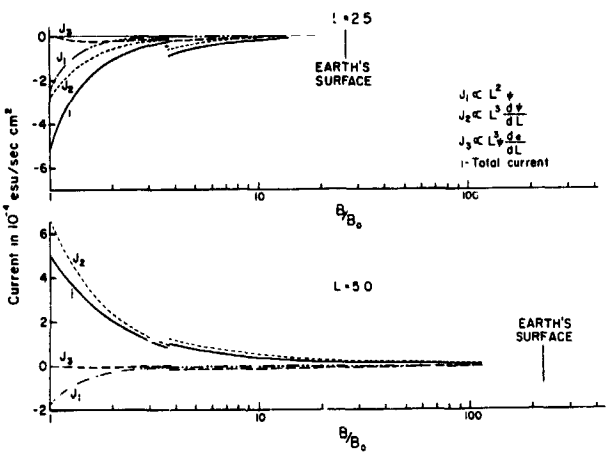

FIGURE 10.—The contributions of each of the terms in equation 23 to the total current for two different L shells.

of the ring current, producing a southward perturbing magnetic field on the earth's surface, arises from the second term J_2, which depends upon the gradiant of the momentum flux on the outer side of the belt.

Since the discontinuities in i appearing in these figures originate in the mathematical expressions used to fit the parameters appearing in the equation for i, a smoothed version of the current contour plot to illustrate the dominant features of the current distribution appears in Figure 11.

An integration has been performed to obtain the

total eastward and westward currents, their algebraic sum, and the magnetic moment of the ring current. These values are tabulated in Table IV.

TABLE IV

	esu/sec	amps
Eastward Current	0.57×10^{15}	0.19×10^{6}
Westward Current	2.34×10^{15}	0.78×10^{6}
Total Current	1.77×10^{15}	0.59×10^{6}

Magnetic Moment $0.029M_E$ ($M_E=8.1\times10^{25}$ gauss-cm³)

VI. MAGNETIC FIELD OF THE RING CURRENT

The magnetic field due to the ring current may be denoted by its components H_p and H_z respectively perpendicular and parallel to the dipole axis. These components refer to a point (r, φ) specified by its polar coordinates (φ is latitude) or alternatively by a point (af, φ) in L space where $f=L\cos^2\varphi$.

The ring current region is then divided into elements dS_3 specified by (r', φ') in polar coordinates or by (af', φ') in L space, where $f'=L'\cos^2\varphi'$. Then (*Stratton*, 1941),

$$H_p=-\frac{2}{(acf\cdot\cos\varphi)}\int\int(f\sin\varphi-f'\sin\varphi')\Big[E(k^2)-K(k^2)+(2f\cdot f'\cos\varphi\cdot\cos\varphi')\frac{E(k^2)}{F_{-}^{2}}\Big](i/F)dS_3 \quad (25)$$

and

$$H_z = -\frac{2}{(ac)}\int\int\left[K(k^2)-E(k^2)+2f'\cos\varphi'(f'\cos\varphi' - f\cos\varphi)\frac{E(k^2)}{F_-^2}\right](i/F)dS_3 \quad (26)$$

Here $K(k^2)$ and $E(k^2)$ denote the complete elliptic integrals of the first and second kind respectively, and

$$k^2 = \frac{(4f\cdot f'\cos\varphi'\cos\varphi)}{F^2},$$

$$F_-^2 = f^2+f'^2-2f\cdot f'\cos(\varphi-\varphi'),$$

$$F^2 = f^2+f'^2+2f\cdot f'\cos(\varphi+\varphi').$$

An element of cross sectional area of the ring current region in the meridian, dS_3, is expressed as $dS_3 = a^2L'\cos^4\varphi' dL' d\varphi'$.

The foregoing formulae appear as in *Akasofu and Chapman* (1961) except for the correction of several misprints.

The components H_p and H_z were calculated separately at each point in the specified current region for particles in both pitch angle intervals. The results were then combined to give the total field components at each point in the current region for all ring current particles.

The integrations involved in calculating these field components were performed numerically on the IBM 7094 computer at Goddard, and the results appear in Figure 12. As with the current calculation, increments of 0.1 in L and 2° (0.0349 radian) in latitude were used.

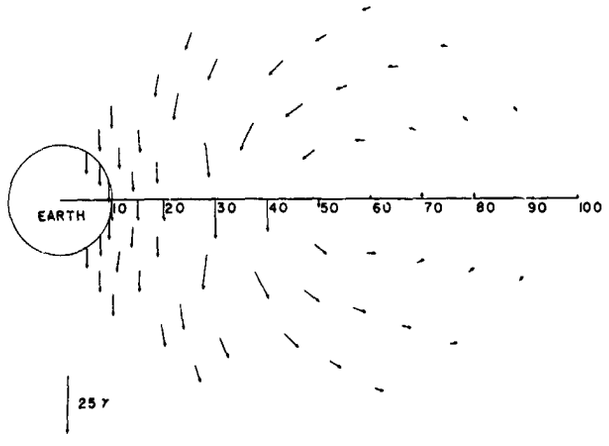

FIGURE 12.—Vector magnetic field on a meridian plane due to the proton ring current.

A discontinuity in the components H_p and H_z arises when $L=L'$ and $\varphi=\varphi'$, since in this case $F_-^2=0$, which appears in the denominator of the argument for each field component. The contribution to the components from the element of integration causing this discontinuity was taken to be zero each time such a discontinuity appeared.

The coordinate system used indicates a negative H_z is in a southerly direction and a negative H_p points toward the earth.

VII. DISCUSSION

(a) Vector Field of the Ring Current

At the magnetic equator on the surface of the earth the magnetic field due to the ring current attained a value of 9 γ in a southern direction, a value considerably smaller than the 38 γ obtained by *Akasofu, Cain and Chapman* (1962) from the preliminary data from the same detector. A reasonable error analysis on the field strength appears virtually impossible to perform. Purely an estimate would place a confidence of about 50 percent (±5 γ) on the field calculations.

The distribution of field vectors from the ring current which appears in Figure 12 indicates a field fairly uniform on the inside of the proton belt and parallel to the dipole axis as expected. In the region of the belt the field shows considerable curl and achieves a maximum value of 23 γ on the equator at an L of 3.6. Outside the belt the field becomes parallel to the earth's field, but has the extremely small value of 2.5 γ. Hence, the ring current field due to these protons above an energy of 100 kev would have little influence on the shape of the boundary of the magnetosphere.

(b) Second Order Calculation

While these protons with energies above 100 kev are showing some magnetic influence, the magnitude is not sufficient to perturb appreciably the magnetic field of the magnetosphere which arises from sources internal to the earth. In fact it appears that the distortion of the field even at the altitudes of the ring current due to the compression of the field by the solar wind is comparable to the disturbance from the ring current (*Cahill and Amazeen*, 1963). Hence the assumption of analyzing the data in the L, equatorial pitch angle coordinate system for the ring current

calculations will produce results as accurate and physically meaningful as would an attempt at a second order calculation (*Beard*, 1962; *Akasofu, Cain and Chapman*, 1961), in which the trapped protons are assumed to move in a magnetic field differing from the internal field by the field of the ring current itself.

(c) Cut-off Rigidity of Solar Protons

In order to explain the observations of low-rigidity solar protons near the earth at latitudes well below those predicted by normal Störmer theory, investigators have included the magnetic effects of a ring current as well as the termination of the geomagnetic field (*Kellogg and Winckler*, 1961; *Akasofu, Lin and Van Allen*, 1963; *Ray*, 1964). In order that a ring current contribute significantly to a reduction in the cut-off rigidity, its magnetic moment must be some appreciable fraction of the magnetic moment of the earth. However, the moment due to the quiet time protons with energies above 100 kev is calculated to be only 0.029 that of the earth, a value much too small to affect solar proton trajectories.

(d) Model Belt Parameters

On the basis of some very preliminary data from the proton detector aboard Explorer XII, the magnetic effects of a model belt that resembled the measured belt were calculated (*Akasofu, Cain and Chapman*, 1962). Since then the properties of a similar belt have been applied to various problems of a geophysical nature (see especially the later articles by Akasofu; *Vestine*, 1963). For this work the following parameters have been utilized to characterize the distribution of protons:

- r_0: distance where the number density attains its maximum value,
- g_1: Gaussian parameter for the inner side of the belt: $n=n_0 \exp(-g_1^2 z^2)$, where $z=(r-r_0)/a$,
- g_2: Gaussian parameter for the outer side of the belt,
- α: pitch angle parameter,
- n_0: maximum number density,
- E: average energy of all protons in the belt.

In table V are listed the values adopted in the literature and a set of suggested values which more accurately produce the results obtained in this more thorough study.

TABLE V

Parameter	Value in Current Literature	Revised Value
r_0	3.0 and 3.2	3.5
g_1	2.990	1.0
g_2	0.419	0.90
α	2.0	2.5
n_0	0.6/cc	0.46/cc
E	500 kev	300 kev

(e) Lower Energy Protons

One must keep clearly in mind in this discussion of the magnetic properties of the trapped protons that only those with energies above 100 kev, the low energy cutoff for the direct detection of proton particle fluxes by the detector, have been considered. However, in another mode of operation the detector could measure proton energy fluxes down to energies of some tens of kev, depending upon the steepness of the spectrum. Beginning at about an L of 5, large fluxes of protons were apparently present with energies extending down to at least 50 kev, and the ratio of the flux between 50 and 100 kev to that above 100 kev became increasingly large with range.

While a complete saturation of the field beyond five earth radii with very low energy protons would significantly contribute to a quiet time ring current, the maximum field produced at the earth's surface by such a particle distribution is insufficient to account for large magnetic storms.

For a rough estimation of this maximum field first assume that the particle energy density is limited by the energy density of the field on the magnetic equator of an L shell. Next assume that the particle intensity is isotropic ($\alpha=0$) and hence constant everywhere on an L shell to latitudes of 60°, which is essentially the surface of the earth for $L\geq 5$. Using equations 23 with $1/h_2$ add $1/R_c$ evaluated at the equator, their maximum values, and with

$$\Psi(L)=2\frac{H_0^2}{8\pi L^6}$$

the current is

$$i(L)=\frac{cH_0}{2\pi aL^4}\cos^3\varphi$$

This produces a field at the center of the earth, and approximately at the surface, of

$$H_z=-\frac{1\times10^4}{L^3}\gamma,$$

where L is the minimum distance of the belt from the center of the earth. For $L=5$, H_z is -76 γ, which is one, and probably two, factors of two too large if compared with a field derived from any realistic distribution of particles exactly calculated.

To account for a large storm of 300 γ (excluding inductive effects in the earth) the field would have to be saturated down to at least an L of 3.2, and probably more like 2.5 for a more reasonable particle distribution. The apparent necessity for such a high intensity, low altitude belt leads one to question whether the current equation 7 includes all the necessary terms to account for the ring current as it naturally occurs. One is tempted to suggest that electric fields may assist in the production of an increased westward movement of the protons already observed. It certainly would seem reasonable to attempt a measurement of electric fields in this region of space.

It is interesting to note that the lifetime of 50 kev protons at 5 earth radii is only on the order of a week (*Liemohn*, 1961). In order to sustain a quiet time belt of such particles it would be necessary to have a source which operates continually.

In passing it is perhaps well to mention that the trapped electrons observed to date produce negligible magnetic fields. Since the magnetic properties of a particle depend upon the square root of its mass, electron fluxes of the order of 10^{10} electrons/cm^2-sec would be required to produce magnetic effects equivalent to those of the protons observed. This flux is two orders of magnitude greater than any reported in the literature.

VIII. CONCLUSION

The protons with energies above 100 kev observed by the low energy proton detector flown by Davis and Williamson aboard Explorer XII are the first group of particles discovered in the trapped radiation region with intensities sufficient to produce significant magnetic effects. However, for applications to other geophysical problems, such as the distortion of field lines, the change in the Störmer cut-off rigidities, and the quiet time remains of a storm time ring current, the observed particle intensities are probably disappointingly small.

For future studies of the proton ring current two improvements in the data acquisition would be desirable. The orbit of the satellite should be more nearly equatorial over all L values, and the detectors should be capable of measuring protons down to nearly one kev in energy.

While this detector has provided information which has advanced our knowledge of the ring current problem, it appears that the complete understanding of the phenomenon will require some years of continued research with new particle detectors and possible complementary measurements of electric fields or a more complete understanding of other source mechanisms for the electric currents.

ACKNOWLEDGEMENTS

The authors appreciate the opportunity of working with the excellent data collected from the proton detector flown aboard Explorer XII by Mr. Leo R. Davis and Mr. James M. Williamson, and for very helpful discussions with them. One of us (R. A. H.) performed most of this study while the recipient of a NAS-NASA Resident Research Associateship, the support of which is gratefully acknowledged.

AURORA*

BENGT HULTQVIST†

1. INTRODUCTORY DESCRIPTION

Descriptions of aurora of great antiquity are known. Some of the most famous are those by Aristotle (Meterologica, Book I, Chap. 5 (ca 340 B.C.)), Pliny (Historia Naturalis, Book II, Chaps. 27 and 33 (ca. 77 A.D.)), and Seneca (Quaestiones Naturales, Book I, Chaps. 14 and 15 (ca. 63 A.D.)). In central Europe the rare auroras were considered as warnings for coming calamities and the descriptions from the Middle Ages, especially, are characterized by superstitions and fears. In northern Europe where auroras are more common such superstitions did not influence the objective observation to the same extent. A remarkably good description can be found in the Norwegian chronicle The King's Mirror of about 1250. It is partly quoted by Störmer (1955) and he also quotes some good descriptions of auroral events of more recent time.

The name aurora borealis, or northern dawn, seems to have been first used by the French philosopher Gassendi in 1621, (Jacka and Paton, 1963) and is an appropriate description of the usual appearance of the northern lights when they are observed in medium latitudes. In analogy with aurora borealis the southern lights have been called aurora australis. "The northern dawn seen from middle latitudes is mostly the upper portion of a display which is overhead at higher latitudes. It is only when aurora moves equatorwards on the rare occasions of the great events that middle latitude observers can see those parts of the display which, being below the horizon, are so frequently concealed from them. Aurora then belies its title, since it is no longer an unspectacular glow on the horizon, like the dawn, and it is more aptly called "The Merry Dancers," the name by which it is known in the northern isles of the Britain" (after Jacka and Paton, 1963). In the last years, aurora has been made by man with the use of high-altitude nuclear explosions. The first artificial aurora was observed in 1958 (Cullington, 1958, Fowler and Waddington, 1958).

This review will concentrate on auroral characteristics which are influenced by the geomagnetic field and on results obtained in the last few years. Excellent extensive reviews of auroral phenomena have appeared, (Harang, 1951; Störmer, 1955; Chamberlain, 1961) some fairly recently, and the reader is referred to them for details on, e.g., the auroral spectrum, older morphological studies, correlations with other phenomena, etc. The emphasis here will be on the morphology, which is largely determined by the geomagnetic field. Rocket and satellite studies of primary auroral particles will also be treated in some detail, since they are not contained in the extensive treatises mentioned above. Finally, proposed theoretical models for various auroral phenomena will be briefly discussed in relation to the observations.

In this first subsection a short description of some auroral characteristics will be given.

1. Intensity and Energy Considerations

Aurora is one of the most intense luminous

TABLE 1.

Source	Flux (ergs cm^{-2} sec^{-1})
Sun	$1.4 \cdot 10^{6}$
Full moon	$3000 \cdot 10^{-3}$
Strong aurora	$1000 \cdot 10^{-3}$
Total starlight	$1.8 \cdot 10^{-3}$
Airglow (visible)	$16 \cdot 10^{-3}$
OH (infrared)	$19 \cdot 10^{-3}$
Lyman-α	$10 \cdot 10^{-3}$
Celestial sources (1230–1350Å)	$0.1 \cdot 10^{-3}$
Cosmic rays	$3.8 \cdot 10^{-3}$

*Published as *Goddard Space Flight Center Document X-611-64-97*, April 1964.

†Goddard Space Flight Center. NASA-National Academy of Sciences—National Research Council Senior Post-Doctoral Resident Research Associate on leave of absence from Kiruna Geophysical Observatory, Kiruna, Sweden.

phenomena in the sky, as is illustrated in Table 1 (after Friedman, 1960, except for the aurora value). The very strongest auroras are even more intense than the value given in Table 1. They are fully comparable to the full moon. The majority of auroras are, however, weaker and the whole scale down to the intensity of the airglow exists.

For estimation of brightness of aurora by visual observers, the following four classes of an International Brightness Coefficient (IBC) are used: I, the brightness of the aurora is equal to that of the Milky Way; II, brightness equal to that of thin moonlit cirrus clouds; III, brightness equal to that of moonlit cumulus clouds; and IV, the aurora provides a total illumination at the ground equivalent to full moonlight. These definitions are extremely crude. Seaton (1954) made a first effort to place the IBC scale on an absolute basis. His results have been slightly modified by Hunten (1955), who proposed the following definitions in terms of number of photons of λ 5577Å (generally the most important emission in aurora) per cm^2 (column) and sec.

IBC I	$10^9 = 1\ kR$
II	$10^{10} = 10\ kR$
III	$10^{11} = 100\ kR$
IV	$10^{12} = 1000\ kR$

10^6 photons/cm^2 (column) sec is called 1 Rayleigh (1R) in accordance with the proposal of Hunten et al. (1956). (For a discussion of the Rayleigh unit see also Chamberlain, 1961, Appendix II). The Rayleigh unit is not limited to a special wave length as is the IBC.

The energy influx required to produce visible aurora has been measured (McIlwain, 1960; O'Brien and Taylor, 1964) and has also been computed from optical emissions (Omholt, 1959; Chamberlain, 1961). The results show reasonable agreement. 0.2–1 percent of the input energy seems to be converted to visible light. The input energy required to produce an IBC I aurora is of the order of a few ergs/cm^2 sec (see e.g. Hultqvist, 1964c). Measurements by means of the Injun 3 satellite show that the average energy input rate required to sustain auroras around the world is of the order of 10^{18} ergs/sec (10^{11} watts) (O'Brien and Taylor, 1964). The average energy flux of the solar wind within a cylinder of radius 10 earth radii is of the order of 10^{20} ergs/sec. Thus in the average about 1 per cent of the solar wind energy has to be transformed into particle precipitation. However, during very strong auroras an appreciable fraction of the relevant solar-plasma energy flux must be converted into kinetic energy of precipitated particles, and the energy density of the solar beam may even be unsufficient on some occasions (Mogilevskiy, 1963). Large auroral events thus contribute much energy to the upper atmosphere. Most of this is probably radiated away (only some 15 percent transformed to heat according to Chamberlain, 1961). It seems quite possible that the temperature of the upper atmosphere in the auroral zones is primarily determined by the particle influx (Bates, 1960b; Chamberlain, 1961; Maeda, 1963).

Recent observations of the drag on Injun 3 indicate that the upper atmosphere temperature in the auroral zone is essentially the same as at the equator on geomagnetically disturbed days (Jacchia and Slowley, 1964). The heating accompanying geomagnetic perturbations in the auroral zones seems to be 4 or 5 times greater than the heating experienced during these perturbations in low latitudes.

2. Definition and Classification of Aurora

In connection with intensity the definition of aurora has to be considered. It has been fairly common to mean by aurora sporadic emissions of intensity at least a few times the airglow intensity but not to include emissions weaker than that. From a physical point of view this is not a good definition. Airglow and aurora, the production mechanisms of which are different, may well be thought of as being of similar brightness.

A definition based on the mechanism of excitation and emission would certainly be preferred. Along this line aurora is often defined as emissions in which the intensity ratio between the 3914 Å nitrogen band—which is produced by collision excitation—and the oxygen atom line at 5577 Å is of the order of unity. In airglow it is usually much less than unity. Unfortunately, however, the excitation mechanisms are complex and are not well-known, which makes it impractical to use them in definitions. One parameter seems to be of widely different importance for airglow and for

aurora: the geomagnetic field. Roach and Roach (1963) have defined aurora as emissions, the geographical location of which is determined by the geomagnetic field. The auroral phenomena then also include the stable red arcs, which are mostly subvisual and located in middle latitudes (see the review of Roach and Roach, 1963). We will in this review consider as aurora all emissions which are produced in one way or the other by particles of energy well above thermal and we will also include the above mentioned medium-latitude red arcs (m arcs), for which it is not known whether they are produced by particles (of very low energy) or not.

The aurora is an extremely complex phenomenon. The various types that occur can be grouped in the following six classes, for instance (due to Elvey, 1964)

1. Polar glow
2. Discrete polar cap auroras
3. High red aurora (Störmer's type III)
4. Intermediate red arcs (Störmer's type II)
5. M-arcs
6. Ordinary displays (Störmer's type I)

The polar glow aurora was discovered by Sandford (1961b). It is produced by the same solar protons in the energy range from some 10 Mev to several 100 Mev, which give rise to polar cap absorption. This type of aurora is thus fairly rare and has a pronounced maximum of occurrence frequency at solar activity maximum. The glow is distributed over the whole polar caps and is often subvisual.

The discrete polar cap auroras have several characteristics which are quite different from ordinary auroral-zone aurora (Störmer's type I). Their occurrence frequency is higher at low solar activity than at high and they also show a negative correlation with magnetic activity. The spectrum is, however, similar to that of ordinary auroral displays.

Class No. 3—high red aurora—is the most common type in low latitudes but it also occurs in the auroral zone sometimes.

The intermediate arcs are very rare. They often look grey due to faintness. The average lower height limit is 196 km (which is between the values for ordinary auroral displays and high red aurora; there-from their name). The red 6300 Å line is the most prominent spectroscopic feature. For more details see Störmer (1955).

The so-called ordinary auroral displays are, by far, the most common type of aurora and the rest of this review will deal mainly with them. Not only visual light is emitted by the aurora but emission also takes place in the ultraviolet (see for instance Chamberlain, 1961) and at radio-frequencies (cf e.g. Hartz, 1958, Murcray and Pope, 1960, Egan and Peterson 1961, and Martin and Helliwell, 1960).

In this review we will include among the auroral phenomena not only emissions of electromagnetic radiation but also the so-called radio aurora. The term radio-aurora refers to the effect on the propagation of radio waves, especially in the VHF and UHF frequency ranges, by the ionization in the atmosphere produced simultaneously with the excitation. Such ionization gievs rise to radio echoes of a special type.

3. The Development of an Auroral Display

The auroral displays show an enormous variety in their temporal development. One can, however, talk about typical sequences of events (see e.g. Heppner, 1954, Akasofu, 1963d). Equatorward of the auroral zones the display may begin with a glow along the poleward horizon. The glow then rises from the horizon and forms one or more quiet and mostly homogeneous bows of light (arc), oriented approximately east-west. An "arc" may remain relatively quiescent for hours, drifting slowly towards north or south. Suddenly it may brighten here and there and "rays" begin to appear across the arc. The arc is then likely to fold and so to lose its regular bow shape and to form an irregular "band." If the rays are very long, the band assumes the appearance of a great "drapery," waving like a curtain in the sky. Rapidly moving and fading irregular forms may appear and disappear all over the sky. As the display dies down, waves of light may surge upwards from the horizon in quick succession causing existing auroral forms to brighten as the waves pass over them (flaming aurora). A continuous glow (veil) may extend over a large part of the sky, serving sometimes as a background to the active forms. At other times, diffuse patches of light, closely resembling clouds, appear here and there in the sky. These

may come and go, often with regular pulsations, until twilight sets in. There is a tendency for reformation into arcs after the diffuse surface phase. The development pattern is closely correlated with the details of the coincident magnetic disturbance. The described sequence is typical equatorward of the auroral zone, as mentioned. On the poleward side, and especially over the central polar caps the development is quite different. This will be discussed in section 3. For some good descriptions of individual auroral events, see for instance Störmer (1955).

4. Auroral Forms

In the last few decades the auroral forms have mostly been classified in accordance with the recommendations of 1930 of the International Union of Geodesy and Geophysics. These recom-

FIGURE 1.1.—Auroral arc.

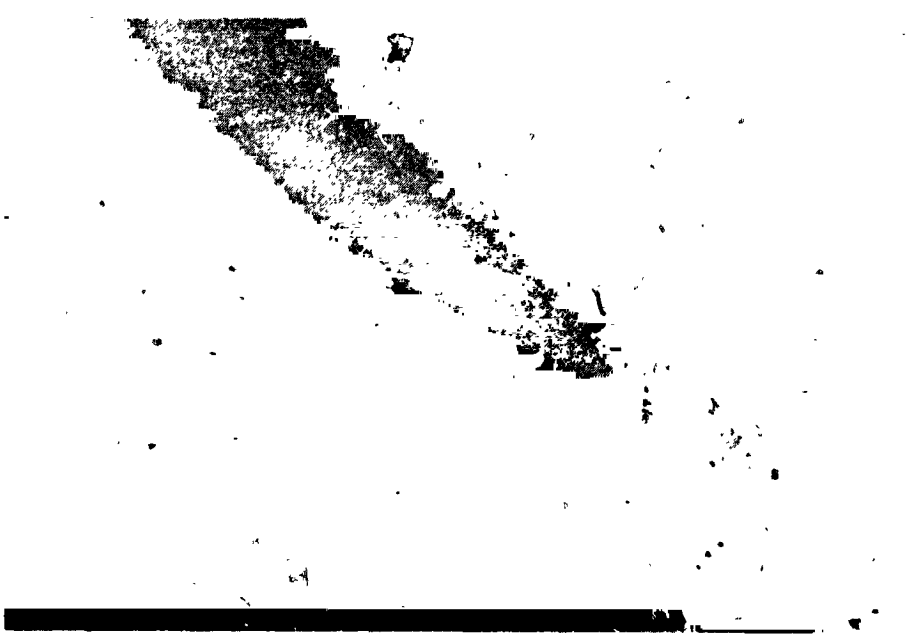

FIGURE 1.2.—A band.

mendations were worked out by Störmer (1930a, b) and are described in detail also in his book (Störmer, 1955).

The Committee for the "International Quiet Sun Year" (IQSY), 1964–1965, of the "Comité International de Géophysique" (CIG) has adopted a new scheme of nomenclature for describing auroras. It will be briefly reviewed below, following Jacka and Paton (1963).

An aurora is described in terms of 4 parameters (6 if brightness and color also are to be included).

1. Auroral forms are divided into three groups

1.1. Band-like forms: These are characterized by a continuous lower border.

(i) When the form appears as a simple, slightly curving arch (Fig. 1.1) or part of an arch, with a regular lower border it is called an arc (A).

(ii) When the lower border is irregular and contains kinks or folds (Fig. 1.2) the form is called a band (B).

1.2. Diffuse forms: These may take the form of a patch (*P*) or a veil (*V*).

(i) The patch is simply a blob of illumination with an ill-defined boundary; it often resembles an isolated cloud.

(ii) The veil refers to the uniform luminosity that may cover a large part of the sky. It may occur alone or as a background to other forms.

1.3 Rays (*R*): These are shafts of light aligned in the direction of the earth's magnetic field (cf. Fig. 1.3). There may be a single ray, a bundle of rays close together or many scattered rays (subscripts 1, 2, 3 may be added to *R* to indicate short, medium, and long rays respectively).

2. Structure is described by the following three adjectives

2.1 Homogeneous (*H*): This term implies an apparent lack of internal structure in the form. The brightness is uniform or it changes only gradually across the form. A homogeneous arc (*HA*), and horseshoe-shaped bands are shown in Fig. 1.4.

2.2. Striated (*S*): The form contains rather irregular striations or filaments aligned roughly parallel with the lower border (Fig. 1.5). Striation is usually recognizable only when the form is nearly overhead.

2.3. Rayed (*R*): Rayed forms are characterized by the appearance within them of rays which are aligned along the lines of force of the geomagnetic field (Fig. 1.6).

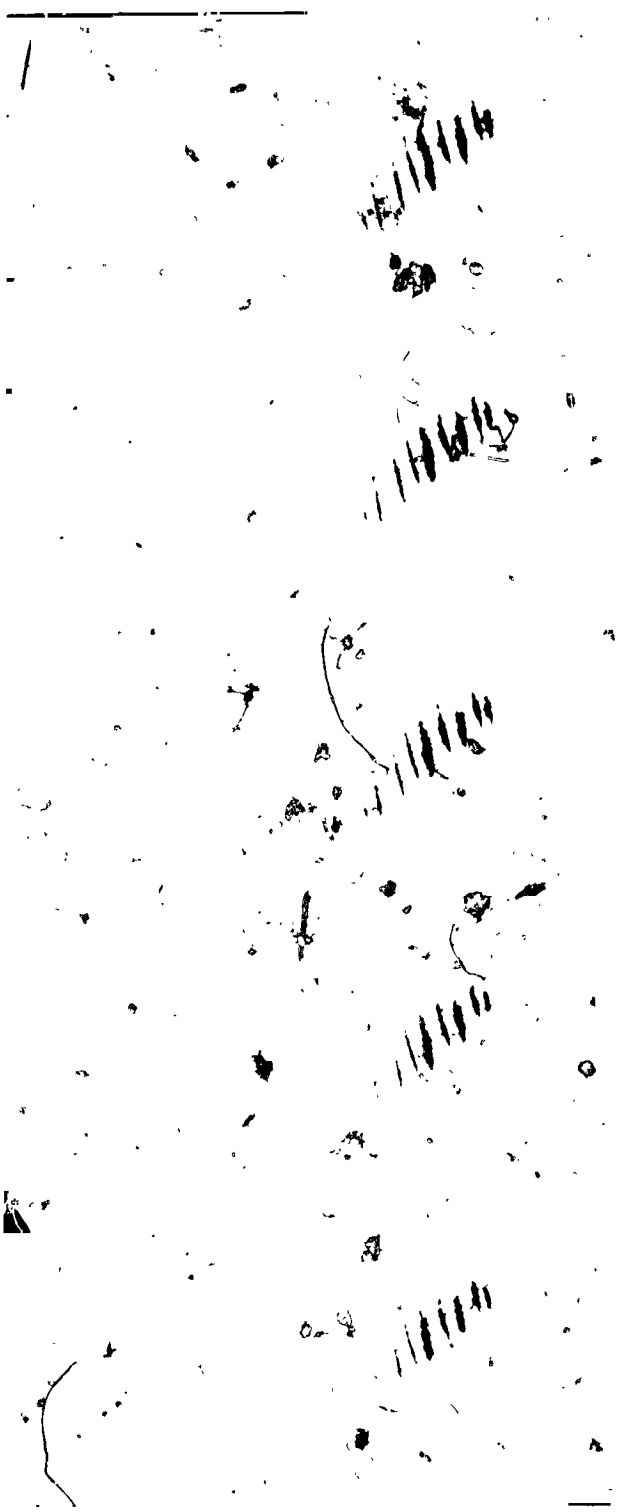

FIGURE 1.3.—Auroral rays photographed with an exposure time of 1/60 sec. 24 pictures per sec. (Courtesy T. N. Davis and G. T. Hicks).

FIGURE 1.4.—Homogeneous auroral arc and bands.

FIGURE 1.5.—Striated auroral arc.

3. *Qualifying parameters: One of three qualifying parameters may, when relevant, be added to the description*

3.1 Multiple (m): This term is used when there occur two or more associated and roughly parallel forms of the same kind. (A subscript numeral indicates the actual number of forms, e.g. m_2HB signifies two closely situated homogeneous bands).

3.2. Fragmentary (f): This term is used when only a portion of an arc or band is present.

3.3 Coronal (c): When any rayed form is viewed in the direction of the lines of magnetic force the rays appear to converge. Homogeneous forms

may also present a similar coronal appearance where they pass over the magnetic zenith.

4. *Condition describes the behavior of a form or of the whole display*

4.1 Quiet (q): The form undergoes only very slow changes in position or shape.

4.2. Active (a): is a form which moves or changes its shape rapidly. Such forms are frequently bright.

(i) a_1—refers to the movement of folds or irregularities along the boundary of a band.

(ii) a_2—refers to the rapid change of shape of the lower border of a form while the form itself may also move rapidly across the sky.

(iii) a_3—indicates the occurrence of a rapid movement of rays horizontally along a form.

(iv) a_4—refers to a display as a whole in which forms fade rather quickly, while new, similar or different forms appear in other parts of the sky. A photograph of such an event is seen in Fig. 1.7.

4.3. Pulsing (p): this describes a condition of fairly rapid and often rythmic fluctuation in brightness. The period of the fluctuation may range from a fraction of a second to the order of minutes.

(i) p_1—pulsating forms: The affected form or forms display a variation in brightness, the phase of which is uniform throughout the forms.

FIGURE 1.6.—Rayed bands.

FIGURE 1.7.—Photograph of an active aurora. The forms move and fade rapidly and new forms appear continuously in other parts of the sky.

(ii) p_2—flaming aurora. This kind of pulsing extends over a large area of the sky which appears lit by surges of light sweeping upwards over it.

(iii) p_3—flickering: A large part of the display undergoes very rapid and more or less irregular changes in brightness as if lit up by flickering flames. This occurs only rarely.

(iv) p_4—streaming: An irregular variation of brightness that progresses rapidly along the horizontal extent of homogenous forms.

Most auroras can thus be fairly well described by four symbols—or sometimes five—with subindices. For instance $a_3\,cfR_2B$ signifies a fragment (f) or a rayed band (R_2B) whose rays are of medium length (R_2) are moving rapidly in a horizontal direction along the form (a_3) and form a corona in the magnetic zenith. Symbols indicating the brightness and color may be added after the symbol for the form (for details see Jacka and Paton, 1963).

The auroral arcs and bands at the auroral zone are characterized by very long extension in east-west direction and a remarkable thinness in north-south direction. From the photographic recordings of aurora made during IGY continuous auroral arcs of lengths 4000–5000 km have been reported (Feldstein et al., 1962, Akasofu, 1963). The values mentioned were limited by the coverage of the net of recording cameras, so arcs may be still longer. Recent measurements of the thickness of 40 zenithal arcs have given values varying between 3.5 and 18.2 km with an average value of 9.1 km (Kim and Volkman, 1963). The thickness was found to increase with increasing magnetic activity. On the other hand, for an active auroral curtain the thickness has been measured to be as narrow as 150–350 m (Akasofu, 1961). No significant diurnal or seasonal variation was found. The vertical extension of the arcs and bands is generally a few ten km. It has been found to vary with solar activity, the extension being smaller and the atmospheric depth greater at the end of a solar cycle (Elvey, 1957). When the sunspot activity starts to increase again, the auroras often appear less deep in the atmosphere and have extension to great heights—the red auroras of type A.

The stable midlatitude red arcs, discovered by Barbier (1958), differ completely from ordinary auroral arcs. They cover some hundreds of kilometers in latitude and in height. Present evidence suggests that they may occur in complete rings around the world (cf. Roach and Roach, 1963).

The rays are characterized by great length and thinness. The length has been extensively studied by Störmer (1955). It may amount to several hundred km, but a more common value is between 100 and 150 km. Especially the sunlit rays can be very long and have been found to extend up to 1100 km sometimes. The diameter of the rays is of the order of 1 km (see e.g. the recent study of Akasofu, 1963b).

Wilcke (1777) first noticed that the auroral rays are aligned approximately along the earth's magnetic field lines. Vegard and Krogness (1920) found that the elevation of the "radiant point," i.e. the point towards which the rays in a corona appear to converge, is systematically one degree or so lower than the magnetic zenith. This difference is too great to be due to the curvature of the field lines. (The rays would have to be at about 1000 km to show a one degree displacement). Störmer (1938) found the auroral zenith to wander around a little in the sky. Abbott (1958) measured a rate of motion for the radiant point of at least 1° in 5 minutes of time. The radiant point was found on either side of the normal (undisturbed) magnetic zenith, but measurements of the disturbed field showed that the instantaneous magnetic zenith was 7 or 8° lower than the radiant point. No relationship between the motions of the magnetic zenith and the auroral zenith was found. Cole (1963) has studied in detail the geometry of the radiant point and found that it commonly differs by 0.5° from the "local auroral zenith," defined by him as the direction of a (hypothetical) ray, regarded as a segment of a straight line, passing through the observer. The difference may amount to as much as several degrees. Observations of the local auroral zenith have not yet been reported. Presuming the rays are oriented along the field lines such observations would give valuable information about the detailed direction of the geomagnetic field lines at auroral heights, which is difficult to obtain with comparable accuracy in other ways.

Detailed studies have shown that fine structures exist not only in auroral forms seen rayed to the eye or the camera but also in what is normally

called homogeneous forms (Nadubovich and Starkov, 1961). Dark filaments of a minimum width of 150 m and an average length of about 20 km have been found. They have been observed most often in the morning hours. The duration is several minutes.

There is a fine structure in aurora not only in space but often also in time. Rapid variations in auroral emission rate have recently been observed and studied by Campbell (1960a, b), Campbell and Rees (1961, Campbell and Leinbach (1961), Iyengar and Shepherd (1961), Omholt (1962), Skrynnikov (1962), Berger (1963), and Gustafsson (1964).

For a more detailed review of older investigations of the characteristics of various auroral forms, see e.g. Störmer (1955) and Chamberlain (1961).

5. Emission Spectrum

But for a very brief introductory survey, the auroral spectrum will not be dealt with in this review. For a detailed review see e.g. Bates (1960) and Chamberlain (1961).

The aurora seen in high latitudes is usually green to the eye. The colour is due to a forbidden transition ($'S \rightarrow 'D$) in the oxygen atom. The wavelength is 5577 Å, which is close to the maximum sensitivity of the eye. The transition probability is very low corresponding to a lifetime of the excited level of about 3/4 sec (Omholt and Harang, 1955).

In lower latitudes the aurora is often seen to be red (high red aurora in the nomenclature used). The spectral characteristic is then the 6300, 6364, 6391 Å triplett of O, which is produced in cascade ($^1D \rightarrow ^3P$) after the 5577 Å line. The 6300 line is also forbidden with a lifetime of the excited level of about 110 sec (Omholt, 1960). Due to the long lifetime, deactivation is important for this line and it is therefore mostly seen in auroras at high altitudes. The long lives of the metastable levels from which the λ 5577 Å and λ 6300 Å lines are emitted give rise to colour variations in active auroras as these lines are emitted for some time after the excitation has ceased.

There exist auroras even in high latitudes with anomalously increased 6300 Å emission. One famous example of this was the one on 11 Feb. 1958. Most other auroral spectra belong to one of three types, between which the boundaries are, however, not very sharp (Krasovskii, 1961). The first type is the low-latitude spectrum mentioned above, in which the ratio of the intensities of the 6300 Å and 5577 Å lines is high, and where these two emissions strongly dominate over e.g. the nitrogen molecule bands. In the next type, lines of neutral and ionized atoms dominate but in addition emissions of ionized and neutral nitrogen molecules are seen. This type of spectrum is observed in both high and low latitudes. Finally, the third type is characterized by numerous intense molecular bands. It is remarkable that in such spectra the green line of atomic oxygen and the first and second positive and negative band systems of N_2 are correlated in great detail. This third type of spectrum most frequently appears in high latitudes. The difference between the spectra are apparently accounted for by the depth of penetration of the exciting agent into the atmosphere, the depth increasing from the first to the third type.

Auroras located at great atmospheric depths usually have a red lower border (red aurora of type B). This is due mainly to the first positive bandsystem of the neutral nitrogen molecule. The reason for the domination of the N_2 emissions at great depths is probably that the $'S$ level of OI is deactivated by collisions to an appreciable amount.

The sunlit auroras have a spectrum different from that of the auroras located in the dark atmosphere. They have a bluish-white color which is produced by resonance emission of primarily the first negative band-system of the positively charged nitrogen molecule (N_2^+).

Of special interest are the hydrogen line emissions. They were first found by Vegard (1939). Analysis of their line contour showed that protons are entering the upper atmosphere with velocities up to 4000 km/sec (Meinel, 1951). They are seen mostly in homogeneous forms. More recently, weak hydrogen glow has been observed preceding the appearance of bright auroras (Romick and Elvey, 1958, and others). Auroras have been observed in which the $H\alpha$ line was so strong compared to other spectral emissions that this aurora might have been produced by proton impact alone (Omholt et al. 1962). In any case it appears certain that in those auroras the

protons supplied, relatively, at least one order of magnitude more energy than in other types of aurora, for which electrons are certainly the main energy contributors. The hydrogen glow is barely visible or even invisible to the eye. It occurs before the electron aurora and, when this has started, on the equatorside of it before midnight. After midnight no hydrogen emission is observed south of auroral forms but rather north of these. A distinct dark region is often seen between the proton aurora and the main forms (Stoffregen and Derblom, 1962). For more details see the reviews of Chamberlain (1961), Krasovskii (1961) and Galperin (1963).

In the midlatitude stable red arcs, mentioned earlier, no other spectroscopic feature than the 6300 Å line has been clearly identified. The location of these arcs is definitely controlled by the geomagnetic field. They are namely lined up along projections of circles from the geomagnetic equatorial plane to the earth's surface along the geomagnetic field lines. It is not clear how they can be produced by collison excitation without any other spectroscopic features being excited. According to Dalgarno (1964), the excitation may be a heating effect caused by low energy particles. On the other hand, if the excitation is chemical it is difficult to understand how the magnetic field control comes in. Megill and Carleton (1964) have proposed that local electric fields may be responsible for the excitation. A number of other proposals for excitation mechanisms are reviewed by Roach and Roach (1963).

6. Methods of Recording Visual Aurora for Morphological Studies

Almost all data concerning the morphology of aurora was taken by visual observers up to IGY. During IGY a large net of so called allsky-cameras, photographing the whole sky automatically every minute, was in operation. Various allsky-cameras have been constructed and used by Gartlein (1947), Lebedinskii (1955), Stoffregen (1955), Park (1957) and Davis and Elvey (see Elvey and Stoffregen, 1957, for a detailed description). A set of allsky-camera pictures are shown in Fig. 1.8. Most allsky films taken hitherto have been 16mm black and white film. The Soviet and Canadian cameras used, however, 35 mm film. In the last few years color film has begun to be used (Sandford and Heiser, 1959; Gadsden, 1960; Sandford, 1961). The committee for the "International Quiet Sun Year," 1964–65, of CIG has recommended the use of 35 mm film, which provides more details of the aurora. For detailed synoptic studies over large areas it is highly desirable that the net of cameras will be denser in the future than it was during IGY. Experience has shown that for most part of the polar regions the possibilities of obtaining large scale synoptic patterns from the IGY records are very limited. A most important contribution to the solution of the morphology problem may be given by very high altitude satellites, taking photographs showing most of the polar caps and auroral regions. Automatic devices for analyzing allsky-camera films have been constructed (Elvey and Belon, 1957; Nagata and Kaneda, 1961).

Davis, Deehr, and Leinbach (1960) have made an evaluation of allsky-camera observations by comparing them with simultaneous visual and photometric observations. They arrived at the following conclusions, among others.

(a) The US model allsky-camera operated during IGY (and probably most other types as well) was slightly less sensitive than an experienced visual observer in detection of very weak diffused forms and is about equal in detecting very weak but well defined forms.

(b) The allsky-camera is much superior to the visual observer in accurately locating and recording the shape of most auroral forms.

(c) The eye is more able to see the details of very bright or fast-moving forms. If the observer were to watch only a small part of the sky, his observations would, in general, be superior to those of the allsky-camera in that small region. However, if the entire sky is to be observed, the allsky-camera is superior in the sense of (b) above.

(d) A greater degree of continuity in auroral forms is often indicated in the compressed image of the sky on all-sky photographs than is apparent to the visual observer.

(e) During the times when visual observers report pulsating aurora, the over-all appearance of the display seems to be quite distinctive and often readily identified on the allsky film.

The exposure time of the ordinary allsky-cameras is generally around 20 sec. By means of image intensifier and TV camera it is possible

to take auroral pictures 24 times a second. Such films allow studies of two to three orders of magnitude more rapid time variations than has earlier been possible. An instrument for rapid filming of aurora was used successfully for the first time in the autumn of 1963 (Davis and Hicks, 1963).

It has recently become possible to observe visual aurora in daytime (Noxon, 1963).

2. MORPHOLOGY OF VISUAL AURORA

1. Geographical Distribution of Auroral Activity

(a) Introduction

That the auroral activity does not increase continuously towards the poles seems to have been noted in print first by Muncke (1837). The dependence of auroral occurrence frequency on latitude was studied by Loomis (1860, 1868) in USA and by Fritz (1868, 1873, 1874, 1881) in Germany. Fritz (1881) made a detailed analysis of a large amount of data on aurora originating from very old times up to about 1878, from which he could delineate the first detailed map of the location of the northern auroral zone.

Fritz's auroral zone was defined as the locus of points where the probability of seeing an aurora in any part of the sky during any part of the night was maximal. It is thus a line, having no width. The curve connecting points with equal probability of seeing aurora in any part of sky at any time of night is called an isochasm. The auroral zone is thus the maximum isochasm. It has been recommended by Chapman (1953) and others to use the probability of seeing aurora overhead in evaluating geographical statistical distribution curves. Lines connecting points of equal probability of auroral occurrence in the zenith are called isoauroral lines or isoaurores.

It has become customary in recent years to think of the auroral zone as having a finite, but generally unspecified and variable, width. In this review, we will use the definition by which the width of the auroral zone is equaled to the distance between the points of half-maximum amplitude of a particular measure of auroral activity. The position of the peak of the auroral zone will be taken as that position at which there is maximum occurrence of overhead auroras, as determined by observations taken over a period of several months. With this definition we cannot talk about variation of the location of the auroral zone through one night or from one night to another, as is often done in the literature. One is then using the notation auroral zone for the area in which aurora exists at a given moment of time. Below, "auroral precipitation area" or "zone" or "momentaneous auroral occurrence zone" will be used for this unique-time distribution of visual auroral activity.

Both the width and the location of the center of the auroral zone is highly dependent on the type of activity-measure employed. The most commonly used measure is the occurrence frequecny of auroral activity, generally defined as the ratio of the number of half-hour (or full-hour) intervals in which aurora could be seen overhead to the total number of half-(or full-) hour intervals. The intensity of the aurora is not taken into account in this measure. Davis (1962 a, b) also employed auroral incidence, defined by the total number of auroral lower borders appearing each hour—as determined by counting the lower borders at 5-minute intervals—in a 1° latitude band passing through the station. It gives similar but somewhat sharper distributions.

The following terminology on auroral geography, suggested by Chapman, is widely used. The auroral regions (north and south) extend from geomagnetic latitudes (ϕ_m) 60° to the poles; the subauroral belts between 45° and 60° magnetic latitude; and the minauroral belt between 45° N and 45° S. The auroral regions include the aurorol zones and the auroral caps (the polar regions within the auroral zones). Alternatively, the regions on the equatorial side of the auroral zones are named cis-auroral regions, while those on the polar side which cover the polar cap, are called the transauroral regions (Jacka and Paton, 1963).

(b) Observed locations of the auroral zones and latitudinal distribution of visual auroral activity

The northern auroral zone delineation of Fritz (1881) and Vestine's (1944) modification of it are shown in Fig. 2.1 together with a zone determined by Feldstein (1960) on the basis of photographic recordings taken at 39 Arctic stations and visual observations made at three sites during the IGY, 1957–58.

While Fritz's auroral zone was based almost entirely on unsystematic auroral observations from several hundred years B.C. up to about 1878, Vestine had at his disposal more systematic observations, particularly those from the two polar years 1882–3 and 1932–3. Both delineations, however, are based on material obtained over very long periods of time with secularly changing geomagnetic field, varying solar activity, partly unknown meteorological conditions, etc. In contrast, Feldstein's curve is based on observations

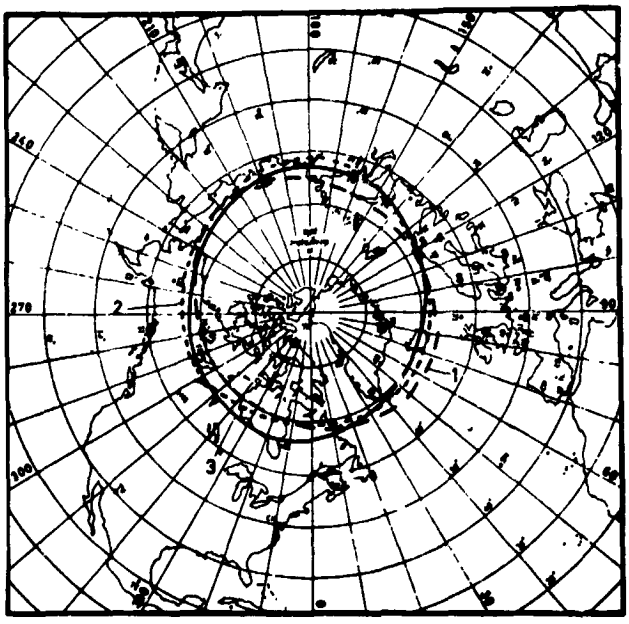

FIGURE 2.1.—Northern auroral zones determined from observations (on a map with geomagnetic co-ordinate system). Curve 1 is that of Fritz (1881), Curve 2 is Vestine's (1944) and Curve 3 Feldstein's (1960).

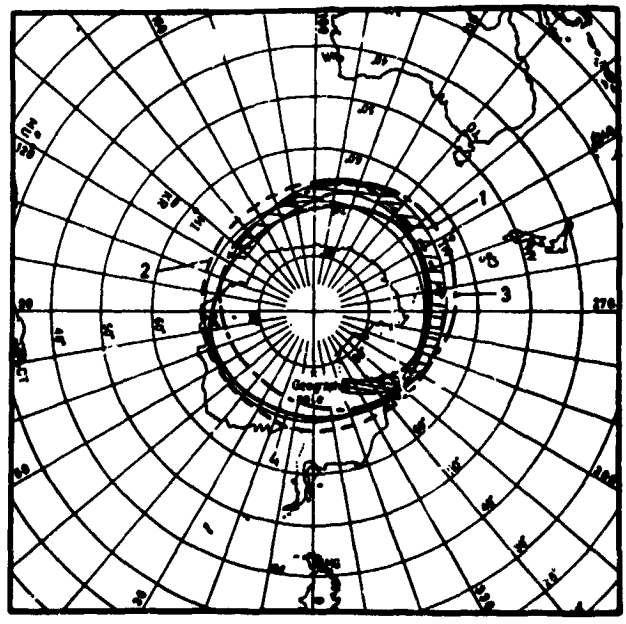

FIGURE 2.2.—Southern auroral zones determined from observations (on a map with geomagnetic co-ordinate system). Zone 1 is according to White and Geddes (1939), Zone 2 to Vestine and Snyder (1945), Zone 3 to Bond and Jacka (1960) and Zone 4 to Feldstein (1960).

made within a few years with the use of a fairly uniform technique at all stations. The auroral indices employed in his determination are more accurate than those previously used, as only the aurora in the zenith has been utilized.

The greatest difference between Vestine's and Feldstein's northern auroral zones is in the region of Hudson Bay, in North America, where Feldstein's curve reaches about 4° farther south than Vestine's.

The first attempt to investigate the auroral statistics in the southern hemisphere was made by Boller (1898). White and Geddes (1939) estimated the location of the zone on the basis of scattered visual observations of aurora australis, and Vestine and Snyder (1945) defined a zone based on geomagnetic observations in the Antarctic. These two zones are shown in Fig. 2.2 together with Bond's and Jacka's (1960) and Feldstein's (1960) zones. The IGY material used by Feldstein was taken at 20 stations on the Antarctic continent and at two stations on islands situated south of Australia. The technique employed in the evaluation was similar to that used in the Arctic.

A recent study of the detailed latitudinal variation of auroral occurrence frequency is that of

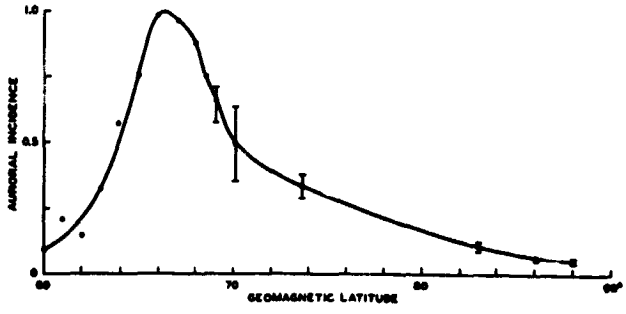

FIGURE 2.3.—(After Davis, 1962b) The incidence of auroral forms at geomagnetic latitudes 60–88°.

Davis (1962 b), shown in Fig. 2.3. It refers in time to the solar activity maximum in 1957–58. The "incidence" of auroral forms, as defined above, was deduced from allsky-camera records taken in Alaska (for the geomagnetic latitude, ϕ_m, less than 69°) and in northern Canada (for $\phi_m > 69°$). The indicated spread for the points representing incidence at high latitude is due to the uncertainty involved in connecting the Alaskan data with those of the high-latitude Canadian stations.

The curve has its maximum between 66° and 67° geomagnetic latitude in Alaska. The width of the zone, as defined above, is about 6° in latitude. The scale for the "incidence" in Fig. 2.3

is a relative one. The hourly occurrence frequency was found by Davis (1962 a) to be between 60 and 70 percent at about 66° geomagnetic latitude at solar activity maximum. Already at $\phi_m = 60°$ it was down to 10 percent, while on the inner side of the auroral zone, the decrease was slower (c.f. Fig. 2.3). Feldstein and Solomatina (1963) found that the frequency of auroral occurrence in the zenith during IGY was about 55 percent on magnetically quiet days and about 90 percent on disturbed days in the auroral zones. The index of activity used was the radio of the number of half-hour intervals with auroras in the zenith to the total number of half-hour intervals of observation, as recorded in the form of ascaplots. The last mentioned investigators also found that the probability of auroral occurrence in the boreal and austral auroral zones are very closely the same.

Nothing was known before IGY about the detailed relations between auroral phenomena in the two hemispheres, but in the last few years some results on this have appeared. They are, however, not consistant. While Jacka (1961) did not find any correlation between the occurrence of aurora at College and MacQuaire Island, which are nearly conjugate points (off by 600–700 k
and Fillius (1960) reported correlation between the general auroral activity at Ellsworth Antarctic station and the conjugate area in USA, but very small correlation (if at all significant) between the detailed pictures in the two areas, DeWitt (1962) observed good detailed correlation of form and motion and of variation of luminosity between auroral events observed at Campbell Island and MacQuaire Island in the southern hemisphere and at Farewell and Kozebue in the northern one. Breakup of the auroras was found to be simultaneous in the conjugate areas. The conjugacy of the observation points employed by DeWitt was certainly better than for any of the other two investigations quoted above. It seems therefore most probable that auroras usually occur as conjugate pairs at either end of geomagnetic field lines, as has long been suspected. More observational data would be of great value.

The occurrence of aurora in very low latitudes (subtropical and tropical) is extremely rare. Even in central Europe and southern USA the probability of seeing aurora is only a few thousandths of that at the center of the auroral zone. Instead, these medium and low latitude auroras are generally very spectacular and have often been noted and recorded also in ancient times. Recent summaries of older observations of auroras extending into the minauroral region have been made by Schove (1955), Matsushita (1956) and Chapman (1957 a, b). Several auroras occurring at very low latitudes have been described rather fully by Chapman (1953, 1957 c), Abbott (1951), and Abbott and Chapman (1959 a). A type of red auroral arcs occurring rather regularly in subauroral latitudes will be discussed later in this chapter.

(c) Comparison of observational auroral zones with various theoretical curves

There are good reasons for postulating circular symmetry in the geomagnetic equatorial plane outside the earth's surface of distance parameters representing statistical averages for corresponding variables of those processes, in and near the equatorial plane, which are associated with the occurrence of auroral phenomena in or near the two auroral zones. Only the dipole field affords a measurable contribution in the equatorial plane at a distance of several earth radii from the earth's surface, and the dipole field is circularly symmetric. Thus the configuration in the geomagnetic equatorial plane will not be influenced by the earth's rotation, provided minor effects of the different directions of the geomagnetic and the rotation axes are disregarded. The equatorial plane process will therefore be seen in the same average distance range at a given geomagnetic time from all geomagnetic meridians on the earth. It follows that—if the processes in the equatorial plane and in the auroral zones are connected by the real magnetic field lines, as seems physically plausible—the only longitudinal dependence of e.g. the averages of a great many auroral locations, observed at fixed points on the earth and equally distributed with regard to geomagnetic time, will be that introduced by the deviation of the earth's magnetic field from a dipole field. This deviation is appreciable at and near the earth's surface.

What has been said here should be true, even if the geomagnetic field is heavily distorted in its outer regions. If that is so, the distance at which the process in the equatorial plane take place may

be quite different from that of the intersection with the equatorial plane of that dipole line which intersects the earth's surface at the same place as the real field line connecting the auroral processes in the earth's atmosphere and in the equatorial plane.

According to this view the configuration in one hemisphere will correspond to the projection of the corresponding one in the other hemisphere along the geomagnetic field lines.

The only assumption made in the foregoing is that an electron or an ion moves from the equatorial plane to one of the auroral zones along a geomagnetic field line or on some surface defined by field lines. Such an assumption seems to be well founded. No other details of the actual physical processes are involved.

The projections of circles in the equatorial plane to the earth's surface along the real field lines, were calculated by Hultqvist (1958) for purposes of comparison with experimental isochasms. The projections are practically identical with the L curves of McIlwain (1961). Hultqvist used a perturbation method consisting of integration along the dipole line of the deflection from a dipole field line of the higher approximation line due to the effect of the second to the fifth terms in the spherical harmonic development of the earth's magnetic field. The calculations yielded deflection vectors for a large number of dipole lines. These gave the deflection for the point of intersection of the higher approximation field line—coinciding with the pertinent dipole line in the equatorial plane well outside the earth's surface—and the earth's surface from the corresponding point of intersection of the dipole line itself.

The calculations were carried out for 36 equidistant longitudes for each of 15 geomagnetic colatitudes, most of them less than 30 degrees. The results of Vestine's et al. harmonic analysis of the earth's magnetic field for epoch 1945, the most recent epoch for which data were then available, were used in the computation.

The projections of equatorial plane circles are ovals with the longest diameter approximately in the plane containing the 170° and 350° geomagnetic meridians. Two circle projections are shown in Fig. 2.4 (northern hemisphere) and Fig. 2.5 (southern hemisphere). They correspond to the two circles in the geomagnetic equatorial plane

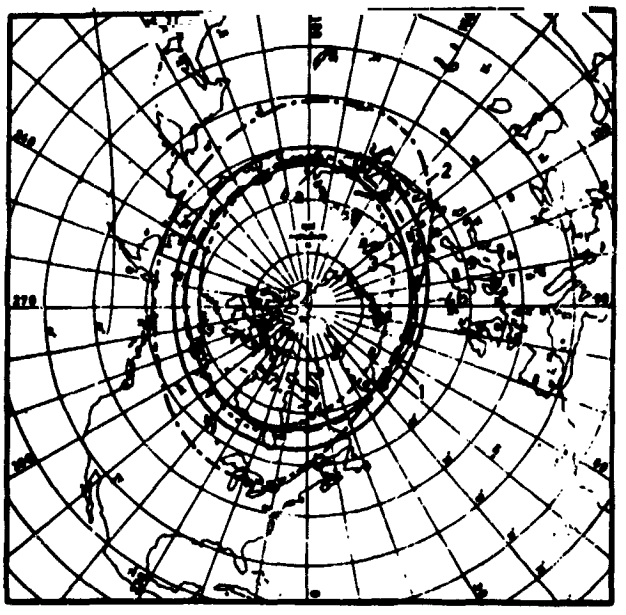

FIGURE 2.4.—Comparison of Feldstein's (1960) northern observational zone (Curve 1) with a number of "theoretical" auroral zones: 2 is according to Gartlein and Sprague (1960), 3 to Quenby and Webber (1959) and 4a and b are projections of two circles in the geomagnetic equatorial plane (corresponding to colatitudes 22 and 25 degrees respectively; Hultqvist, (1958).

having radii of 7.13 and 5.60 earth radii, for which the projections along the dipole lines are the geomagnetic colatitude circles 22° and 25° respectively.

Hultqvist pointed out that the experimental northern auroral zone of Vestine accorded well with the circle projections except over the North American continent, where the calculated curve extended about 4° farther south than the observational one. The IGY data as presented by Feldstein and illustrated in Fig. 2.4 show that the configurational agreement between the IGY northern auroral zone and the projections of circles is good. The maximal difference in latitude between Feldstein's zone and that projection which conforms best to it amounts to about one degree.

Since the network of observation stations in and near the northern auroral zone was quite dense during the IGY, it seems probable that the error in location of the experimentally determined auroral zone is only of the order of 1° in latitude. The geomagnetic data used in the calculations are for epoch 1945, which may account for minor inconsistencies with the observations of 1957–58. It is probable, however, that this error also is less than one degree of latitude. It is thus evident

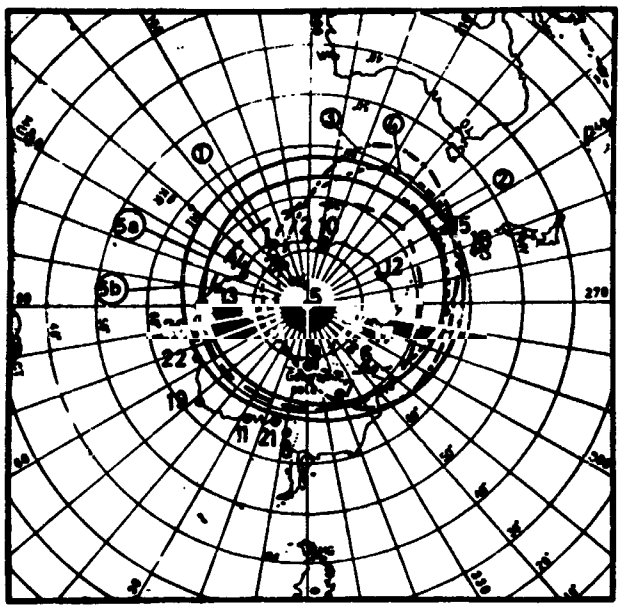

FIGURE 2.5.—Comparison of Feldstein's (1960) southern observational zone (Curve 1) and that of Bond and Jacka (1960) (Curve 2) with different "theoretical" auroral zones: 3 is according to Gartlein and Sprague (1960), 4 to Quenby and Webber (1959) and 5a and b are projections of two circles in the geomagnetic equatorial plane (corresponding to colatitudes 22 and 25 degrees, respectively; Hultqvist, 1958). The numbered points show the approximate locations of the stations at which the IGY observational material—the basis of Feldstein's auroral zone—was collected. The numbering is that of Feldstein (1960).

that the IGY northern auroral zone is, within the limits of probable error, in full configurational accord with the calculated projections of circles in the equatorial plane.

Feldstein's auroral zone in the southern hemisphere is shown in Fig. 2.5 together with the projections of the circles of radii 5.60 and 7.13 earth radii. The experimental curve differs quite significantly from the computed ones. While it follows the course of the latter in the geomagnetic longitude range of 320° E—90° E, it is much nearer to the Antarctic continent for the rest of the longitude circle where it is located over the sea. In fact, Vestine's and Snyder's (1945) auroral zone agrees better with the computed one than Feldstein's does.

A question of interest is whether the discrepancy between the IGY southern auroral zone and the projections of circles is a real one or attributable merely to inaccuracy of the observational data and/or of the computed curves. The errors of the geomagnetic data, used in the computations, are certainly greater for the Antarctic than for the Arctic. As mentioned earlier, the computations were based on Vestine's et al. harmonic analysis of the geomagnetic field for epoch 1945, when the southern hemisphere data were very sparse. Although this fact may partially account for the discrepancy, it seems likely that only a minor part of the 6 latitude degrees difference over the sea is parimarily attributable to errors in the harmonic analysis of the geomagnetic field, especially as a comparison with recent numerical computations by Dudziak et al. (1963) on the basis of the spherical harmonic coefficients for epoch 1960 by Jensen and Cain (1962) show only minor deviations.

All observational stations in the discrepant region were situated on or close to the coast of the Antarctic continent far inside the auroral zone. This means in effect that the auroras occurring in the auroral zone were visible from these stations at low elevation, a circumstance which implies considerable error in the observational results.

Indeed, since publication of Feldstein's paper, Bond and Jacka (1960) have communicated a report in which they note that the latitude of the auroral zone in the region of MacQuarie Island, south of Australia (point 15 on Fig. 2.5), is only one or two degrees more than that of the station. A small part of their auroral zone—the one near MacQuarie Island—is shown in Fig. 2.5 as curve No. 2. Taking this and the above mentioned considerations into account, it would appear that the auroral zone is fairly consistent with the computed curves, with which it shows agreement over the Antarctic continent. This seems so much the more plausible in view of the close accord between observed auroral zone and circle projections for the northern hemisphere. Indeed, it would be surprising if the two hemispheres showed entirely different degrees of agreement between the two types of curves.

Although, as mentioned above, there are good reasons for postulating circular symmetry in the geomagnetic equatorial plane for the processes producing aurora in the earth's atmosphere, it is certainly not the only possible approach. If e.g. the drift around the earth of the primary auroral particles is accordance with the adiabatic invariants is the determining process for the configuration

of auroral occurrence curves, it is perhaps reasonable to expect that the isoaurores should be identical with the lines of constant second adiabatic invariant. Vestine and Sibley (1960) computed such curves. They are very nearly identical with the projected equatorial-plane circles and it is therefore not possible to judge between the two approaches on that basis. Vestine and Sibley also calculated, using the spherical harmonic analysis of Finch and Leaton (1957), the mirror height of electrons for which the second adiabatic invariant, $J = \int_{\parallel} d\ell/v$, has the value 15.7. Their heights range from 57 km to 420 km in the northern hemisphere and from -15 km to 633 km in the southern hemisphere.

Figure 2.4 and 2.5 include, for purposes of comparison, curves showing two other types of more or less theoretical auroral zones: the zones suggested by Gartlein and Sprague (1960), which are almost identical with the isoclines 76°, and Quenby's and Webber's (1959) curves, which are based on calculations of vertical cut-off rigidities for cosmic ray particles in the earth's magnetic field, and take into account both the dipole and non-dipole parts of the internal field. Neither of these two curves conforms as closely to observed data as do the circle projections.

What conclusions can be drawn from the similarity between observed isoaurores and projections of circles in the earth's geomagnetic equatorial plane into the earth's atmosphere along the geomagnetic field lines? Not too many, in fact, since no details of the actual physical processes are involved. The geomagnetic field can be strongly distorted and we still expect to find the circular symmetry for the statistical data.

However, it can be concluded from the data presented above that local conditions close to the earth probably play a negligible role for the average auroral distribution over the earth's surface. The adiabatic drift of the primary particles around the earth seems not to be important for the shape of the insoaurores. If this process were important, one would expect the mirroring height to have a profound influence on the precipitation rate of particles and therefore on the frequence of occurrence of aurora. Since the mirror height varies very much with longitude for one $J = \text{const}$ shell, important variations in intensity and auroral occurrence frequency for various points along such a curve would be expected. This is not observed. That the drift motion is not important in this respect is also expected because of the fact that most primary auroral electrons need a time very much longer than the time scale of auroras in order to drift around the earth.

There are other statistical parameters than the isoaurores that may be expected to show circular symmetry in the equatorial plane. One is the average southern extent of the aurora a a definite degree of magnetic disturbance. Such curves have been evaluated by e.g. Gartlein et al. (1960) and Feldstein (1963). A comparison of

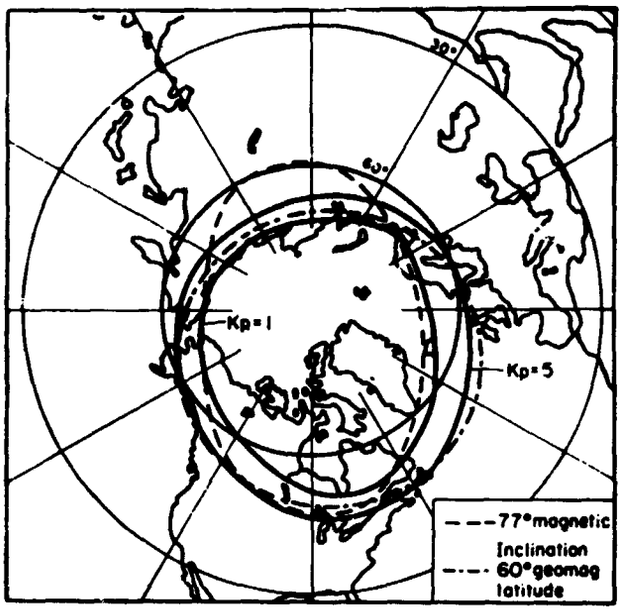

FIGURE 2.6.—Southern extent of aurora borealis for two different levels of geomagnetic activity (after Gartlein, Gartlein and Sprague, 1960).

the curves in Fig. 2.6 with the circle projections in Fig. 2.4 shows a good agreement. The southern extent increase with increasing K_p.

(d) Dependence of auroral zone location on the solar cycle

The pole distance of the auroral zone has been found to be dependent on the phase of the solar activity cycle. Sheret and Thomas (1961) made a detailed analysis of the auroral observations made at Halley Bay, Antarctica, in the years 1956–59. The position of the auroral zone, obtained from observations of quiet arcs, was the following in the four years.

TABLE 1.

Year	1956	1957	1958	1959
median south geomagn. lat	70.8	71.8	71.9	71.0

The auroral zone was thus closer to the pole at the solar-activity maximum in 1957 than before and after. This result is opposite to that of Feldstein (1962), who compared the location of the auroral zone in the Asian Arctic at solar activity maximum (1957–58) and at solar minimum (1954–55). He found the auroral zone to be 2.5—3° closer to the geomagnetic pole at the minimum of the solar cycle than at maximum. These variations in the location are discussed also in subsection 6 on motions.

(e) Auroral type effects

The distribution of auroral activity described above refers to all types and forms of aurora. Most of the basic data are obtained from black and white allsky-camera films of fairly long exposure times, which makes it impossible to distinguish between various spectroscopic characteristics as well as between quiet and rapidly varying auroral forms.

It is, however, of great theoretical interest to know whether there are significant differences in location between different types of aurora, especially between auroras caused by positive and negative primary particles. This is because relations—at least qualitative—between the locations of proton and electron precipitation areas is contained in several theoretical models. For instance, it seems difficult to think of electromagnetic acceleration processes if possitive and negative particles are precipitated together along the geomagnetic field lines.

In fact, it has been found that hydrogen line emitting aurora (see p. 13) usually is located on the equator side of the electron produced aurora before midnight (cf. the reviews of Omholt, 1963, and Galperin, 1963). (After midnight no hydrogen emission is observed south of auroral forms, but rather north of these; Stoffregen and Derblom, 1962). There is often a distinct dark region (up to 1° wide in latitude) between the "proton aurora" and the main forms. One would therefore expect the isoaurores and the auroral zone for "proton aurora" alone to be located one or a few degrees farther from the poles than the ordinary auroral zones (which certainly are the electron precipitation zones).

As mentioned in section one, there are several different types of auroral phenomena. The latitudinal distribution of the occurrence probability for high red arcs, for instance, certainly has its maximum in the subauroral regions. No detailed statistical studies of their geographical distribution exist as yet. Stoffregen (1962) has investigated the occurrence of different auroral forms in the geomagnetic latitude band 58–76° N (at the longitude of Scandinavia). His results, which he considered as a rough approximation, are shown in Fig. 2.7. As can be seen in the figure, the

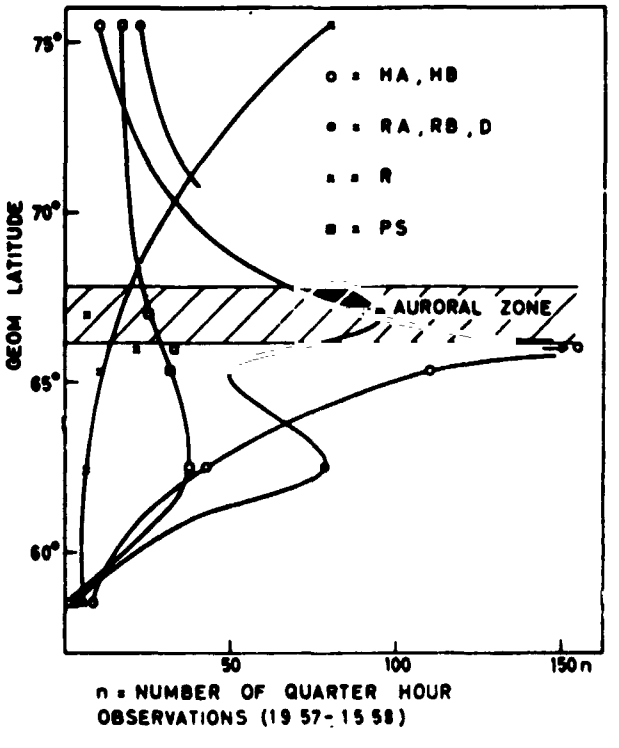

FIGURE 2.7.—(After Stoffregen, 1962) Approximate latitude distribution for different auroral types.

pulsating auroras occur most frequently some 5 degrees south of the auroral zone. This was also found by Heppner et al. (1952).

The low latitude aurora mentioned above is different from the stable subauroral red arcs described on p. 10. The red arcs populate sub-

auroral mid-latitude regions with shape very similar to the projections of circles along the field lines from the equatorial plane, described above (see Roach and Roach, 1963). The regions have their centers somewhere between the circle projections corresponding to equatorial plane circles of radii 2.5 and 3 earth radii (i.e. $L=2.5$ and 3 respectively). These red arcs seem not to exist in the auroral zones.

There certainly exist still other differences in the latitudinal distribution of the occurrence frequency for different types of aurora. The aurora inside the auroral zone has several characteristics that distinguish it from the aurora seen at and outside the auroral zone. In general, the high-latitude forms are relatively weak in intensity and more fleeting than those seen at the auroral zone. The forms consist, in part, of weak diffuse arcs and of bands that frequently show ray structure. Ray bundles are common, and these are usually arranged so as to appear as part of arcs, bands or draperies with variable intensity (cf. Davis, 1962 b).

(f) Inner auroral zones

Alfvén (1955) proposed on theoretical grounds that there should exist secondary auroral zones inside the ordinary ones, at geomagnetic colatitudes between 5 and 10 degrees. Since this proposal was made, a large number of attempts have been made to determine from observations if the inner auroral zones exist or not. At this time, it does not seem possible to draw firm conclusions. It is clear that the zone, it if exists, is much less pronounced than the main zones (which is not unexpected from Alfvén's theoretical point of view).

Observations in favor of and against the existence of the inner zones will be briefly reviewed.

Nikolskiy (1963) has discussed the Soviet data relevant to the existence of inner auroral zones. Most data is geomagnetic. What is generally found is a morning maximum in magnetic activity between 75 and 80° N geomagnetic latitude, most pronounced in the summer. The shape of the zone, found by Nikolskiy, is a spiral in a circular latitude-time coordinate system, unwinding in a clockwise direction. Meek (1957) found that the maxima of ionospheric disturbances are concentrated along a similar spiral.

On the other hand Lassen (1959), observing at Godhaven (about 80° geomagnetic latitude), could not find any magnetic evidence for an inner zone of high activity but instead he observed a type of zenithal aurora occurring around 6 h. local time, which seemed not to come up from south (i.e. from the main auroral zone) but to be produced sporadically at great elevation in the sky seen from Godhaven. The elevation did not change significantly in the course of the morning. Lassen found that the morning-type of aurora is uncorrelated not only with the local magnetic activity but with the planetary state of disturbance too. Analyzing data obtained in other parts of Greenland and in the northernmost Canada, Lassen concluded that morning aurora of the described kind is observed in the zenith only along a curve coinciding with the projection of the circle with radius 20 earth radii in the geomagnetic equatorial plane ($L=20$) on the earth's surface.

Witham et al. (1960), for instance, investigated the magnetic disturbance characteristics. They, and many other investigators of various parameters, could not reach any definite conclusion about the existence of an inner zone of high disturbance.

Davis (1962 b) analyzed allsky-camera films taken at Thule ($\phi_m=88°$), Alert ($\phi_m=86°$), Resolute Ray ($\phi_m=83°$), Baker Lake ($\phi_m=74°$) and Churchill ($\phi_m=69°$). The scaling was made by counting the number of auroral forms within zenith distance 80° on each fifteenth frame of the film from each station. The total number of forms was recorded. The result can be seen in Fig. 2.3. There is no indication from this diagram of an inner auroral zone. However, the lack of stations in the critical region between 74° and 82° prevents the making of a strong statement of the absence of a zone there. It appears that if there is an inner auroral zone, it must lie between 76° and 81° latitude over northern Canada, and that the enhancement of the number of auroral forms within this zone must not be great.

2. Diurnal Variation of Visual Auroral Activity

As does the geographical distribution of aurora, the diurnal variation of auroral activity varies considerably with the measure of the activity

used. In addition, it depends on the type of auroral display and perhaps on season and phase of the sunspot cycle. Very much still remains to be done before our knowledge of the diurnal variation of auroral activity is consistent and complete.

The most widely used measures of auroral activity are "occurrence frequency" and "incidence," defined in the previous subsection. Fig. 2.8 (after Davis, 1962 a) shows the occurrence

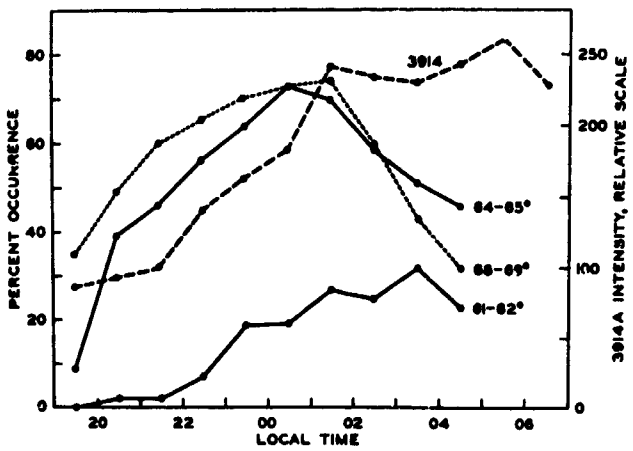

FIGURE 2.8.—(After Davis, 1962a) Percentage hourly occurrence in a latitude belt of width 1° centered over each of the stations: Barrow (68°–69°), College (64°–65°), and Farewell (61°–62°). The curve (3914) is drawn from data by Murcray (1959) and represents relative all-sky 3914Å intensity over College during 1955 and 1956.

frequency of visual aurora in a latitude belt of width 1° centered over each of the Alaskan stations Barrow (68–69°), College (64–65°), and Farewell (61–62°). Geomagnetic midnight occurs 1 to 2 hours after local midnight, the displacement from local midnight being largest for Barrow and smallest for Farewell. These curves demonstrate a shift of the auroral occurrence toward earlier local time with increasing latitude. In Fig. 2.8 there is also a curve marked 3914. It is drawn from data by Murcray (1959) and represents relative allsky 3914 Å intensity over College during 1955 and 1956. As can be seen in the figure, this curve has its point of gravity located several hours later than the others. This is due to an important difference between the auroral intensity distribution in premidnight and postmidnight hours. Before midnight the auroral forms stand out sharply above the low intensity of the background, but after midnight the intensity of the background is enhanced so that individual auroral forms are not easily distinguished.

Davis and DeWitt (1963) have evaluated the per cent of hours in which aurora was observed at Byrd, Antarctica, close to the southern auroral zone, for every hour of day and night in a two-months period of southern winter. Their result is shown in Fig. 2.9. The auroral occurrence

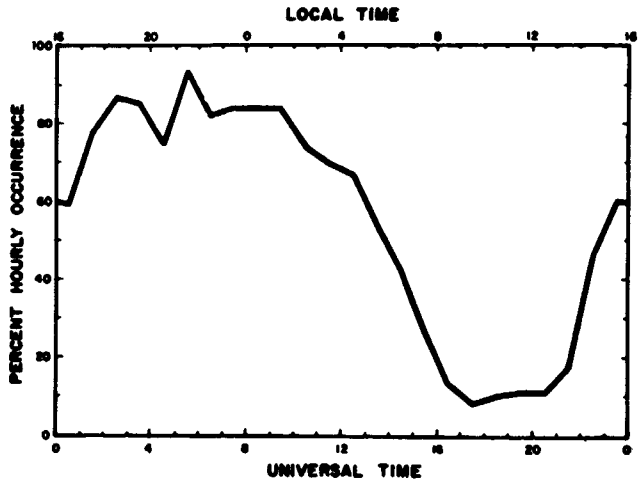

FIGURE 2.9.—(After Davis and DeWitt, 1963) Diurnal variations of hourly occurrence of visual aurora within 150 km of Byrd Station for all clear, dark hours in May and June 1960.

frequency has a maximum around geomagnetic midnight (at about 2200 local time) and a deep minimum around geomagnetic noon.

Reports on diurnal variation of aurora have also been given by Tromholt, 1882; Carlheim-Gyllenskiöld, 1886; Paulsen, 1893; Vegard, 1912; Chree, 1927; Sverdrup, 1927; Lee, 1930; Fuller, 1933, 1935; Currie and Edwards, 1934; Davies, 1935 a, 1950; Stagg, 1937; Stetson and Brooks, 1942; Jacka, 1953; Elvey et al., 1955; Murcray, 1959; Hale, 1959; Lassen, 1959, 1961; Malville, 1959; Chamberlain and Thorson, 1960; Feldstein, 1960; Feldstein and Solomatina, 1961; Loginov, et al., 1962 and others. A large number of these investigators have found diurnal variation curves similar to the occurrence curves in Fig. 2.8 and 2.9 with miximum fairly close to geomagnetic midnight.

There have been many suggestions of a less pronounced, secondary maximum in the early morning hours but it has not been possible to

find at some stations (Hulbert, 1931). Studies of ascaplots for IGY by Feldstein (1960) and Feldstein and Solomatina (1963) have resulted in the curves of Fig. 2.10 showing the geomagnetic time of maximum auroral occurrence frequency as function of the distance of the observation place from the observed auroral zone (curve 3 in Fig. 2.1), which distance is an approximately linear function of the geomagnetic latitude, corrected for the higher terms in the spherical harmonic expansion. There are two spiral-shaped curves in Fig. 2.10 unwinding in opposite directions. At the auroral zone, Feldstein found only one maximum (around geomagnetic midnight). Also, at geomagnetic latitudes around 78° only one maximum occurred (on the dayside) and at latitudes in between there were two maxima. The same result has been presented by Malville (1964). Similar functions of latitude have been found for the time of maxima of various other disturbance measures: e.g. for geomagnetic distrubances by Meek (1955), Burdo (1957) and Nikolskiy (1957), for sporadic-E ionization by Hagg et al. (1959), for redio aurora by Forsyth et al. (1960) and Egeland et al. (1962) and for radio wave absorption by Thomas and Piggot (1960).

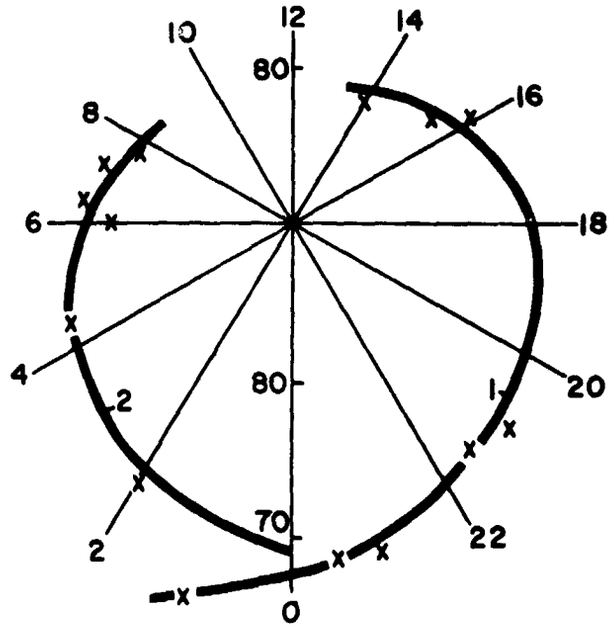

FIGURE 2.10.—(After Feldstein and Solomatina, 1963) Geomagnetic times of maximum frequency of auroral occurrence in the zenith as function of geomagnetic latitude corrected for the non-dipole part of the geomagnetic field.

On the basis of their observational results, Feldstein and Solomatina (1961) and Khorosheva (1961, 1962) (see also Feldstein, 1964) have proposed that the precipitation curve for aurora at a given time has the shape of the two combined spirals in Fig. 2.10. An instantenous auroral zone of a similar shape has been proposed by Akasofu, (1963 d). Support for this shape are among other observations those of Khorosheva (1961), who mapped 17 cases of momentary auroral distribution over the eastern hemisphere and found parts of oval-shaped curves similar to that in Fig. 2.10. However, the simple regularity of Fig. 2.10 was not found by Davis (1962 b) and the results of the case studies of some strong auroral events made by Akasofu (1960, 1962, 1963) and Akasofu and Chapman (1962) gave instantaneous configurations of the aurora, which were very closely similar to the projections of equatorial-plane circles on the earth's surface along the geomagnetic field lines (see previous subsection). The extensive auroral studies by Morozumi (1963) at the South Pole (geomagnetic latitude 78° S) did not show one, but two peaks in the diurnal variation curve for auroral occurrence. Instead for a maximum at magnetic noon there was a minimum.

A theoretical motivation for an oval auroral zone, being at higher latitude at noon than at midnight, is obtained when one considers the drift motion of particles around the earth in a magnetosphere, which is compressed by the solar wind on the dayside. The mirror points are at lower latitudes in the night than in the day. On this theoretical basis oval instantaneous auroral zones have been proposed by Rees and Reid (1959) and by Liemohn (1960). Detailed calculations by Malville (1960) show, however, that the expected effect is much less than the observed (less than 2° as compared with 8° observed). O'Brien (1963) therefore, concludes that if the diurnal variations are related at all, it is only in the sense that they are effects of a common and as yet unknown cause. More observational data are evidently needed before a conclusion about the existence or nonexistence of the oval instantaneous auroral zone can be reached.

That the main maximum in the diurnal distribution of auroral activity occurs close to geomagnetic noon at geomagnetic latitudes of about 78°, as Feldstein found, need not necessarily mean

that the corresponding processes in, or close to, the equatorial plane take place on the dayside, namely if the topology of the geomagnetic field is the one proposed by Johnson (1960) and others. A fairly evident hypothesis is that the neutral points or lines of that model are responsible for the daytime maximum in auroral occurrence.

Two spiral arcs of a kind described above are incorporated in the qualitative model for magnetic disturbances and associated phenomena proposed by Axford and Hines (1961).

That the diurnal variation differs for different auroral forms has been found by e.g. Fuller (1935) at College, Alaska, which is close to the auroral zone (cf. Fig. 2.11). Strong and brilliant forms have some predominance during the evening hours, and the faint and quiet forms in the morning. The hydrogen glow generally precedes the appearance of bright auroras, as first found by Romick and Elvey (1958) near the auroral zone, and the diurnal variation curve for this type of aurora therefore has its maximum well before midnight. Pulsating aurora occurs most often in the morning hours (Heppner, 1954).

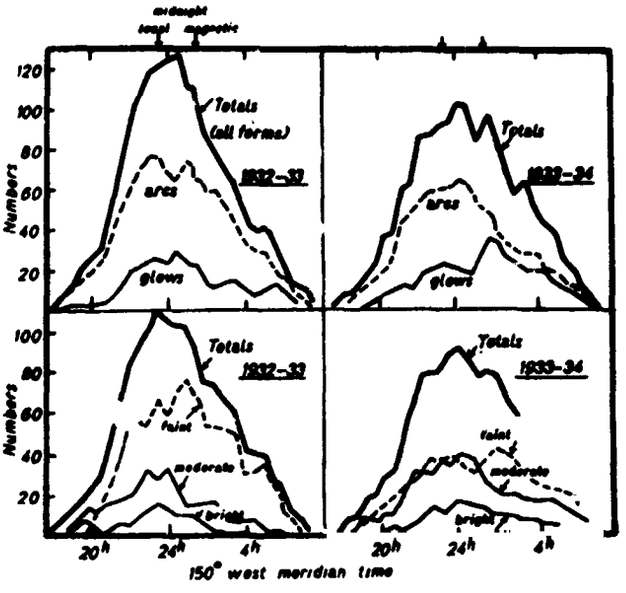

FIGURE 2.11.—(After Fuller, 1953) Diurnal variation of different auroral forms and of auroras of different intensitities at College, Alaska.

3. Other Time Variations of Visual Auroral Activity

(a) 27 day recurrence tendency

Auroras tend to repeat with a period of about 27 days, which is the synodic rotation period of the sun. As the moon considerably influences the possibilities of observing aurora, the apparent repetition tendency of auroral activity is enforced by the synodic lunar period (29.5 days), which is fairly close to the solar one. When the analysis is corrected for the lunar effect, a small but definite indication of a recurrence maximum around 26 and 27 days remains, which evidently is due to the rotation of the sun (Meinel et al., 1954). By the second and third solar rotations, no recurrence tendency remains.

(b) Seasonal variation

In the subauroral regions the annual curve of auroral occurence frequency has two maxima at the equinoxes. Fig. 2.12 shows the monthly aurora occurrence frequency distribution found by Meinel et al., (1954) at Yerkes Observatory.

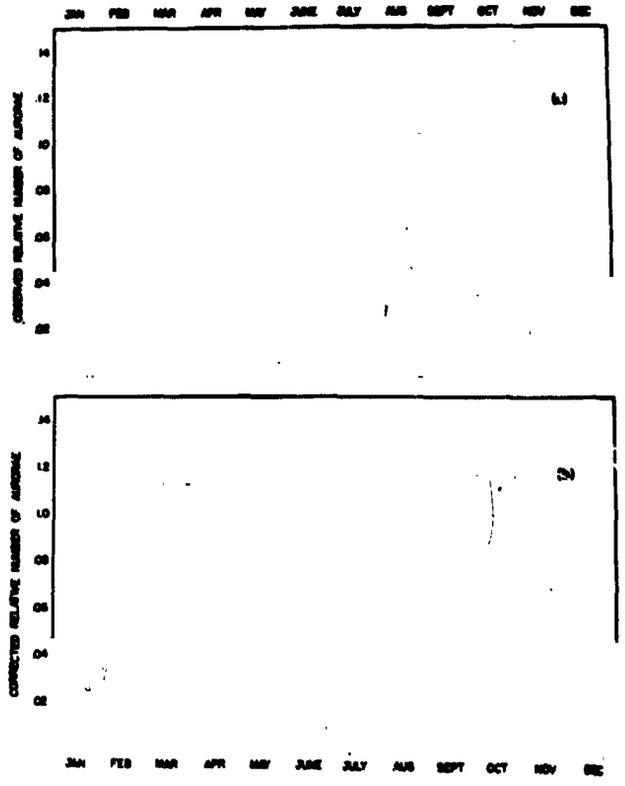

FIGURE 2.12.—(After Meinel et al., 1954) (a) Fraction of all auroras observed in each calendar month at Yerkes Observatory; (b) monthly frequency distribution corrected for cloudiness and number of dark hours in each month.

The existence of spring and fall maxima were known already to Mairan (1733). It was proposed by Cortie (1912) that the similar maxima in geomagnetic disturbances are due to the earth being at highest heliographic latitudes in March and September. If this is true, the angular diameters of the solar plasma beams do usually not exceed about 5° as seen from the sun. This is certainly not so for the very largest solar events, however.

The dependence of the seasonal variation on latitude is obscured by the change with latitude of the ratio of the lengths of day and night. If this change is ignored, as it usually is, then the summer minimum becomes progressively deeper with increasing latitude, while the winter minimum becomes progressively shallower, disappears and is replaced by a maximum, which is then the only one in the distribution (cf. e.g. Chree, 1911). Gartlein and Moore (1953) found that the ratio of the mean of the numbers of overhead auroras in North America occurring in June and December to that for auroras in March and September is a steadily increasing function of geomagnetic latitude. Between about 58 and 60° N the level of activity appears to be constant throughout the year. Feldstein and Shevnina (1961) investigated the seasonal variation in auroral occurrence frequency in two hours centered on local midnight—thereby eliminating the influence of the diurnal variation—for six stations between 63 and 83° geomagnetic latitude in the northern hemisphere and for five stations between 66° and 90° geomagnetic latitude in the southern one. They found the same seasonal variation as described above at and close to the auroral zones, but no perceptible seasonal variation in auroral frequency on the central auroral caps.

(c) Sunspot cycle variation

Fig. 2.13, after Tromholt (1902), shows the correlation between the number of days with aurora per year, observed in Norway between 1761 and 1877 and the sunspot number. The correlation is good and the maxima seem to coincide. Meinel et al., (1954) found a similar correlation when analyzing auroral observations made at Yerkes Observatory between 1897 and 1951. The maximum auroral activity occurred, however, during those 5 eleven year sunspot cycles some 2 years after the sunspot maximum. Egedal (1937) too, found a time delay of the maximum occurrence frequency of aurora in relation to the solar activity in Denmark during the 3 solar cycles from 1897 to 1929, but the delay was only 1 year.

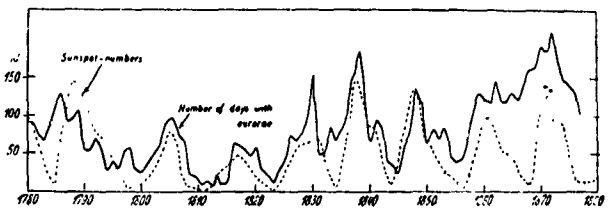

FIGURE 2.13.—(After Tromholt, 1902) Variation of the number of auroral days, N, in each year, observed in Norway, and the sunspot number between 1761 and 1877.

4. Orientation of Auroral Arcs

Hitherto various characteristics or auroral "activity," i.e. of statistical parameters describing the probability of occurrence of aurora, have been described. Now we will go somewhat more into detail. In this section the orientation of auroral arcs, which can be readily measured from photographic recordings, will be discussed.

(a) Average orientation

There exist fairly much data on the average orientation of auroral arcs. Even the very early studies of aurora showed that quiet auroral arcs tend to be oriented in a preferred direction, approximately perpendicular to the horizontal component of the geomagnetic field. A number of these early investigations were discussed by Fritz (1881). Vegard and Krogness (1920) referred the directions to the geomagnetic meridian and the Norwegian school made a large number of accurate direction determinations in northern Scandinavia.

In the majority of the pre-IGY investigations average values of all observed quiet arcs and bands were estimated. The fact that the observations were often made only during a certain period of the night—and in different periods for different investigations—was not considered.

A fairly extensive collection of such data is contained in Fig. 2.14 (after Hultqvist, 1962 b). Also included are a number of computed projections of circles in the equatorial plane on the earth's surface along the geomagnetic field lines (Hultqvist, 1958).

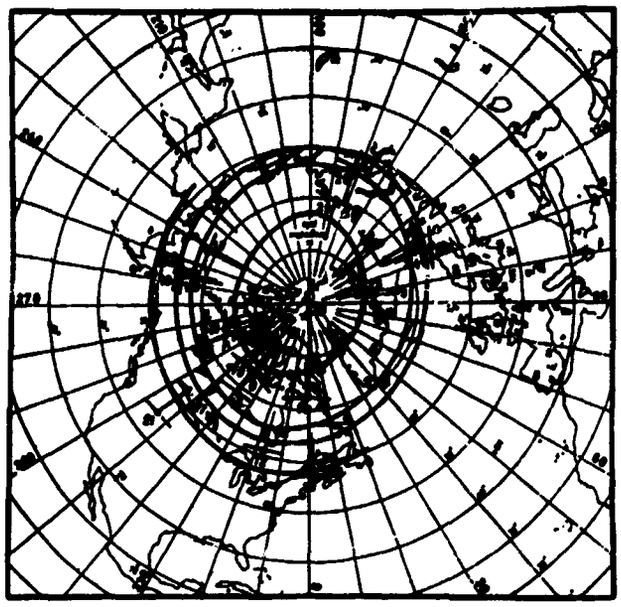

FIGURE 2.14.—Directions of quiet auroral arcs in the northern hemisphere. 1. Haldde and Bossekop; 2. Cap Thordsen; 3. Jan Mayen; 4. Nain; 5. Kingua Fjord; 6. Fort Rae; 7. Sagastyr (the data for points 1-7 are after Vegard and Krogness, 1920); 8. Chesterfield; 9. Coppermine; 10. Cape Hope's Advance; 11. Saskatoon; 12. Coral Rapids; 13. Aroostook; 14. Gjöahavn (the data for points 8-14 are taken from Currie and Jones, 1941; the dotted lines at Chersterfield and Coppermine refer to all types of aurora); 15. Baker Lake; 16. Churchill; 17. Barrow; 18. Fort Yukon; 19. College; 20. Farewell; 21. Choteau (the data for points 15-21 are after Davis, 1961; the values are averages for the hour around geomagnetic midnight); 22. Godhavn (the data are after Lassen, 1959, and refer to the early morning hours); 23. the region of Micardbu (approximate data after Störmer, 1944); 24. Tromsö (the data are after Harang, 1945, and refer to geomagnetic midnight); 25. Wiese; 26. Dixon; 27. Cape Schmidt (data for points 25-27 are after Feldstein, 1960, and refer to local midnight); 28. Thule (data of Harang, taken from Störmer, 1955); 29. Kiruna (refers to geomagnetic midnight). The map has a geomagnetic coordinate system.

Despite the above-mentioned reservations concerning the observational material, it is evident from Fig. 2.14 that, in general, the alignment of the arcs conforms to the direction of the relevant circle projection quite closely, and that the agreement with the circle projections is better than with the geomagnetic latitude circles. The observed arc azimuth is in most cases, greater than 90° in those quadrants where the azimuth of the circle projections exceeds 90°, and less than 90° in quadrants where this is under 90°. Thus, it has been verified experimentally that on the eastern and western coasts of Greenland the observed average azimuths deviate in opposite directions from 90°, as do the azimuths of the circle projections.

Starkov and Feldstein (1960) and Evans and Thomas (1959) investigated the alignment of arcs at two places where the isoclines and the geomagnetic latitude circles differ greatly (Dixon near the northern auroral zone and Halley Bay near the southern one). They found that the preffered direction of alignment is far more consistent with geomagnetic latitude circles, and therefore with the higher approximation circle projections, than with the isoclines.

The available observational results for the southern hemisphere are relatively exiguous. A collection of IGY and subsequent data is contained in Fig. 2.15. The arrows indicate results of

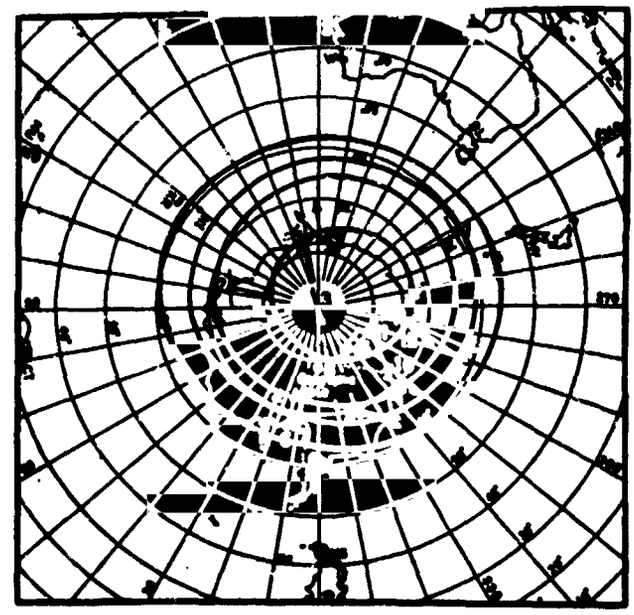

FIGURE 2.15.—Directions of quiet auroral arcs and sighting directions to the highest points of quiet arcs and bands (arrows) in the southern hemisphere. 1. Macquarie Island. 2. Mawson (data taken from Bond and Jacka, 1960); 3. Vastok; 4. Oasis (The data, after Feldstein, 1960 refer to local midnight); 5. Halley Bay; 6. Shackleton (data from Evans and Thomas, 1959); 7. Ellsworth; 8. South Pole; 9. Byrd; 10. Little America; 11. Scott Base (the long arrows at points 11 and 12 are after Hatherton and Thomas, 1959); 12. Hallett (short arrow); 13. Wilkes (the data for points 7-13 are from Gartlein et al., 1960, the two arrows at points 8 and 13 show the average directions for the two years 1957 and 1958, the 1957 arrow being the one nearest the meridian at both points); the map has a geomagnetic coordinate system.

TABLE 2

No.	Station	Geomagn. Coord. °N	Geomagn. Coord. °E	Observed azimuth (degr.)	Approx. measure of deviation	Azimuth of circle projection ("theor. azimuth")	Diff. obs. azimuth and "theor. azimuth"
1	Baker Lake	73.8	314.8	94	Diff. max-min ~60°	93	1
2	Churchill	68.8	322.5	99	Diff. max-min ~60°	95	4
3	Barrow	68.6	241.2	92	Diff. max-min ~60°	84	8
4	Fort Yukon	66.6	256.8	90	Diff. max-min ~80°	87	3
5	College	64.6	256.5	86	Diff. max-min ~60°	87	−1
6	Farewell	61.4	253.2	83	Diff. max-min ~60°	86	−3
7	Choteau	55.5	306.0	88	Diff. max-min ~70°	95	−7
8	Schmidt	62.6	226.6	80	Diff. max-min ~30°	80	0
9	Dixon	63	162	98	Stand. deviat. $< \pm 10°$ for magn. quiet periods	98	0
10	Vise	69	176	103	$\sim \pm 15°$	100	3
11	Pyramid	---	---	111	$\sim \pm 15°$	113	−2
12	SP-7 1957–58	---	---	96	---	96	0
13	SP-7 1958–59	---	---	0	---	0	0
14	Tromsö	67	117	98	Diff. max-min ~27°	106	−8
15	Kiruna	65.3	115.6	106	Stand. deviat. ±5°	105	1

observations of directions, as sighted to the auroral point of highest elevation. Two arrows for any single station represent the results of observations during each of the two years 1957 and 1958. The differences in direction of the arrows for the two years demonstrate the uncertainty of the results.

As will be seen from Fig. 2.15, the agreement between observed directions with those of the projected equator plane circles is fairly good for all places except Byrd (No. 9), and the agreement is certainly better than for the geomagnetic latitude circles.

Because of the existence of a diurnal variation in the orientation of the auroral arcs, increased accord between the directions of the arcs and of the circle projections is to be expected if values for a short period (e.g. 1 hr.) of the night are compared. The results of such a comparison for local midnight at twelve stations, most of them in or near the northern auroral zone, are presented in Table 2 and Fig. 2.16. A comparison with Fig. 2.14 clearly shows that the concordance of the arc directions with the circle projections is better for the selected material of Fig. 2.16 than for the unselected values of Fig. 2.14.

Table 2 contains azimuths of quiet auroral arcs at local midnight in the northern hemisphere (measured from northern geomagnetic meridian towards the east). The observed azimuths for stations 1–7 are after Davis (1961), those for stations 8–13 are after Feldstein (1960), and that for Tromsö is after Harang (1945).

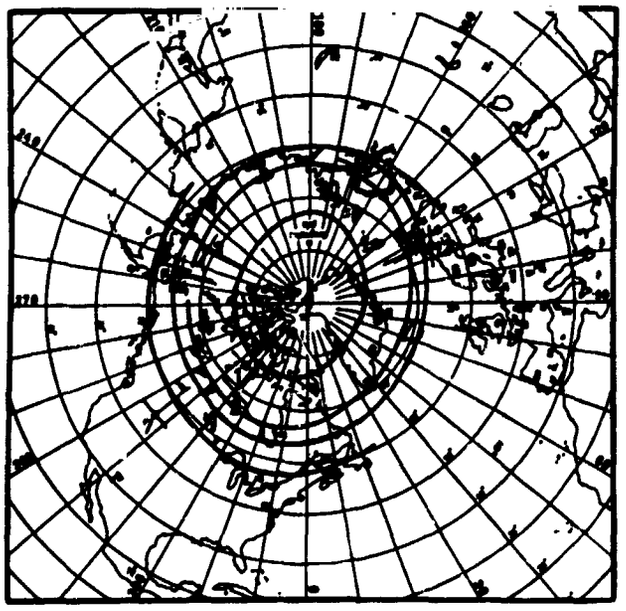

FIGURE 2.16.—Directions of quiet auroral arcs and bands at local midnight in the northern hemisphere. 1. Baker Lake; 2. Churchill; 3. Barrow; 4. Fort Yukon; 5. College; 6. Farewell; 7. Choteau (data for points 1-7 taken from Davis, 1961); 8. Cape Schmidt; 9. Dixon; 10. Wiese (data taken from Feldstein, 1960); 11. Tromsö (after Harang, 1945); 12. Kiruna. The map has a geomagnetic coordinate system.

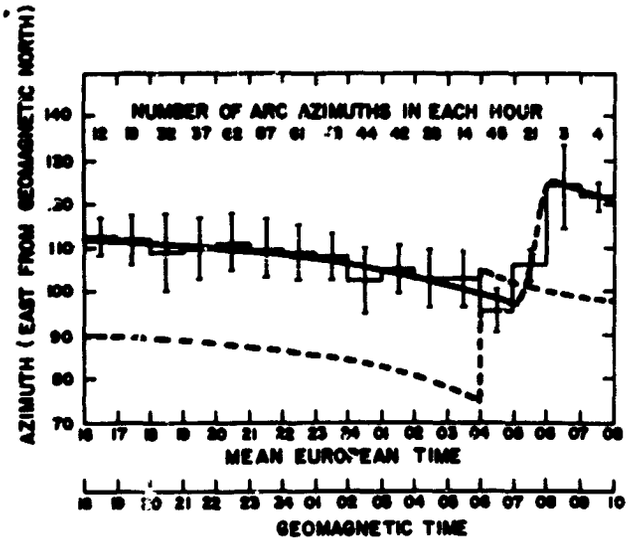

FIGURE 2.17.—Observed directions of quiet auroral arcs at Kiruna as function of MET and of approximate geomagnetic time. For each hour the average direction and the standard deviation are given. The lower, dashed curve is Alfvén's theoretical diurnal variation curve (see Alfvén, 1950).

(b) Diurnal variation in the orientation in and near the auroral zones

Although it was evident from the observations of Bravais at Bossekop in northern Norway as early as 1938–40 that the directions of the arcs and bands show a diurnal variation, very little attention was paid to this phenomenon until the nineteen-thirties, and even now only few studies exist.

From allsky-camera recordings taken at Kiruna ($\phi_m = 65.3°$ N) in the period December 1958 to end of 1962, the directions of 559 quiet auroral arcs were estimated. Only arcs reaching from horizon to horizon or, in the case of the most distant ones, covering an azimuth angle of view of about 100° were used in the analysis. The error in the measured direction of an arc probably does not exceed 4°.

The result of the alignment investigations is shown in Fig. 2.17.

For each hour of Mean European Time (MET) the average direction and the standard deviation were computed, for which procedure the direction value of each arc was weighted with the arc's duration. The durations vary over a wide range—from less than a minute to about an hour.

The total average azimuth for the whole material is 109°. A typical standard deviation for a 1 hr. period is 5°.

At the top of Fig. 2.17 is shown the number of arcs used for each hour. The number is maximal around geomagnetic midnight. In the morning hours the aurora is usually unsuitable for direction determination; as a rule, it is diffuse and situated far to the north. That is the reason why the observational material is smallest for that part of the night.

The azimuth charge in the morning is so rapid as to resemble a discontinuity of the type predicted by the Alfvén theory (see e.g. Alfvén, 1950).

In fact, the "discontinuity" can probably be observed only in longitudes where geomagnetic time runs ahead of local time, since daylight will preclude auroral observations in or close to the auroral zones until 8 or 10 o'clock geomagnetic time in other longitudes.

A number of similarly obtained diurnal variation curves for auroral arc orientation, based on observations in or fairly near the northern auroral zone (up to a geomagnetic latitude of 80°), are shown in Fig. 2.18.

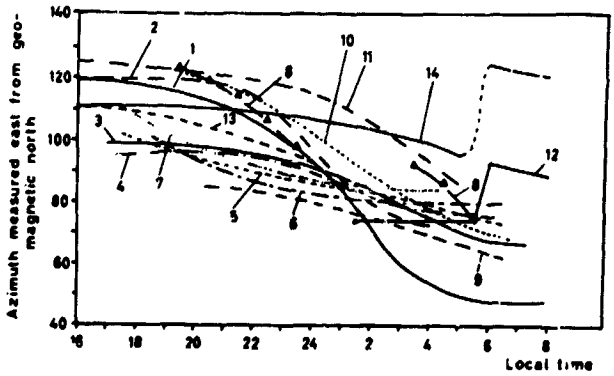

FIGURE 2.18.—Observed (smoothed) diurnal variation curves for the orientation of quiet auroral arcs and bands in and near the northern auroral zone. 1. Baker Lake (geom. lat. 74°); 2. Churchill (geom. lat. 69°); 3. Barrow (geom. lat. 69°); 4. Fort Yukon (geom. lat. 67°); 5. College (geom. lat. 65°); 6. Farewell (geom. lat. 61°); 7. Choteau (geom. lat. 56°) (curves 1-7 are after Davis, 1962b); 8. Dixon (geom. lat. 63°); (after Starkov and Feldstein, 1960); 12. Godhavn (geom. lat. 80°) (after Lassen, 1959); 13. Tromsö (geom. lat. 67°) (after Harang, 1945); 14. Kiruna (geom. lat. 65°).

The wide dispersion of the location and form of the different diurnal variation curves is striking. The amplitude of the diurnal variation also varies greatly. Here a regularity emerges, the amplitude increasing rapidly with latitude. Thus, the auroral arc direction varies at Baker Lake (geomagnetic latitude 74°) over a range of 70°, while at Choteau (geomagnetic latitude 56°) the range is only 20° (and at Kiruna, 65° N, 15°, if the final rapid increase in azimuth is ignored).

A "discontinuity" in the morning hours has been observed only at Godhaven and at Kiruna. As mentioned above, observation is likely to be possible only in the eastern geomagnetic hemisphere, where the geomagnetic time is running ahead of the local time. The difference between geomagnetic and local times is greatest in the region of northern Scandinavia (about 2 hours), where it is possible to observe aurora up to 1000 hrs. geomagnetic time. The reason why such "discontinuity" has not been observed at the Siberian stations could be that the geomagnetic times differs less from local time at those sites than it does at Godhavn and Kiruna.

For the southern hemisphere there is still a paucity of published observational data concerning the diurnal variation of arcs in and near the auroral zone. One such diurnal variation curve, of Evans and Thomas (1959) for Halley Bay, is shown in Fig. 2.19. From this curve it can be seen that at the southern auroral zone the azimuth —measured east from geomagnetic north—increases with time instead of diminishing as in the northern hemisphere. The range of variation (about 15°) is similar to that for the stations of lowest latitude in Fig. 2.18. This lends support to the assumption that the northern and southern momentaneous auroral occurrence curves are geomagnetically conjugated.

Comparison of the curve for Halley Bay in Fig. 2.19 (No. 1) with that for Oasis (No. 2 in Fig. 2.19) of geomagnetic latitude 78° shows that the range of variation increases with latitude in the southern hemisphere also.

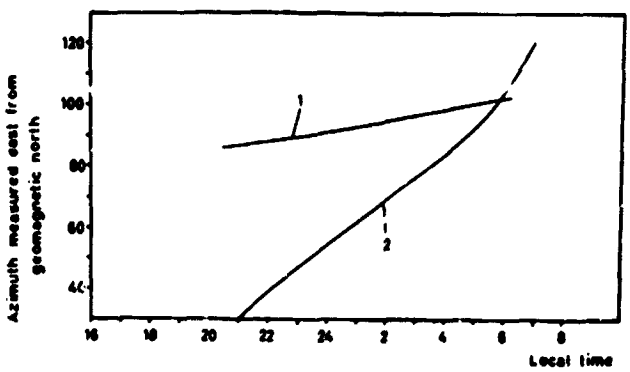

FIGURE 2.19.—Observed (smoothed) diurnal variation curves for the orientation of quite auroral arcs in the southern hemisphere. 1 Halley Bay (geom. lat. 66°S; outside the auroral zone) (after Evans and Thomas, 1959); 2. Oasis (geom. lat. 78°S; far inside the auroral zone) (after Feldstein, 1960).

(c) Discussion of the diurnal variation near the auroral zones

In order to ascertain the degree to which the differences between the curves in Fig. 2.18 could be attributed to referral of the direction of the geomagnetic meridian, i.e. to overlooking of the effect of the non-dipole part of the geomagnetic field, Hultqvist (1962 b) made a correction for this factor in respect of several stations near the northern auroral zone. The direction, instead of being referred to the geomagnetic meridian, was referred to the perpendicular to the projection of circles in the geomagnetic equatorial plane on to the earth's surface along higher approximation geomagnetic

field lines. The azimuths of these circles at a number of stations are given in Table 2. By changing the time scale to the geomagnetic one, the curves of Fig. 2.20 were obtained.

A comparison of Figs. 2.18 and 2.20 shows that the agreement between the North American stations on the one hand and Cape Schmidt and Kiruna on the other, was much improved by this modification.

Fig. 2.20 also includes the theoretical curve of Alfvén (1939, 1940, 1950). A comparison shows that the time derivative sign is the same, but that all the experimental azimuths are higher than the theoretical ones before midnight and that the amplitude of the diurnal variation for most stations is greater than theoretically expected.

The "discontinuity" observed at Kiruna has the same amplitude as that on the theoretical curve but is displaced about 1½ hour in the positive time direction.

From the observed diurnal variation curves of Fig. 2.20, a third type of auroral precipitation curve can be evaluated by integration according to formula (1)

$$\theta = \theta_0 \exp\left(-\int_{\lambda_0}^{\lambda} \cot a \, d\lambda\right) \qquad (1)$$

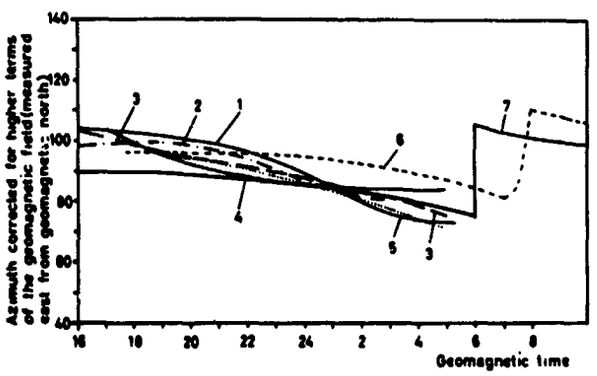

FIGURE 2.20.—Observed diurnal variation curves (smoothed) for the direction of quiet arcs, corrected for the non-dipole part of the geomagnetic field, given as a function of geomagnetic time for a number of stations situated in or near the northern auroral zone. 1. Barrow (geom. lat. 69°); 2. Fort Yukon (geom. lat. 67°); 3. College (geom. lat. 65°); 4. Farewell (geom. lat. 61°); (curves 1-4 are based on data taken from Davis, 1961); 5. Cape Schmidt (geom. lat. 63°) (based on a curve presented by Feldstein, 1960); 6. Kiruna (geom. lat. 65°); 7. Alfvén's theoretical diurnal variation curve (cf. e.g. Alfvén, 1950).

where θ is the geomagnetic colatitude,
λ is the geomagnetic time angle,
a is the azimuth of the auroral arcs measured from geomagnetic north towards east,
λ_0 is the geomagnetic time angle at the start of the observational curve, and
θ_0 is an integration constant that determines the polar distance of the curve.

This curve is Alfvén's theoretical I curve. It is defined by the orientation of the auroral arcs around the auroral zone, considered to be fixed in relation to the sun.

From the Kiruna diurnal variation curve of Fig. 2.20 the I curve of Fig. 2.21 has been derived. The whole curve is situated outside the circle with which it coincides at 1800 hours, in contrast to Alfvén's theoretical curve, which is inside the circle. The difference is due to the fact that the observation curve in Fig. 2.20 is situated almost completely above azimuth 90°. The difference between the experimental and theoretical curves

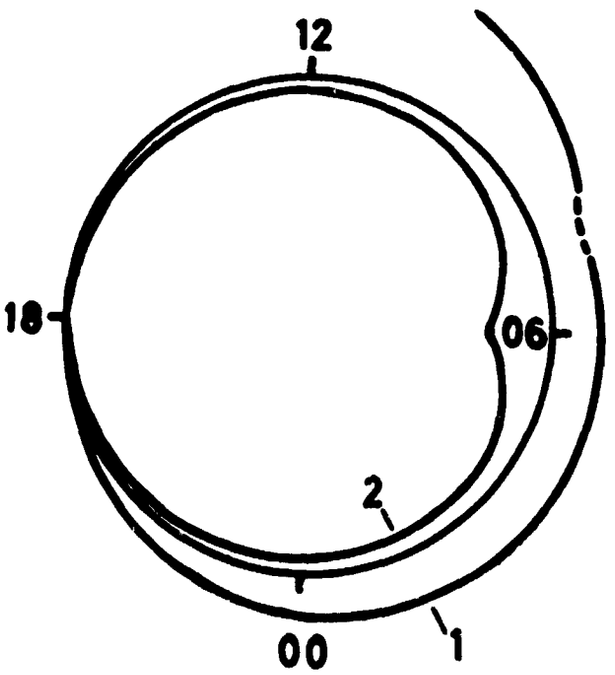

FIGURE 2.21.—Curve 1 is the auroral zone corresponding to Alfvén's I curve, evaluated from the Kiruna curve of Fig .17 for diurnal variation in the orientation of quiet auroral arcs. It is corrected for the non-dipole part of the geomagnetic field. Curve 2 is Alfvén's theoretical I curve (see Alfvén, 1950).

varies between 7 and 9°, which means that the theoretical curve is situated outside the standard deviation "region" of the observational material.

The very high amplitudes of the diurnal variations found for high latitude stations are not contained in Alfvén's model, according to which the greatest deviation of the arc azimuth from 90° should be at 0600 hours geomagnetic time, where the I curve has a singular point and the azimuth changes from 105° to 75° in the auroral zone.

Even for L = 70 earth radii, corresponding to a geomagnetic auroral latitude of above 80°, the azimuth is only 76° at 0600 hours.

Khorosheva (1961, 1962) investigated recordings of aurora made simultaneously at widely different longitudes in the arctic of the eastern hemisphere and found that the auroras form a single, physically related band which changes synchronously in brightness, width and latitude over its entire extension. On the basis of these observations, Khorosheva and Feldstein proposed that the momentaneous auroral precipitation zone forms an oval-shaped curve around the geomagnetic axis pole, at the normal distance of the auroral zone (about 23°) on the night side but only 10–12° from the pole on the day side, i.e. the zone is similar in shape to the combination of two spiral arcs shown in Fig. 2.10. The proposal (Feldstein, 1964) also implies that the auroral arcs are lined up along the momentaneous precipitation zone of the described shape. This would explain the existence of two maxima in the diurnal variation curve for auroral occurrence at latitudes inside the ordinary auroral zones. It would, however, mean that the aximuth of the auroral arcs, measured from the perpendicular to the auroral zone (curve 3 in Fig. 1), would be smaller than 90° after midnight, with the most rapid change in direction around midnight. That is usually not observed.

(d) Diurnal variation on the central auroral caps

On the central auroral caps (inside about 80° geomagnetic latitude) the diurnal variation of the orientation of quiet auroral arcs has been reported to be entirely different from the one described above. Observed (smoothed) diurnal variation curves are shown in Fig. 2.22 for both the northern and southern central caps. Curve 2 in Fig. 2.19 also belongs to this category.

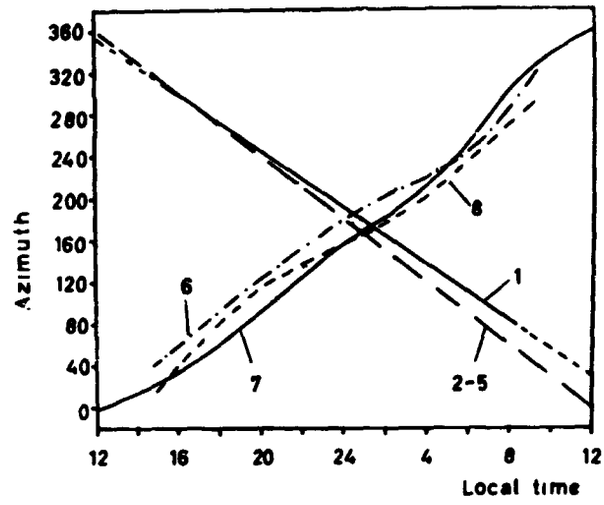

FIGURE 2.22.—Observed diurnal variation curves (smoothed) for the direction of quiet arcs at stations deep inside the auroral zones. The azimuth is measured towards the east from geographic north for curves 1-5 and from geomagnetic north for curves 6-8. 1. Dumon d'Urville (geom. lat. 76°S) (after Weill, 1958); 2. Wilkes (geom. lat. 77°S); 3. Dumont d'Urville; 4. Scott Base (geom. lat. 79°S); Hallet (geom. lat. 74°S) (the curves for points 2-5 are after Denholm and Bond, 1961); 6. Thule (geom. lat. 88°N); 7. Alert (geom. lat. 86°N); 8. Resolute Bay (geom. lat. 83°N) (the curves for points 6-8 are after Davis, 1961).

If the azimuth in Fig. 2.22 is taken from geographic north, the diurnal variation curves imply that the arcs are continuously pointing to the sun while the earth rotates below the auroral pattern. The first to report such a 360° diurnal variation of the auroral arc direction seems to have been Mawson (1914), but it was forgotten and rediscovered by Weill (1958). In the last few years it has also been reported by Davis (1960, 1961, 1962 b), Feldstein (1960), and Denholm and Bond (1961). Consistent data showing this 360 degrees rotation of the arcs during the 24 hours of day and night have thus been presented by several investigators and there seems to be no doubt that the effect is real. There are, however, a number of inconsistencies between observational results found by different observers (see Hultqvist, 1962 b) and there is, therefore a need for more observations.

It has been suggested by Cole (1959, 1960) and Davis (1960, 1961, 1962 b) that the geometric pattern of aurora over the polar caps is the same as the pattern of the ionospheric current system which is equivalent to the local-time-dependent

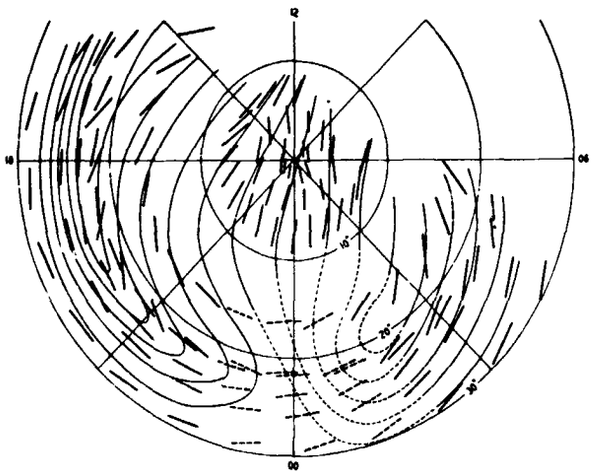

FIGURE 2.23.—(After Davis, 1962b) The alignment of auroral forms in a polar coordinate system with geomagnetic colatitude and approximate geomagnetic time as polar and azimuthal coordinates. The dashed lines represent the discontinuous post break-up aurora.

component of the geomagnetic disturbance—the DS current system (see Fig. 2.23). These views were incorporated as important constituents of the qualitative model of geomagnetic storms and associated phenomena by Axford and Hines (1961). According to this model the DS currents and the auroral arcs should have the same direction over the auroral caps.

The angle between auroral arcs and the direction of the horizontal currents, corresponding to the observed magnetic disturbance, has been evaluated by Sobouti (1961), Davis and Kimball (1962), Pudovkin and Yevlashin (1962), Feldstein (1964) and others for auroral and transauroral latitudes. Near the auroral zone, all investigators found the directions being identical within measuring accuracy. While Feldstein's results in the near polar regions were that the directions mentioned form an angle of, in the average, about 50°, Sobouti (1961) did not see any difference at Resolute Bay (geomagnetic latitude 83.2° N). A disagreement between directions of auroral arcs and the ionospheric current lines has also been found in the Antarctic (see Cole, 1963). A difference between the two directions introduces difficulties for theoretical models which require that the geographical pattern of auroral arcs and of the DS current system should be identical (like the model of Axford and Hines, 1961). It is, however, to be remembered that the horizontal geomagnetic disturbance component shows the direction of the ionospheric current only for simple current patterns.

(e) Other variations in arc orientation

Jensen and Currie (1963) found a pronounced seasonal variation in the auroral arc orientation in the years 1949–51 at Saskatoon (lat. 52.1° N) and Chesterfield (lat. 63.3° N) Canada. The peak to peak variation in azimuth over a year amounted to about 30°, with a maximum azimuth of 115° in February at Saskatoon and minima in October-November and April-May. The seasonal-variation investigation of Jensen and Currie (1953) seem to be the only one made.

Those authors also studied the dependence of the arc direction on the activity of the auroral display. No significant difference between quiet and active displays could be found. When grouping their observational material for auroral arc orientation with regard to magnetic disturbance level, Jensen and Currie obtained for Saskatoon an average azimuth of $93° \pm 1°$ (standard deviation) for the highest degree of activity, $100° \pm 1°$ for median disturbance and $100° \pm 2°$ for the lowest degree of disturbance. More investigations of the kinds undertaken by Jensen and Currie, made for different geomagnetic longitudes, would be of great value.

No theoretical models of aurora contain any seasonal variations in the auroral activity at all. The difference in direction between the earth's rotation axis and the dipole axis has been neglected so far.

5. The Height and Vertical Extent of Visual Aurora

The height of auroras was studied extensively especially in the first two to three decades of this century by the Norwegian school of auroral physics, with Störmer as the originator. Detailed reports of the methods used and the results obtained can be found in the books by Harang (1951) and Störmer (1955). Observations in Canada and Alaska have been reported by McLennan et al. (1931), Currie (1934, 1955), Fuller and Bramhall, (1937), and McEwen and Montalbetti (1958). Southern hemisphere observations have been published by Geddes (1939). Only a very short review will be given here.

The height can be measured only if the auroral form contains some well defined features which can be identified on photographs taken from two places at a distance from each other comparable to the height of the aurora (paralactic photography).

In most auroras the lower border is well defined and the height given in most reports is the height of the lower limit of the aurora, as seen on photographic pictures. Fig. 2.24 shows the height distribution of lower limits for different auroral forms (after Vegard and Krogness, 1920). The differences between the various types represented in the figure are fairly small.

The dependence of the heights of the lower borders of auroral arcs on their intensity is shown in Fig. 2.25 (after Harang, 1951). As can be seen from Fig. 2.25, there is a difference of 20 km

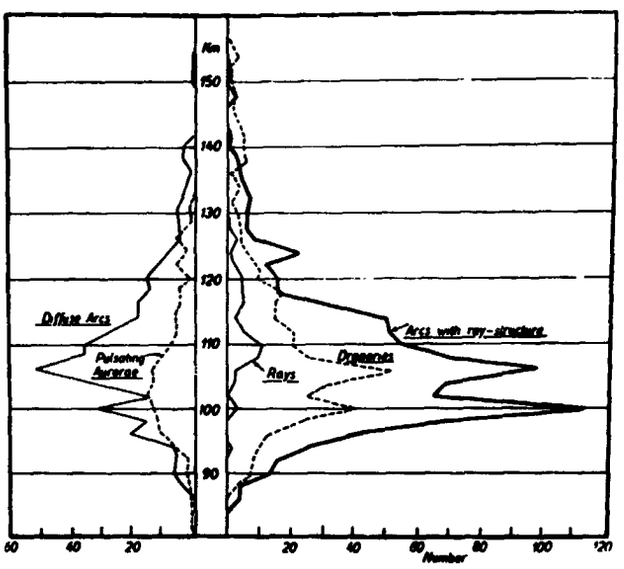

FIGURE 2.24.—(After Vegard and Krogness, 1920) Distribution of lower limits for different auroral forms.

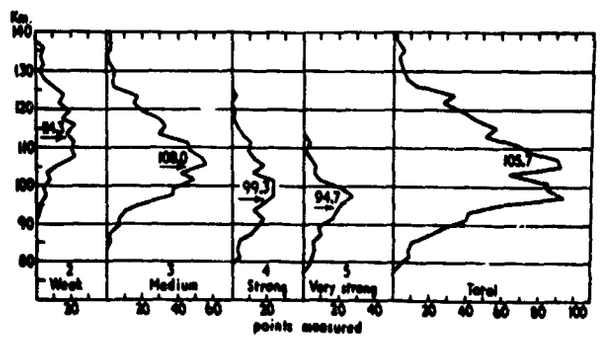

FIGURE 2.25.—(After Harang, 1944) Lowering of the heights of arcs with increasing intensities, as observed from Tromsö 1929-1938.

in height between weak and very strong arcs. Harang found a similar but less strong dependence on intensity also for other forms.

The results described above were obtained in or close to the northern auroral zone. The height of subauroral zone aurora has been extensively studied by Störmer (cf. Störmer, 1955) over southern Scandinavia. Compared with the auroral heights determined in the vicinity of the auroral zones the height diagram for southern Norway shows a far greater extension towards increasing heights. The lower limits are, however, the same in both cases. According to Barbier (1963) the majority of auroras seen over central Europe have lower limits situated above 250 km altitude.

In addition to the type effects shown in Fig. 2.24, there are a number of others. Störmer (see Störmer 1955) determined the height of the lower limit of sunlit auroras and found a height distribution completely different from those in Fig. 2.24. The distribution was very extended in height, with its maximum of probability at about 300 km.

Aurora of type B, i.e. aurora with the lowest part red due to emissions from the first positive band system of N_2 and first negative system of O_2^+, usually occurs at altitudes for the lower border of between 80 and 100 km. The lowest height of aurora reported was found by Harang and Bauer (1932) for a type B display. Numerous measurements were made on an intense arc and they obtained some points extending down as low as 95 km with an average height of 70 km.

On the other hand, red aurora of type A (with the 6300 Å O line dominating) is observed mostly at heights greater than those shown in Fig. 2.24. The medium latitude aurora mentioned above, which has a lower limit greater than 250 km, is mostly of this kind.

Störmer has reported a type of homogeneous arc, lying in the dark atmosphere near 200 km, which may be of a different kind from the aurora observed at 100 km level (Barbier, 1963; see also p. 6).

Finally, the quiet mid-latitude red arcs have been found to occur at heights between 390 and 560 km, but most often in the interval 400-450 km (see the review by Roach and Roach, 1963).

The extent along the field lines of an auroral form is quite different for different forms. Fig. 2.26 (after Vegard; cf. Harang, 1951, p. 35) shows

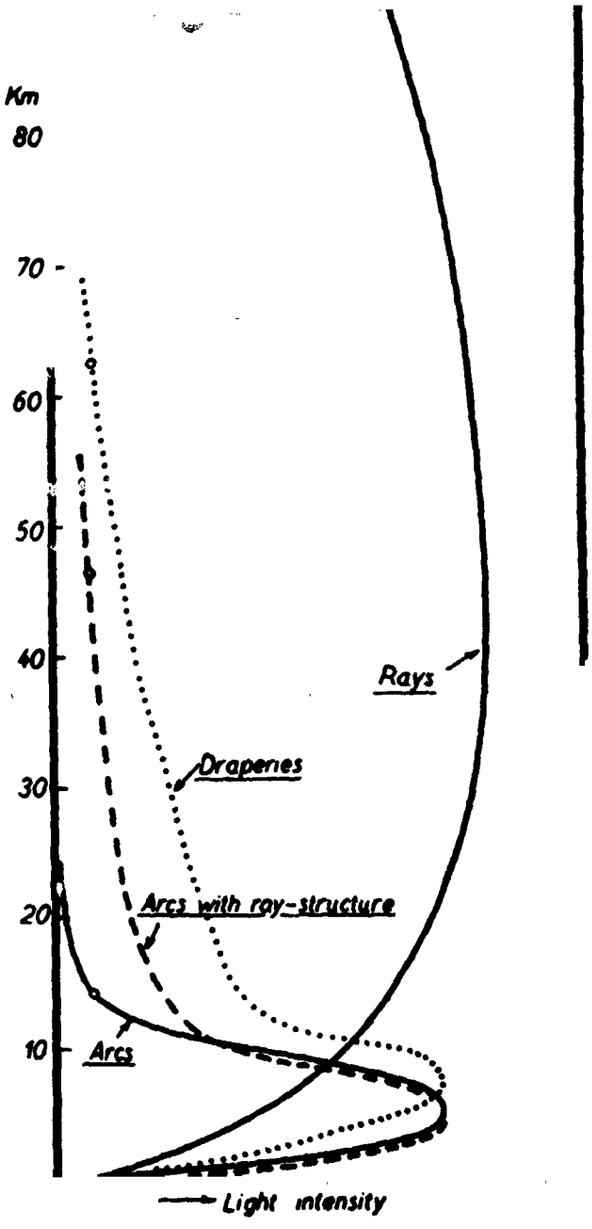

FIGURE 2.26.—(After Harange, 1951) Distribution of light intensity along different auroral forms.

the mean variation of light intensity in vertical direction for different auroral forms. An ° indicates the upper limit of photographic impression. Some average numerical parameters have been collected in Table 3 (after Vegard and Krogness, 1920).

Here l_1, l_2 and l_3 are the distances from the lower limit to the height of maximum luminosity, the upper limit of strong luminosity, and the upper limit of faint luminosity, respectively. It is evident from Fig. 2.26 and Table 3 that the rays differ entirely from the other auroral forms in respect of luminosity distribution with height.

There is a solar-cycle variation in the height of the lower boundary of aurora as well as in vertical extent (Elvey, 1957). Both height and vertical extension are lower in years with solar-activity-minimum than at high solar activity.

TABLE 3

Type	l_1	l_2	l_3
arcs	6.4 km	14.0 km	14.0 km
arcs with ray-structure	5.8 km	13.6 km	46.7 km
draperies	9.1 km	16.3 km	63.4 km
rays			137.0 km

6. Motions

There are many different types of motions associated with the auroral activity and individual auroral forms. Some of the motions for which observational data are available will be discussed here. From the point of view of the theoretical models of aurora, we are interested in how the auroral precipitation zones change location with time under various conditions as well as in how individual complete forms, or irregularities in the forms, move. These types of motion will be discussed in this subsection, where we will deal with the statistical properties. In subsection 7 examples of motion in connection with changes of momentaneous auroral geographical distributions will be discussed.

(a) Changes in the geographical pattern of auroral activity

It has been mentioned already before in this review that the location of the auroral zone shifts towards lower latitudes when the solar activity increases (although inconsistency exists in the available data). The first one who deduced this motion from observational data seems to have been Tromholt (1882). Davies (1950) evaluated a change of about 3 degrees of latitude between solar maximum and solar minimum. Tromholt

(1882) and Davies (1950) also arrived at a seasonal variation in the polar distance of the auroral zones. This is large around the equinoxes and small at solstizes. This is supported also by the recent study by Feldstein and Shevnina (1961), but the opposite result was found by Sheret and Thomas (1961).

With the statistical definition of the auroral zone adopted earlier in this section, seasonal variation in its location are the shortest that can exist. We will, however, now consider briefly the average behavior of the momentaneous auroral precipitation zone as a function of geomagnetic disturbance level (this momentaneous region of auroral activity is often called the auroral zone in the literature). There exist two types of data of relevance in this respect: those which concern the equator-ward boundary of the region where auroras occur, and those referring to the region of maximum occurrence frequency for the aurora at a given moment of time.

Gartlein et al. (1960) found the southern boundary of aurora in the northern hemisphere to be at almost 10° lower latitude for $K_p=5$ than for $K_p=1$, the $K_p=5$ boundary passing through Stockholm, southernmost Alaska and the Great Lakes in North America (see Fig. 6). Akasofu and Chapman (1963) found the southern limit of latitude of northern quiet auroral arcs to be approximately a linear function of Dst(H), i.e. of the ring current field, for 16 magnetic storms studied. The latitude variation with the ring current amounted to more than 10°, the southern limit reaching 49° geomagnetic latitude for the strongest storms investigated.

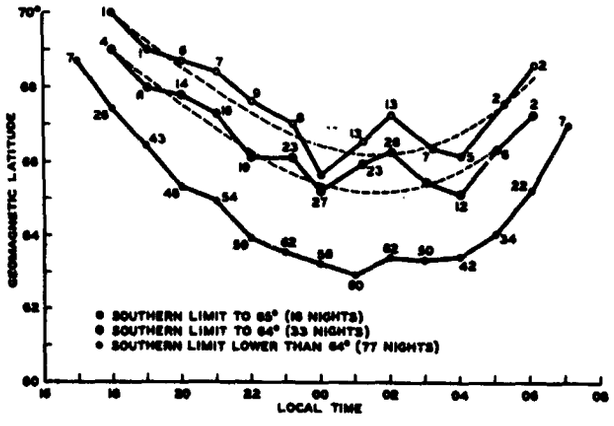

FIGURE 2.27.—(After Davis, 1962a) Diurnal variation of average southern extent for each of three groups of displays extending to geomagnetic latitudes 65°, 64°, and beyond 64°. The number beside each point gives the number of displays contributing to that particular mean position.

The southern border of auroral activity in Alaska, taken to be the lowest latitude position at which defined auroral forms appear, was found by Davis and Kimball (1960) to move regularly in the course of the night in the manner shown in Fig. 2.27. The extreme southern extent of the smoothed curves occurs, as can be seen in Fig. 2.27, around geomagnetic midnight (which is 1-2 hours after local midnight in Alaska). Davis (1962 b) states that the decrease in the number of discrete forms in low latitudes in the morning must be due to the actual disappearance of the forms in place—either because of a decrease of auroral luminosity or to a tendency for the forms to diffuse —and not to withdrawing to the north.

Jacka (1953) studied the location of the region of maximum auroral occurrence around MacQuarie Island in the southern hemisphere. He found that the southern auroral precipitation zone moves towards the equator with increasing K_p as $\Delta\phi = 2.95 - 0.605\,K_p$, where $\Delta\phi$ is the latitude departure of the homogeneous arcs from MacQuarie Island. From Jacka's relation, it can be seen that the latitude of the auroral precipitation zone can vary with as much as 5–6°. This is the same amount as found by Feldstein and Solomatina (1961).

A question of interest is the following: is the detailed shape of the distribution of auroral activity within the auroral precipitation zone changed when its center or southern boundary moves in latitude. Studies of this have been reported in the last few years. Some investigations of individual events will be reviewed in subsection 7, below. Here the average behavior will first be discussed.

Feldstein and Solomatina (1961) reported that at the same time as the auroral precipitation zone withdraws from the pole, there is an expansion of the zone, also towards higher latitudes, but they did not present quantitative results. Davis and Kimball (1960) and Davis (1962 b) give some details. Fig. 2.28, after Davis (1962 b) shows several measures of auroral activity vs. geomagnetic latitude for weak and strong displays. For curve A the maximum K index at College during

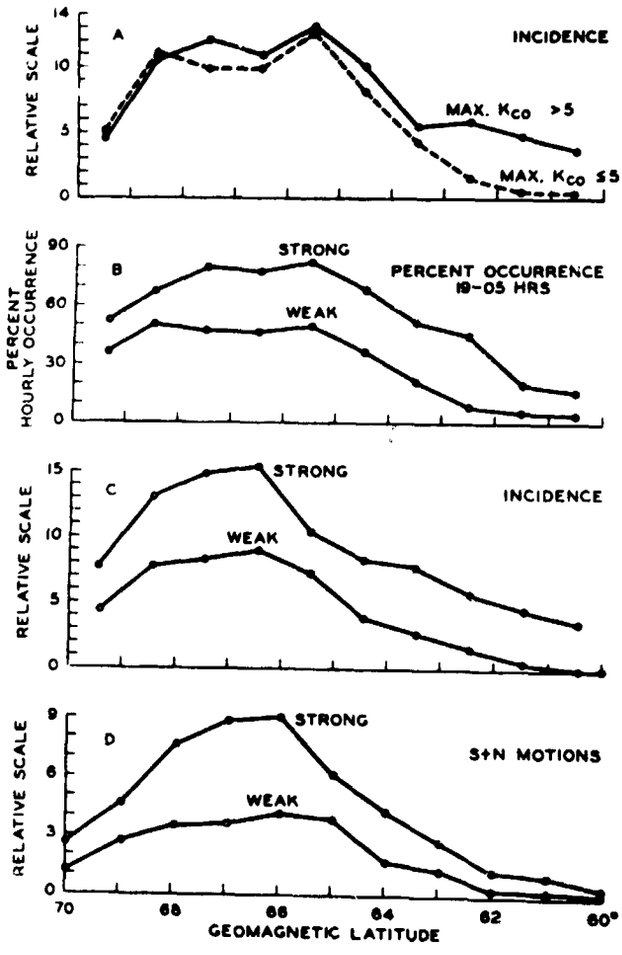

FIGURE 2.28.—(After Davis, 1962b) Several measures of auroral activity versus latitude for weak and strong displays observed in Alaska in the season 1957-58. (A) Curves of total incidence for 25 displays during which the maximum K-index for College did not exceed 5 (dashed line) and for 25 displays for which it exceeded 5 (solid line). (B) Average percentage hourly occurrence of overhead auroras (local time interval 19-05[h]) during 24 strong and weak displays. (C) Total incidence of forms during the 24 strong and 24 weak displays used to draw curves B. (D) Total south and north moving forms observed throughout 31 strong and 30 weak displays.

the display has been the criterion for classing. Davis points out that the small difference between strong and weak events at high latitudes, shown in Fig. 2.28, does not mean that there is no connection between magnetic and auroral activity in those latitudes, but only that the highest K index achieved during a display at an auroral-zone station is a poor indicator of the auroral activity at the auroral zone. In Fig. 2.28 B, C, and D the division of the displays into strong and weak was made on the basis of the total number of forms observed in Alaska between geomagnetic latitudes 60° and 70° during each display. In Fig. 2.28 D the total number of auroral forms moving north or south through the zenith of the station has been taken as measure of auroral activity.

Fig. 2.28 clearly indicates that the position of the maximum activity is at essentially the same geomagnetic latitude (66° to 67°) for both small and large displays, but at the lower latitude positions the relative increase of activity for the large displays is considerably greater than at higher latitudes.

(b) Motion of individual auroral forms

A drift of distinct luminous auroral features must be due either to a drift or change of the source of the impact particles or to a change in the electric and magnetic fields experienced by the particles on their way to the atmosphere. The studies of the drift motion of auroral forms is therefore, of course, of considerable interest.

The available observational data in general give the motion in N–S and E–W direction. Considering the deviation from the E–W direction of both geomagnetic isolatitude lines and the average orientation of the auroral forms, it would be preferable in the future to have the motions measured parallel and perpendicularly to the observed auroral zone or to the individual auroral arcs. In this review the motion will, however, have to be divided into N–S and E–W direction.

With regard to the motions of individual auroral forms there are two cardinal observations, which are valid irrespective of direction. First, all parts of rays, which can be several hundred km long, appear to move at the same velocity, aligned with the geomagnetic field in the first approximation, and secondly, auroral forms and inhomogeneities have not been reported to overtake one another.

(i) *Meridional Motion*

The motion of individual auroral forms varies with latitude and local time.

Davis and Kimball (1960) found, when scaling allsky-camera films from Alaska to determine the meridional motions, that the direction of first motions observed each evening at the various latitude positions followed definite trends. On many nights, there existed a geomagnetic latitude

between 60° and 70°, north of which the first motions were to the north, and south of which the first motions were to the south. This latitude they referred to as the "latitude position of origin." According to Davis (1962 b), the auroral forms do not necessarily form at this latitude. Rather, they seem to develop within a few degrees of the "latitude position of origin" and have a direction of first motion determined by whether the forms develop on the poleward or equatorward side of the "latitude position of origin." Davis and Kimball found the "latitude position of origin" to be between 60° and 70° on 86 of the 180 nights when aurora was observed over Alaska during the 1957–1958 season. On 58 other nights the aurora first moved south across the whole latitude band 60°–70°. Approximately 10 nights were found on which either the first motions were without pattern or there were more than one latitude of origin.

The regularity mentioned was for the first direction of motion seen in the evening. Later on in the night both northward and southward moving forms are observed. In fact, Davis and Kimball (1960) and Davis (1962 b) found that during IGY the number of auroral forms moving southward within the geomagnetic latitude band 60° to 70° over Alaska was greater than the number of north-moving forms at any time in the night. Bhattacharyya (1961) observed near Ottawa, well to the south of the auroral zone, that the number of equatorward moving forms outnumbered those in the reverse direction only up to 0200 hours (75th meridian time). Fillius, Gartlein and Sprague found a similar result at the southern auroral zone (according to Cole, 1963). The data presented by Davis (1962 b) differs from those of Bhattacharyya and Fillius et al, in that Davis gave the number of forms within a 10° latitude range, whereas the others presented observations from one place.

Older observational results of local time dependence of meridional motion in subauroral latitudes have been reviewed by Harang (1951) and Störmer (1955.) They can be roughly summarized in the following way: the motion is on the average equatorwards before midnight and polewards after. The apparent discrepancy between the results of Davis and Kimball (1960) and most older results may be due to the difficulty to distinguish, without the use of allsky films, between motion of the equatorward boundary of auroral activity and actual meridional movement of individual forms.

Kim and Currie (1958) analyzed the N–S motion south of the northern auroral zone with regard to velocity. They found the velocity to be greatest (about 160 m/sec) at the latitude of the auroral zone. The number of occasions of equatorward movement exceeded those polewards in every 50 m/sec speed range up to 670 m/sec except in the range 0–50 m/sec.

(ii) *Longitudinal Motion*

At the auroral zones and in subauroral latitudes both east and west longitudinal motions of auroral forms occur during the night, westerly predominating early in the night and easterly in the morning. (Meinel and Schulte, 1953; Meek, 1954; Bless et al., 1955; Malville, 1959; Evans, 1959, 1960; Kim and Currie, 1960; Bond, 1960; Stoffregen, 1961; Davis and DeWitt, 1963). Most investigators are agreed that east–west motions are in general much faster—by at least a factor of 3—than north-south motions, amounting to several hundred m/sec for average disturbance levels. Kim and Currie (1960) observed a general increase of speed with proximity to the auroral zone and also with increasing geomagnetic disturbance level.

Davis (1962 b) and several before him found that during the simplest type of auroral display, one accompanied by positive disturbance of the horizontal magnetic field in the evening and negative disturbance in the morning, the auroral motion is westward during the positive disturbance and eastward during the negative. The reversal from westward to eastward auroral motion is abrupt to within 30 minutes and occurs at the time of, or some minutes after, the change of sign of the horizontal magnetic disturbance.

Mawson (1914) and Stoffregen (1961 b) observed inside the southern and northern auroral zones, respectively, that the longitudinal motion in auroras was, in general, from the daylight to the dark side of the earth, i.e. opposite the general trend outside the zone.

According to Davis (1961, 1962 b), the moderate evening aurora at the auroral zone is typified by the existence of a partial or complete array of west-opening loop structures along which clockwise (as seen from above) motions of irregularities occur. These motions are superimposed on the

general westward drift of the auroral forms. Following the change from positive to negative horizontal disturbance, broken forms are prevalent, but now counter clockwise motions occasionally can be seen. Auroral displays accompanied by magnetic disturbance of variable sign have correspondingly complicated auroral motion.

The motion pattern observed by Davis agrees with Mawson's and Stoffregen's observations inside the auroral zones and it also fits well to the theoretical model of Axford and Hines (1961).

Recently, Omholt (1962) has reported east–west speeds of rays in a very active auroral curtain as high as 30 km/sec. These observations were made with a new technique. The data reported are only preliminary and more measurements of this kind will certainly add much to our knowledge about the auroral mechanisms. Still higher velocities of irregularities along auroral forms (up to 124 km/sec) have been observed by Davis and Hicks (1963) with the use of image amplifier technique, permitting 30 exposures/sec or more.

7. Dynamic Morphology of Individual Auroral Displays

A few synoptic studies of auroral displays have been published since IGY (but much fewer than would be desirable). This type of investigation is certainly one of the most important that can be made at the present stage of our knowledge about aurora. Those published have revealed several previously unknown characteristics of the auroral morphology. A brief review will be given here.

Khorosheva (1963) found that auroras observed simultaneously at different longitudes in the eastern hemisphere form a single, physically related band, which changes synchronously in brightness, width, and latitude over its entire extension.

Davis (1962 b) and Davis and Kimball (1962) analyzed synoptic auroral maps for Alaska and evaluated the results reviewed earlier concerning auroral motion and auroral configurations. Cood evidence for the configuration pattern of aurora being similar to that of the DS current system was found.

Synoptic maps covering still larger areas than those of Davis (1962 b), namely eastern Siberia, Alaska, and western and central Canada; have been prepared and analyzed by Akasofu (1960, 1962, 1963) and Akasofa and Chapman (1962). The disturbance periods studied are the very great ones. (Sept. 22–23, 1957, Feb. 11, 1958, Feb. 13, 1958; March 24, 1958).

A short report of the time history for the Feb. 13, 1958 aurora, given by Akasofu (1963), will be included here, because it illustrates better than has been done before the development of a large aurora on a world-wide scale. Fig. 2.29, a-e, shows snapshots of the situation at five different moments of time.

Three arcs extended across Alaska at 0830 UT but only one to the north of eastern Siberia (Fig. 2.29 a). Five minutes after the break-up, the auroras over Alaska were completely disrupted. A few arcs rapidly moved northward and one of them went to the north of Barrow (Fig. 2.29 b). To the west of Alaska a remarkable loop formation can be seen in Fig. 2.29 b. It seemed to be produced at the time of the breakup over Bering Strait. There is a great difference in the latitude range of the aurora between Alaska and Canada in Fig. 2.29 b. This is because the zone with aurora did not expand simultaneously over the longitude range shown. It started over Alaska. There was, however, a strong increase in brightness also over Canada when the breakup began in Alaska.

At 0900 UT the expansion had spread to central Canada (Fig. 2.29 c). A new breakup started at 0907 UT in Alaska and the broken bands became much brighter also in central Canada. At 1030 UT the auroral forms in Alaska and the Siberian Arctic Sea were quiet again and there were several faint arcs. The aurora was, however, still irregular in Canada and did not recover to this quiet phase, although it became fainter. The auroral precipitation zone was still expanding to the north there.

Some of the observations made by Akasofu in analyzing synoptic sequences similar to the one in Fig. 2.29 are summarized here.

(1) The auroral precipitation zone starts to move away from the pole when the ring current starts to build up. It may reach latitudes 10° (or more) less than that of the auroral zone. The width of the precipitation zone in quiet periods (between polar magnetic (DP) substorms) is not increased (5° wide or less).

(2) The breakup occurs when a DP substorm starts. It is characterized by a sudden increase

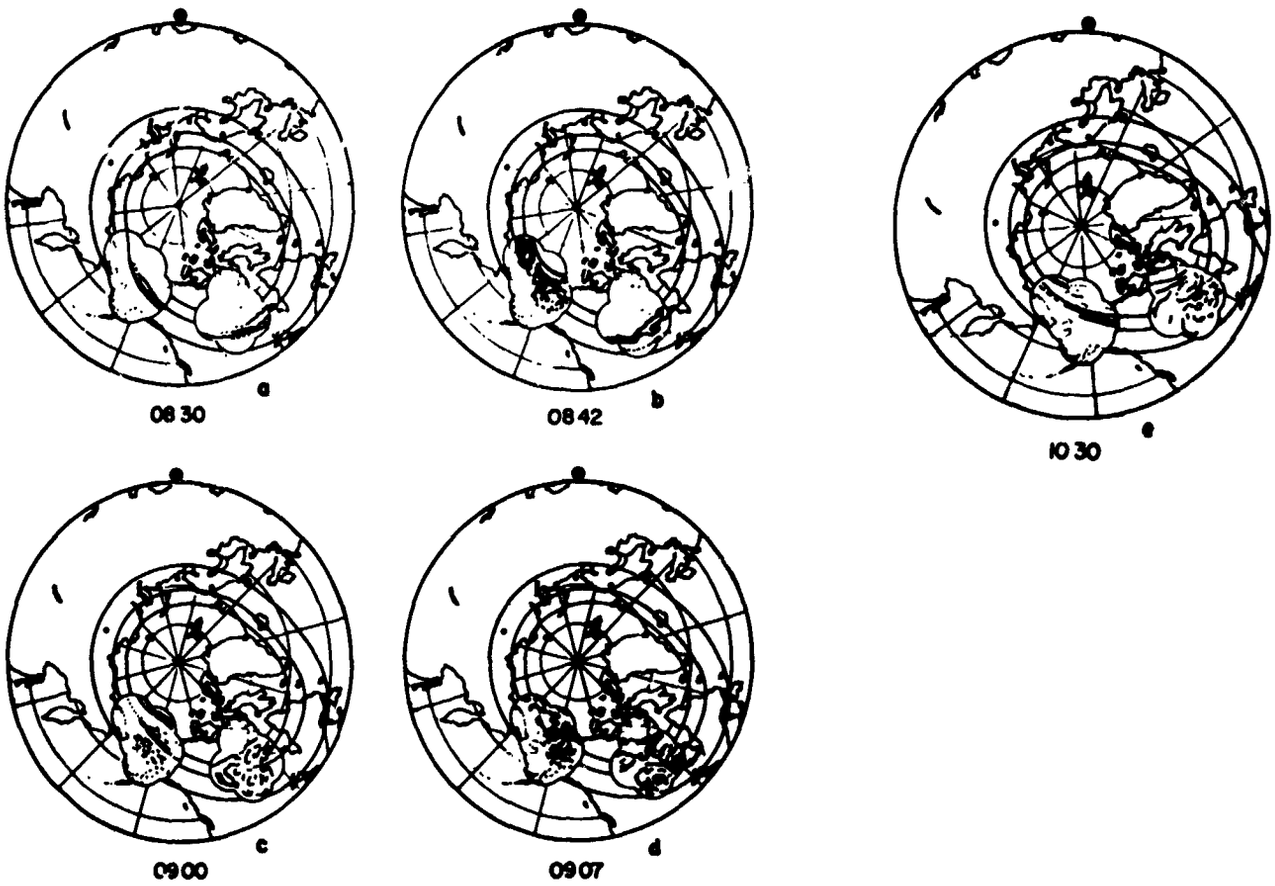

FIGURE 2.29.—(After Akasofu, 1963) The distribution of the auroras on February 13, 1958. The field of view of each allsky camera station is indicated by a circle of radius 500 km. The dark dot on the top of each map shows the direction of the sun. L-curves 4, 6 and 8 are also shown.

of the brightness and rapid and complicated folding or wavy motions of all arcs and bands over a large area on the morning side, together with a rapid expansion polewards of the precipitation zone. The northward expansion often starts around midnight or in the early morning and propagates into the morning side. It may amount to more than 10°.

(3) Breakup with poleward expansion has been observed in the auroral zone already 4 minutes after the sudden commencement.

(4) At the breakup, westward traveling folds are often formed. They propagate with velocities of 300–600 m/sec and have characteristic lengths of a few hundred km. Akasofu thinks it is possible the folds are identical with those observed and studied by Davis (1962 b).

(5) Some of the auroral forms in the auroral caps move up there from auroral zone latitudes during and after the breakups.

(6) Complete breakup of the quiet auroral forms are not so common on the auroral caps as in the auroral zones or on their equatorward side.

(7) An arc extending at least 5000 km in E–W direction was seen on March 24, 1958.

It is evident that a large number of the characteristics found by Akasofu do not fit into any theoretical model, in most cases because the existing models are not detailed enough. Some of the results presented above seem to disagree with some proposed models. The disrupted auroral forms shown in Fig. 2.29 are not similar to the DS-current pattern to be expected on the basis of Axford's and Hines' (1961) model for magnetic storms and aurora, just to mention one of the most recent ones. Also, the observation of large scale activation of aurora, with breakup and northward expansion of the auroral precipitation zone already 4 minutes after a sudden commencement, seems not fit their model.

Akasofu (1963 d) has worked out a model of simultaneous auroral activity over the entire polar region in terms of the auroral substorm, which corresponds to the polar geomagnetic substorm (DP).

3. CORRELATION WITH SOLAR AND GEOPHYSICAL PHENOMENA

In this section observed statistical relations between visual aurora and solar and geophysical phenomena will be briefly reviewed.

1. Solar Disturbances

Except for the investigations of the variation of the occurrence frequency of aurora with the solar cycle, which have been mentioned in Section 2 (see page 32), detailed investigations of the correlation between visual aurora and solar disturbances seem not to have been made. A large number of studies of relations between solar events and geomagnetic disturbances exist in the literature and are reviewed in Chapter 00 of this book. Since the correlation between occurrence of aurora and planetary magnetic activity is good (cf. below), most of the relevant conclusions reached for magnetic storms are also valid for aurora. The 27-day recurrence tendency seems to be less pronounced for aurora than for magnetic disturbances (Chamberlain, 1961).

2. Geomagnetic Disturbances

That worldwide magnetic disturbances occur at the times when aurora can be observed was discovered in 1741 by Celsius and Hiorter in Uppsala, Sweden (cf. Chapman and Bartels, 1940).

A detailed investigation of the correlation between the occurrence of aurora and the planetary magnetic activity has been made by Bartels and Chapman (1958). It has been known for long to aurora investigators that the start of a magnetic storm in the day almost invariably leads to the occurrence of aurora in auroral zone latitudes in the following night. This is true in subauroral latitudes only when the storm is a strong one—in which cases very little aurora may be seen in the auroral zone (see Section 2).

Over the central polar caps (geomagnetic latitude above 80°) the visual aurora is negatively correlated with the local as well as with the planetary K indices (Davis, 1963). In the region between geomagnetic latitudes 75 and 80° the relationship between auroral occurrence and geomagnetic activity is more complicated and of a transitional nature. Feldstein (1962 b) found that auroras are observed in the zenith at Murchison Bay (geomagnetic latitude 75°N) most frequently when there is a weak magnetic disturbance ($K=2$–3). When auroras appearing to the south were also taken into account the auroral occurrence frequency increased with the K-index up to high values of it. Morozumi (1963) found positive correlation between auroral occurrence and magnetic disturbance even at 78° geomagnetic latitude (at the South Pole).

There is not only a correlation between the general occurrence of aurora, but a fairly detailed relationship exists between the development of the visual aurora, as seen in auroral zone latitudes, and the development of the associated geomagnetic disturbance. These relations have been studied by Meek (1953, 1954b), Heppner (1954a, b, 1955), Zaborshchikov and Fediakina (1957), Fan (1958), Bless et al. (1959) and Akasofu (1963d).

Heppner (1954b) summarizes his observations at College (geomagn. lat. 64.5°N) in the following way. The magnetic disturbance and simultaneous auroral activity on a large majority of, and perhaps all, nights may be represented by means of two patterns, which apply individually or in combination. This is a consequence of recognizing that magnetic disturbances are made up of individual bay disturbances and that coincident with each bay there is a distinct sequence of auroral activity. The two patterns differ in respect to what happens when the disturbance in the horizontal component of the geomagnetic field changes from being positive to being negative. In the first pattern the aurora undergoes a distinct change in form and in the second it disappears at this time or recedes very far northward. The first pattern is more frequent than the second.

In the early part of the night the aurora is generally far north as seen from College and has quiet forms (arcs and glow). The luminosity advances slowly equatorwards. A positive magnetic bay is generally observed in this period. Close to the moment when a negative bay sets in, the aurora becomes active, moves southward and breaks up (first pattern) or disappears (second

pattern). In the first pattern of Heppner the recovery of the horizontal component takes place during the appearance of diffuse and pulsating aurora. In the majority of cases there is a short period following the negative bay in which the horizontal magnetic disturbance component is positive. A homogeneous arc is frequently formed again during this period.

A close correlation between rapid variations in the auroral luminosity and geomagnetic micropulsations has been found by Campbell and Nebel (1959), Campbell (1960 a,b,c), Campbell and Rees (1961) and Berger (1963) (see also Chapter).

3. Earth Currents

The occurrence during the day of induced voltages in long telegraph wires was used by Störmer in his extensive program for paralactic height measurements on aurora with good success for many years as a warning that aurora would occur in the next night. As the electric conductivity of the ground is generally not known with adequate precision it is difficult to relate the details of the induced electrical field and the resulting earth currents to the aurora in individual cases. The correlation of occurrence of the two phenomena is, however, good (cf. e.g. Hessler and Wescott, 1959). Freier (1961) has reported evidence for the accumulation of negative charges at the earth's surface during auroras, corresponding to an influx of negative charges into the upper atmosphere.

4. Radio Aurora

Reflections of radio waves of frequencies well above the critical frequencies of the ionosphere from ionization associated with aurora—radio aurora—were first investigated in 1938 by Harang and Stoffregen (1938, 1940). That radio wave propagation via auroral ionization is possible was, however, discovered earlier in the 1930's by amateur radio operators. After the second world war and particularly during the last ten years radio aurora has been studied by a number of researchers in North America, Britain, Norway, Sweden, Germany, Russia, New Zealand and the Antarctic. For a review of radio aurora with detailed references, see for instance Egeland (1962), Huitqvist and Egeland (1964) and Leadabrand (1964).

The diurnal variation of radio aurora as observed in the auroral zone has an afternoon maximum as well as a night maximum (Fig. 3.1). The seasonal variation in the auroral zone has maxima at the equinoxes. The long term occurrence frequency variation has its maximum about 2 years after the solar activity, as is the case with visual aurora.

Radio aurora is observed in the same general regions as optical aurora. With high power radars auroral type echoes can be recorded very often even in latitudes far from the auroral zones.

The reflection process has been found to take place in a fairly narrow height interval with mean value between 90 and 110 km, i.e. in the same height range as the lower border of visual aurora, by a large number of investigators. Also the motions of radio aurora correlate quite well with those of visible aurora, described in Section 2 (see p. 44). Fig. 3.2 shows an example of simultaneous recording of visual and radio aurora. As can be seen, there is a significant but not perfect correlation. The correlation is, however, good only at low elevation angles in a sector centered somewhere around geographic or geomagnetic north, in the northern hemisphere, and south in the southern hemisphere (cf. Fig. 3.3). Even extremely strong aurora overhead does not give any echoes at all.

The mentioned limitations of the regions in which auroral echoes are found is due to the fact that the reflection mechanism is aspect sensitive: reflections occur predominantly from a direction perpendicular to the magnetic field lines at the reflection point. This can be understood if the reflection mechanism is one of weak scattering from small irregularities strongly elongated along the lines of force, as well as if it is a critical reflection from larger magnetic-field-aligned irregularities. Recently it has been suggested that the irregularities may be ion sound waves (Buneman, 1963). The fine structure of the received echoes shows that a large number of reflecting centers are active at the same time.

As radio aurora has been observed for frequencies up to 2850 Mc/s (Groth et al., 1964) it seems most probable that weak scattering from small irregularities in the electron density distribution is the most important process at higher frequencies, whereas critical reflection—i.e. reflection

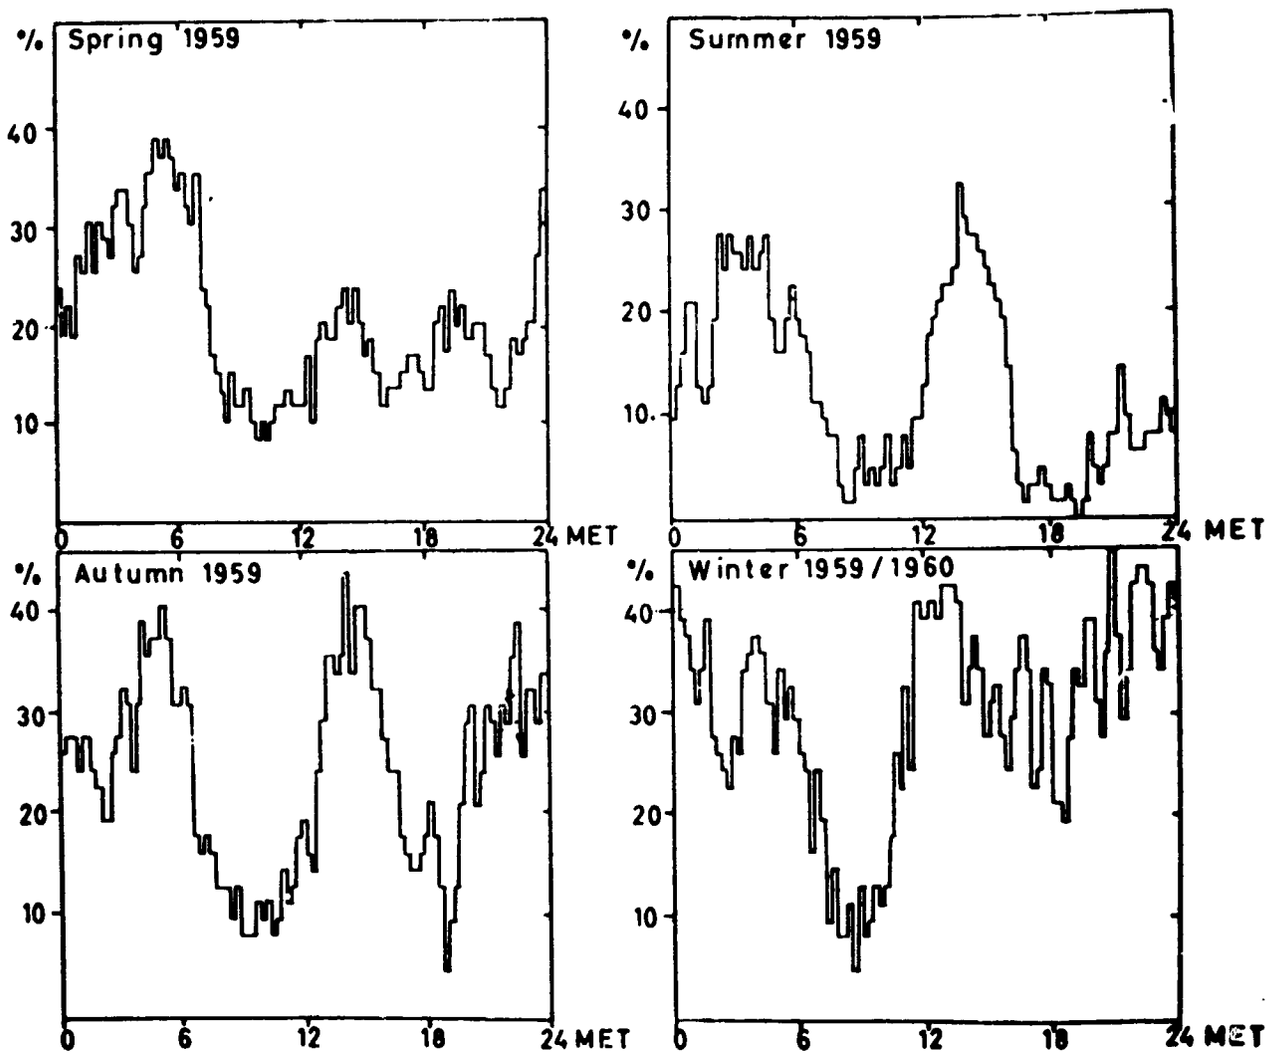

FIGURE 3.1.—Diurnal variation of the occurrence frequency for radio aurora at about 90 Mc/s, observed at Kiruna Sweden (geomagnetic latitude 65.3°). After Egeland (1962a).

from an electron density so large that the refractive index is zero—may be of importance in the lowermost part of the VHF band. How the irregularities are produced is far from clear. See the above mentioned review papers for more details.

5. Bremsstrahlung X-rays at Balloon Altitudes

In the auroral zone the probability of occurrence of x-rays has been found to be fairly well correlated to large scale magnetic activity. But the detailed correlation between aurora and precipitation of the energetic electrons, which generate bremsstrahlung, is in general quite poor there (cf. Anderson, 1960, 1962; Anderson and Enemark, 1960). It does, however, happen that auroral luminosity and x-ray flux follow each other extremely well (see Fig. 3.4, after Anderson and DeWitt, 1963). This seems to be fairly exceptional in auroral zone latitudes.

In subauroral latitudes strong x-ray events occur almost only during strong magnetic storms, and the correlation between the occurrence of visual aurora and bremsstrahlung at balloon heights is quite good (see the review by Winckler, 1962, for instance).

The balloon observations thus show that the high-energy electrons responsible for the bremsstrahlung production in general do not constitute the high energy tail of the electron spectrum producing the visible aurora in auroral zone latitudes, whereas they usually do in subauroral latitudes. The spectrum of the primary electrons is discussed in some more detail in Section 4.

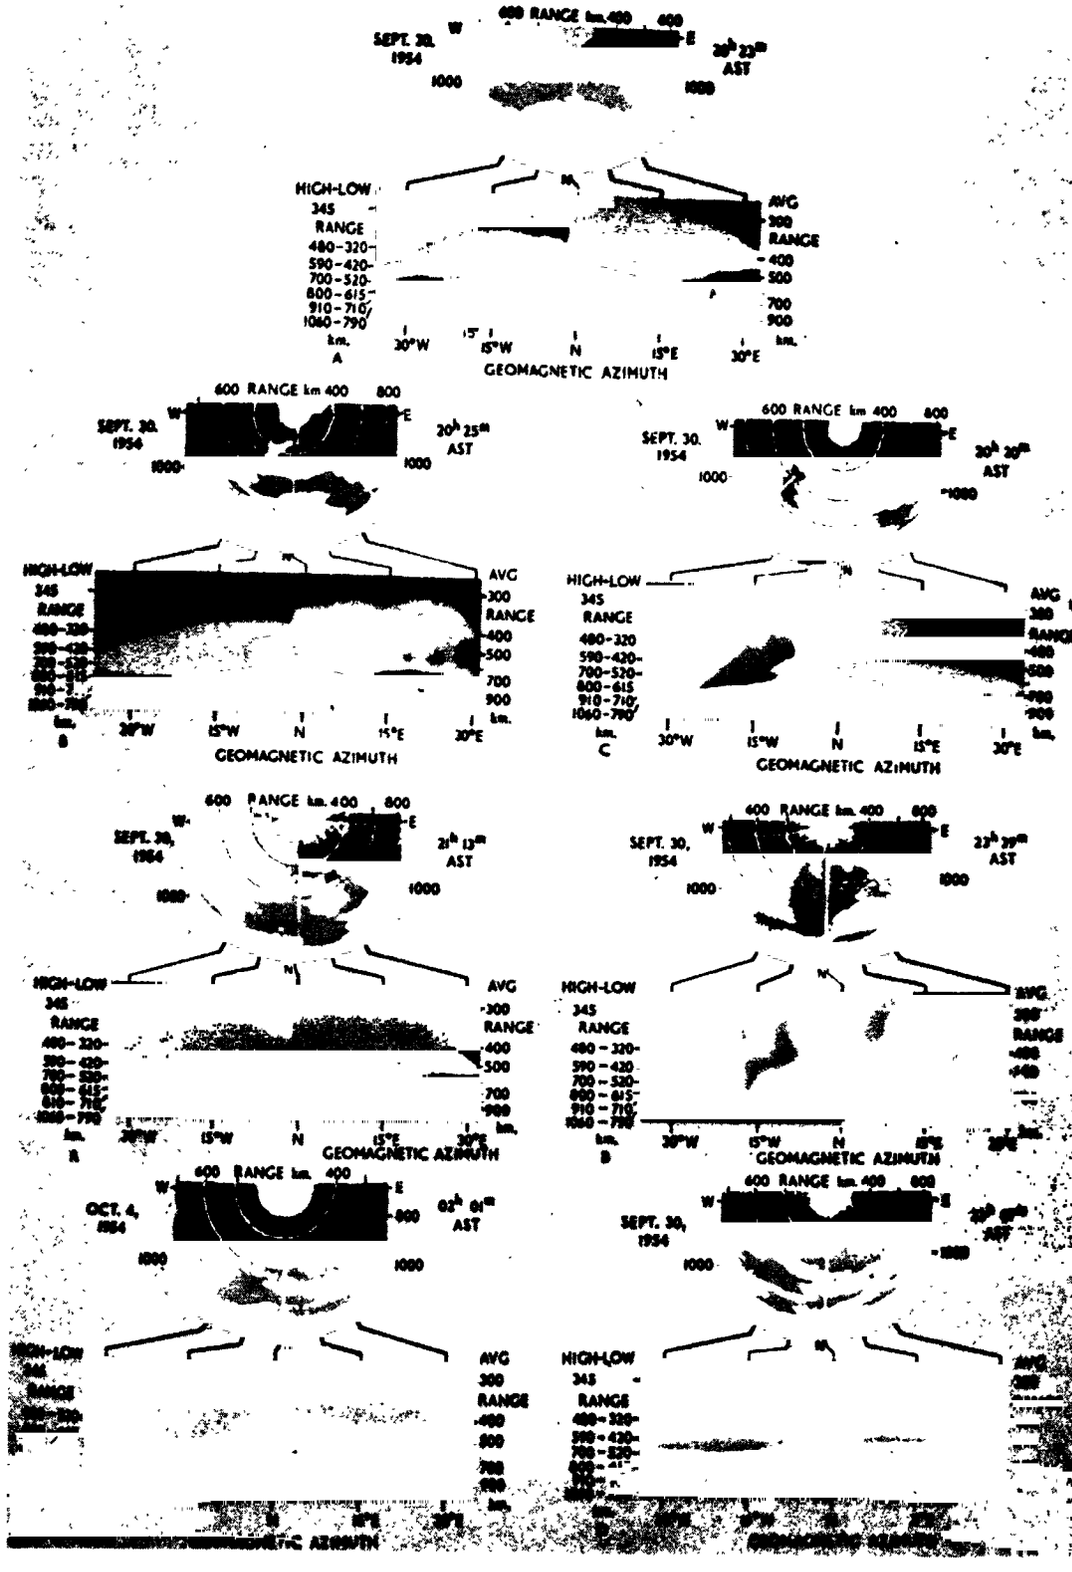

FIGURE 3.2.—Allsky-camera photographs of visible aurora compared with simultaneous 106 Mc/s radar echoes obtained at College, Alaska. After Bowles (1954).

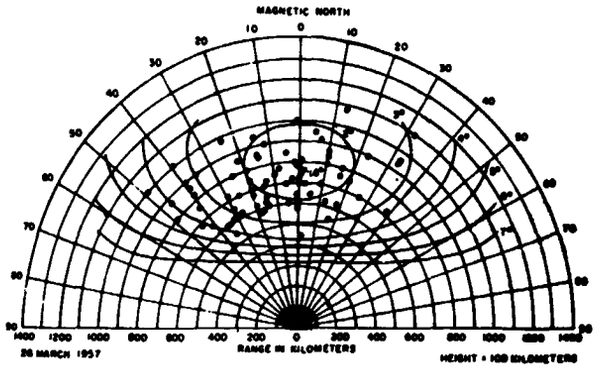

FIGURE 3.3.—Mass plot of 398/Mc/s echoes as a function of range and azimuth, College, Alaska, March 26, 1957. The points represent observations. The numbers attached to the various curves give the off-perpendicular angle with regard to the geomagnetic field lines at the reflection point. After Leadabrand, et al. (1959).

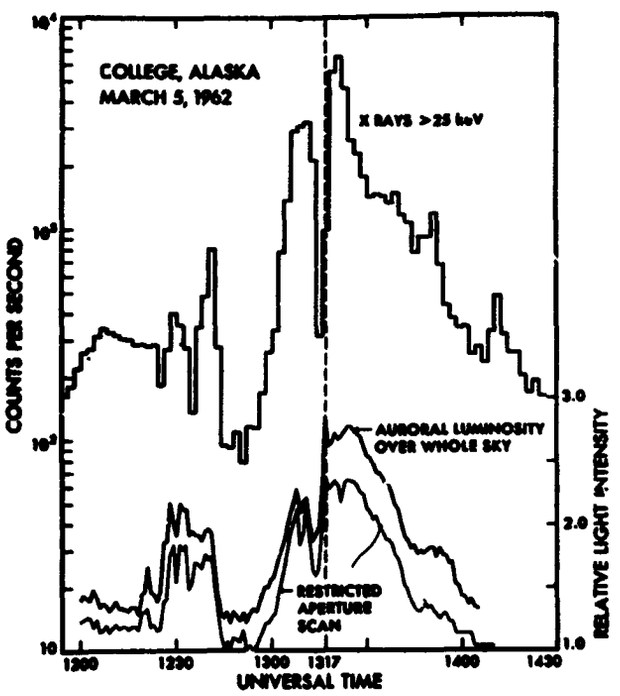

FIGURE 3.4.—Comparison of auroral luminosity obtained from allsky-camera pictures with x-ray flux at balloon altitude. After Anderson and DeWitt (1963).

6. Auroral Absorption

During aurora and magnetic storms the ionospheric absorption of radio waves recorded by means of riometers most often shows an irregular time structure. Although the period of absorption may last several hours, individual peaks often have durations of only a few minutes. Rates of increase and decrease may be as high as 3–2 db/minute, and the magnitude of the absorption can be 8–10 db at about 30 Mc/s for short periods. The character of the record differs definitely from that seen during SIDs or polar cap absorption events (PCA) (cf. Chapter). This type of absorption is usually called auroral absorption. Thus, the auroral absorption (AA) is defined as all absorption observed when there is no SID or PCA. It is then not surprising that Ansari (1963) has been able to show that AA consists of more than one type of absorption phenomenon, different with regard to the energy spectrum of the ionizing particles. One type, primarily occurring in the pre-breakup phase of aurora, is well correlated with the visual aurora (see also Gustafsson, 1964). It is limited approximately to the luminous forms and its intensity is generally fairly low ($\lesssim$1 db at about 30 Mc/s). During the break-up of the visual aurora the AA is intensified and is still mostly limited to the luminous forms.

After break-up, and practically only after magnetic midnight at College, strong fairly slowly varying absorption often occurs. It is sometimes associated with faint and diffuse aurora all over the sky, but there is no detailed correlation between light intensity and AA.

Even if there, thus, is a good statistical correlation between auroral absorption and visible aurora, bright coronas may appear without being associated with any measurable amount of absorption (see e.g. Kavadas, 1962). Ansari (1964) reported cases in which the absorption even decreased when an auroral form brightened up.

The auroral absorption has been found to have its maximum average value in a zone located a few latitude degrees further from the pole than the visual aurora (Gorbushina, 1962; Hartz, 1963; Holt, 1963; Basler, 1963).

The height where the auroral absorption takes place is a parameter of great importance for the understanding of the electron reactions in the lowermost ionosphere (see Hultqvist 1963b, 1964). The observation that the effect of sunrise and sunset on AA is much lower than expected on the basis of existing models (see e.g.Hultqvist,1963a) has been interpreted as indicating that all AA takes place above 90 km (Brown and Barcus, 1963). Such an interpretation is, however, in

contradiction with a large body of other experimental data (see Hultqvist, 1963b). Recent extensive multi-frequency riometer measurements (Little et al., 1963) which provide height information for the AA in the interval 35-75 km, have shown that in some 40 percent of 112 studied cases the height distribution of the absorption per km had its maximum at or below 72 km. In some 10 percent of the cases the peak was even at or below 60 km.

The multi-frequency riometer technique cannot tell about possible existence of appreciable AA in the *E*-layer in the presence of AA also below the *D*-layer, for instance. Analysis of recent satellite measurements of electron precipitation has shown that most of the auroral absorption in general is located between 60 and 90 km (Hultqvist 1964a, b) in good agreement with the riometer measurements mentioned. The satellite data show that AA is due mainly to electrons of energy above 40 kev, whereas the visual aurora is caused by electrons of energies between a few kev and a few ten kev (see the review by Hultqvist 1964c). This is illustrated by Figures 3.5 and 3.6.

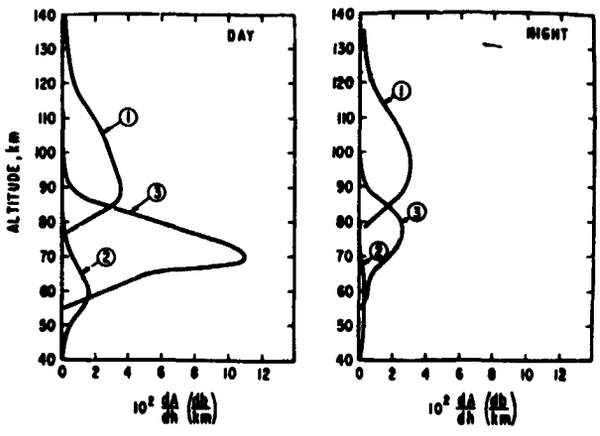

FIGURE 3.5. —Curves 1 show the height distribution of the absorption produced by the differential energy spectrum $N(E)=5.10^9\ e^{-E/5}$ electrons (cm² sec ster kev)$^{-1}$. The total absorption under the curve amounts to 1.04 db in the day and to 0.89 db at night. Curves 2 give the absorption due to the bremsstrahlung of the mentioned electron spectrum. Total absorption in the day is 0.27 db and in the night 0.061 db. Curves 3, finally, represent the absorption distribution produced by the differential energy spectrum $N(E)=7.10^4e^{-E/41}$ electrons (cm² sec kev)$^{-1}$ coming in along the field lines. Total daytime absorption is 1.9 db and the nighttime one is 0.52 db. After Hultqvist (1964a).

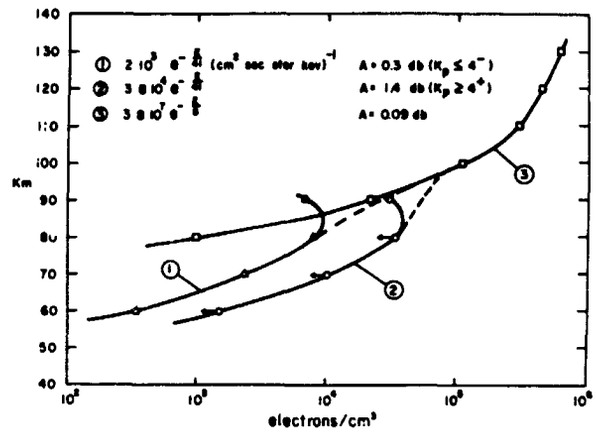

FIGURE 3.6.—Equilibrium electron density profiles due to three energy spectra of precipitated electrons. The spectra as well as the total absorption, A, at 27.6 Mc/s are given in the figure. Curve No. 2 gives an upper limit for the equilibrium electron density distribution produced by the spectrum $3.8\cdot10^4e^{-E/30}$ electrons (cm² sec ster kev)$^{-1}$ which is the equivalent spectrum for the average fluxes when $K_p>4$ as found by McDiarmid et al. (1963) a lower limit for this spectrum is curve No. 1. After Hultqvist (1964b).

Fig. 3.5 shows an estimation of the height distribution of the absorption produced by the primary electrons of a strong visible aurora of International Brightness Coefficient (IBC) between III and IV (curves nos. 1; spectrum of the electrons being that observed by McIlwain, 1960). The absorption due to the bremsstrahlung of those primary electrons (curves 2) and the absorption due to high energy electrons observed in the auroral zone with satellites by Mann et al. (1963) (curves 3). In Fig. 6 the equilibrium electron density profiles produced by the average precipitation fluxes of electrons in the auroral zone, as observed by means of the satellite Alouette (McDiarmid et al., 1963) and Injun 3 (O'Brien, 1964) are shown. For electrons of energy above 40 kev data are available for low ($K_p<4$) and high ($K_p>4$) magnetic activity. Curve 1 gives the average distribution for low magnetic activity, while curve 2 gives only an upper limit for the electron density profile when $K_p>4$. Curve 3 finally is due to the average electron flux in the energy range 1–40 kev.

The total absorption values computed from the satellite measured electron fluxes (0.3 db, <1.4 db, and 0.09 db for curves 1, 2, and 3, respectively) for the two ranges of magnetic activity are in quite

good accordance with the average absorption during the five most disturbed days and five most quiet days in each month, as observed over several years at College by Basler (1963). For the disturbed days he found a daily average of about 1 db in the summer and between 1 and 2 db in the winter and at equinoxes. This should be compared to the value $\sim$ 1 db of Fig. 3.6. For the quiet days the daily average observed by Basler was 0.3 db, which is identical to the value obtained from the satellite data.

The bremsstrahlung x-rays are most probably always negligible as compared to the primary electrons for producing AA (Ansari 1963, Hultqvist 1963, 1964, Brown, 1964).

The fluxes of the high-energy electrons causing AA and the low energy electrons producing aurora vary independently of each other. This explains the variable degree of correlation between aurora and AA. One can expect to observe aurora without AA and AA without aurora and all combinations in between. Ansari's (1963) results indicate that the electrons of energy above 40 kev are precipitated mainly after magnetic midnight. In the same way it is also understandable why auroral absorption has its maximum in the morning (Fig. 3.7), while aurora is most frequent in the middle of the night. The good correlation that has been found between AA and bremsstrahlung x-rays (see Brown, 1961, and Pfotzer et al., 1962, for instance) fits also well into the picture.

From the data presented above it seems reasonable to conclude that the absence of a significant influence of sunlight on the auroral absorption cannot be explained by the absorbing ionization being located, as a rule, above 90 km altitude.

For a discussion of other aspects of auroral absorption see e.g. the reviews of Ansari (1963), Holt (1963), and Hultqvist (1963c) and Chapter 0 of this book.

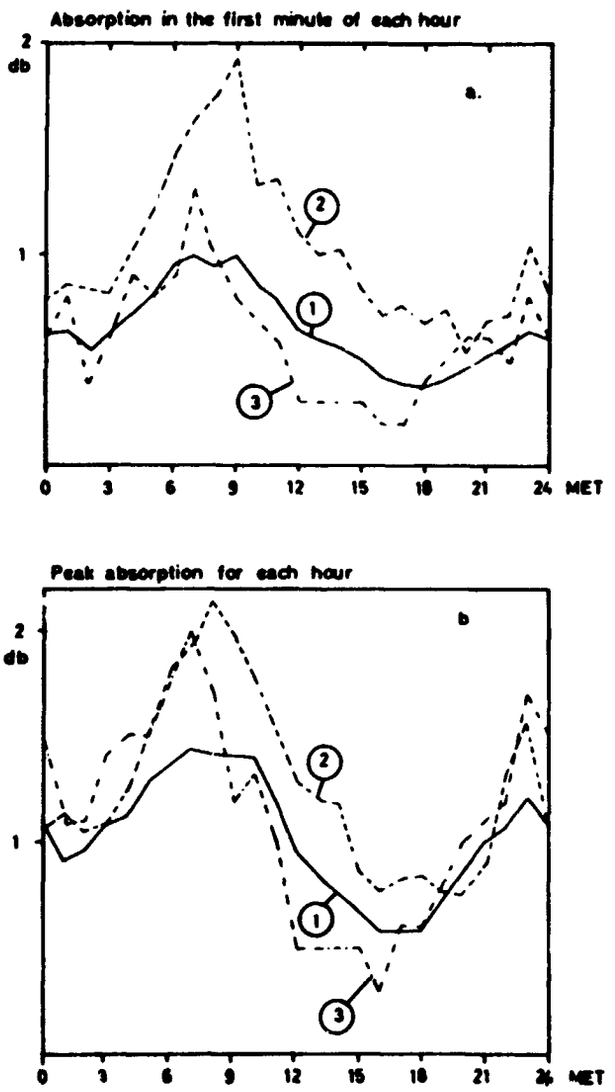

FIGURE 3.7.—Diurnal variation of the average intensity of 27.6 Mc/s cosmic noise absorption for the equinoxes at Kiruna. Months in which PCA's occurred are excluded. Curve 1 represents the average for the following months: April 1959, September 1959, October 1959, March 1960, October 1960, March 1961, April 1961, September 1961, and October 1961. Curve 2 is for September 1961 alone and curve 3 for September 1959. After Hultqvist (1963a).

7. Other Ionospheric Disturbances Associated with Aurora

The first phase of an auroral situation in the ionosphere is usually characterized by increasing height of the $F2$-layer. In about 100–110 km height an auroral sporadic E-layer is formed, which is quite similar to the daytime E-layer but has greater vertical extension. The critical frequency of this layer may rise up to 7–8 Mc/s and has usually well pronounced ordinary and extraordinary components. Multiple reflections are quite common, thus little absorption below this layer is often observed. In the second phase more absorption takes place, the minimum frequency of the E-layer increases and less multiples are recorded. Auroral forms with ray structure is often seen at this time. The third phase is characterized by high absorption of radio-waves,

often resulting in black-out and strong aurora with ray-structure (after Stoffregen, 1958).

During the second and third phases low-frequency reflections are often observed at abnormally low altitudes of down to 60 km (Stoffregen, 1958; Stoffregen et al., 1960; Gregory, 1961; Pedersen, 1962; and others.)

Only few detailed studies of the correlation between visual aurora and sporadic *E* in the auroral zones have been reported (Heppner et al., 1952; Knecht, 1956; Hunsucker and Owren, 1962). The most recent one is that of Hunsucker and Owren. They compared auroral type sporadic-*E* recorded with ionosondes in Alaska during the IGY with simultaneous allsky camera observations and other data for times of auroral activity. They found a high correlation between zenithal aurora and the critical frequency of the sporadic-*E* layer (*fEs*). From detailed studies of simultaneous visual aurora and ionospheric sounding data Hunsucker and Owren drew the following conclusions:

The motion of an auroral arc or band from a low elevation angle to a position near the zenith is accompanied by an increase in the value of *fEs*.

fEs is more than two times as great when there is aurora in the zenith as when there is not.

The highest value of *fEs* is observed when an auroral arc or band is present at the astronomical zenith (not the magnetic zenith).

A general survey of existing knowledge concerning sporadic-*E* phenomena of all kinds can be found in the paper by Thomas and Smith (1959). For other ionospheric disturbance effects associated with aurora, see Chapter 0.

8. Scintillation of Radio Waves from Radio Stars and Satellites

Although no statistical studies of the correlation between auroral occurrence and scintillation of radio-waves from point sources outside the ionosphere have been made, it can be said that a good correlation certainly exists. A correlation exists namely between scintillation and geomagnetic activity (cf. e.g. Little et al. 1962, and Liszka, 1963), as well as between occurrence of visual aurora and geomagnetic activity (see above) and a few detailed studies of situations in which the radio waves have propagated through an observed visual aurora have shown that the scintillation is higher when the waves pass through the aurora than when they do not. This has been found both for ordinary aurora (Little and Maxwell, 1952a; Benson 1960; Morcroft and Forsyth) and for the subauroral-latitude red arcs (Roach, 1963).

9. Radio-Noise Emission

There is some evidence for VHF radio noise being emitted by the auroral primary electrons. The situation is still somewhat unclear. If the reported emissions are of auroral origin, a strong solar cycle variation in their occurrence frequency seems to exist. Observations have been reported only for solar activity maximum. Leadabrand (1964) has given a review of published observational results. Synchrotron radiation from the auroral primaries seems to be a possible mechanism of generation (Hower, 1963).

Whereas, thus, the association of aurora with significant VHF noise emission still must be considered as somewhat doubtful or at least as of rare occurrence, observational results showing a close relationship between visual aurora and a type of very-low-frequency noise emissions, the so-called auroral hiss, have recently appeared. Hiss differs from the other types of VLF emissions in that discrete emissions are not distinguishable in the emission spectra. A class of hiss known as "auroral hiss" has been shown to be closely associated with the occurrence of aurora on the basis of ground observations (Martin and Helliwell, 1960; Jörgensen and Ungstrup, 1962; Morozumi, 1962) although VLF hiss emission is sometimes undetectable on the ground even in the presence of an intense and active aurora. Morozumi (1963) has found that VLF hiss usually occurs in the prebreakup phase of aurora and is well correlated with homogeneous auroral arcs and bands. He observed, however, also that intense auroral hiss sometimes occurs unaccompanied by auroras. Fig. 3.8 shows simultaneous records of VLF noise, visual emission, and precipitated electrons obtained on board Injun 3 (Gurnett and O'Brien, 1964). The agreement between the time functions of the various variables is quite good. The satellite was between 250 and 350 km while the records in Fig. 3.8 were taken. The photometer was looking along the field lines, and the measured electrons were on their way down into the atmosphere. The antenna on the satellite received the

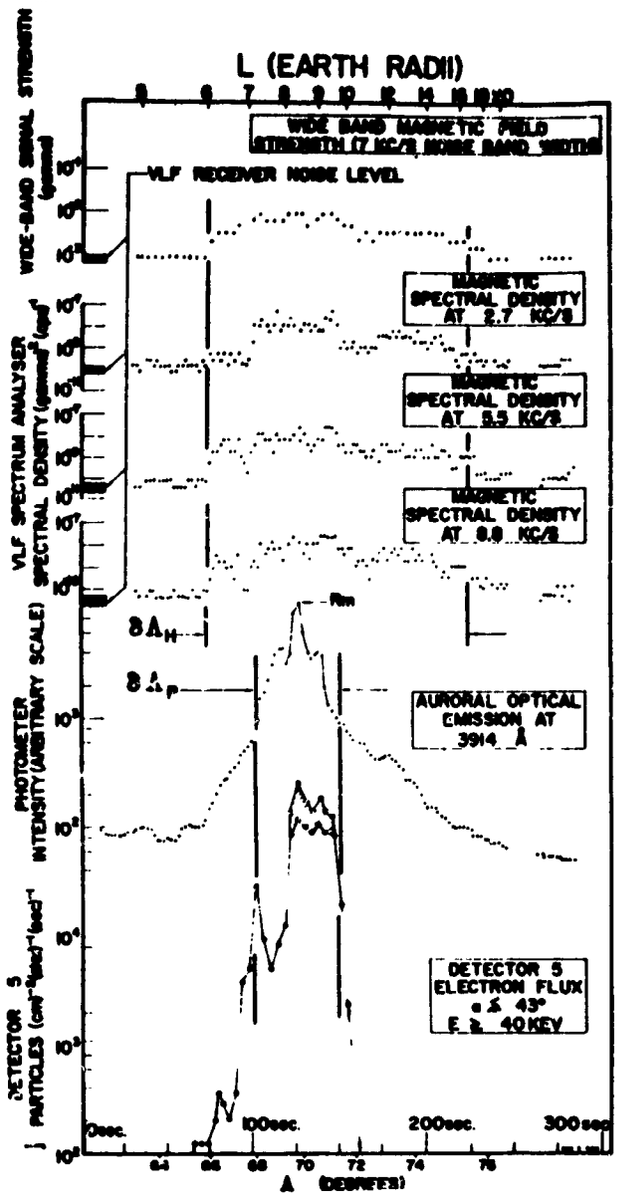

FIGURE 3.8.—A simultaneous observation of VLF electromagnetic emission, auroral luminosity and precipitated electrons on board Injun 3 on March 3, 1963, 0720-0725 UT. After Gurnett and O'Brien (1963).

VLF magnetic component perpendicular to the geomagnetic lines of force. The emission spectrum of the auroral hiss record in Fig. 3.8 is essentially a flat noise spectrum starting below 2.7 kc/s and extending above 8.8 kc/s. The Injun 3 measurements suggest that, at least sometimes, the same precipitated electrons cause both visual aurora and VLF hiss emission.

10. Auroral "Sound"

A large number of reports of aural observations of sound in connection with aurora exist. A review has recently been presented by Campbell and Young (1963). According to these reports, some of which have been given by experienced auroral researchers, a sound is heard in a few per cent of the active auroras, mainly in the years of maximum in the eleven-year solar activity cycle. The sounds are said to be at the upper frequency limit of the observers' auditory response.

Chapman (1931, 1932) has pointed out that the mean free path in the height interval where aurora occurs is too large compared with the wave length of sound waves in the audible frequency range, for transmission down to the earth's surface to be possible. The aurora has to reach down below 65 km for the sound waves to be able to propagate to the earth's surface. But if this occurred, the variations in luminous and acoustic intensity could not be simultaneous, as has been reported, because of the low sound propagation velocity (unless the aurora extended to the ground level). It seems probable that the reported acoustic effects are due to the electric fields that are induced in any suspended wire connected to the earth by the geomagnetic variations associated with strong auroras, as proposed by Harang (1951), Störmer (1955) and others. During very strong auroras these voltages may be of sufficient magnitude to produce discharges.

For infrasonic waves in the period range 10–110 seconds the ratio of wavelength to mean free path is large, and propagation to the ground from the auroral altitudes is physically possible. Such waves have also been observed (Chrzanowski et al., 1961, 1962). Maeda and Watanabe (1964) have pointed out that auroral activity is expected to be associated with the appearance of infrasonic waves due to periodic heating of the ionosphere by the primary auroral particles. Such correlation was found by Campbell and Young (1963) in Alaska, where they observed that every night of bright visual aurora, or ionospheric evidence of aurora, was associated with 10–110-sec-period pressure oscillations of about 1 to 10 dynes/cm^2 amplitude. Nights of no auroral activity showed no infrasonic effects.

4. DIRECT OBSERVATIONS OF ENERGETIC PARTICLES ASSOCIATED WITH AURORA

1. Introduction

The first definite observational evidence for fast charged particles entering the earth's upper atmosphere along the geomagnetic field lines was obtained from a spectrogram taken by Meinel (1950a, b, 1951). He pointed his instrument toward the magnetic zenith during a strong aurora and obtained an $H\alpha$ profile that was shifted—as well as broadened—with its peak corresponding to a doppler velocity of roughly 500 km/sec, but the short wavelength tail of the profile extended to more than 2000 km/sec. In the direction of the magnetic horizon the profile was not shifted but only broadened to about 500 km/sec on either side of the center. The broadening on the red side arises probably in part from scattering of light from other parts of the sky and in part from motions of protons away from the observer. The latter may be due to many small-angle scatterings of protons that initially were moving nearly perpendicularly to the magnetic field.

Proton fluxes as high as 10^8 $(cm^2\ sec)^{-1}$ with velocities below 500 km/sec have been deduced from spectroscopic measurements (Malville, 1960). That proton velocities much above 2000 km/sec have not been observed, does not mean that higher velocities do not exist in the incoming proton beam. The observed limit is due to the effect that much more rapid protons cannot take up electrons to form neutral hydrogen atoms which then can emit the hydrogen lines on its continued way.

In this section will be given a brief review of some recent direct measurements of particles related to aurora which have been made by means of balloon-, rocket-, and satellite-borne instruments.

2. Observed Fluxes and Energy Spectra of Electrons Precipitated Into the Upper Atmosphere

In the summer of 1953 a group from the State University of Iowa when carrying out a program for study of the low-energy end of the primary cosmic-ray spectrum recorded an anomalous soft radiation by means of rockoons launched from a ship west of Greenland (Meredith et al., 1955). The radiation was identified as x-rays of energy 10–100 kev. Some two dozen rockoon launchings at various latitudes showed that the latitude dependence of the radiation intensity was very similar to that for the occurence of visual aurora (Van Allen, 1957).

X-rays directly coincident with auroras were first observed at balloon levels in 1957 (Winckler et al., 1958). A few rockets were launched through visible auroral forms in 1958 (Davis et al., 1960; and McIlwain, 1960). The first proof that electrons are precipitated into the atmosphere from altitudes of 1000 km or more was obtained from Sputnik 3 in a period of about one minute on May 15, 1958, by Krasovskii et al. (1962). A number of reports of measurements on electrons precipitated into the atmosphere have been collected in Table 1. Nos. 1–3 are rocket measurements, no. 4 refers to the rockoon results of the Iowa group, nos. 5–9 are measurements obtained by means of balloons (only x-ray maesurements for which the existence, or nonexistence, and characteristics of visual aurora in the period of measurement have been reported are included in Table 1), nos. 10–21, finally are satellite results.

The early rocket measurements (Davis et al., 1060; McIlwain, 1960) as well as the satellite results (e.g., O'Brien, 1962a, 1964) have verified the conclusions of Omholt (1957, 1959) based on spectroscopic observations of aurora that the protons play a very minor role in the excitation of most auroras.

The first somewhat detailed satellite studies of particles that were definitely precipitated into the atmosphere were made by means of Injun 1 (O'Brien, 1962a, b). O'Brien and others working with satellite data define precipitated particles as such which would mirror at or below 100 km altitude (if the atmosphere had not been present). The satellite results have also shown that electrons on the average carry much more of the energy to the lower ionosphere than do protons (O'Brien, 1962b).

(a) Latitudinal Distribution and Other Spatial Characteristics

The recent simultaneous measurements on Injun 3 (O'Brien and Taylor, 1964) of flux of precipitated electrons and of auroral light emission below the satellite have shown that above auroras there are electron fluxes several orders of

*This value is obtained from the energy flux value in the way described by McIlwain (196C). It is, however, a factor of about 2π smaller than the value given by McIlwain himself.

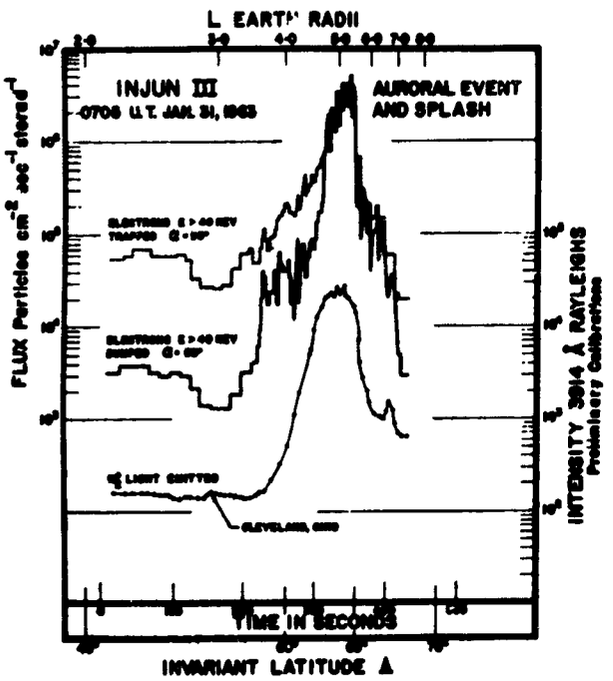

FIGURE 4.1.—Data from a northbound pass of Injun 3 over North America, which shows simultaneous detection of an aurora, of the precipitated electrons (pitch angle ~50°) partially responsible for causing it, and of trapped electrons. Note the approach to isotropy of the particle flux over the aurora. No attempt has been made to subtract the low-latitude contamination of the photometer signal, part of which was the detection of Cleveland, Ohio, and its surrounds. (After O'Brien and Taylor, 1964.)

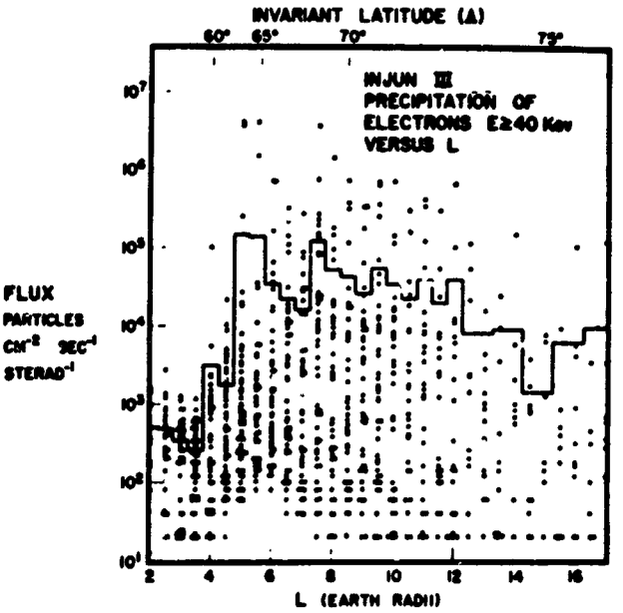

FIGURE 4.2.—Samples of precipitated fluxes over North America in January 1963. Each point is an 8-sec average of thirty-two measurements made at half-integral values of L. The solid line gives the average flux. (After O'Brien, 1964.)

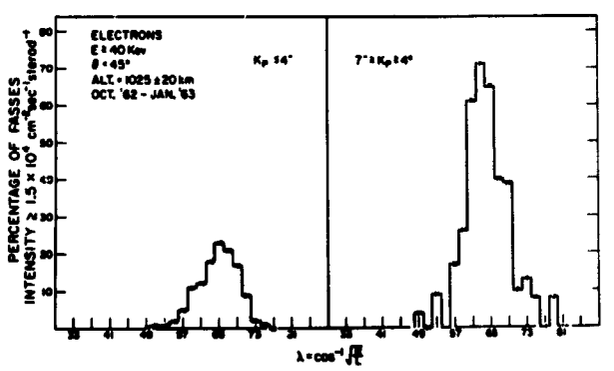

FIGURE 4.3.—Percentage of passes in which the intensity of precipitated electrons with energies greater than 40 kev is greater than 1.5 x 10^4 cm^{-2} sec^{-1} plotted against invariant latitude. (After McDiarmid et al., 1963.)

magnitude larger than outside the aurora (see Fig. 4.1).

Fairly extensive statistical data on the spatial characteristics of precipitated electrons have recently been published by O'Brien (1962a, b, 1964) and McDiarmid et al. (1963). Fig. 4.2 shows the scatter diagram of the Injun 3 observations of precipitated electrons of energy above 40 kev for the range of the invariant latitude Λ (defined by $\Lambda = \cos^{-1}(1/L)^{1/2}$ and at the most a few degrees different from geomagnetic latitude in the latitude range of interest here) between 45 and 76 degrees. As can be seen from the figure, the precipitated flux of electrons of $E \gtrsim 40$ kev has a maximum of about 10^5 (cm^2 sec ster)$^{-1}$ for Λ between 60 and 70 degrees. The flux is 2–3 orders of magnitude lower in subauroral latitudes. Fig. 4.2 also shows that some 10 degrees inside the auroral zone the precipitation rate is down by 1–2 powers of ten. Similar results have been found by McDiarmid et al. (1963) for electrons of energies above 40 kev and above 250 kev. Fig. 4.3 shows their data presented in a manner different from that of O'Brien (1964).

The histograms give, for two different ranges of magnetic activity, the percentage of passes in which the intensity of precipitated electrons with $E \gtrsim 40$ kev was above $1.5 \cdot 10^4$ (cm^2 sec ster)$^{-1}$ (corresponding to 0.2 db absorption at about 30 Mc/s). The flux of $1.5 \cdot 10^4$ (cm^2 sec ster)$^{-1}$ was one half of the maximum average intensity for

$K_p<4$ and 1/20 for $K_p>4$. Fig. 3 shows that during quiet geomagnetic conditions the precipitated intensity was greater than half the average value during some 25 percent of the passes through $\Lambda=65°$, while for moderately disturbed conditions —there were no strong storms represented in the data—the intensity exceeded 1/20 of the average value in about 72 percent of the passes over that latitude.

Simultaneous observations on two satellites indicate that at least sometimes the area of precipitation has a fairly limited longitudinal extent (O'Brien and Laughlin, 1962). On the other hand the precipitated flux seems on occasions to be uniform over as much as 80 degrees of longitude, i. e., over more than 4000 km (O'Brien, 1964).

The flux of precipitated electrons has its maximum close to the poleward boundary of the region of trapped electrons, as observed on the same satellite (McDiarmid et al., 1963, O'Brien, 1964).

Electron precipitation occurs simultaneously in magnetically conjugate areas at least sometimes, according to balloon observations of x-rays (Brown et al., 1963). This is in accordance with observations of aurora (cf. e.g. DeWitt, 1962).

A 100 fold change in the flux over two km has often been observed by Injun 3, which is in agreement with results of rocket measurements in aurora by Davis et al. (1960). They found the electron flux being concentrated in the visible auroral forms, whereas protons were found over a much larger volume than that occupied by the aurora.

The statistical latitude profile of the intensity of dumped electrons with $E\gtrsim 40$ kev has been found by O'Brien and Taylor (1964) to have its maximum at a few degrees lower latitude than the frequency of occurrence of visual aurora as observed on the same satellite. Sometimes the visual emission has been found to extend to higher latitudes than the precipitation of electrons with energy greater than 40 kev, indicating electrons of $E<40$ kev are being precipitated up to higher latitudes than the higher energy ones. The lower latitude limit of the aurora coincides with the lower latitude limit of appreciable precipitation (O'Brien, 1964; O'Brien and Taylor, 1964).

Precipitation was found all the time in the auroral zone by Injun 3 (O'Brien, 1964). It can be seen in Fig. 4.2 that at $L=6$ there was never

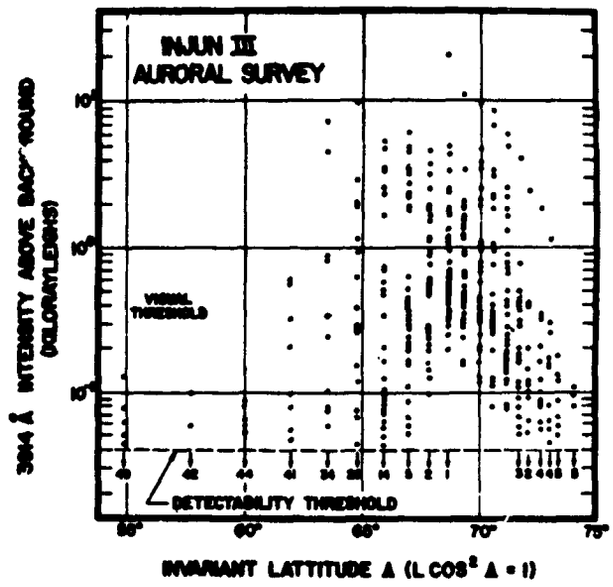

FIGURE 4.4.—Intensity of 3914 Å auroral light averaged over 4 sec at half-integral values of L in about fifty passes of Injun 3 early in 1963. (After O'Brien and Taylor, 1964.)

observed any flux lower than about 80 electrons $(cm^2\ sec\ ster)^{-1}$.

The corresponding continuous photon emission in the auroral zone is evident from Fig. 4.4. The minimum emission rate is, however, below visual threshold even in the auroral zone.

Figs. 4.2 and 4.4 also give a good impression about the enormous variability of precipitation and photon emission at all latitudes, but especially near the auroral zone. At $L=6$ there are values of about $6\cdot 10^6$ electrons $(cm^2\ sec\ ster)^{-1}$ shown in the figure. This is some 10^5 times the minimum value observed there

The latitudinal extent of the precipitation can be very restricted (e.g., over $L\sim 1$ earth radius) or very extensive (over $L>20$ earth radii). This is illustrated in Fig. 4.5.

(b) Time Characteristics of Precipitation

It is not possible to differ between time and space variations in satellite measurements. Balloon observations show, however, that time variations as rapid as of periods of a tenth of a second can occur in the electron flux (Winckler et al., 1962).

No systematic variation in the intensity of electron precipitation over periods as long as a day could be found by O'Brien (1964) from the

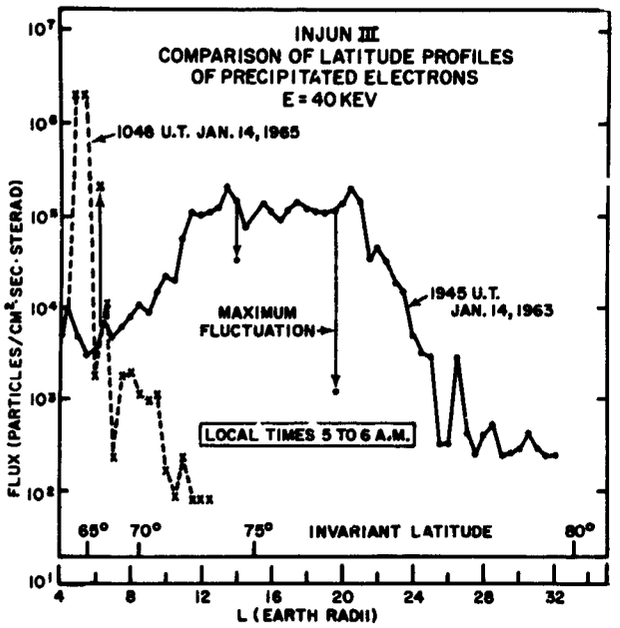

FIGURE 4.5.—Comparison of the latitude, or L profile, of precipitation for two successive passes at about the same local time. Arrows illustrate range of fluctuation of intensities at given locations. (After O'Brien, 1964.)

Injuns 1 and 3 measurements, in contrast with the case for trapped electrons. Sharp et al. (1964) observed a higher nighttime than daytime precipitation flux of electrons in the energy range 0.08–24 kev—as well as of protons—during the 5 days lifetime of an oriented polar-orbiting satellite. They also found the energy distribution of the electrons to be harder on the dayside than on the nightside of the earth (Johnson et al., 1964). With the enormous variability of the precipitation phenomenon a large amount of data seems, however, necessary for deducting statistically significant diurnal variation curves.

(c) Pitch Angle Distribution

Figure 4.1 shows that over the aurora, where the precipitation is intense the directional flux of precipitated electrons becomes equal to the flux of trapped electrons, which also is increased over the aurora. Figure 4.1 illustrates a general rule that has been found by O'Brien (1962a, b, 1964) namely that for electrons of $E \geq 40$ kev the pitch angle distribution approaches isotropy in the regions of intense precipitation. An isotropic pitch angle distribution in regions of strong precipitation has also been observed by Krasovsk" et al. (1962) at an energy of about 10 kev. No cases have been found in which the directional flux of precipitated electrons has been higher than the corresponding value of trapped electrons. The mentioned observations were made fairly close to the earth's atmosphere.

The tendency to isotropy seems to indicate that the acceleration of the electrons—if it is directed along the field lines—takes place far away from the atmosphere. This, as well as the mentioned observations of precipitation of electrons from above 1000 km in auroras, suggest that the role of the ionosphere in the production of the energetic electrons is not important. O'Brien (1964) found a flux upwards along the field lines, which was some 10 percent of the precipitated electron flux. He interpreted these observations as backscattering of electrons from the atmosphere.

(d) K_p Dependence of Precipitation

The K_p dependence of the precipitation of electrons of energy above 40 kev is illustrated in Fig. 4.3. The average intensity was ten times higher near the auroral zone when K_p was above 4 than when it was below 4. The data material for the higher K_p range in Fig. 4.3 does not contain data from any strong magnetic storm, so still higher values may be expected.

O'Brien (1964) found that the flux of precipitated electrons above 40 kev increased on the average by a factor of 5 for every step of K_p. A close correlation between precipitation intensity was also observed for the 0.8–24 kev energy range by Sharp et al. (1964). O'Brien's results, obtained on Injun 3 in a low orbit, are shown in Fig. 4.6

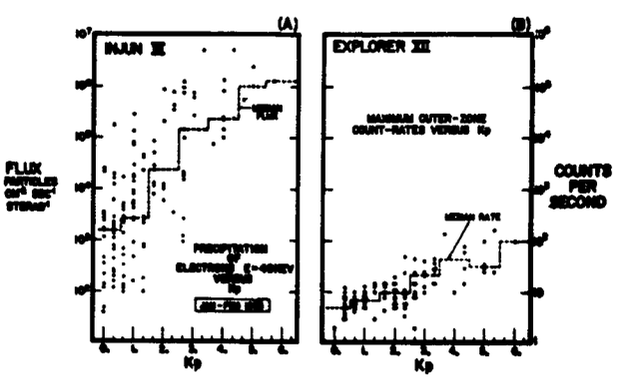

FIGURE 4.6.—Illustration that the flux of precipitated electrons (in A) varies more with K_p than does the omnidirectional flux (mainly of trapped electrons) in the equatorial plane (in B). Each point shows the maximum respective flux encountered on an outer-zone pass. (After O'Brien, 1964.)

together with the dependence of the omnidirectional flux above 40 kev as observed in the eqautorial plane far from the earth by Explorer 12 (Freeman, 1963). As can be seen, the K_p dependence is very much larger close to the earth (at one end of the field line) than in the equatorial plane (at the middle of the field line). If one assumes that both increases are due to a common acceleration mechanism it follows that it acts preferentially parallel to the geomagnetic field lines (O'Brien, 1964).

The change of omnidirectional flux above 40 kev with K_p, shown in Fig. 4.6b, is opposite to what has mostly been observed for electrons of $E \gtrsim 2$ Mev (Arnoldy et al., 1960; Hoffman et al., 1962).

The dependence of the poleward boundary of precipitation on magnetic activity has been studied by Maehlum and O'Brien (1963). They used data for trapped electrons, but since O'Brien (1964) has shown that the precipitation has its maximum close to the poleward boundary of the region of trapped electrons, their results may be interpreted in terms of possible extension of precipitated electrons.

Maehlum and O'Brien (1963) found that during magnetic storms there was a very sharp boundary of the region where trapped electrons of energy above 40 kev could be observed at about 1000 km altitude. For this boundary, measured in L, they used the symbol L_n. It can be seen as a function of the K_p index during one geomagnetic storm in Fig. 4.7. When K_p reached its maximum value of 9, L_n had its minimum value of 4. Maehlum and O'Brien (1963) also found that the poleward edge of strong radio wave absorption followed the L_n quite closely during the storm.

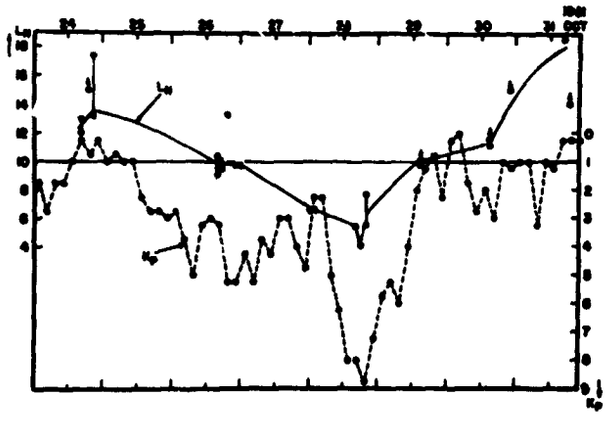

FIGURE 4.7.—Variation of the northern boundary of trapping with K_p during a geomagnetic storm, as observed by Injun 1 at a height of about 1000 km. (After Maehlum and O'Brien, 1963.)

The effect of K_p on L_n is similar to the equatorward movement of the region of visual aurora during strong magnetic storms, which has been studied in the last few years in detail for some storms by Akasofu (1962, 1963a,b) Akasofu and Chapman (1962) and Davis and Kimball (1962).

(e) The Spectrum of Precipitated Electrons

Up to now only rough measurements of the energy spectrum of the precipitated electrons have been reported. In most cases the proposed spectra have been obtained from two instruments with different energy characteristics. They thus are to be considered as rough equivalent spectra for measurements made in a defined way. In addition, it has been found that the equivalent spectrum is highly variable both in space and time (cf. O'Brien et al., 1962). Nonetheless the available spectral data are of great interest at the present stage of knowledge in the field, and they even make it possible to draw some interesting conclusions about ionospheric effects of the precipitated electrons (see Section 3).

Most spectra that have been reported hitherto can be divided in two categories if they are expressed in an exponential form. On one hand, the e-folding value, b, in the spectrum of precipitated electrons, written in the form $\alpha \exp(-E/b)$, has been found often to be in the range 2–8 kev (McIlwain, 1960; Stilwell, 1963; Sharp et al. 1964 a,b,c.) This is a very steep spectrum, but even steeper ones have been observed. McIlwain interpreted his rocket measurements in a strong aurora as indicating a monoenergetic flux of electrons with an energy of about 6 kev. Krassovskii et al. (1962) has observed steep spectra for precipitated electrons with a most common equivalent energy value of 14 kev.

The majority of the existing measurements have been made with Geiger tubes, for which the minimum detectable electron energy is about 40 kev. These measurements have mostly given e-folding values much higher than those mentioned above namely between 20 and 45 kev. (Davis et al. 1960; McDiarmid et al. 1960; O'Brien et al. 1962; Mann et al. 1963; McDiarmid et al. 1963; O'Brien and Taylor, 1964). Mann et al. (1963) found

from measurements during only some 20 orbits that the values within this range were grouped in two classes, 25 ± 5 kev and 42 ± 3 kev.

The balloon measurements of x-rays at 30–35 km altitude also, in general, give spectra of a fairly flat type, corresponding to e-folding energies in the range 20–45 kev mentioned (see e.g., Anderson and Enemark, 1960), although power law spectra often are found to fit the observations somewhat better than exponential spectra.

Recently the first direct measurements of precipitated electrons below 1 kev energy have been reported (Sharp et al. 1963, 1964c; Evans et al. 1964). They showed that there is generally not very much energy flux below 1 kev. This is also evident from observations of the luminosity distribution with height in aurora. (O'Brien and Taylor, 1964). It therefore seems probable that the spectrum, in general, does not increase very fast below 1 kev, which means that it is not of the power law type at these low energies.

Sharp et al. (1964c) reported a significantly harder spectrum on the dayside than on the nightside of the earth. This observation agrees with multifrequency riometer measurements of auroral absorption by Lerfald et al. (1964) according to which the absorbing ionization is located lower down in the atmosphere in the day than in the night.

Of special interest are the statistical data on electron precipitation, published recently. As mentioned earlier the precipitation is most intense near the auroral zone. O'Brien (1964) found an average flux of 4.10^5 electrons/cm^2 sec in the precipitation cone at an invariant latitude of 65°. Injun 1 had a CdS detector, measuring electrons of energy above about 1 kev (O'Brien, 1962b). O'Brien and Taylor (1964) stated that the flux of 4.10^5 electrons/cm^2 sec of energy greater than 40 kev was associated with an energy flux of 4 erg/cm^2 sec for electrons of $E \gtrsim 1$ kev. These data should be considered as accurate to a factor of about three. Using these two values an equivalent electron spectrum in the range 1–40 kev can be duduced. It is found to be $n(E) = 7.8 \cdot 10^7 e^{-E/5.7}$ electrons (cm^2 sec kev)$^{-1}$

For the energy values 40 and 250 kev similar average fluxes have been obtained from the Alouette measurements reported by McDiarmid et al. (1963). While the flux above 40 kev had its maximum at an invariant latitude of 65 degrees, the flux above 250 kev was maximal at about 60 degrees. McDiarmid et al. (1963) did not present any details for the latitudinal variation of this latter integral flux. By applying a rough correction factor of 0.1 for the latitude variation of the average flux above 250 kev from 60 to 65 degrees invariant latitude the following approximate equivalent spectra for the energy range 40–250 kev can be derived for two ranges of magnetic activity in the auroral zone, if isotropy is assumed for the upper hemisphere:

$$K_p < 4 : n(E) = 1.2 \cdot 10^4 e^{-E/41}$$

electrons (cm^2 sec kev)$^{-1}$,

$$K_p > 4 : n(E) = 2.4 \cdot 10^5 e^{-E/30}$$

electrons (cm^2 sec kev)$^{-1}$

(cf. Hultqvist 1964b). The applied latitude correction is probably too large and the resulting spectra are thus too steep rather than too flat. As mentioned, the spectra of precipitated electrons are very variable. There is also an important latitude variation in the steepness which increases with latitude (O'Brien et al. 1962; McDiarmid et al. 1963; O'Brien, 1964). On the other hand there seems to be no significant dependence of the spectrum on pitch angle or on the intensity of precipitation (O'Brien, 1964). The averaging on which the equivalent spectra given above are based has been made over a large number of measured fluxes. With a variation of a factor of 10^5 the use of averages may be questioned. It is also questionable whether average integral fluxes are the best values to use when the interest is in the average electron density produced by the particle influx. The average electron density is then defined by the averaging process, and this method of averaging is not identical with the averaging made in measuring the ionospheric absorption, for instance. It can, however, be shown that the average electron density produced by the precipitated electrons can be expressed in the average integral fluxes measured on satellites (Hultqvist, 1964). Since only two experimental integral flux values are available one has to fit a two-parameter energy relation for the average flux to these experimental data, as has been done above.

3. Observed Fluxes and Energy Spectra of Protons Precipitated Into the Atmosphere

The number of observations of protons on their way down into the atmosphere is much less than that for electrons. Some rocket results observed in passing through aurora or close to distinct auroral forms, or from launchings made under quite disturbed upper atmosphere conditions with no auroral information available, are collected in Table 2.

While electrons were observed only within the auroral form in the case of no. 1a, protons were found over much larger volumes. In the flights 1b, c, and d, when no auroral form was penetrated and no electrons were recorded, protons (and/or heavier ions) were found in appreciable amounts. The proton precipitation thus seems to have that wide spread and diffuse character that the hydrogen emissions generally show. This may possibly be due to protons taking up an electron also well outside the atmosphere. As a neutral atom it is not locked to the magnetic field lines and the particle flux may be spread out before reaching the atmosphere (Shklovskii, 1958). In all cases of Tables 1 and 2 in which both electrons and protons were measured, the energy flux of the electrons was about two orders of magnitude, or more, greater than the proton energy flux.

The satellites Injun 1 and Injun 3 did not measure any auroral event in which the electrons were not the dominant constituent in radiation of a given penetrability (O'Brien and Taylor, 1964). The possibility that there were as many protons/cm² sec with an energy about 40 kev, say, as there were electrons/cm² sec with the same energy could, however, not be excluded on the basis of the Injun measurements. Such protons would be stopped above the normal auroral heights and one would expect hydrogen emissions well above the ordinary aurora. They could, however, be quite weak, especially as the protons flux generally is spread out over a much larger surface than the electron flux, as mentioned above. It seems difficult to judge on these things on the basis of ground observations, as the hydrogen emissions are mostly diffuse and therefore unsuitable for height determination with standard ground techniques. Rocket measurements of the height distribution of the hydrogen emissions would be valuable.

4. Quantitative Relations Between Electron Precipitation and Photon Emission in Aurora

There are two direct measurements reported of the quantitative relations between precipitation and photon emission which will be discussed here, namely those of McIlwain (1960) and O'Brien and Taylor (1964). It is of interest to compare their results with what is expected on theoretical grounds.

McIlwain did not use any filter, but measured the photon flux integrated over the transmission curve of the photomultiplier. If we assume that ⅕ of the light was λ3914 Å, the measured photon flux corresponds to an emission rate of about 3 kilorayleigh at this wavelength. The fraction ⅕ is fairly arbitrary, but it seems reasonable (cf. e.g. Dalgarno, 1964) and is probably in error by less than a factor of 2 and ½, respectively, for an ordinary auroral-zone aurora. McIlwain's (1960) measured electron flux corresponds to an energy flux of 20 erg/cm² sec if the spectrum obtained was extrapolated to $E=0$. Thus, the resulting electron energy flux required per unit of λ3914 Å emission rate is 7 ergs cm^{-2} sec^{-1} per kR.

O'Brien and Taylor (1964) reported an average λ3914 Å intensity of $2\binom{+4}{-1.5}kR$ at the maximum of the latitude distribution i.e. in the auroral zone. As mentioned before the electron measurements gave a corresponding average of the electron flux above 40 kev of $4\cdot10^5$cm^{-2} sec^{-1} and an average energy flux for $E\gtrsim1$ kev of about 4 ergs cm^{-2} sec^{-1}, which values they consider as accurate to a factor of about three. In order to get a value directly comparable with that of McIlwain one would have to extrapolate the energy spectrum from 1 kev down to $E=0$ and evaluate the total energy flux. Using the equivalent exponential spectrum, we find 5 ergs cm^{-2} sec^{-1} for $E>0$. Thus the Injun 3 results give 2.5 ergs cm^{-2} sec^{-1} per kR. Considering the uncertainties in measurements and the method of evaluation, this is a good agreement.

What energy flux per kR does one expect on the basis of existing knowledge about the emission processes? Omholt (1957, 1959) Chamberlain (1961), Rees (1963) and Dalgarno (1964), among others, have discussed this. It has been shown by Stewart (1956) that the ratio between the

excitation cross section for the λ3914 Å band of N^{2+} and the total ionization cross section is constant at least up to 200 ev energy and has the value 0.02. Assuming that this value is true over the whole energy range of interest, one finds that 50 electrons-ions pairs are produced for each 3914 Å photon. Since the mean energy expended by fast electrons in nitrogen per electron ion pair is 35 ev (at least for energies down to a few hundred ev; it is assumed the figure is correct down to zero energy) we find that $50 \times 35 = 1750$ ev is dissipated per 3914 Å photon. Since each photon has an energy of 3.2 ev, the efficiency with which energy is converted into 3914 Å radiation is $1.80 \cdot 10^{-3}$. When the initial energies of the fast electrons fall below perhaps 100 ev, these efficiencies must decrease sharply (Dalgarno and Griffing, 1958; Dalgarno, 1964). 1*kR* of 3914 Å photons corresponds to an energy influx of 2.8 erg/cm² sec, if the efficiency figure $1.8 \cdot 10^{-3}$ is employed. Dalgarno (1964) has used the value $1 \cdot 10^{-3}$. With this conversion efficiency we find the energy flux requirement to be 5.1 erg cm^{-2} sec^{-1} per *kR*. The agreement between these values and the experimental ones of McIlwain (1960) and O'Brien and Taylor (1964) is much better than expected, when the uncertainties in the analysis are taken into account.

The total efficiency of converting particle energy into photons of any energy is expected to be about 1 percent on theoretical basis (cf. Chamberlain, 1961). McIlwain found from his rocket measurements a value of only 0.2 percent, while preliminary Injun 3 results point towards 1 percent (O'Brien and Taylor, 1964).

5. Relation of Precipitated Electrons to the Outer Radiation Belt

The idea about the relations between the electrons that are precipitated into the atmosphere in auroras and elsewhere and the trapped radiation in the radiation belts, which was prevailing one or two years ago, was roughly that the precipitated particles were dumped from the large storage of energetic trapped particles in the magnetosphere through the influence of disturbing effects caused by the solar plasma, as, for example the magnetic disturbances. The number of trapped particles was thought to be sufficiently large to allow the precipitation rates observed to occur with only weak and perhaps independent processes of injection and acceleration required to replenish the particles in the radiation belt, and the occurrence of which is necessary to be assumed in any case for understanding the existence of the trapped radiation. This picture has been completely changed recently, through the investigations by O'Brien (1962b, 1964) of the measuring results of Injun 1 and Injun 3 and also through a number of balloon studies of x-ray fluxes in the lower atmosphere (Winckler et al., 1962; Anderson, 1964).

O'Brien (1962b) estimated the lifetime of the trapped electrons in the outer radiation belt assuming that the source was stopped but the loss mechanisms operated at the same rate as observed by Injun 1. He found that the outer zone beyond $L \sim 2$ would drain empty of electrons in a few hours. Similar average lifetimes have also been evaluated from x-ray measurements (cf. e.g. Winckler et al. 1962 and Anderson, 1964). Sometimes precipitation rates several orders of magnitude above the average (more than 1000 ergs/cm² sec) have been observed (Krasovskii et al. 1961; O'Brien and Laughlin, 1962, Winckler et al., 1962). Thus Winckler et al. (1962) recorded an electron burst reaching 10^{11} electrons $(cm^2\ sec)^{-1}$, a flux which would have used up the total energy of trapped particles in the field tube in half a second, but yet it persisted for about 100 seconds.

O'Brien (1964) has also shown that the flux of trapped radiation increases when precipitation takes place instead of diminishing, which would be expected if the trapped particles were simply dumped into the atmosphere. An acceleration mechanism seems to influence precipitated and trapped particles simultaneously.

Finally, O'Brien (1964) has demonstrated that the precipitation is highly energy dependent. There was no significant (<10 percent) precipitation or change in the flux of electrons of energy greater than 1.5 Mev observed in the middle of a strong burst of electrons of energy above 40 kev. This demonstrates that the precipitation could not be due simply to a lowering of the mirror point through a decrease in the geomagnetic field, since such a mechanism would be active over the whole spectrum.

Taken together, this new evidence clearly demonstrates that the precipitated electrons which produce aurora and ionospheric ionization are not

produced by simple dumping of trapped electrons into the atmosphere. An acceleration machanism must be involved. This mechanism must be one that can act with full strength very quickly (in a fraction of a second) and it should not change the flux of Mev electrons more than 10 percent when the simultaneous changes for trapped electrons of energy above 40 kev is a hundredfold, and of the precipitated electron flux above 40 kev is more than three orders of magnitude.

5. THEORETICAL MODELS

1. Introduction

In the last few years many new observational facts have been added to the picture of the aurora. Important new information has been obtained primarily from satellites, but also through detailed synoptic studies of individual auroral storms on the basis of allsky camera recordings taken during IGY.

Some important examples of such new information, some of which have been mentioned earlier in this review, are the following. Electrons are precipitated into the atmosphere over a very wide latitude range, with the maximum intensity in the auroral zone where some precipitation always takes place. The flux of trapped electrons of energy above 40 kev increases simultaneously with the precipitated flux. The increase is such that isotropy over the upper atmosphere is approached. The precipitated flux has never been found to be greater than the trapped flux.

The precipitation mechanism has been found to be energy dependent. During strong precipitation of electrons of energy greater than 40 kev the flux of Mev electrons was not significantly changed. During strong storms the poleward boundary, L_N, of the precipitation zone is very distinct and may be located at L-values as low as 4. During the quiet phase no aurora is seen on the poleward side of a certain L-value, probably identical with the L_N boundary. Following the break up, the aurora may extend rapidly polewards from the pre-break-up position as far as 10° of latitude or even more. Then it returns slowly toward the low L boundary again. It has also been definitely established that the energy content of the particles precipitated into the atmosphere in a period of the order of a minute may be orders of magnitude greater than the total energy content of the particles trapped in the corresponding field tube. Both virtually monoenergetic electrons and exponential and power law spectra have been observed in aurora. Evidence has accumulated that the local properties of the geomagnetic field in the upper atmosphere is not very important for the aurora. This indicates that drift motion around the earth of the particles which at some stage are precipitated into the atmosphere is not an important process. It has been proven that discharge acceleration within the ionosphere is not necessary for auroral production (O'Brien, 1962b).

Special chapters in this book are devoted to the description of some theoretical models of the relations between solar disturbances and geophysical effects, thereamong aurora. The reader is referred to them for details about the models.

The development of our experimental knowledge about the aurora and of our understanding of the physical processes in it is very rapid at present. It is, therefore, not a suitable stage for summing up and comparing experimental data with theoretical models. In this section only a very short summary of some main lines of proposed theories will be given in connection with a comparison of the models with some observational data which seem to be significant today.

2. Some Specifications of the Theoretical Problem

There is a general agreement that auroras, as well as magnetic storms, are caused by plasma streams which are emitted from disturbance centers on the sun. The problem of the interaction between the solar plasma and the geomagnetic field is one of great complexity, which has not as yet been solved in quantitative detail in a rigorous way. Simplified models have been used and the broad picture obtained differs very much depending on the theoretical approach.

Observations by Mariner II (Snyder and Neugebauer, 1963) and other space vehicles have shown that the interplanetary space usually has a number density, N, of charged particles of the order 10 cm^{-3}, the equivalent temperature, T, obtained from the velocity dispersion of the plasma, for instance, is typically a few times 10^5 degrees Kelvin, there exists a magnetic field, B, of

the order of a few gamma, mostly directed about 45° from the sun-earth line in the equatorial plane (see e.g. Ness, 1964). This means that the mean free path for Coulomb collision is a few astronomical units (see e.g. Parker, 1962, Kellogg, 1962, and Alfvén and Fälthammar 1963). In the plasma beams from disturbance centers on the sun somewhat higher values (but less than one order of magnitude higher) of N, B and T have been observed. A plasma of the mentioned characteristics is a "low density plasma" when the system sun-earth is considered (cf. e.g. Alfvén and Fälthammar, 1963). For such a plasma the ordinary fluid theory cannot be applied, as the statistically defined parameters have no meaning. Especially, the electric conductivity is not defined and the hypothesis that the magnetic field lines are "frozen" into the plasma may possibly not be applicable. Electric fields may exist along the geomagnetic field lines (Persson, 1963, Alfvén and Fälthammar, 1963). No macroscopic theory for the interaction of a low density plasma with the geomagnetic field seems to have been developed.

The plasma contained in the magnetosphere is probably also a low-density plasma, at least during disturbed conditions according to Alfvén and Fälthammar (1963) and Alfvén et al. (1964).

Although the theoretical basis for fluid-dynamic models of the interaction between the solar plasma and the geomagnetic field, which have been proposed, thus must be considered as weak at the present time, some of the characteristics of these models agree well with observations. They all require that the geomagnetic field shall be enclosed in a finite region around the earth, the so-called magnetosphere. A discontinuity in the magnetic field has been observed by Explorers XII, XIV and XVIII (Cahill and Amazeen, 1963; Freeman et al., 1963; Ness, 1964) at distances of about 10 earth radii on the side facing the sun, where it is expected to be according to the fluid-theory models.

The discussion below will be limited to a comparison of some observations with results of two fundamentally different types of theoretical approach, namely the fluid-dynamic (macroscopic) one, leading to a closed magnetosphere, and a microscopic model in which the plasma penetrates into the geomagnetic field to some extent.

3. Closed Magnetosphere Models

Chapman and Ferraro (1930, 1931, 1932, 1933) first discussed a model containing a confinement of the geomagnetic field lines in a finite volume around the earth. They considered a neutral unmagnetized plasma beam approaching the earth with a velocity of about 1000 km/sec and applied the boundary condition that the magnetic pressure is equal to the dynamic pressure of the plasma. Their model did not contain any details about the generation of aurora. The basic concept treated by Chapman and Ferraro has in recent years been further developed. Accurate calculations of the shape of the boundary of the magnetosphere have been made, the most recent and accurate one being that of Mead and Beard (1964). Extensive qualitative models of the geophysical effects caused by the solar plasma have been worked out on the basis of the Chapman-Ferraro model. The most comprehensive one is that of Axford and Hines (1961). In this model the acceleration of the particles is due to the plasma in the interface between magnetosphere and solar beam being convected into the interior of the magnetosphere, during which process it is adiabatically compressed. The theory is described in detail in Chapter

The closed magnetosphere models are characterized by a distinct boundary between the magnetosphere and the interplanetary medium. No model contains any details about how particles can enter the magnetosphere. For stable flow no particles can pass the boundary, except possibly at the neutral points. As the energy of the particles precipitated into the atmosphere with all probability must originate in the solar beam, one has made hypothesis about how the energy transport takes place over the boundary. Magnetohydrodynamic waves have been proposed. Axford and Hines assumed that some type of viscous interaction takes place at the boundary of the magnetosphere. Other types of instabilities have also been invoked (cf. e.g. Gold, 1962). It seems to be common to all of the proposed ways of energy transport over the magnetospheric boundary that only a minor fraction of the energy content in the solar wind is transferred to the magnetospheric plasma.

The existing fluid theories all are based on the assumption that the magnetic field lines are

equipotential lines and are "frozen" into the plasma. Therefore, acceleration of particles inside the magnetosphere must in these models be due to other effects than electrostatic fields along the lines of force. Of known acceleration processes the Fermi and betatron mechanisms and possibly electromagnetic radiation in the VLF band may be of importance in the magnetosphere (see Kaufmann, 1963, for a review). All these mechanisms require a large number of acceleration steps, and therefore fairly long time, and they produce a wide energy spectrum due to statistical fluctuations in the process. It has also been proposed that electric fields perpendicular to the magnetic field lines may cause acceleration of electrons and ions along neutral lines, i.e. lines where the geomagnetic field is zero (see Kaufmann, 1963). The existence of neutral lines has been proposed and their properties discussed by Dungey (1958, 1961, 1963) and Akasofu and Chapman (1961).

Since the discovery of the radiation belts and up till recently it was fairly generally believed that the trapped radiation was the source of those particles which produce the aurora, as was mentioned in the previous section. The density of trapped radiation was then thought to be three or four orders of magnitude greater than now (cf. e.g. O'Brien, 1963b). It was considered possible that some of the slow acceleration mechanisms mentioned above might be responsible for the acceleration of the particles from their energy in the solar wind to that observed inside the magnetosphere, although no quantitative theories existed neither for the particle transport into the magnetosphere nor for the acceleration of the particles in the outer radiation belt. An important unsolved problem was and is still how the electrons, which are most important in aurora, are energized, since most of the mentioned acceleration mechanisms give most energy in the ions.

The precipitation of the primary aurora particles into the atmosphere was thought to be produced by more or less transient instabilities of various kinds. A number of such were proposed by Akasofu and Chapman (1961), Chamberlain (1961, 1963), Kern (1962) and others. Other studies of possible auroral effects associated with adiabatically invariant motions of trapped charged particles, some of which are scattered into the atmosphere, were those of Chamberlain et al. (1960), Kern and Vestine (1961) and others.

The recent observations mentioned in the introduction to this section have completely changed the picture in regard to the importance of the trapped radiation as source for the aurora.

The fact that precipitated energies have been found sometimes to be several orders of magnitude greater than the total particle energy in the corresponding magnetic field tube (see previous section) shows that dumping without acceleration cannot be the important process for precipitation of electrons into the atmosphere, at least on some occasions. The observations of O'Brien (1964) that the flux of trapped particles always increases when precipitation takes place and is never less than the precipitated flux demonstrates clearly that the trapped radiation is not the source of the precipitated ones but is rather produced by the same acceleration mechanism that accelerates the precipitated electrons.

The observation of energy dependence of the precipitation mechanism (O'Brien, 1964) demonstrates that the precipitation is not due to a lowering of the mirror point by some geomagnetic disturbance, since such a lowering would affect the whole energy spectrum, contrary to what has been observed.

The acceleration mechanism responsible for the production of trapped as well as precipitated particles according to this mentioned picture is unknown. An electrostatic voltage of the order of 10 kilovolt along the magnetic field lines was mentioned as a possible source of acceleration by O'Brien (1964). That electrostatic field acceleration is important in aurora is supported by the observation by McIlwain (1960) of monoenergetic electrons of 6 kev energy in strong aurora. In the closed magnetosphere models that have been presented electrostatic fields along magnetic field lines cannot exist. The mechanism must therefore be an unknown one.

In the described "splash-catcher" model of O'Brien (1962b, 1964) the precipitated electrons are "fresh," i.e. they have existed with the energy they have at precipitation only for a very short time. This means that drift motion around the earth of the source of auroral primaries is not important, which is in agreement with the earlier

mentioned independence of the isoauroral curves on the mirror height.

The recent observations described above have thus modified the early closed magnetospheric models considerably. Some of the observations are even difficult to accommodate in such models. This is true for the very high energy fluxes of precipitated electrons which have been observed. While, in the average, only of the order of one percent of the solar wind energy has to be converted into kinetic energy of precipitated electrons (O'Brien and Taylor, 1964) an appreciable fraction of the solar wind energy has to be given off in electron precipitation during strong magnetic storms. This is difficult to associate with a closed magnetosphere, where energy is transported over the boundary by second order effects.

Another important difficulty with models of the closed magnetosphere type which have been proposed hitherto, is that the solar plasma is supposed to be unmagnetized, whereas observations by a number of space vehicles have shown that the interplanetary plasmas are magnetized. Alfvén (1964) has pointed out that the difference between the two cases with unmagnetized and magnetized solar plasma is more than a question of mathematical method. As the magnetic flux passing through a certain mass of gas must be fairly constant during the motion, a plasma with an initial magnetization may be brought into a stronger field if it is compressed. Thus a plasma with any value of the initial magnetization may be brought into a strong magnetic field. If the initial magnetization is zero this is not the case. The assumption $B=0$ leads therefore to conclusions which are fundamentally different from the assumption $B\neq 0$ even if B is very near zero.

The entire surface of the closed magnetosphere maps into one neutral point in each hemisphere. These are not in the auroral zones and there are no obvious reasons for the precipitation of particles taking place preferably in the auroral zones. Some complicated mechanism, like the one devised by Axford and Hines (1960), is needed to get the aurora in the proper regions of the earth.

The topology of the magnetospheric field lines is very complicated in some regions of the closed models. Aurora shows a fairly high degree of order on the earths surface with arcs often being aligned along L-curves (see e.g., Akasofu, 1963; Akasofu and Chapman, 1962 and Hultqvist, (1962). This corresponds to high degree of order also in the equatorial plane with the processes taking place at about constant distance from the earth, if the field is axisymmetric. If such an auroral arc is projected to the equatorial plane along the field lines in the closed magnetospheric model, the equatorial cross section of which is shown in Fig. 5.1, curves are found which seem to have no relation to simple physical processes. They differ significantly from particle drift surfaces, for instance (Hones, 1964).

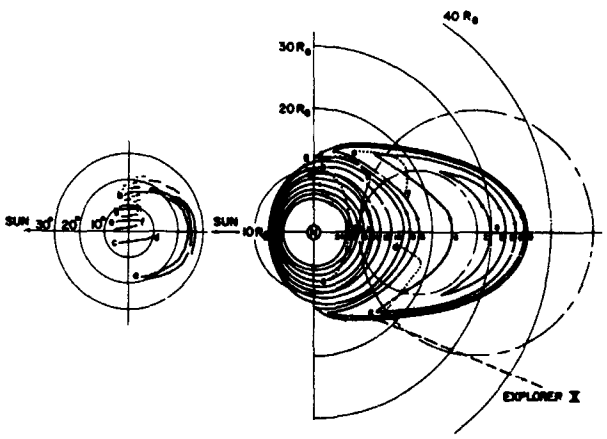

FIGURE 5.1.—Projections of auroral arcs along the geomagnetic field lines to the equatorial plane in a closed magnetosphere model. The letters a-h in the two figures indicate corresponding points in the earth's atmosphere and in the geomagnetic equatorial plane (Courtesy, Dr. E. W. Hones, Jr.).

4. Model with the Solar Plasma Penetrating into the Geomagnetic Field

Alfvén (1939, 1940, 1950, 1955; Alfvén and Fälthammar, 1963; Alfvén et al., 1964) has pointed out that a low-density magnetized plasma can penetrate into the geomagnetic field through the action of the electric field that is associated with a moving magnetic field. The depth of penetration is determined by the electric and magnetic fields and the temperature in the incoming plasma and not by the dynamic pressure as in hydromagnetic models. The penetration is stopped at a forbidden region, from which electrons and protons may be accelerated down into the atmosphere by an electric field. The acceleration field is thought to be due to charge separation,

which takes place during the invasion of the geomagnetic field. The particles from the forbidden zone moving along the field lines reach the auroral latitudes, if the properties of the plasma are in agreement with space vehicle observations. The particles may be accelerated to energies of tens or hundreds of kev.

In the first model of Alfvén it was assumed that no space charges are collected around the earth, but that immediate discharging takes place along the magnetic lines of force as soon as space charges start to build up. Karlsson (1963) has investigated the case of maximal space charge accumulation. He assumed that no discharging at all takes place along the field lines. In that way he found the general picture derived by Alfvén is preserved when space charges are taken into account. The forbidden zone is, however, smaller and more nearly circular than in the case studied by Alfvén. The general picture is thus not influenced very much by the amount of space charge accumulation.

There seems to be no basic difficulties in incorporating the above mentioned large fluxes of precipitated particles, observed by Winckler et al. (1962) and others, in the Alfvén model. This mechanism may well be active in the presence of simultaneous dumping of trapped particles due to disturbances of the geomagnetic field. For the mechanism to meet the requirements that O'Brien (1962b) has derived from the Injun 1 data, it is necessary that a rapid diffusion of particles scattered into trapped orbits takes place from the forbidden zone into the inner part of the radiation belt. If the quantitative requirements can be met is not known to this author.

Together with other large-scale charge-separation mechanisms, Alfvén's has the difficulty that electrons and protons are expected to be precipitated in two distinctly separated areas over the earth. Spectral observations from the ground as well as satellite observations of particle precipitation (Evans et al., 1964) show that electrons and protons often are precipitated simultaneously in the same auroral form.

Electrostatic acceleration of electrons and protons into the atmosphere is an inherent feature of Alfvén's model. The observations of O'Brien (1962b, 1964) thus fit well into his model in this respect. On the other hand it does not contain the observed discontinuity in the geomagnetic field at about 10 earth radii from the center of the earth, which have been observed by means of Explorers XII, XIV, and XVIII. Alfvén's model was made with the magnetic field of the solar plasma parallel to the earth's magnetic field in the equatorial plane. This direction was originally chosen in order to have the model fit observed diurnal variations in auroral occurrence. Dungey (1961, 1963) has discussed the case with the magnetic field of the solar plasma being antiparallel to the geomagnetic field in the equatorial plane. In that case neutral points or lines occur. The plasma does not penetrate further than to the neutral line and is precipitated from there along the field lines into the atmosphere. Recent laboratory experiments with magnetized plasma beams moving towards and interacting with a dipole magnetic field (Alfvén et al., 1963) have verified that there is a fundamental difference between the cases with parallel and antiparallel magnetic fields in the equator plane.

The observed discontinuity in the magnetic field may thus be due to Dungey's mechanism. Magnetic field measurements on space vehicles seem, however, to indicate that the interplanetary magnetic field lines mostly form only a small angle with the geomagnetic equatorial plane and the component parallel or antiparallel to the geomagnetic field lines is generally small and variable in magnitude and sign (Ness, 1964). In spite of this the discontinuity in the field seems always to have been observed by Explorer XVIII, at least on the side of the earth facing the sun. This does not seem to fit Dungey's model.

It is probable that within the near future space vehicles will provide experimental information that will make it possible to determine which of the two above-mentioned types of approach is relevant to nature—if any.

The theories discussed concern the large scale configuration of the auroral precipitation pattern. For the breakup of aurora and the extremely complicated phenomena that then occur on a global scale (see p. 49) no comprehensive theoretical models exist. The theories for this certainly will have to be sought in the realm of plasma instabilities, a field where the theoretical understanding of many basic phenomena still is poor.

ACKNOWLEDGEMENT

I am grateful to many colleagues at Goddard Space Flight Center for having read the manuscript, or part of it, and proposed improvements.

AURORA AND THE LOWER IONOSPHERE IN RELATION TO SATELLITE OBSERVATIONS OF PARTICLE PRECIPITATION*

BENGT HULTQVIST†

The direct observations of electron precipitation by means of rockets and satellites is reviewed. Upon comparison of the observed energy fluxes with those expected on the basis of optical measurements of aurora, the agreement is found to be good. It is demonstrated that the satellite observations make understandable the observed variable degree of correlation between visual aurora and auroral absorption of radio waves. The precipitated electrons contribute significantly to the night time ionosphere not only in the auroral zone but also over the polar caps and in sub-auroral latitudes. It does not seem impossible that the observed precipitation of electrons is the main source of nighttime ionization in the lower ionosphere. The airglow is briefly discussed in relation to observed particle precipitation. Finally, the recent demonstrations of the insufficiency of the Van Allen belt as a source for the precipitated electrons is briefly reviewed.

INTRODUCTION

The first rocket investigations of particles precipitated into the atmosphere were made by the Iowa group in the early 1950's. In IGY and thereafter a few more direct rocket measurements of high energy particles in auroral altitudes have been reported. Although of extreme value as exploratory studies, these few rocket measurements suffer from the weakness of being very limited in space and time. Some data about the rate of precipitation of electrons having energies greater than about 25 kev have been obtained from balloon observations of X-rays, but it is only in the last two years that systematic satellite measurements of precipitated particles, primarily by the two Injun satellites (O'Brien, 1962, a, b, 1964) and Alouette (McDiarmid, et al., 1963) have provided statistical data, on the basis of which some rough estimates of the average influence on the ionosphere can be made. In addition to precipitated electrons Injun 3 also measured the emission rate below the satellite of 3914Å and 5577Å photons along the magnetic field line upon which the satellite was located. The measurements have recently given very valuable information about detailed relations between electron precipitation and photon emission rate (O'Brien and Taylor, 1964).

One primary purpose of this review is to summarize some of the knowledge about relations between particle influx into the atmosphere and the resulting aurora and ionospheric effects. It should be said, however, that most reports on satellite observations published hitherto concern particles of fairly high energies (greater than 40 kev for electrons). For particles in the lowest energy range (i.e., from a fraction of 1 kev for electrons and some tens of kev for protons) the available experimental results are still scanty. What is going to be said about the influence of observed precipitation on the ionosphere above 100 km will therefore be most preliminary.

OBSERVATIONS OF PRECIPITATED ELECTRONS

The early rocket measurements (e.g., Davis et al., 1960; McIlwain, 1960) as well as the satellite results (e.g., O'Brien, 1962a, 1964) have verified the conclusions of Omholt (1957, 1959), based on spectroscopic observations of aurora, that the protons play a very minor role in the excitation of most aurorae and in producing ionization in the

lower ionosphere. Therefore only electrons will be discussed in this review.

The first somewhat detailed satellite studies of particles that were definitely precipitated into the atmosphere were made by means of Injun 1 (O'Brien, 1962a, b). O'Brien and others working with satellite data define precipitated particles as those particles which would mirror at or below 100 km altitude (if the atmosphere had not been present).

(a) Latitudinal Distribution and Other Spatial Characteristics

The recent simultaneous measurements on Injun 3 (O'Brien and Taylor, 1964) of flux of precipitated electrons and of auroral light emission below the satellite have shown th... above aurorae there are electron fluxes several orders of magnitude larger than outside the aurora. (Fig. 1).

Fairly extensive statistical data on the spatial characteristics of precipitated electrons have recently been published by O'Brien (1962a, b, 1964) and McDiarmid et al. (1963). Figure 2 shows the scatter diagram of the Injun 3 observations of precipitated electrons of energy above 40 kev for the range of the invariant latitude Λ (defined by $\Lambda = \cos^{-1}(1/\sqrt{L})$ and at the most a few degrees different from geomagnetic latitude in the latitude range of interest here) between 45 and 76 degrees. As can be seen from the figure, the precipitated flux of electrons of $E \gtrsim 40$ kev has a broad maximum of about 10^5 electrons/cm² sec ster for Λ between 60 and 70 degrees. The flux is 2–3 orders of magnitude lower in subauroral latitudes. Figure 2 also shows that some 10 degrees inside the auroral zone the precipitation rate is down by 1–2 powers of ten.

Similar results have been found by McDiarmid et al. (1963) for electrons of energies above 40 kev and above 250 kev. Figure 3 shows their data presented in a manner different from that of O'Brien (1964). The histograms give, for two different ranges of magnetic activity, the percentage of passes in which the intensity of precipitated electrons with $E \lesssim 40$ kev was above $1.5 \cdot 10^4$ electrons/cm² sec ster (corresponding to 0.2 db absorption at about 30 Mc/s). The flux of $1.5 \cdot 10^4$/cm² sec ster was one-half of the maximum

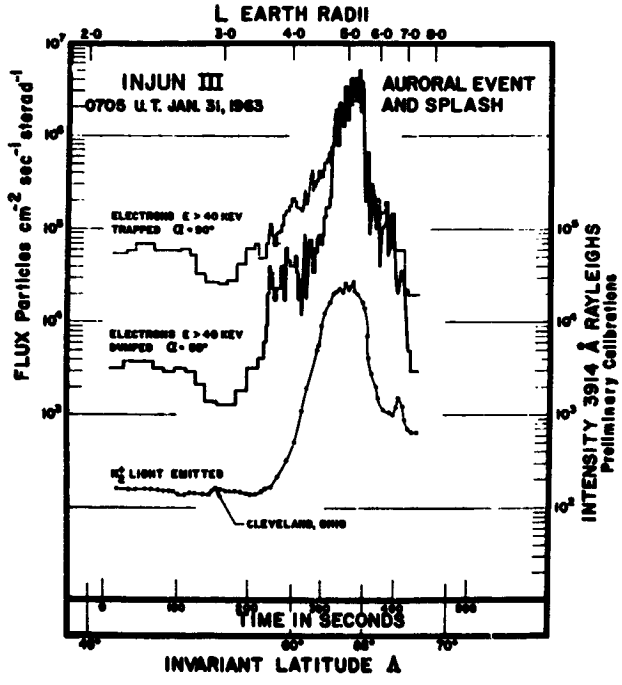

FIGURE 1.—Data from a northbound pass of Injun 3 over North America, which shows simultaneous detection of an aurora, of the precipitated electrons (with pitch angle 50°) partially responsible for causing it, and of trapped electrons. Note the approach to isotropy of the particle flux over the aurora. No attempt has been made to subtract the low-altitude contamination of the photometer signal, part of which was the detection of Cleveland, Ohio, and its surroundings. (After O'Brien and Taylor, 1964.)

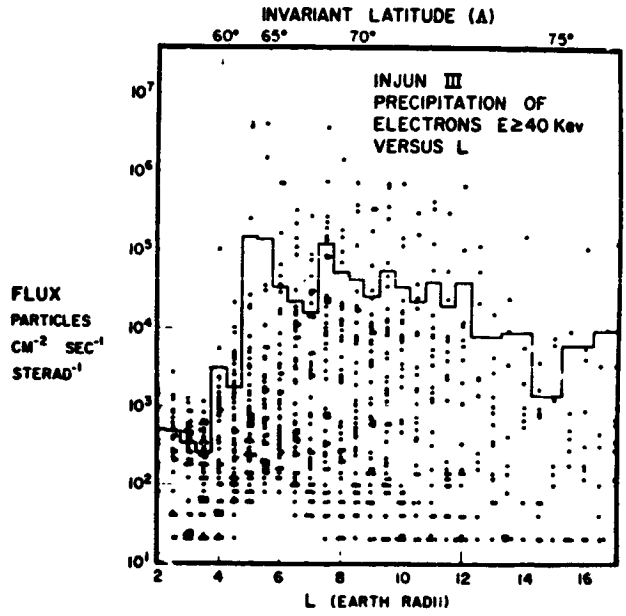

FIGURE 2.—Samples of precipitated fluxes over North America in January 1963. Each point is an 8-sec average of thirty two measurements made at half-integral values of L. The solid line gives the average flux. (After O'Brien, 1964.)

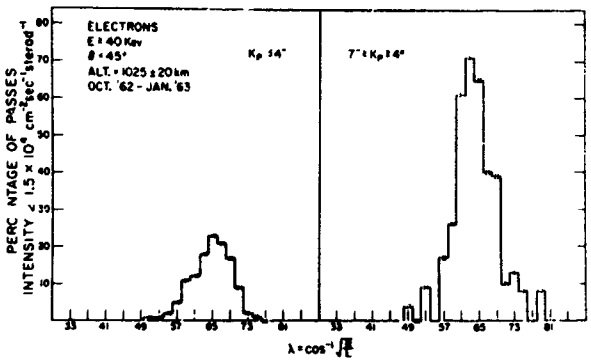

FIGURE 3.—Percentage of passes in which the intensity of precipitated electrons with energies greater than 40 kev was greater than 1.5×10^4cm^{-2} sec^{-1} sterad^{-1} corresponding to 0.2 db of 30 Mc/s absorption, plotted against invariant latitude. (After McDiarmid et al., 1963.)

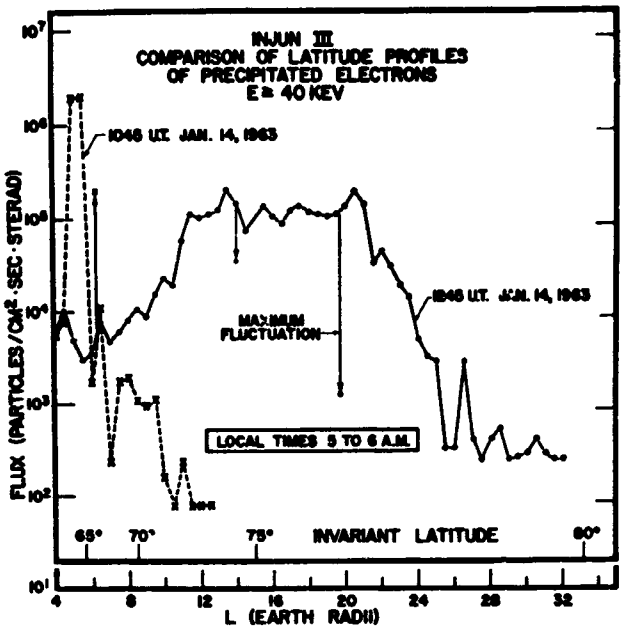

FIGURE 4.—Comparison of the latitude, or L profile, of precipitation for two successive passes at about the same local time. Arrows illustrate range of fluctuation of intensities at given locations. (After O'Brien, 1964.)

average intensity for $K_p<4$ and 1/20 for $K_p>4$. Figure 3 shows that during quiet geomagnetic conditions the precipitated intensity was g[illegible] than half the average value during some 2[illegible] percent of the passes through $\Lambda=65°$, while for moderately disturbed conditions—there were no strong storms represented in the data—the intensity exceeded 1/20 of the average value in about 72 percent of the passes over that latitude.

Simultaneous observations on two satellites indicate that at least sometimes the area of precipitation has a fairly limited longitudinal extent (O'Brien and Laughlin, 1962). On the other hand the precipitated flux seems on occasions to be uniform over as much as 80 degrees of longitude, i.e., over more than 4000 km (O'Brien, 1964).

The latitudinal extent of the precipitation can be very restricted (e.g., over a range of $L\backsim1$ earth radius) or very extensive (over an L interval >20 earth radii). This is illustrated in Figure 4.

The flux of precipitated electrons has its maximum close to the poleward boundary of the region of trapped electrons, as observed on the same satellite (McDiarmid et al., 1963; O'Brien, 1964).

Electron precipitation occurs simultaneously in magnetically conjugate areas at least sometimes, according to balloon observations of X-rays (Brown et al., 1963). This is in accordance with observations of aurora (cf. e.g. DeWitt, 1962).

A 100 fold change in the flux over two km has often been observed by Injun 3 which is in agreement with results of rocket measurements in aurora by Davis et al. (1960). They found the electron flux being concentrated in the visible auroral forms whereas protons were found over a much larger volume than that occupied by the aurora.

The statistical latitude profile of the intensity of dumped electrons with $E\gtrsim40$ kev has been found by O'Brien and Taylor (1964) to have its maximum at a few degrees lower latitude than the frequency of occurrence of visual aurora as observed on the same satellite. Sometimes the visual emission has been found to extend to higher latitudes than the precipitation of electrons with energy greater than 40 kev, indicating electrons of $E<40$ kev are being precipitated up to higher latitudes than the higher energy ones. The lower latitude limit of the aurora coincides with the lower latitude limit of appreciable precipitation (O'Brien, 1964; O'Brien and Taylor, 1964).

Precipitation was found all the time in the auroral zone by Injun 3 (O'Brien, 1964). It can be seen in Figure 2 that at $L=6$ there was never observed any flux lower than about 80 electrons (cm^2 sec ster)$^{-1}$.

The corresponding continuous photon emission in the auroral zone is evident from Figure 5. The

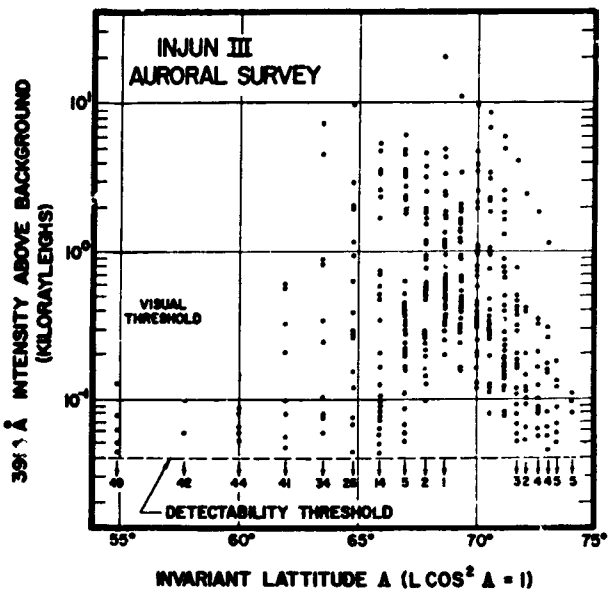

FIGURE 5.—Intensity of 3914Å auroral light average over 4 sec at half-integral values of L in about fifty passes of Injun 3 early in 1963. (After O'Brien and Taylor, 1964.)

minimum emission rate is, however, below visual threshold even in the auroral zone.

Figures 2 and 5 also give a good impression about the enormous variability of precipitation and photon emission at all latitudes, but especially near the auroral zone. At $L=6$ there are values of about $6 \cdot 10^6$ electrons/cm^2 sec ster shown in the figure. This is some 10^5 times the minimum value observed there.

(b) Time Characteristics of Precipitation

It is not possible in satellite measurements to differ between space variations and time variations short compared to the period of revolution. Balloon observations show, however, that time variations as rapid as of periods of a tenth of a second can occur in the electron flux (Winckler et al., 1962).

No systematic variation in the intensity of electron precipitation over periods as long as a day could be found by O'Brien (1964) from the Injun 1 and 3 measurements in contrast with the case for trapped electrons. Sharp et al. (1964) observed a higher nighttime than daytime precipitation flux of electrons in the energy range 0.08–24 kev—as well as of protons—during the 5 days life time of an oriented polar-orbiting satellite. They also found the energy distribution of the electrons to be harder on the dayside than on the nightside of the earth (Johnson et al., 1964). The Iowa group has recently reported the existence of a diurnal variation in the precipitated flux of electrons of energy above 40 kev at high latitudes. The maximum in the diurnal variation curve was reported to be on the dayside of the earth (Frank et al., 1964). It is not clear if the difference in the results found by various observers is due to the diurnal variation being different for different energy ranges or if it is due to some of the results being not statistically significant because of the enormous variability of the precipitation phenomenon.

(c) Pitch Angle Distribution

Figure 1 shows that over the aurora, where the precipitation is intense, the directional flux of precipitated electrons becomes equal to the flux of trapped electrons, which also is increased over the aurora. Figure 1 illustrates a general rule that has been found by O'Brien (1962a, b, 1964), namely that for electrons of $E \geq 40$ kev the pitch angle distribution approaches isotropy in the regions of intense precipitation. An isotropic pitch angle distribution in regions of strong precipitation has also been observed by Krasovskii et al. (1962) at an energy of about 10 kev. No cases have been found in which the directional flux of precipitated electrons was higher than the corresponding value for trapped electrons. The mentioned observations were made fairly close to the earth's atmosphere.

The tendency to isotropy seems to indicate that the acceleration of the electrons—if it is directed along the field lines—takes place far away from the atmosphere. This, as well as the mentioned observations of precipitation of electrons from above 1000 km in aurorae, suggest that the role of the ionosphere in the production of the energetic electrons is not important.

O'Brien (1964) found a flux upwards along the field lines, which was some 10 percent of the precipitated electron flux. He interpreted these observations as backscattering of electrons from the atmosphere.

(d) K_p—Dependence of Precipitation

The K_p dependence of the precipitation of electrons of energy above 40 kev is illustrated in

Figure 3. The average intensity was ten times higher near the auroral zone when K_p was above 4 than when it was below 4. The data material for the higher K_p range in Figure 3 does not contain data from any strong magnetic storm, so still higher values may be expected.

O'Brien (1964) found that the flux of precipitated electrons above 40 kev increased on the average by a factor of 5 for every step of K_p. A close correlation between precipitation intensity has also been observed for the 0.08–24 kev energy range by Sharp et al. (1964). O'Brien's results, obtained on Injun 3 in a low orbit, are shown in

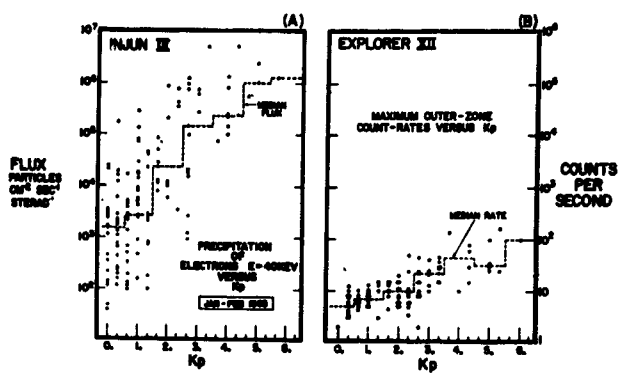

FIGURE 6.—Illustration that the flux of precipitated electrons (in A) varies more with K_p than does the omnidirectional flux (mainly of trapped electrons) in the equatorial plane (in B). Each point shows the maximum respective flux encountered on an outer-zone pass. (After O'Brien, 1964.)

Figure 6 together with the dependence of the omnidirectional flux above 40 kev as observed in the equatorial plane far from the earth by Explorer 12 (Freeman, 1963). As can be seen, the K_p dependence is very much larger close to the earth (at one end of the field line). If one assumes that both increases are due to a common acceleration mechanism it follows that it acts preferentially parallel to the geomagnetic field lines (O'Brien, 1964).

The change of omnidirectional flux above 40 kev with K_p, shown in Figure 6b, is opposite to what has mostly been observed for electrons of $E \gtrsim 2$ Mev (Arnoldy et al., 1960; Hoffman et al., 1962).

The dependence of the poleward boundary of precipitation on magnetic activity has been studied by Maehlum and O'Brien (1963). They used data for trapped electrons, but since O'Brien (1964) has shown that the precipitation has its maximum close to the poleward boundary of the trapped electrons, their results may be interpreted in terms of possible extension of precipitated electrons.

Maehlum and O'Brien (1963) found that during magnetic storms there was a very sharp boundary of the region where trapped electrons of energy above 40 kev could be observed. For this boundary, measured in L, they used the symbol L_n. It can be seen as a function of the K_p index during one geomagnetic storm in Figure 7. When K_p

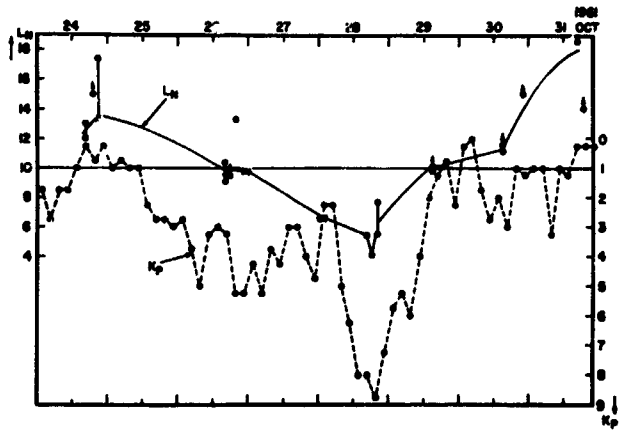

FIGURE 7.—Variation of the northern boundary of trapping with K_p during a geomagnetic storm, as observed by Injun I at a height of about 1000 km. (After Maehlum and O'Brien, 1963.)

reached its maximum value of 9, L_n had its minimum value of 4. Maehlum and O'Brien (1963) also found that the poleward boundary of strong radio wave absorption followed the L_n quite closely during the storm.

The effect of K_p on L_n is similar to the equatorward movement of the region of visual aurora during strong magnetic storms, which has been studied in the last few years in detail for some storms by Akasofu (1962, 1963a, b) and others.

(e) The Spectrum of Precipitated Electrons

Up to now only very rough measurements of the energy spectrum of the precipitated electrons have been reported. In most cases the proposed spectra have been obtained from two instruments with different energy characteristics. They are to be considered as rough equivalent spectra for

measurements made in a defined way. In addition, it has been found that the equivalent spectrum is highly variable both in space and time (cf. O'Brien et al., 1962). Nonetheless the available spectral data are of great interest at the present stage of knowledge in the field, and they even make it possible to draw some interesting conclusions about ionospheric effects of the precipitated electrons. These will be discussed in the following sections.

Most spectra that have been reported hitherto can be divided in two categories if they are expressed in an exponential form. On one hand, the e-folding value, b, in the spectrum of precipitated electrons, written in the form $\alpha \exp(-E/b)$, has been found often to be in the range 2–8 kev (McIlwain, 1960; Stilwell, 1963; Sharp et al., 1964a, b, c). This is a very steep spectrum but even steeper ones have been observed. McIlwain interpreted his rocket measurements in a strong aurora as indicating a monoenergetic flux of electrons with an energy of about 6 kev. Krasovskii et al. (1962) has observed steep spectra for precipitated electrons with a most common equivalent energy value of 14 kev.

The majority of the existing measurements have been made with Geiger tubes, for which the minimum detectable electron energy is about 40 kev. These measurements have mostly given e-folding values much higher than those mentioned above, namely, between 20 and 45 kev. (Davis et al., 1960; McDiarmid et al., 1960; O'Brien et al., 1962; Mann et al., 1963; O'Brien and Taylor, 1964). Mann et al (1963) found from measurements during only some 20 orbits that the values within this range were grouped in two classes, 25 ± 5 kev and 42 ± 3 kev.

The balloon measurements of X-rays at 30–35 km altitude also, in general, give inferred spectra of incident electrons of a fairly flat type, corresponding to e-folding energies in the range 20–45 kev (cf. e.g., Anderson and Enemark, 1960), although power law spectra often are found to fit the observations somewhat better than exponential spectra.

Recently the first direct measurements of precipitated electrons below 1 kev energy have been reported (Sharp et al., 1963; Evans et al., 1964). They showed that there is generally not very much energy flux below 1 kev. In some passages through the auroral zone Sharp et al. (1964c) found the integral fluxes above 0.18 and 10 kev to correspond to equivalent exponential spectra with e-folding values between 2 and 5 kev. On other occasions they did not find any energy flux at all below 1.5 kev. That there is not very much energy flux below 1 kev is also evident from observations of the luminosity distribution with height of aurorae. O'Brien and Taylor (1964) give an example of measurement results obtained on board Injun 3, according to which less than 0.1 percent of the auroral light originated above the satellite, that was at 250 km altitude. From this they conclude that the number of 10 ev electrons in the precipitated flux was no larger than the number of 10 kev electrons. It therefore seems probable that the spectrum, in general, does not increase very fast below 1 kev, which means that it is not of the power law type at these low energies.

Sharp et al. (1964c) found a significantly harder spectrum on the dayside than on the nightside. This observation agrees with multifrequency riometer measurements of auroral absorption by Lerfald et al. (1964), according to which the absorbing ionization is located lower down in the atmosphere in the day than in the night.

Of special interest are the statistical data on electron precipitation published recently. As mentioned earlier the precipitation is most intense near the auroral zone. O'Brien (1964) found an average flux of about 4.10^5 electrons/cm^2 sec in the precipitation cone at an invariant latitude of 65°. Injun 1 had a CdS detector, measuring electrons of energy above about 1 kev (O'Brien, 1962b). O'Brien and Taylor (1964) state that the flux of 4.10^5 electrons/cm^2 sec of energy greater than 40 kev was associated with an energy flux of 4 ergs/cm^2 sec for electrons of $E \gtrsim 1$ kev. These data should be considered as accurate to a factor of about three. Using these two values an equivalent electron spectrum in the range 1–40 kev can be deduced. It is found to be

$$n(E) = 7.8 \cdot 10^7 e^{-E/5.7} \text{ electrons/cm}^2 \text{ sec kev.}$$

For the energy values 40 and 250 kev similar average fluxes have been obtained from the Alouette measurements reported by McDiarmid et al. (1963). While the flux above 40 kev had its maximum at an invariant latitude of 65°, the

flux above 250 kev was maximal at about 60 degrees. McDiarmid et al. (1963) did not present any details for the latitudinal variation of this latter in integral flux. By applying a rough correction factor of 0.1 for the latitude variation of the average flux above 250 kev from 60 to 65 degrees invariant latitude, the following approximate equivalent spectra for the energy range 40–250 kev can be derived for two ranges of magnetic activity in the auroral zone ($\Lambda = 65°$), if isotropy is assumed for the upper hemisphere

$K_p < 4$: $n(E) = 1.2 \cdot 10^4 e^{-E/41}$ electrons/cm^2 sec kev

$K_p > 4$: $n(E) = 2.4 \cdot 10^5 e^{-E/30}$ electrons/cm^2 sec kev

(cf. Hultqvist, 1964b). The applied latitude correction is probably too large as judged from a comparison of the latitude distribution of passes in which the intensity of precipitated electrons with energies greater than 250 kev was greater than $3.2 \cdot 10^3$/cm^2 sec ster (Figure 8 of McDiarmid et al., 1963) and the corresponding diagram for

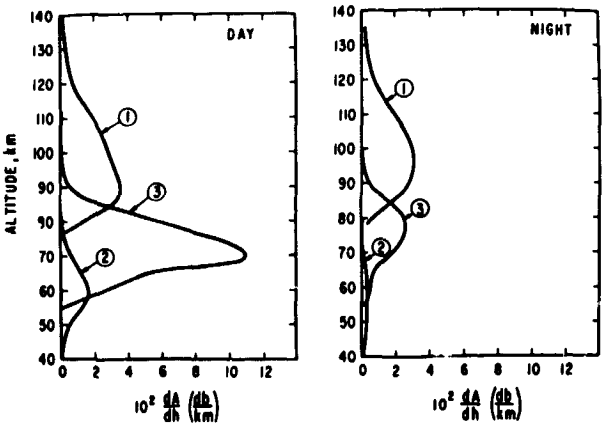

FIGURE 8.—(a) is for daytime and (b) for night. Curves in (a) and (b) show the height distribution of the absorption produced by the differential energy spectrum $N(E) = 5.10^8 e^{-E/5}$ kev electrons cm^{-2} sec^{-1} ster^{-1} kev^{-1}. The total absorption values corresponding to curves 1 amount to 1.04 db in the day and to 0.89 db at night. Curves 2 give the absorption due to the bremsstrahlung of the same electron spectrum. Total absorption in the day is 0.27 db and in the night 0.061 db. Curves 3, finally, represent the absorption distribution produced by the differential energy spectrum $N(E) = 7.10^4 e^{-E/41}$ kev electrons cm^{-2} sec^{-1} kev^{-1}, coming in along the field lines. Total daytime absorption under curves 3 is 1.9 db. The nighttime one is 0.52 db, if the height profiles of the ratio of negative ion to electron density used by Nicolet and Aikin (1960) and others are employed. 40 kev. The resulting spectra are thus too steep rather than too flat, and the absorption caused by electrons in the energy range 40–250 kev is probably larger than the values presented below.

As mentioned, the spectra of precipitated electrons are very variable. There is also an important latitude variation in the steepness, which increases with latitude (O'Brien et al. 1962; McDiarmid et al., 1963; O'Brien, 1964). On the other hand there seems to be no significant dependence of the spectrum on pitch angle or on the intensity of precipitation (O'Brien, 1964).

To obtain the equivalent spectra the averaging has been made over a large number of measured integral fluxes. With a variation of a factor of 10^5 the use of averages may be questioned. It is also questionable whether average integral fluxes are the best values to use when the interest is in the average electron density produced by the particle influx. The average electron density is then defined by the averaging process employed and this method of averaging is not identical with the averaging made in measuring the ionospheric absorption, for instance. It can, however, be shown that the average electron density produced by the precipitated electrons can be expressed in the average integral fluxes measured on the satellites. Since only two experimental integral flux values are available, one has to fit a two-parameter energy relation for the average flux to these experimental data (Hultqvist, 1964b), as has been done above.

QUANTITATIVE RELATIONS BETWEEN ELECTRON PRECIPITATION AND PHOTON EMISSION IN AURORA

Two direct measurements of the quantitative relation between precipitation and photon emission will be discussed here, namely those of McIlwain (1960) and O'Brien and Taylor (1964). It is of interest to compare their results with what is expected on theoretical grounds.

McIlwain did not use any filter, but measured the photon flux integrated over the transmission curve of the photomultiplier. If we assume that $\frac{1}{5}$ of the light was λ 3914Å, the measured photon flux corresponds to an emission rate of about 3 kilorayleigh at this wavelength. The fraction, $\frac{1}{5}$, is fairly arbitrary, but it seems reasonable (cf. e.g., Dalgarno, 1964) and is probably in error by

less than a factor of 2 and ½, respectively, for an ordinary auroral zone aurora. McIlwain's (1960) measured electron flux corresponds to an energy flux of 20 erg/cm² sec, if the spectrum obtained was extrapolated to $E=0$. Thus, the resulting electron energy flux required per unit of λ 3914Å emission rate is 7 ergs/cm² sec per *kR*.

O'Brien and Taylor (1964) reported an average λ 3914Å intensity of $2(+4/-1.5)$ *kR* at the maximum of the latitude distribution, i.e., in the auroral zone. As mentioned above, the electron measurements gave a corresponding average of the flux above 40 kev of $4\cdot10^5$ electrons/cm² sec and an energy flux for $E>1$ kev of about 4 ergs/cm² sec, which values they consider as accurate to a factor of about three. In order to get a value directly comparable with that of McIlwain one would have to extrapolate the energy spectrum from 1 kev down to $E=0$ and evaluate the total energy flux. Using the equivalent exponential spectrum, we find 5 ergs/cm² sec for $E>0$. Thus the Injun 3 results give 2.5 ergs/cm² sec per *kR*. Considering the uncertainties in measurements and the method of evaluation, this is a good agreement.

What energy flux per *kR* does one expect on the basis of existing knowledge about the emission processes? Omholt (1957, 1959), Chamberlain (1961), Rees (1963), and Dalgarno (1964), among others, have discussed this. It has been shown by Stewart (1956) that the ratio between the excitation cross section for the 3914Å band of N^+_2 and the total ionization cross section is constant, at least up to 200 ev energy, and has the value 0.02. Assuming that this value is true over the whole energy range of interest, one finds that 50 electron-ion pairs are produced for each 3914Å photon. Since the mean energy expended by fast electrons in nitrogen per electron-ion pair is 35 ev (at least for energies down to a few hundred ev; it is assumed that the figure is correct down to zero energy), we find that $50\times35=1750$ ev is dissipated per 3914Å photon. Since each photon has an energy of 3.2 ev the efficiency with which energy is converted into 3914Å radiation is $1.8\cdot10^{-3}$. When the initial energies of the fast electrons fall below perhaps 100 ev, these efficiencies must decrease sharply (Dalgarno and Griffing, 1958; Dalgarno, 1964). One *kR* of 3914Å photons corresponds to an energy influx of 2.8 ergs/cm² sec, if the efficiency figure $1.8\cdot10^{-3}$ is employed. Dalgarno (1964) has used the value $1\cdot10^{-3}$. With this conversion efficiency we find the energy flux requirement to be 5.1 ergs/cm^{-2} sec^{-1} per *kR*. The agreement between these values and the experimental ones of McIlwain (1960) and O'Brien and Taylor (1964) is better than expected, when the uncertainties in the analyses are taken into account.

The total efficiency of converting particle energy into photons of any energy is expected to be about 1 percent on theoretical basis (cf. Chamberlain, 1961). McIlwain found from his rocket measurements a value of only 0.2 percent while preliminary Injun 3 results point towards 1 percent (O'Brien and Taylor, 1964).

AURORAL ABSORPTION

Auroral absorption is in general defined on riometer records as all the absorption, generally irregularly varying, which is usually observed during magnetically disturbed conditions and which is not associated with either polar cap absorption (PCA), produced by high energy solar protons, or sudden cosmic noise absorption (SCNA), which is caused by solar ultraviolet radiation. The auroral absorption is thus defined as the remainder when one has excluded two well defined types of absorption. It is therefore not surprising that it recently has been found to contain a number of phenomena differing, for example, in the energy characteristics of the ionizing agent (Ansari, 1963). The name may, however, be motivated by the fact that there is a fairly good correlation between auroral absorption and the general level of magnetic disturbance (cf. e.g., the review by Hultqvist, 1963c).

It has long been known that some of the auroral absorption is located below the *E*-layer, i.e. in or below the *D*-layer. Such evidence arises, for instance, from ionosondes, which frequently are blacked out during magnetic storms. This shows that all the radio energy is absorbed between the earth's surface and the *E*-layer. It has not been clear, however, whether all the absorption, for sufficiency high frequency cosmic noise, takes place below the *E*-layer or whether there may be as much or even more absorption at *E*-layer heights. In fact, there are reasons to believe that the absorption produced by those electrons which

are the cause of the visible aurora should be located mainly up in the altitude range where the aurora occurs. Evidence has recently been presented against the hypothesis of Chapman and Little (1957) that the main part of the radiowave absorption is produced below 90 km by X-rays from the primary auroral electrons. The absorption due to primary electrons of an energy spectrum as measured in visual aurora by McIlwain (1960), is probably at least an order of magnitude greater than that due to the bremsstrahlung X-rays the electrons give rise to (Ansari, 1963; Hultqvist, 1963, 1964; Brown, 1964).

The height of the main part of the auroral absorption became an important parameter for the understanding of the electron reactions in the lower ionosphere when it was found that there is a much smaller influence of the sunlight on the absorption value than was expected on the basis of existing models (cf. e.g., the review by Hultqvist, 1963c). A very small sunlight effect would be expected if all auroral absorption took place up in the height interval of the ordinary visible aurora. But such a height distribution would be in conflict with a large body of other experimental observations (cf. e.g., Hultqvist, 1963a, b, c). It would appear that the satellite measurements reported by Mann et al. (1963), McDiarmid et al. (1963), O'Brien (1964) and O'Brien and Taylor (1964) give a solution of this problem.

An important satellite observation in this respect is that of Mann et al. (1963) that there occurs frequently beside the soft type of spectrum of the precipitated electrons, observed in visible aurora by McIlwain (1960), a harder type with the e-folding energy between 25 and 45 kev. The averages of the extensive statistical satellite data of McDiarmid et al. (1963) and O'Brien (1962b, 1964) correspond to equivalent spectra given on page 11. Thus the e-folding energy is about McIlwain's value for the low energy range and is appreciably higher in the higher range.

Having these average spectra it is possible to calculate how much absorption is produced by the electrons below and above 40 kev energy. This has been done by Hultqvist (1964a, b). Figure 8 shows the height distribution of absorption per km due to the following spectra (Hultqvist, 1964a)

Curves No. 1: $5 \cdot 10^8 e^{-E/5}$ electrons/cm² sec ster kev corresponding to a very strong visual aurora of international brightness coefficient between III and IV;

Curves No. 2: Due to the bremsstrahlung X-rays produced by the electrons giving rise to curve No. 1;

Curves No. 3: $7 \cdot 10^4 e^{-E/41}$ electrons/cm² sec ster kev which was observed over the auroral zone by Mann et al. (1963).

It can be seen from Figure 8 that although curve No. 1 corresponds to a very strong aurora, the riometer absorption due to the hard electron spectrum (curve 3), which has its peak as low as 70 km altitude, is larger. The total absorption for daytime was found to be 0.9 db for the soft electron spectrum and 1.9 db for the hard one. Even if the uncertainty in the computed absolute absorption values is fairly high (cf. Hultqvist, 1964a) it is probably less than a factor of three for the relative values due to the various spectra.

The profiles shown in Figure 8 can, with proper absorption scale, be used for estimating the absorption caused by the average precipitation spectra observed by the Injun and Alouette satellites. The e-folding value in the range 1–40 kev was found to be 5.7 kev (see page 11). This is very close to McIlwain's (1960) value 5.0 kev. In fact, the spectrum $2.4 \cdot 10^8 e^{-E/5}$ electrons/cm² sec kev contains the same number of electrons above 40 kev as the average observed by Injun 3 ($4 \cdot 10^5$ electrons/cm² sec; O'Brien and Taylor, 1964). It corresponds to a total energy flux above 1 kev about twice as high as the average value (4 ergs/cm² sec) given by O'Brien and Taylor (1964). However, the corresponding energy flux per kilorayleigh is about 5 ergs/cm² sec which is equal to the average of the values found by McIlwain (1960) and O'Brien and Taylor (1964).

Using the equivalent spectrum $2.4 \cdot 10^8 e^{-E/5}$ electrons/cm² sec kev for the 1–40 key range and the $1.2 \cdot 10^4 e^{-E/41}$ electrons/cm² sec kev for 40–250 kev during low magnetic activity ($K_p < 4$), the electron density profiles 3 and 1 in Figure 9 are found. The total absorption produced by these two spectra are 0.09 db and 0.32 db, respectively.

For $K_p > 4$ the average fluxes of McDiarmid et al. (1963) above 40 and 250 kev correspond to the exponential spectrum $2.5 \cdot 10^6 e^{-E/30}$ electrons/cm² sec kev. For this spectrum only an upper limit of the electron density and absorption can be obtained with the use of Figure 8. Curve 2 in

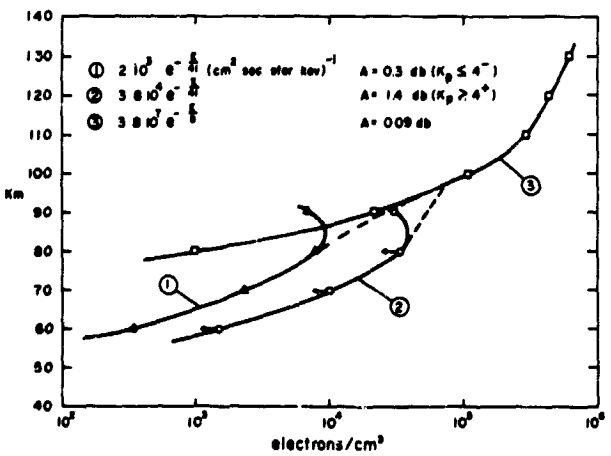

FIGURE 9.—Electron density profiles due to three different energy spectra of pecipitated electrons. The spectra as well as the total absorption, A, at 27.6 are given in the figure. Curve No. 2 gives an upper limit for the equilibrium electron density distribution produced by the spectrum $3.8 \cdot 10^4 \epsilon^{-E/30}$ (cm³ sec ster kev)$^{-1}$. A lower limit for this spectrum is curve No. 1.

Figure 9 shows this upper limit for the electron density. The corresponding upper limit of the total absorption is 1.4 db. Lower limits for the average electron density distribution and absorption are the values given for $K_p < 4$, i.e., curve 1 in Figure 9 and the corresponding absorption value of 0.32 db. The total riometer absorption due to the average electron spectrum in the energy range 40–250 kev is thus found to be about 1 db during the moderately disturbed conditions for which the observations are representative.
