Two assumptions were made in the computations described above, which both tend to increase the relative importance of the absorption caused by precipitated electrons in the range 1–40 kev. One is that the equivalent average spectrum for the energy range 40-250 kev is probably less steep than the spectra used in the calculations. The other is that the equilibrium relation between electron density and the ionization rate was used. The computed absorption is therefore certainly overestimated. Since the effective recombination coefficient decreases from 60 km upwards the overestimation will be most important at greater heights. It does not seem probable that the error in the average absorption per unit height in the lowermost part due to unequilibrium would exceed a factor of two, since the rate of variation of the electron content, as seen on riometer records, mostly is slow compared with the recombination time in that part of the ionosphere. It is thus probable that the relative contribution of the absorption caused by the low energy electrons (corresponding to curve no. 3 in Figure 9) is smaller than shown by the figures given above.

Since the average absorption values produced by "soft" and "hard" electrons differ by an order of magnitude at least in the day, it seems possible to draw some conclusions on their basis.

Most of what is called auroral absorption seems to take place below 90 km. Hence the reason for the observed very small influence of sunlight on the intensity of the absorption is *not* that the absorption is located mostly above 90 km altitude, (where, according to virtually all models that have been proposed in the last few years, the density of negative ions is negligible in both day and night). One apparent interpretation of this observation is that the negative ions in fact are negligible, even in the night, down to about 60 km (as proposed by Hultqvist, 1962, 1963a, b). In any case it seems that the electron chemistry in the lowest ionosphere is quite different from what has hitherto been believed.

The virtual absence of sunlight influence on auroral absorption taking place mainly in the range 60–90 km thus leads to the conclusion that photo detachment is not important in that height interval. If this is true, the problem cannot be solved by assuming that the detachment of electrons from negative ions, in the height range mentioned, requires ultraviolet radiation, as proposed and discussed by Eriksen et al. (1960) and Reid and Leinbach (1962), and Reid (1961).

The result that the auroral absorption is produced mainly by electrons of energy above 40 kev, while the visible aurora is caused by lower energy electrons (cf. e.g., McIlwain, 1960) makes the fairly poor observed correlation between visible aurora and absorption understandable. By combining low-energy and high-energy electron spectra in various proportions, one may expect to see visible aurora practically without absorption, strong absorption without visible aurora, and all combinations in between. This is what has been found in the detailed study by Ansari (1963). There is a different local time dependence of the occurrence frequency of the low and high energy parts of the precipitated electron spectra. The auroral absorption has a pronounced maximum

in the auroral zone in the morning hours, whereas the visual aurora has its maximum in the middle of the night. So there seems to be some mechanism that accelerates the electrons on the average to higher energies over the morning side of the auroral zone.

The quantitative estimations of average absorption values presented above refer to the auroral zone. As has been pointed out earlier there is a tendency for the electron spectrum to grow steeper with increasing latitude and the conclusions drawn may not be true far inside the auroral zone. On the other hand the conclusion that auroral absorption is located mainly below 90 km is probably valid at subauroral latitudes. This is indicated also by the observed good correlation between bremsstrahlung X-rays and visual aurora at these latitudes (cf. e.g., the review by Winckler, 1962).

The deductions in this section are based on average fluxes and average spectra derived from widely varying, measured electron fluxes at two energies each, only. Conclusions should certainly be drawn from them with great care (cf. also page 12), but it seems that the order of magnitude results presented above should be fairly significant.

The height distribution of auroral absorption is quite similar to what has recently been found by means of multifrequency riometer measurements by Lerfald et al. (1964). The multifrequency absorption measurements can, however, provide height information only in the interval 35–75 km. A possible contribution from ionization up in the visible aurora in the presence of absorption also at lower altitudes cannot be measured by that technique, whereas the satellite measurements, reviewed above, clearly indicate that, on the average, most absorption is produced 90 km altitude.

The total absorption values obtained from the Injun and Alouette measurements are in quite reasonable accordance with the average absorption during the five most disturbed and five most quiet days per month, as observed over several years at College (geomagnetic latitude 64.5°) by Basler (1963). For the disturbed days he found a daily average of about 1 db in the summer and between 1 and 2 db in winter and at equinoxes—as compared to about 1 db given above for $K_p>4$. For the quiet days the daily average at College was about 0.3 db (to be compared to the value 0.3 db for $K_p<4$ above).

Figure 3 shows the fraction of passages for which the absorption would be estimated to be greater than about 0.2 db for high and low magnetic activity.

THE LOWER IONOSPHERE AT NIGHT

A number of hypothesis of corpuscular ionization of the ionosphere have been advanced to explain the existence of appreciable electron densities in the night and especially during the polar night (see Antonova and Ivanov-Kholodny, 1961). Mariani (1964) has invoked a corpuscular flux with a peak value of about 0.1 erg/cm² sec of electrons with energies of the order of 1 kev at geomagnetic latitudes between 55 and 65° to explain the correlation of maximum electron density in the *F*-region at noon with solar activity. Willmore (1964) has found evidence for a particle energy influx of the order of 20 percent of the UV photon flux from Ariel I measurements of temperatures in the *F*-region. He also found good agreement between the geographical distribution of the temperature and of particle fluxes observed by Sputnik II. Harris and Priester (1962) assume a corpuscular heat source comparable in influence to the ultraviolet solar radiation, i.e. of the order of a few ergs/cm² sec, in their model for the solar cycle variation of the upper atmosphere.

The electron density in the *F*-layer should decrease by a factor of 100 or more in 5–10 hours after sunset, at that altitude, if no ionization took place. As the observed decrease in general is only a factor of 10–20 in the altitude interval 120–200 km and 3–10 in the *F*-region, the obvious conclusion is that some nighttime ionization process exists. The need for such a process is still stronger in order to explain the fairly high electron densities observed over the central polar caps during the long polar nights. For instance, at the Pole Station (latitude 90°*S*) at midnight in the midwinter the *foF* was about 5 Mc/s in the high-solar activity year 1958 and a little above 3 Mc/s three years later. The nighttime *foF* was not very much less than the noon value in the summer. It is true that *foF* is not a good measure of the electron production rate in the upper ionosphere, especially not in the polar night, as dynamical effects within the ionosphere are very important, but

even so it can definitely be said that an ionization source must exist.

Does the observed flux of precipitated electrons contain enough energy to produce the lower ionosphere at night? It is not possible to give any accurate answer to that question now, since no extensive measurements of energy fluxes below 1 erg/cm² sec have been made in the lowest part of the electron energy spectrum of interest. Another piece of missing information is the energy flux associated with low energy protons. Krasovskii et al. (1963) have observed appreciable fluxes of positive ions with energy above 200 ev at low and medium latitudes ($\leq 49°$). The ion flux was usually about 10^8/cm² sec ster and the energy flux associated with it was probably ≤ 0.1 erg/cm² sec. It is not known whether the ions were trapped or precipitated. Above 100 km altitude not only precipitated electrons, as defined in the introduction, but also trapped ones contribute to the production of free electrons, and their contribution may even exceed that of the precipitated electrons. No observational results are yet available from which the energy dissipation into the atmosphere by protons can be evaluated.

It is obvious from Figure 9 that the average electron flux produces quite sufficient electron densities down in the *E*-layer in the auroral zone. A numerical calculation using the same spectrum as for curve 3 in Figure 9, for 200 km altitude gives an electron production rate of 1400 electrons/cm³ sec, corresponding to an equilibrium electron density of from $4 \cdot 10^5$ to $2 \cdot 10^6$/cm³, depending on the recombination coefficient used (Mitra, 1959, Van Zandt et al., 1960, or Schmerling and Grant, 1961). Therefore the corpuscular energy source is probably sufficient for production of the nighttime *F*-layer too in the auroral zone.

The electron densities shown in Figure 9 are astonishingly high. They correspond to critical frequencies higher than are normally observed in the auroral zones. They were derived, however, without taking dynamic effects into account and there may very well be uncertainties of a factor of four or so due to the inaccuracy in the experimental average particle fluxes, as well as in the atmospheric parameters used in the derivation. To this comes that the equilibrium relation has been used in computing the electron density from the ionization rate. Too large values of electron density and absorption is probably obtained in that way. On the other hand the ionization produced by electrons mirroring above 100 km has not been taken into account which counteracts the effect of the use of the equilibrium relation between electron density and ionization rate.

It is not known to this author whether the observed enormous variability of the precipitation fits into the time behaviour of the nighttime ionosphere.

What can be said about the ionosphere over the central polar cap in respect of observed particle energy dissipation? The average flux of precipitated electrons above 40 kev energy was found to be 10–100 times smaller than in the auroral zone at 76° invariant latitude by Injun 3 (O'Brien, 1964) and 100–1000 times smaller by Alouette (McDiarmid et al., 1963). Precipitation did not take place continuously well inside the auroral zones, but it varied in intensity from cosmic ray background to 10^5 electrons/cm² sec ster. Spectral information for the central polar caps is not available at the time or writing. The best that can be done to obtain an idea about the electron production rate over the polar caps from earlier presented results, seems to be to assume that the spectrum is about the same as used above for the auroral zone and to reduce the ionization rate in proportion to the difference between the two regions in counting rate found by Injun 3 and/or Alouette.

The corresponding energy flux for electrons of energy above 1 kev will thus be in the range 10^{-2} to 1 erg/cm² sec and the steady state electron densities 1/30 to 1/3 of those for curve no. 3 in Figure 9. For a 200 km electron density of 10^6 cm^{-3} in the auroral zone a corresponding electron density range of $3 \cdot 10^4 - 3 \cdot 10^5$ electrons/cm³ is obtained for the polar caps, neglecting all dynamical effects. The corresponding plasma frequency is between 1.6 and 4.9 Mc/s. These values should be compared with the *foF* value of about 3 Mc/s observed at the Pole Station during somewhat higher solar activities. At 100 km altitude the plasma frequency would be between half an Mc/s and one and a half Mc/s. Despite the roughness of this estimate it seems possible to state that the observed precipitation of electrons of energies above 1 kev must contribute significantly to the nighttime ionosphere over the polar caps and that one

cannot rule out the possibility that it is the main source.

At subauroral latitudes the average values found from the Injun 3 data (O'Brien, 1964) by making the same assumptions as for the polar caps are the following:

energy flux: $10^{-2}-10^{-1}$ erg/cm² sec,

equilibrium electron density at 200 km: $3\cdot10^{4}-10^{5}$ electrons/cm³

at 120 km: $1.5\cdot10^{4}-4.5\cdot10^{4}$ electrons/cm³

corresponding plasma frequency at 200 km: 1.6−2.8 Mc/s

at 120 km: 1.1−1.9 Mc/s.

Also in this case it seems possible to draw the same conclusion as for the polar caps: the observed precipitation of electrons of energy above 1 kev is certainly of major importance for the nighttime lower ionosphere in subauroral latitudes and it does not seem possible at the present time to exclude the possibility that it is the main source.

A problem with the precipitated-electron source of ionization is that it it is highly discontinuous in space and time. It is not known to this author if the time constants of the ionospheric processes can explain that much slower variations are observed in *foF*, for instance.

If the electron precipitation observed by the Injun and Alouette satellites is the main source of nighttime ionization, one expects a maximum for the average nighttime electron density in the auroral zone. It seems not to be clear if such a maximum exists or not. The situation is complicated by the frequent strong disturbances there, which tend to hide an average effect.

The average absorption at riometer frequencies corresponding to the given electron densities for polar cap and subauroral latitudes is below the lower measurable limit.

The electron density produced in and below the *D*-layer by the average precipitation fluxes described above is orders of magnitude greater than that due to the ordinary cosmic radiation (see e.g. Mohler, 1960) in the auroral zone and is probably of the same order of magnitude or is even larger than that due to cosmic rays in subauroral latitudes, if the height profile of the ratio of negative ion to electron densities of Nicolet and Aikin (1960) and others is valid.

The average energy flux of precipitated electrons observed by Injun 3 and Alouette meets the requirements of Mariani (1964) but is somewhat smaller than that deduced by Willmore and orders of magnitude smaller than that hypothesized by Antonova and Ivanov-Kholodny (1961) and Harris and Priester (1962).

AIRGLOW

The following questions about airglow in connection with particle precipitation are of great interest.

(1) What limits can be put on the particle energy flux in low and medium latitudes on the basis of airglow intensities?

(2) Is it possible that the observed precipitated electrons of energy above 1 kev are responsible for part of, or all airglow?

The second question has been answered with no by O'Brien (1962b) on the basis of energy considerations. The average zenith intensity of 5577Å at midlatitudes is about 250 rayleighs (Hunten et al., 1956) which requires a precipitation rate of the order of 1 erg/cm² sec. The precipitation rate observed at midlatitudes is equivalent to orders of magnitude smaller than this.

The first question has been discussed by e.g. Ivanov-Kholodny (1962), Galperin (1962), and Galgarno (1964). The N^{+}_{2} bands are produced by impact excitation. According to Roach (see Dalgarno, 1964) 60R of 3914Å emission would not occur undetected. This puts an upper limit of about 0.3 erg/cm² sec on the possible electron precipitation rate. Galperin (1962) has claimed that the observable limit can sometimes be put much lower and the corresponding limit of the energy flux has been given as $2\cdot10^{-2}$ erg/cm² sec by Dalgarno (1964).

The energy fluxes derived above from the satellite measurements reported by McDiarmid et al. (1963) and O'Brien (1964) amount to $10^{-2}-10^{-1}$ erg/cm² sec in subauroral latitudes. From this it seems that the limit given by Roach is a safe one, whereas the observed energy flux sometimes may exceed the limit given by Galperin (1962).

RELATION OF PRECIPITATED ELECTRONS TO THE OUTER RADIATION BELT

The idea about the relations between the electrons that are precipitated into the atmosphere and the trapped electrons in the radiation belts, which was prevailing one or two years ago, was roughly that the precipitated particles were dumped from the large storage of energetic trapped particles in the magnetosphere through the influence of disturbing effects caused by the solar plasma, as, for example, the magnetic disturbances. The number of trapped particles was thought to be sufficiently large to allow the precipitation rates observed to occur with only weak and perhaps independent processes of injection and acceleration required to replenish the particles in the radiation belt, the occurrence of which is necessary to be assumed in any case for understanding the existence of the trapped radiation.

This picture has been completely changed recently through the investigations by O'Brien (1962b, 1964) of the measuring results of Injun 1 and Injun 3 and also through a number of balloon studies of X-ray fluxes in the lower atmosphere (Winckler et al., 1962, Anderson, 1964).

O'Brien (1962b) estimated the lifetime of the trapped electrons in the outer radiation belt, assuming that the source was stopped but the loss mechanisms operated at the same rate as observed by Injun 1. He found that the outer zone beyond $L \sim 2$ would drain empty of electrons in a few hours. Similar average lifetimes have also been evaluated from X-ray measurements (see e.g., Winckler et al., 1962 and Anderson, 1964). Sometimes precipitation rates several orders of magnitude above the average (more than 1000 ergs/cm^2 sec) have been observed (Krasovskii et al., 1961, O'Brien and Laughlin, 1962, and Winckler et al., 1962). Thus Winckler et al. (1962) recorded an electron burst reaching 10^{11} electrons/cm^2 sec, a flux which would have used up the total energy of trapped particles in the field tube in half a second, but yet it persisted for about 100 seconds. Some efficient acceleration mechanism, which can reach full efficiency in a fraction of a second, seems required.

O'Brien (1964) has also shown that the flux of trapped radiation increases when precipitation takes place instead of diminishing, which would be expected if the trapped particles were simply dumped into the atmosphere. An acceleration mechanism seems to influence precipitated and trapped particles simultaneously.

Finally, O'Brien (1964) has demonstrated that the precipitation is highly energy dependent. There was no significant precipitation or change in the flux of trapped electrons of energy greater than 1.5 Mev observed in the middle of a strong burst of electrons of energy above 40 kev. This demonstrates that the precipitation could not be due simply to a lowering of the mirror point through a decrease in the geomagnetic field, since such a mechanism would be active over the whole spectrum.

Taken together, this new evidence clearly demonstrates that the precipitated electrons which produce aurora and ionospheric ionization are not produced by dumping trapped electrons into the atmosphere. An acceleration mechanism must be involved. This mechanism must be one that can act with full strength very quickly (in a fraction of a second) and it should not change the flux of Mev electrons more than 10 percent, when the simultaneous changes for trapped electrons of energy above 40 kev is a hundred-fold and for the precipitated electrons above 40 kev is more than three orders of magnitude. O'Brien (1964) mentioned acceleration in an electrostatic field directed along the magnetic field lines and involving a voltage drop of the order of 10 kilovolts as one possible mechanism from the precipitation-observation point of view.

The development in the last one or two years has thus in some respects brought the model of the auroral mechanism back into the situation that existed before the discovery of the Van Allen belts. These belts have been demonstrated to be probably an effect of the same acceleration mechanism that precipitates particles into the atmosphere and produces aurora, but not the source of these particles. The "leaky bucket" model has been replaced by the "splash catcher" model, in the vocabulary of O'Brien.

ACKNOWLEDGEMENT

I am grateful to L. R. Davis, D. S. Evans, and R. A. Hoffman for reading the manuscript and proposing improvements.

N64-

ON THE HEIGHT OF AURORAL ABSORPTION, II

BENGT HULTQVIST†

Statistical data from Alouette and Injun 3 giving the average precipitation rate of electrons in the auroral zone as a function of energy, are analyzed with regard to the average radio wave absorption produced by ionization by electrons in the energy ranges 1—40 kev and 40—250 kev. From the satellite data, it is found that the higher energy range for the primary electrons is the dominating one in producing absoprtion at riometer frequencies. From this it follows that the majority of auroral absorption takes place below 90 km altitude in the auroral zone.

INTRODUCTION

The observation of a very small difference between ionospheric absorption of cosmic radio noise associated with aurora and magnetic disturbances, so called auroral absorption, before and after sunrise and sunset as compared to what was expected from existing models has made the height of auroral absorption a parameter of great importance for the understanding of the electron reactions in the lowest ionosphere (cf. e.g. Hultqvist 1963 a, b, 1964). There would be fewer difficulties in obtaining consistency between different types of experimental results if the auroral absorption could be shown to take place mainly in the height interval where the light emissions are mostly produced, i.e. in the *E*-layer. Proposals have been offered that, in fact, this is what in general occurs (Brown and Barcus, 1963). Several kinds of observational data indicate, however, that most of the auroral absorption is caused by ionization well below the *E*-layer (cf. Hultqvist, 1962, 1963 b, 1964).

Recently more observations relevant to the height of auroral absorption have been obtained. Ansari (1963) has analysed more carefully than before the correlation between auroral type of absorption and visual aurora and has found that "auroral absorption" is not one well defined type of phenomenon but contains at least two absorption phenomena different with regard to the energy characteristics of the ionizing corpuscular radiation. While some radio wave absorption is well correlated with the intensity of visual aurora, especially in the early part of the night, he found that there is one type, occurring after local midnight, that is not correlated with the light intensity. This is the type of auroral absorption which is causing the morning peak of the diurnal variation of the absorption in the auroral zone. The low light emission per absorption unit indicates that the energy of the primary electrons is much higher than for the electrons that cause the visible aurora. The increased penetrability of the higher energy electrons produces the enhancements in ionization much deeper in the atmosphere.

New extensive multiple-frequency riometer measurements of auroral absorption (Little et al., 1963, Lerfald et al., 1964) have shown that some 60 percent of 112 studied cases had the maximum in the absorption-per-km of altitude for 20 Mc/s cosmic radio noise at an altitude higher than 72 km, while for some 10 percent of the cases the maximum absorption-per-km was located at or below 60 km altitude. The multi-frequency absorption technique provides height information in the altitude range 35–75 km. It cannot tell whether there is some significant amount of absorption taking place up in the *E*-layer in the presence of absorption also in the 35–75 km interval, for instance. But even so the fact that in some 40 percent of 112 auroral absorption cases studied the peak absorption-per-km was at or below 72 km taken together with the fact that bremsstrahlung x-rays are probably negligible in producing riometer absorption (Ansari 1963, Hultqvist 1963

c, 1964, Brown, 1964) is enough for demonstrating the importance of higher energy electrons penetrating well below the visible aurora. The above-mentioned new results were obtained from ground observations of cosmic noise absorption.

Measurements on satellites (Mann et al., 1963) of the primary particles which cause the absorption have shown that there sometimes exists an influx of electrons with a spectrum so flat that the absorption-per-km height-profile caused by them has its maximum at about 70 km (Hultqvist, 1964). The total absorption produced by these observed flat-spectrum-electrons is higher than that caused by the steep electron spectra of McIlwain (1960) type, observed in visible aurora, even for very strong aurorae. These direct observations of the primary particles thus showed that at least sometimes most of the auroral absorption is located below 90 km altitude. However, due to the short life time of the satellites from which the measurements were made (only a few days) no good statistical information about the occurrence frequency of the various types of primary electron spectra was obtained. It is the purpose of this note to point out that the measurements by means of Alouette (McDiarmid et al., 1963) and Injun 3 (O'Brien, 1964) of precipitation of electrons into the atmosphere make it possible to attain a rough idea about how important the electrons in the energy ranges 1–40 kev and 40–250 kev, respectively, are for producing the auroral absorption, and, therefore, to provide another piece of experimental information independent of the ground observation of cosmic noise absorption about the height distribution of the auroral absorption. This information, in principle, covers the whole height interval of interest, contrary to the multi-frequency riometer measurements.

SATELLITE OBSERVATIONS OF ELECTRON PRECIPITATION IN THE AURORAL ZONE

McDiarmid et al., (1963) have reported results of electron flux measurements on board the Alouette satellite during several hundred passes through the auroral zone at an altitude of about 1025 km in the period October 1962 through January 1963. The measurements of special interest here were made by means of two Geiger-Müller tubes having electron energy thresholds of 40 and 250 kev. McDiarmid et al., found that the electron spectrum becomes progressively softer and very variable above about 59° invariant latitude. The flux of electrons with energy greater than 40 kev precipitated into the atmosphere had its maximum at an invariant latitude of 65 to 67°. The data were analyzed for two different ranges of K_p, namely <4 and >4. The average flux of precipitated electrons at the maximum in the auroral zone was found to be 3.10^5 electrons/cm^{2}sec ster for the high K_p range and 10 times less for the low K_p range. The half value width of the latitude distribution was some 8 degrees for $K_p > 4$ and about 12 degrees for $K_p < 4$.

On the average, the peak intensity of precipitated electrons with energies greater than 250 kev occurred at an invariant latitude of 60° and was approximately $1.9 \cdot 10^3$ electrons/cm^{2}sec ster and $2.6 \cdot 10^3$ electrons/cm^2 sec ster for the low and high ranges of K_p, respectively. The latitude spread was found to be smaller than for 40 kev electrons.

Because no detailed latitude distribution of the flux of 250 kev electrons is given by McDiarmid et al., we will assume that the average fluxes at an invariant latitude of 65° is down by a factor of ten from the peak values mentioned above. This latitude correction is probably too large (i.e. the correction factor 0.1 is too small) as judged from a comparison of the latitude distribution of passes in which the intensity of precipitated electrons with energies greater than 250 kev was greater than $3.2 \cdot 10^3$/cm^{2}sec ster (Fig. 8 of McDiarmid et al., 1963) and the corresponding diagram for 40 kev. The resulting spectra are thus too steep rather than too flat. The absorption caused by electrons in the energy range 40–250 kev is therefore probably larger, rather than smaller, than the values presented below.

From the two integral flux values given above for each range of magnetic activity we can derive equivalent two-parameter spectra. For $K_p < 4$ an exponential equivalent differential spectrum is found to be $n(E) = 2.10^3 e^{-E/41}$ electrons/cm sec ster kev and for $K_p > 4$: $n(E) = 3.8 \cdot 10^4 e^{-E/30}$ electrons/cm^{2}sec ster kev.

An equivalent two-parameter average differential spectrum for the primary electrons in the energy range 1–40 kev can be obtained from the results of the Injun 3 measurements presented by (O'Brien, 1964).

The data were taken in early 1963 at altitudes between 237 and 2785 km. The inclination of the orbit of Injun 3 was 70.4° and the satellite thus passed over the central polar cap over northern Canada. O'Brien gives the average integral flux for precipitated electrons with $E \geq 40$ kev as 4.10^5 electrons/cm²sec in the auroral zone. This was obtained by means of a Geiger-Müller tube. A Cds-detector on Injun 1 gave the energy flux associated with electrons of energy greater than about one kev. The integral flux of 4.10^5 electrons/cm²sec corresponded to an energy flux of about 4 ergs/cm² sec. O'Brien and Taylor (1964) state that these data can be considered as accurate to a factor of about 3. Corresponding to these two average flux values is the average equivalent exponential spectrum $n(E) = 7.8 \cdot 10^7 e^{-E/5.7}$ electrons/cm²sec kev. This spectrum is fairly close to the spectrum ($\propto e^{-E/5}$) considered in some numerical detail by Hultqvist (1964). In fact $n(E) = 2.4 \cdot 10^8 e^{-E/5}$ electrons/cm²sec kev gives the same integral electron flux for $E \geq 40$ kev as $7.8 \cdot 10^7 e^{-E/5.7}$ electrons/cm²sec kev, but the corresponding energy flux for $E \geq 1$ kev is 9 ergs/cm² sec instead of 4. In fact the energy input rate per unit of light emission rate obtained with the value 9 ergs/cm²sec is 5 ergs/cm²sec per kR, which is midway between the corresponding values of McIlwain (1960) and O'Brien (1964) (cf. Hultqvist, 1964b).

RELATIONS BETWEEN AVERAGE INTEGRAL FLUXES MEASURED IN SATELLITES AND AVERAGE ABSORPTION VALUES

The radio-wave absorption for the riometer frequency 27.6 Mc/s in the auroral zone is given for the ordinary ray by the Appleton-Hartree expression as

$$A = 0.46 \int_0^\infty \frac{N_e \nu}{3.34 \cdot 10^{16} + \nu^2} dh \quad db,$$

where N_e is the electron density and ν the electron collision frequency. The temporal structure of the electron precipitation measured by Alouette and Injun 3 is unknown. However, if the equilibrium relation between N_e and the ionization rate, $q(h)$, is used for evaluation of electron density and absorption, overly large values will certainly be obtained. Since the effective recombination coefficient decreases from 60 to 100 km altitude the overestimation will be most important in the upper part of this height interval. The relative contribution to the absorption from the lowest part of the height interval mentioned will therefore be higher than what is found below in this note. It does not seem probable that the error in the average electron density in the lowermost part of the height range 60 to 100 km due to unequilibrium would exceed a factor of two, since the rate of variation of the electron density, as seen on riometer records, generally is slow compared with the recombination time in that part of the ionosphere. As such an inaccuracy does not invalidate the conclusions drawn in this note we thus write

$$N_e(h) = \{q(h)/\alpha_{eff}\}^{1/2} \quad \text{and}$$

$$\bar{A} = 0.46 \int_0^\infty \frac{\nu}{3.34 \cdot 10^{16} + \nu^2} \overline{\left\{\frac{q(h)}{\alpha_{eff}}\right\}^{1/2}} dh,$$

where the bars indicate average values for the time function in question.

The data obtained from the above-mentioned satellite measurements above the atmosphere are the following time-average values:

$$\int_{40}^\infty \overline{n(E)} dE = \overline{N(>40)}$$

electrons/cm²sec,

$$\int_{250}^\infty \overline{n(E)} dE = \overline{N(>250)}$$

electrons/cm²sec,

and

$$\int_1^\infty \overline{En(E)} dE = \overline{\phi(>1)} \quad \text{ergs/cm²sec.}$$

Here $\overline{N(>40)} = \frac{1}{m} \sum_{i=1}^{m} N_i(>40)$,

$$\overline{n(E)} = \frac{1}{m} \sum_{i=1}^{m} n_i(E) \quad \text{and}$$

$$\overline{En(E)} = \frac{E}{m} \sum_{i=1}^{m} n_i(E) = E\overline{n(E)}.$$

$N_i(>40)$ represents a single satellite measurement of the integral flux above 40 kev energy.

The average ionization rate at height h is given by

$$\overline{q(h)} = \frac{1}{Q}\frac{d}{dh}\int_0^\infty E\overline{n(E,h)}dE \qquad \text{electrons/cm}^3\text{sec},$$

even if the electron precipitation is not homogenous over a large area, due to the effect of the geomagnetic field. Q is the average amount of energy used in producing one electron-ion pair (35 ev in molecular nitrogen) and $n(E,h)$ is the omnidirectional differential flux of electrons of energy E at altitude h. For a given particle energy, E, and angular distribution outside the atmosphere, $n(E,h)$ can be written

$$n(E,h) = n(E)\cdot F(E,h)$$

where $n(E)$ is the omnidirectional differential flux outside the atmosphere and $F(E,h)$, which contains the information about the angular distribution outside the atmosphere, gives the attenuation in the atmosphere. Thus

$$\overline{q(h)} = \frac{1}{Q}\int_0^\infty En(E)\frac{dF(E,h)}{dh}dE$$

$$= \frac{1}{Q}\int_0^\infty E\overline{n(E)}\frac{dF(E,h)}{dh}dE,$$

where the last equality is true if $\frac{dF}{dh}$ is the same for all fluxes used in the averaging i.e. if the directional distribution of the electrons outside the atmosphere does not vary from one passage to another. This is, of course, not necessarily so, but there is some experimental support for angular distribution being identical, namely isotropic, at least in the cases of intense precipitation (O'Brien, 1964), i.e. in those measuring values that contribute most to the average. It was also pointed out by Hultqvist (1964 a) that the radio wave absorption produced by an $e^{-E/b}$ differential spectrum of electrons enetering the atmosphere vertically is smaller by less than 50 percent of its value than the absorption produced by an isotropic flux of identical energy distribution but of 2 π times greater omnidirectional flux value. The variation of the directional distribution of the precipitated electrons from one precipitation event to another does therefore probably not affect the average significantly, and it is neglected in the considerations below.

When the two energy ranges about which information was obtained from Injun 3 (1–40 kev) and Alouette (40–250 kev) are considered, it can be found by numerical computations that the contribution to $\bar{q}$ from particles outside the energy ranges is negligible.

Thus we can write, with the use of the mean value theorem for integrals, for the low energy range

$$\overline{q(h)}_{1-40} = \frac{1}{Q}\int_1^\infty E\overline{n(E)}\frac{aF(E,h)}{dh}dE$$

$$= \frac{1}{Q}\left\{\frac{dF(E,h)}{dh}\right\}_{E_1}\int_1^\infty E\overline{n(E)}dE$$

$$= \frac{1}{Q}\left\{\frac{dF(E,h)}{dh}\right\}_{E_1}\overline{\phi(>1)},$$

where E_1 is a value between 1 and ∞, and for the high energy range

$$\overline{q(h)}_{40-250} = \frac{1}{Q}\int_{40}^\infty E\overline{n(E)}\frac{dF(E,h)}{dh}dE$$

$$= \frac{1}{Q}\left\{E\frac{dF(E,h)}{dh}\right\}_{E_2}\cdot\overline{N(>40)}.$$

If we, for instance, adopt the approximate formula for $F(E,h)$ of Maeda (1963) and derive a two parameter average energy distribution from $\overline{N(>40)}$ and $\phi\ (>1)$ for the energy interval 1–40 kev and from $\overline{N(>40)}$ and $\overline{N(>250)}$ for the interval 40–250 kev, simple closed expressions can be derived for $\left\{\frac{dF(E,h)}{dh}\right\}_{E_1}$ and $\left\{E\frac{dF(E,h)}{dh}\right\}_{E_2}$.

If the differential energy distribution corresponding to the experimental average integral flux values are assumed to be exponential in both energy intervals the expressions are as follows:

$$\left\{\frac{dF(E,h)}{dh}\right\}_{E_1} = -2\pi\zeta(h)\frac{e^{1/b_1}}{b_1(1+b_1)}\int_1^\infty Ee^{-E/b_1}\frac{1}{\sigma(E)}Ei\left(-\frac{x}{\sigma(E)}\right)dE \qquad (4)$$

and

$$\left\{E\frac{dF(E,h)}{dh}\right\}_{E_1} = -2\pi\zeta(h)\frac{e^{40/b_2}}{b_2}\int_{40}^{\infty} Ee^{-E/b_2}\frac{1}{\sigma(E)}Ei\left(-\frac{x}{\sigma(E)}\right)dE \tag{5}$$

b_1 is the e-folding value in the energy interval 1–40 kev and b_2 in the range 40–250 kev. $1/\sigma\ (E) = 3.18\cdot10^6E^{-2.2}$ (Maeda, 1963) and $E_i\ (-x/\sigma)$ is the exponential integral defined by $-E_i(-y) = \int_y^\infty e^{-z}z^{-1}dz$. x is the atmospheric depth in g/cm², $\zeta(h)$ is the atmospheric density, and E is everywhere measured in kev.

We thus see that $\overline{q(h)}$ can be expressed in terms of the satellite-measured averages $\overline{\phi(>1)}$ and $\overline{N(>40)}$. But the average cosmic noise absorption is given in terms of $\overline{q^{\frac{1}{2}}}$ in (1) and not in terms of $\bar{q}$.

However,

$$(\overline{q^{\frac{1}{2}}})^2 = \left\{\frac{1}{n}\sum_{i=1}^{n}q_i^{1/2}\right\}^2 = \frac{1}{n^2}\left\{\sum_{i=1}^{n}q_i + \sum_i q_i^{1/2}\sum_{j\neq i}q_j^{1/2}\right\} = \frac{1}{n^{\frac{1}{2}}}\left\{n\bar{q} + (n-1)n\bar{q}^{\frac{1}{2}}\cdot\bar{q}^{\frac{1}{2}}\right\} = \frac{1}{n}\bar{q} + \left(1-\frac{1}{n}\right)(\bar{q}^{\frac{1}{2}})^2.$$

Thus

$$\overline{q^{1/2}} = (\bar{q})^{1/2}$$

if

$$\sum_{i\neq j} q_j^{1/2} = (n-1)\overline{q^{1/2}}.$$

Numerical calculations show that $\overline{q^{\frac{1}{2}}}$ and $(\bar{q})^{\frac{1}{2}}$ do not differ by as much as 50 percent even for a small number of terms and for ratios between the various q_i as high as 10^6.

We can therefore write with sufficient accuracy for the considerations below:

$$\overline{A_{1-40}} = \frac{0.46}{\overline{Q_{1/2}}}\left\{\overline{\phi(>1)}\right\}^{1/2}\int_0^\infty \frac{\nu\alpha_{\text{eff}}^{-1/2}}{3.34\cdot10^{16}+\nu^2}\left[\left\{\frac{dF(E,h)}{dh}\right\}_{E_1}\right]^{1/2}dh \tag{6}$$

$$\overline{A_{40-250}} = \frac{0.46}{\overline{Q^{1/2}}}\left\{N(>40)\right\}^{1/2}\int_0^\infty \frac{\nu\alpha_{\text{eff}}^{-1/2}}{3.34\cdot10^{16}+\nu^2}\left[\left\{E\frac{dF(E,h)}{dh}\right\}_{E_2}\right]^{1/2}dh \tag{7}$$

where

$$\left\{\frac{dF}{dh}\right\}_{E_1}$$

and

$$\left\{E\frac{dF}{dh}\right\}_{E_2}$$

may be obtained from (4) and (5), respectively. The average absorption is thus expressed in terms of the average integral fluxes measured by the satellites.

The integrands in (6) and (7) depend only on atmospheric properties and the average flux as function of energy and can therefore be evaluated from satellite-measured average spectra. If the average spectrum is defined only in two points, as is the case with the Injun 3 and Alouette results, an assumption has to be made about the shape of the spectrum between those points. Exponential spectra are used below. The main uncertainty in the results obtained is certainly due to the limited amount of available statistical data and the enormous variation that there is in it, while the uncertainty in the detailed shape of the spectrum between the measuring points probably introduces only minor uncertainties.

ELECTRON DENSITY PROFILES AND ABSORPTION DUE TO THE EQUIVALENT AVERAGE SPECTRA

The exponential electron energy spectrum for $K_p<4$ is exactly the same as the spectrum for which Hultqvist (1964) calculated the height profile. The equilibrium electron density curve No. 1 in Fig. 1 has been obtained from Hultqvist's

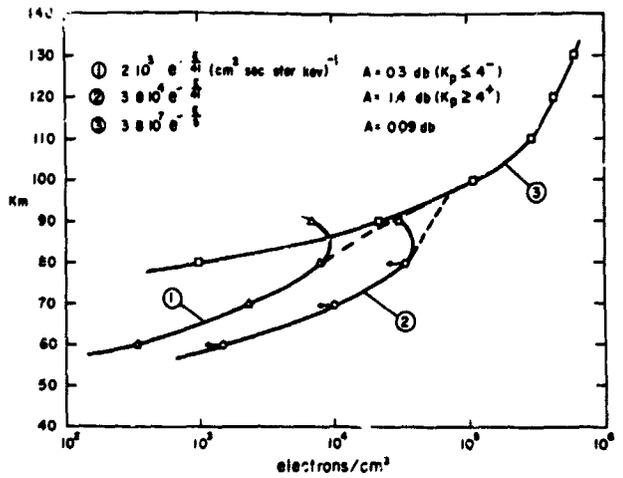

FIGURE 1.—Equilibrium electron density profiles due to three energy spectra of precipitated electrons. The spectra as well as the total absorption, A, at 27.6 Mc/s are given in the figure. Curve No. 2 gives an upper limit for the equilibrium electron density distribution produced by the spectrum $3.8 \cdot 10^4\ e^{-E/30}$ (cm² sec ster kev)$^{-1}$. A lower limit for this spectrum is curve No. 1.

(1964) results by multiplying by $\sqrt{2/70}$. Hultqvist's computations were made for vertically incident electrons of energy spectrum proportional to $\exp(-E/41)$. However, the absorption produced by $ce^{-E/41}$ electrons/cm²sec kev, entering the atmosphere vertically, is probably less than that caused by $ce^{-E/41}$ electrons/cm²sec ster kev, having isotropic directional distribution outside the atmosphere, by less than 50 percent of this higher value. The total absorption for a frequency of 27.6 Mc/s expected from the electron density curve No. 1 in Fig. 1 is 03.2 db.

An upper limit to the electron density profile and total absorption produced by an electron energy spectrum of $3.8 \cdot 10^4 e^{-E/30}$ is obtained from $3.8 \cdot 10^4 e^{E/41}$, which in turn can easily be found from the values computed by Hultqvist (1964). In this way curve No. 2 in Fig. 1 has been derived. The corresponding limiting total absorption for radio waves of frequency 27.6 Mc/s is 1.4 db. Probably the correct value for the spectrum with an e-fold value of 30 kev is close to 1 db. A lower limit for it is, of course, the value given above for $K_p < 4$ (0.32 db).

For the equivalent average spectrum for the range 1–40 kev, $2.4 \cdot 10^8 e^{-E/5}$ electrons/cm²sec kev, the numerical calculations of Hultqvist (1964) can be employed. The electron density profile No. 3 in Fig. 1 has been derived by means of them. The total absorption at 27.6 Mc/s due to this electron density profile is 0.09 db.

DISCUSSION

The increase of the pitch angle of an electron due to the magnetic forces when it passes along the field line down into the atmosphere has not been taken into account. As all measurements were made close to the earth's surface this neglection does certainly not introduce any large error. Its effect, if any, would be to increase the height of the ionization produced by the particle precipitation.

There are several simplifying assumptions and approximations made, which tend to make the deduced effect on the electrons in the energy range 40–250 kev too small relative to that of the 1–40 kev electrons. One is that Hultqvist's (1964a) numerical values for vertically penetrating electrons have been employed. As mentioned earlier, this may make the absorption too small by not more than 50 percent of the value for the case of isotropic electron angular distribution outside the atmosphere, and by still less of the value for the electrons in the loss cone. A second fact contributing to the computed absorption value for 40–250 kev electrons being too small is that the equivalent average spectrum in this energy interval is probably less steep than the spectra used in the numerical estimations. A third approximation working in the same direction is that the equilibrium relation between electron density and the ionization rate was used. This makes the computed absorption overestimated. Since the effective recombination coefficient decreases from 60 km upwards the overestimation will be most important at greater heights. It does not seem probable that the error in the average absorption per unit height in the lowermost part due to unequilibrium would exceed a factor of two, since the rate of variation of the electron content, as seen on riometer records, mostly is slow compared with the recombination time in that part of the ionosphere.

On the other hand there was an assumption made which tends to make the contribution by electrons in the 1–40 kev range too small compared to that of the 40–250 kev electrons. The average precipitated electron flux above 40 kev

energy was given by O'Brien as 4.10^5 electrons/cm²sec. It was assumed above that this omnidirectional flux was isotropic over the upper hemisphere just outisde that level where the energy loss of the electrons starts to be significant, i.e. at 200 km, say. This is probably not far from the truth, but the flux may have been limited to a somewhat smaller solid angle than 2π. Had this real angular distribution been known and taken into account the calculated absorption would have been somewhat greater.

Although only the order of magnitude of the absolute values of absorption seems to be significant, the ratio of contributions of the two energy intervals of precipitated electrons, discussed in this note, is probably uncertain by no more than a factor of three. A more accurate analysis than the one given above seems not worthwhile or possible on the basis of existing experimental data.

The electron density profiles in Fig. 1 as well as the total absorption values derived from them are those for the daytime. On the night side of the earth the electron densities may possibly be somewhat lower than those in Fig. 1 for altitudes less than 90 km due to negative ion production.

The values used as basis for the model spectra are average fluxes. The range of variation is, as mentioned, very large. O'Brien (1964) found that there was always some precipitation in the aurotal zone. The lowest value observed by him there was about $2 \cdot 10^{-4}$ of his average value quoted above. The maximum values shown in his paper were about 15 times greater than the average. To these minimum and maximum values of the ionization rate correspond extreme values of equilibrium electron densities 70 times smaller and 4 times greater than the average respectively. McDiarmid et al. (1963) showed similar variation ranges.

The use of exponential model spectra was motivated simply by the fact that numerical values were already available from Hultqvist (1964). It should be remembered that each of these spectra were obtained from only two pieces of experimental information and they are only very rough descriptions of spectra which are not known in detail. If an equivalent spectrum is to be used, as in this case, there seems to be at least as good reasons to use exponential ones as power law spectra. The observational indications of a fairly flat spectrum without any "infrared catastrophy" below a few kev (O'Brien, 1964, O'Brien and Taylor, 1964) support the use of exponential spectra in the low energy range.

The observations of both McDiarmid et al. (1963) and of O'Brien (1964) indicate a fairly strong latitude dependence of the spectral slope and the equivalent spectra used above should therefore be considered as representative only in the auroral zone.

The average total absorption values for 27.6 Mc/s given above for the various electron spectra:

(a) $n(E) = 3.8 \cdot 10^7 e^{-E/5}$ electrons/cm²sec ster kev $A = 0.090$ db

(b) $n(E) = 3.8 \cdot 10^4 e^{-E/30}$ electrons/cm²sec ster kev $(K_p > 4)$ $A < 1.4$ db

(c) $n(E) = 1.9 \cdot 10^3 e^{-E/41}$ electrons/cm²sec ster kev $(K_p < 4)$ $A = 0.32$ db,

indicate that the flat type of electron spectrum with e-fold values generally between 25–45 kev are the dominating one in producing auroral absorption in the average. The absorption due to these spectra takes place mainly between 60 and 90 km and not in the height interval where most visible auroae are located.

The range of variation of the 27.6 Mc/s absorption corresponding to the wide variations of electron fluxes reported by McDiarmid et al.(1963) and O'Brien (1964) is from the order of 0.01 db to 4 db, if smoothing due to time constants in the ionosphere is neglected, and is caused by the variation of the flux of the hard spectrum electrons. It should be remembered that there were no strong geomagnetic storms included in the material presented by McDiarmid et al. (1963).

The absorption values computed from the satellite measured electron fluxes for the two ranges of magnetic activity are in quite good accordance with the multifrequency riometer measurements mentioned in the introduction, as well as with the average absorption during the five most disturbed days and five most quiet days in each month, as observed over several years at College (geomagnetic latitude 64.5°) by Basler (1963). For the disturbed days he found a daily average of about 1 db in the summer and between 1 and 2 db in winter and at equinoxes. For the quiet days the daily average obtained from his figure 7 is about 0.3 db.

ON THE STRUCTURE OF A COLLISION FREE WAVE IN A PLASMA TRANSVERSE TO A MAGNETIC FIELD*

R. K. JAGGI AND A. P. STOKES

In this paper we have considered the problem of the structure of a strong collision free wave in a plasma perpendicular to its magnetic field. It is shown that conditions on the two sides of the wave are the same and are separated by a solitary pulse provided the kinetic energy of the motion at one end of the wave ($x=-\infty$, say) is less than the sum of magnetic and thermal energy of the plasma. If the kinetic energy is more than the sum of magnetic and thermal energy, no wave exists and the constant solution at $x=-\infty$ is the only solution of the equations describing the wave form.

1. INTRODUCTION

The subject of the structure of a strong collision free wave, in a plasma perpendicular to the magnetic field has been treated by Adlam and Alan[1], Burgers[2] and Hain, Lüst and Schlüter[3]. Hain, Lüst and Schlüter in particular have obtained solutions of the wave structure by solving the non-linear equations on a computer.

In this paper we have investigated mathematical properties of the equations which help us to guess the correct solution out of the many solutions obtained on a computer. As an illustrative example we shall consider a plasma with isotropic pressure. The generalization to the anisotropic case is quite straight forward. Burgers has made an extensive study of the wave structure when the plasma pressure is anisotropic and he arrives at the same general result that there is no change of state on the two sides of the wave, i.e., that no shock wave exists in a collisionless plasma perpendicular to the magnetic field.

The result of our paper is that a solitary wave only exists if the kinetic energy of motion, which produces the wave, is less than the sum of magnetic and thermal energy of the plasma; that no stationary wave exists if the kinetic energy of motion is more than the sum of magnetic and thermal energy of the plasma. In the latter case the constant solution at one end of the wave is the only solution of the differential equation (section 4).

*Goddard Space Flight Center Document X-640-64-34, February 1964.

2. EQUATIONS DESCRIBING THE WAVE FORM

Consider a stream of plasma at $x=-\infty$ with a constant velocity u along x-axis and a constant magnetic field B_1 along z-axis. The electrons and ions of the plasma will drift in the y-direction because of the magnetic field.

Our object is to obtain conditions at $x=+\infty$ and the form of the wave or waves which start from the given solution at $x=-\infty$. As a simplification we assume that the electrons and ions satisfy Maxwellian distribution function with variable number density, velocity components and the temperature. Therefore, if f_e, f_i denote the electron and ion distribution functions

$$f_e(x, v)=n_e(x)\left(\frac{m}{2\pi kT_e(x)}\right)^{3/2}\cdot$$

$$\exp\left\{-\frac{m}{2kT_e(x)}[(u-u_e(x))^2+(v-v_e(x))^2+w^2]\right\} \quad (1)$$

$$f_i(x, v)=n_i(x)\left(\frac{M}{2\pi kT_i(x)}\right)^{3/2}\cdot$$

$$\cdot\exp\left\{-\frac{M}{2kT_i(x)}[(u-u_i(x))^2+(v-v_i(x))^2+w^2]\right\} \quad (2)$$

In cartesian coordinates, assuming steady state, the Boltzmann equation can be written as

$$mu_e\frac{\partial f_i}{\partial x}-eE_x\frac{\partial f_e}{\partial u}-eE_y\frac{\partial f_e}{\partial v}-$$

$$-\frac{eB}{c}\left(v\frac{\partial f_e}{\partial u}-u\frac{\partial f_e}{\partial v}\right)=0 \quad (3)$$

for electrons, and

$$Mu\frac{\partial fi}{\partial x}+eE_x\frac{\partial fi}{\partial u}+eE_y\frac{\partial fi}{\partial v}+ +\frac{eB}{c}\left(v\frac{\partial fi}{\partial u}-u\frac{\partial fi}{\partial v}\right)=0 \quad (4)$$

for the ions. Multiplying by 1, u_e, v_e, u_e^2 and $u_e^2+v_e^2+w_e^2$ and generating moments of equation (3) we obtain

$$\frac{\partial}{\partial x}[n_e(x)u_e(x)]=0 \quad (5)$$

$$mn_eu_e\frac{du_e}{dx}+\frac{d}{dx}(n_ekT_e)+n_eeE_x+\frac{1}{c}n_eev_eB=0 \quad (6)$$

$$mn_eu_e\frac{dv_e}{dx}-n_eeE_y-\frac{1}{c}n_eeBu_e=0 \quad (7)$$

$$\frac{d}{dx}\left(u_e^2+\frac{3kT_e}{m}\right)+\frac{2eE_x}{m}+\frac{2eB}{mc}v_e=0 \quad (8)$$

$$\frac{d}{dx}u_e[mn_eu_e^2+mn_ev_e^2+5n_ekT_e]+ 2en_eu_eE_x-2en_ev_eE_y=0 \quad (9)$$

and similar equations for the ions. Let us call the similar ion equations as (5)′—(9)′. Maxwell's equations yield

$$E_y=\text{constant} \quad (10)$$

$$\frac{dE_x}{dx}=4\pi e(n_i-n_e) \quad (11)$$

$$\frac{dB}{dx}=-\frac{4\pi e}{c}(n_iv_i-n_ev_e) \quad (12)$$

To further simplify the problem, we will make the assumption that the space charge can be neglected. The characteristic length of space charge oscillations is of the order of the Debye length[4] $R_D=\left(\frac{kT}{4\pi ne^2}\right)^{1/2}$ while, as we shall see in this paper, that of magnetohydrodynamic oscillations is of the order of $c/w_p=c\sqrt{\frac{m}{4\pi Ne^2}}$. Thus assuming that the electron thermal velocity is well below the velocity of light, the space charge oscillations are of much lower scale than the oscillations we are interested in. With the assumption $E_x\simeq 0$ and $n_e=n_i=n$ (to a good approximation we then have $u_e=u_i=u$, say) equation (6), (6)′ and (8), (8)′ yield, respectively

$$\frac{d}{dx}[Mnu_i^2-n_ikT_i+nkTe]=-\frac{1}{8\pi}\frac{dB^2}{dx} \quad (13)$$

$$\frac{d}{dn}[Mu_i^2+3kTi+3kTe]=-\frac{1}{2\pi}\frac{B}{n}\frac{dB}{dn} \quad (14)$$

Equation (5) now gives

$$nu=n_1v_1 \quad (15)$$

where $\underset{x\to-\infty}{\text{Limit}}\, n(x)=n_1$ and $\underset{x\to-\infty}{\text{Limit}}\, u(x)=u_1$.

Equation (13) can be integrated and yields

$$Mnu^2+nkTi+nkTe+\frac{B^2}{8\pi}= Mn_1u_1^2+2nkT_1+\frac{B_1^2}{8\pi} \quad (16)$$

where $\underset{x\to-\infty}{\text{Limit}}\, B(x)=B_1$. Eliminating T_i+T_e from equations (16) and (14) we obtain

$$u\frac{d}{dx}\left[u\frac{dB}{dx}\right]+\frac{4\pi n_1e^2}{mc^2}u_1uB-\frac{4\pi n_1e^2}{mc^2}u_1^2B_1=0 \quad (17)$$

Dividing by $\sqrt{8\pi Mn_1u_1^2}$ and using the transformations

$$\frac{u}{u_1}=U,\ \frac{B}{\sqrt{8\pi n_1M}u_1^2}=H,$$

$$\frac{kT_{i,e}}{Mu_1^2}=\theta_{i,e},\ \beta_1^2=\frac{B_1^2}{8\pi n_1Mu_1^2} \quad (18)$$

we finally obtain the equations

$$H^2=\alpha-U-\frac{2\theta_1}{U^3} \quad (19)$$

and

$$U\frac{d}{dy}\left(U\frac{dH}{dy}\right)+UH-\beta_1=0 \quad (20)$$

where

$$\alpha=1+2\theta_1+\beta_1^2 \quad (21)$$

Equations (19), (20) satisfy the boundary conditions $H=\beta_1$, $U=1$ at $y=-\infty$.

3. A MATHEMATICAL DISCUSSION OF EQUATIONS (19), (20)

The pair $(U, H)=(1, \beta_1)$ is a constant solution of these equations. We shall study other constant solutions represented by (19), (20), but we first examine the stability of the solutions of (19), (20) in the neighborhood of $(1, \beta_1)$ and determine the nature of this critical point.

Let $U=1+U_1$, $H=\beta_1+H_1$. We then obtain from (19)

$$H_1=U_1\,F\,(H_1, U_1) \quad (22)$$

where

$$F(H_1, U_1)=\frac{2\theta_1(3+3U_1+U_1^2)-(1+U_1^3)}{(2\beta_1+H_1)(1+U_1)^3} \tag{23}$$

From (22) and (23) we obtain

$$H_1=b_1U_1+b_2U^2_1-b_3U_1^3+\cdots \tag{24}$$

where

$$b_1=F(0, 0)=\frac{6\theta_1-1}{2\beta_1} \tag{25}$$

$$b_2=F(0, 0)\frac{\partial F}{\partial H_1}(0, 0)+\frac{\partial F}{\partial U_1}(0, 0)$$

$$=-\frac{(6\theta_1-1)^2}{8\beta_1^3}-\frac{6\theta_1}{\beta_1} \tag{26}$$

etc.

Equations (20), (24) yield,

$$\frac{d^2U_1}{dy^2}+\gamma_1(U_1)\left(\frac{dU_1}{dy}\right)^2+KU_1+\gamma_2(U_1)=0 \tag{27}$$

where γ_1, γ_2 are analytic in U_1 near $U_1=0$, $\gamma_2(U_1)=0(U_1^2)$ and

$$K=1+\frac{\beta}{b_1}=\frac{1-2\beta_1^2-6\theta_1}{1-6\theta_1} \tag{28}$$

To determine the nature of the point $U=1$, we linearize equations (23), (27). The linearized form of equation (27) is

$$\frac{d^2U_1}{dy^2}+KU_1=0 \tag{29}$$

In all the discussion that follows we shall assume the flow velocity to be much higher than the thermal velocity of particles constituting the plasma, so that $6\theta_1<1$ or $1-6\theta_1>0$. The sign of k^1 is therefore determined by the expression $1-2\beta_1^2-6\theta_1$. In case I when $1-2\beta_1^2-6\theta_1>0$, k^1 is positive and therefore $U=1$ is a center in both (27) and (29) according to a known result of Lyapounov, see Malkin[5], pp 123–4, (as no odd powers of dU_1/dy occur). In case II when $1-2\beta_1^2-6\theta_1<0$, k^1 is negative; the point $U=1$ is a saddle point in both equations (27) and (29).

Let us now consider all the constant solutions represented by the equations (19), (20). According to equation (20) constant solutions satisfy the equation $HU=\beta_1$. This condition, together with equation (19) then gives the equation

$$f(U)\equiv U^4-U^3(1+2\theta_1+\beta_1^2)+\beta_1^2U+2\theta_1=0 \tag{30}$$

$f(U)$ may also be written as

$$f(U)=(U-1)[U^3-(\beta+2\theta_1)(U^2+U)-2\theta_1]$$
$$=(U-1)\,h(U) \tag{31}$$

From Descarte's rule of signs $h(U)$ cannot have more than one positive root. Also it is easy to see that it has a positive root. Let this positive root be denoted by U_o. Since $f(0)<0$, U_o will be less than or greater than 1 when $f'(1)>0$, $f'(1)<0$ respectively. We therefore again have two cases:

(I) $f'(1)=1-2\beta_1^2-6\theta_1>0$

and

(II) $1-2\beta_1^2-6\theta_1<0$.

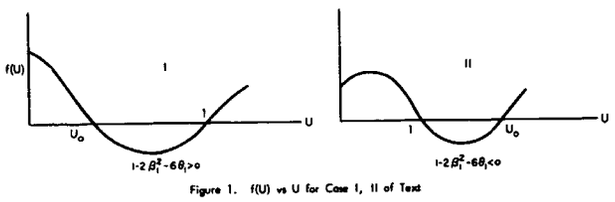

Figure 1. f(U) vs U for Case I, II of Text

FIGURE 1.—$f(U)$ vs U for Cases I, II of text.

As we require that $6\theta_1<1$, Case I may occur. Figure 1 shows a rough sketch of $f(U)$ versus U for cases I and II above.

To find the nature of the other critical point $U=U_o$, we write equation (20) as

$$\frac{d^2U}{dy^2}+\left(\frac{dU}{dy}\right)^2\left[\frac{Ug''(U)+g'(U)}{Ug'(U)}\right]+\frac{Ug(U)-\beta_1}{U^2g'(U)}=0 \tag{32}$$

where

$$H\equiv g(U)\left[a-U-\frac{2\theta_1}{U^3}\right]^{1/2} \tag{33}$$

$g'(U)$ has a zero at $U^*=(6\theta_1)^{1/4}$. It is interesting to note that this singularity of the differential equation can be quite close to 1. For example, for $\theta_1=.1$, $(6\theta_1)^{1/4}\simeq.880117$. Higher values of θ_1 can bring this singularity still closer to $U=1$.

When equation (32) is linearized about the zero U_o of $f(U)$, we obtain the equation

$$\dot{U}_1+L(U_o)U_1=0 \tag{34}$$

where $U=U_o+U_1$ and $UL(U)=1+\dfrac{2\beta_1^2}{U^2(6\theta_1-U^4)}$.

The nature of the point $U_o=1$ has already been discussed. Now let us assume in addition to

$6\theta_1<1$, that $U_o^4>6\theta_1$. We wish to establish for equation (32) that in case I when the point $U=1$ is a center the other equilibrium point $U_o<1$ is a saddle point and conversely, in case II when $U=1$ is a saddle point, the other equilibrium point $U_o>1$ is a center. By arguments similar to those given above for equation (27) and (29), this is equivalent to showing that if $h(U_o)=0$, h gvien in (31), then $U_o<1$ implies $L(U_o)<0$ and $U_o\cdot 1$ implies $L(U_o)>0$.

It can be shown that

$$Ug(U)-\beta_1=\frac{-f(U)}{U[\beta_1+Ug(U)]} \tag{35}$$

Now, consider case I. $f(U)$ has a zero at $U=U_o$ (<1) and $U=1$. In the $U,\dot{U}$ plane construct a closed loop C enclosing U_o and 1 and lying so close to the U-axis that the sign of $\dot{U}$ is determined by the last term on the left in (32).

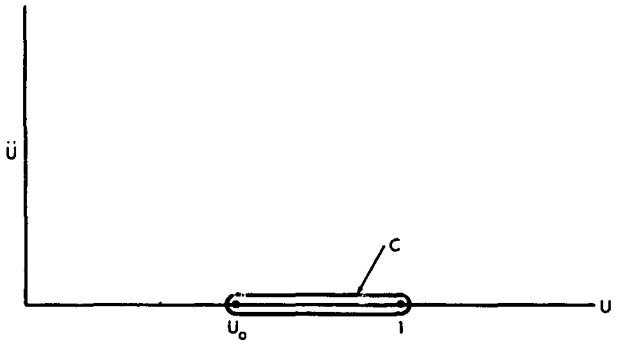

FIGURE 2.—The closed curve C enclosing the points $U=U_0$ and $U=1$ and lying close to the U axis.

(see Figure 2). Then using (35) and upon considering the changes in the sign of $f(U)$, it follows that the index of C with respect to (32) is 0[6]. As the index of a center $(U=1)$ is 1, this implies that the index of U_o is -1. If $L(U_o)\neq 0$, i.e., if U_o is an elementary critical point, then U_o of necessity must be a saddle point and $L(U_o)<0$ will hold. A similar arrangement for $U_o>1$ in case II shows that the index of U_o is 1 and therefore $L(U_o)>0$ holds (provided of course $L(U_o)\neq 0$).

Thus the problem is reduced to showing that the two polynomials $h(U)=U^3-bU^2-h_2-2\theta$, and $M(U)=U_6-6\theta_1U^2+4\theta_1-2b$ have no common positive zeros in either case I or case II. Here we have used the definition $b=2\theta_1+\beta_1^2$ in deriving the form of $M(U)$ which is the numerator of $UL(U)$.

This has not been shown in general, although for particular choices of β_1, θ_1, it is relatively straightforward. The critical case, however, is when $b+\theta_1=\frac{1}{2}$ or $2\beta_1^2+6\theta_1=1$, for then the two roots U_o and 1 become equal and, of course, in this case $M(1)=0$.

Let us suppose that $b+\theta_1$ is close to $\frac{1}{2}$, i.e., U_o is close to 1 so that $(U_o-1)^2$, $(U_o-1)^3$ are negligible in comparison with U_o-1. Now let $R=U^2$ and expand h and M about $U=1$ and $R=1$. This gives

$$h(U)=1-2(b+\theta_1)+3(1-b)(U-1)+(3-b)(U-1)^2+(U-1)^3 \tag{36}$$

and

$$M(R)=1-2(b+\theta_1)+3(1-2\theta_1)(R-1)+3(R-1)^2+(R-1)^3 \tag{37}$$

The zeros U_o, R_o $(=U^2-1)$ of h and M may be approximated by

$$U_0=1+\frac{2(b+\theta_1)-1}{3(1-b)}$$

$$R_0=1+\frac{2(b+\theta_1)-1}{3(1-2\theta_1)} \tag{38}$$

Now suppose we are in case I, that is $b+\theta_2<\frac{1}{2}$. Then as $b>2\theta_1$, we have $U_o-1<R_o-1=\bar{U}^2-1<0$; where $M(\bar{U})=0$, $\bar{U}>0$. This implies

$$1-U_o>(1-U)(1+U)>(1-U)$$

Therefore

$$U_o<\bar{U}<1$$

In case II, $b+\theta_2>\frac{1}{2}$, it follows similarly from $U_o-1>\bar{U}^2-1$, that $1<\bar{U}<U_o$. Thus the positive roots of M and R, which coincide for $b+\theta_1=\frac{1}{2}$, do separate as required, for $b+\theta_1$ near $\frac{1}{2}$. Although a proof for the general case is lacking, the following calculations may be of some interest.

Taking $\theta_1=.1$, $b=.3$, we find $(6\theta_1)^{1/4}=.880117$, $U_o\simeq.88978$ and $M(U_o)=-.1788<0$. With $\theta_1=.1$, $b=.5$, we find $U_o\simeq1.1116$ and $M(U_o)\cong.54567>0$. Thus we observe that at $b=.3$, U_o is very close to $U^*=(6\theta_1)^{1/4}$ and so b could not be decreased further and still have $U_o^4>6\theta_1$.

Thus we have seen that in case II, that is $U_o>1$, if $M(U_o)>0$, then U_o is a center. In this

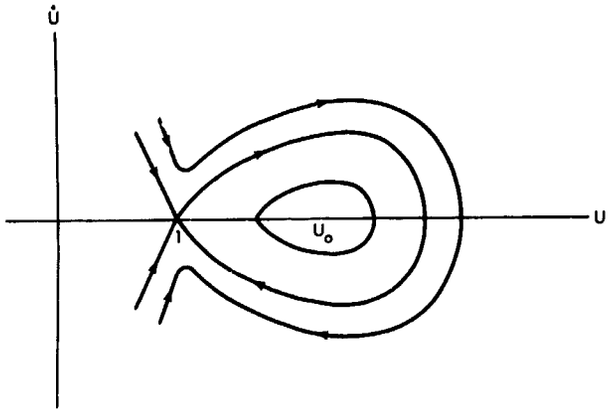

FIGURE 3.—Approximate phase plane picture of the solution for the case II when $U=1$ is a saddle point and $U=U_0$ is a center.

case the phase plane portrait of the solution is shown in figure 3. In the other case, in which U_0 is a saddle point and 1 a center, the phase plane picture is the same as figure 3 with the role of 1, U_0 reversed. As is clear from our analysis we have tried to determine the structure of the solutions of equations (19), (20) from the properties of the differential equations (27) or (32). In the next section, we shall verify our predictions by obtaining some solutions on a computer.

4. COMPUTER CALCULATIONS

Some of the results given in the previous section were verified by computing the solution of equations (19), (20) on an IBM 7094. The way to do this is to choose values of U, H (different from 1, β_1) lying on the eigen solution by using the linear equation (29). All calculations were started close to $U=1$, $H=\beta_1$. Since the solution depends critically on the position of the point of start in the phase plane we ran several cases using values slightly different from those obtained from the linear equation (29). For example, for $\beta_1=.81$, $\theta_1=.05$, we obtained the solution using (a) $U=1.0001$, $\frac{dU}{dy}=.00001$ and (b) $U=1.0001$,

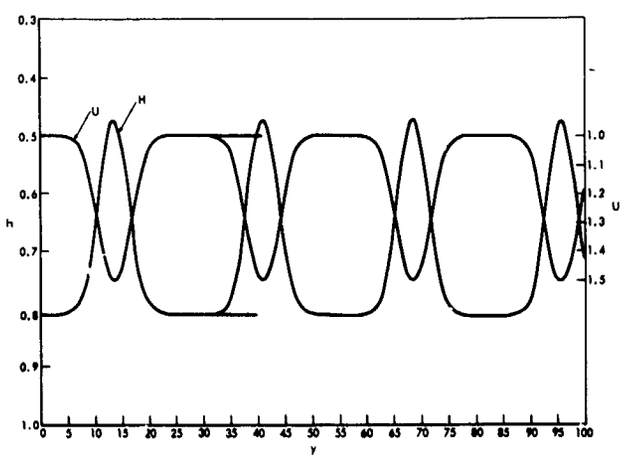

FIGURE 4a.—Computed solution of equations (19), (20) for $\beta_1=.81, \theta_1=.05$, using perturbed values $U=1.0001$, $\frac{dU}{dy}=100$.

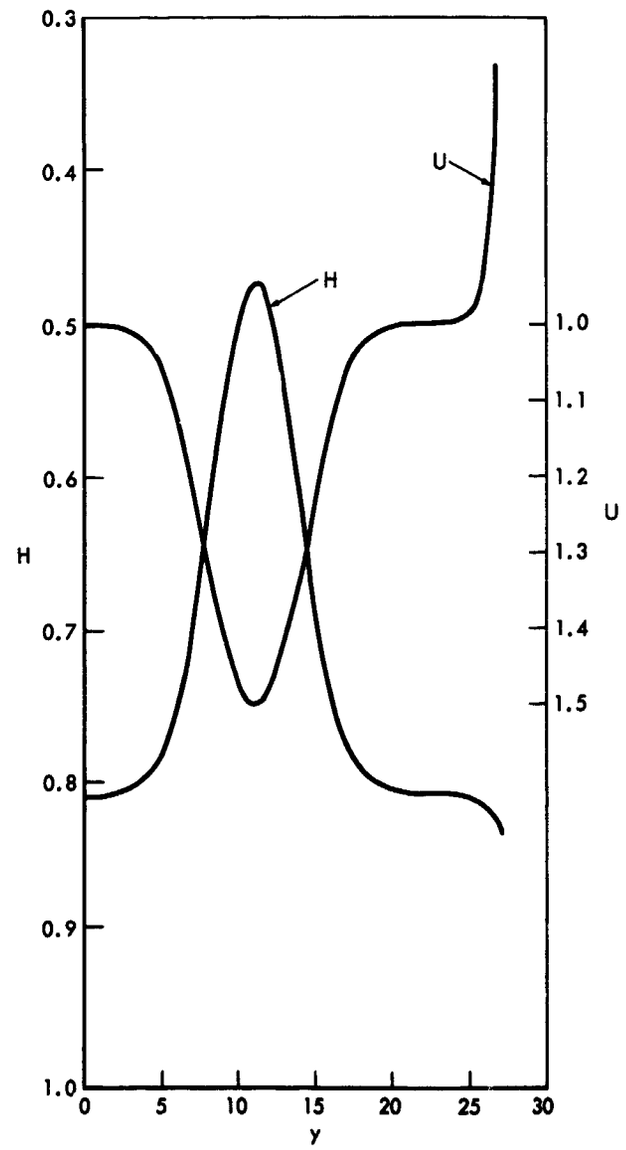

FIGURE 4b.—Computed solution of equations (19), (20) for $\beta_1=.81, \theta_1=.05$, using perturbed values $U=1.0001$, $\frac{dU}{dy}=.001$.

$\frac{dU}{dy}=.001$ while from the linear equation we obtain a value of $\frac{dU}{dy}$ which lies between .00001, .001. Figures 4a and 4b give the solution for the cases (a), (b) above. In the case (b) the solution becomes unstable because we happen to use a value of $\frac{dU}{dy}$ which lies outside the oval of figure 3. In the case (a), we obtain a solution which almost returns back to its initial value and repeats itself. (The repetitions are evidently the cause of the computational error, which if decreased will show that the solution is a solitary pulse. Since only two branches of the curve approach $U=1$, $U=0$ the solitary pulse is the required solution of the wave form.)

We now turn to a calculation of case I considered in section 3. We used $\beta_1=.1$, $\theta_1=.1$. Taking a point away from $U=1$, $\frac{dU}{dy}=0$, we obtained a solution consisting of oscillations having $U=1$ $\frac{dU}{yd}=0$ for its center in accord with the fact that $U=1$, $\frac{dU}{dy}=0$ is a center. We see therefore that in case (I) even the solitary wave does not exist.

We have not made any computations about the point $U=U_0$ as this point is of no interest to us. This corresponds to a solution lying just within the oval pictured in figure 3. A more accurate choice of initial conditions would show that the boundary of this oval corresponds to a solitary pulse, that is, the solution forming the boundary of the oval leaves $U=1$, $U=0$ at $y=-\infty$, and returns to this point at $y=+\infty$.

EVIDENCE FOR RAPID MOTION OF THE OUTER BOUNDARY OF THE MAGNETOSPHERE*

ANDREI KONRADI AND RICHARD L. KAUFMANN†

A sudden increase of the particle intensity and of the magnetic field strength on September 25, 1961 at 17:31 U.T. was detected by the ion-electron detector and the magnetometer on board Explorer XII outside the earth's magnetosphere. From the physical extent of the region and the energy of the trapped protons the temporal nature of the event was established. Similarities between particle fluxes as well as between magnetic fields during the increase and within the outer belt make it probable that the increase represents an impulse-like extension of at least a portion of the outer belt. A deduced lower limit on the outward radial velocity of the extension is 156 km/sec. Crude calculations show that either the proton density near the outer edge is less than 100 cm^{-3} or the temperature is greater than 15 ev.

INTRODUCTION

The Explorer XII satellite was well suited for the study of the outer boundary of the trapping region. With an apogee of over 13 R_e (earth's radii) it usually penetrated the boundary on the sunward side twice during each orbit. The position of the boundary ranged from about 8 R_e to beyond the apogee of the satellite with an average value of somewhere about 10 R_e (Cahill and Amazeen, 1963).

Data from the ion-electron detector flown by Davis and Williamson and from the magnetometer flown by Cahill on board Explorer XII has yielded more than 100 transitions of the outer boundary.

For our purposes a transition shall be defined to occur when on an inbound pass the output current of the photomultiplier, measured in the mode which is most sensitive to the incident energy flux, rises significantly above the dark current (usually at least by an order of magnitude) in a time interval of the order of minutes corresponding to a radial distance of about one hundred kilometers covered by the satellite. The reverse is of course true for an outbound pass (Davis and Williamson, 1963). Similarly, a transition of the boundary is indicated by the magnetometer when there is usually an abrupt change in either both the magnitude and direction of the magnetic field, or just a change in the direction of the magnetic field. Several typical transitions are shown in Figures 1a and 1b. As can be seen from Figure 1a,

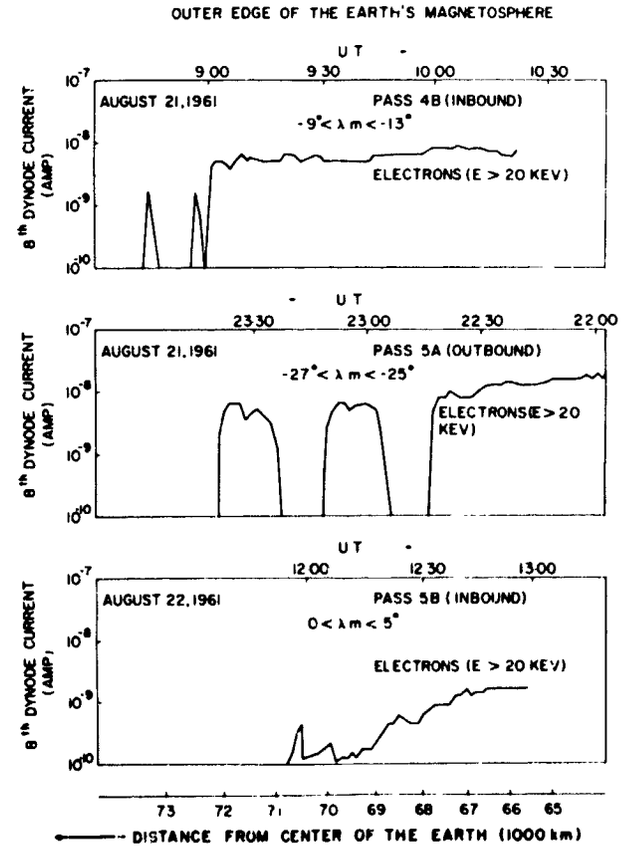

FIGURE 1a.—Three samples of Explorer XII transitions of the outer boundary of the trapping region as seen by the ion-electron detector. The 8th dynode current is a measure of the electron intensity for electrons with 20 kev < E < 1 Mev.

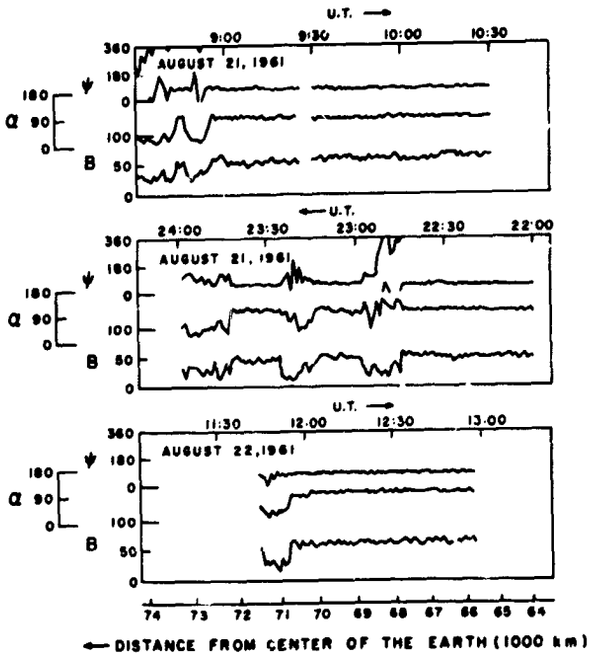

FIGURE 1b.—Magnetic field directions and intensity for the same transitions as in Figure 1a. The strength is measured in gammas and the directions are given in the satellite centered spherical coordinates α and ψ.

at times the satellite passes through regions of enhanced particle intensity which are separated from the boundary by stretches where the particle intensity falls below the threshold of detectability. Unfortunately, in most cases it is impossible to separate temporal and spatial phenomena on the basis of only particle data. One could argue equally well that the intensity represent actually a part of the outer belt that for some reason is separated from the rest of the belt by particle free regions, or that they represent an expansion and contraction of the trapping region in such a way that the satellite crosses the boundary several times during one orbit. Figure 1b shows the magnitude and direction of the magnetic field during the same transitions. The directions of the magnetic field are given in satellite centered spherical coordinates (Cahill and Amazeen 1963). It should be noted that in analogy to particle intensities during the transition of the boundary the magnetic field sometimes shows the same direction and magnitude in regions separated from the magnetosphere as were observed in the trapping region. Using magnetic field data alone one again cannot distinguish between temporal and spatial phenomena.

In the analysis of the data thus far, one case was found in which a combination of magnetic field data and particle data can resolve this question.

The present paper shall be concerned with a sudden increase of the particle flux on September 25, 1961 at 17:31 U.T. at a radial distance of 77,465 km as seen by the ion-electron detector and changes in the magnetic field as seen by the magnetometer on board Explorer XII.

INSTRUMENTATION

A brief review of some of the features of the ion-electron detector pertinent to the following discussion will be given here. A detailed description of the apparatus will be published elsewhere (Davis and Williamson, to be published).

The detector is a scintillation counter consisting of a photomultiplier tube on the face of which is deposited a 5 mg/cm² thick layer of crystalline ZnS covered by a 1000 A° thick layer of Al. It has a geometric factor of 5.4×10^{-3} cm² ster. A collimator allows particles to enter from a viewing cone with a half angle of 11°.

A wheel driven by a stepping motor introduces varying thicknesses of Ni absorber between the collimator and the phosphor. Three positions on the wheel carry Au discs which scatter the incident flux entering through an alternate collimator into the phosphor.

There are three modes of operation:

1. Pulse output from the anode measures protons between the energies of 100 kev and 5 Mev.
2. 8th dynode current measures the total incident energy flux from both protons and electrons.
3. Electrons can be selected preferentially by scattering an incident beam of both protons and electrons from an Au disc. In this mode of operation the 8th dynode current measures the total incident energy flux due to electrons alone.

In all three modes of operation the lower energy cutoff can be raised by introducing varying thicknesses of Ni absorber.

Throughout the following discussion we shall make the assumption that for different absorbers we are measuring the integral proton flux above some energy for which the detector efficiency is 50 percent. The situation is more complicated for electrons because of the shape of the sensitivity

curves and the necessity to use approximation methods to obtain electron spectrums.

The magnetic field data was obtained from the magnetometer flown by L. J. Cahill of the University of New Hampshire and its operation had been described earlier (Cahill and Amazeen, 1963).

ANALYSIS

The inbound pass of September 25, 1961 had a geomagnetic latitude of less than 5° for radial distances of more than 40,000 km. Figure 2 shows intensities of low energy protons and the value of the photomultiplier 8th dynode current obtained with 5μ inch Ni absorber when the detector was looking at particles with local pitch angles of around 90°. Also shown are the intensity and direction of the magnetic field in the satellite coordinate system.

The electrometer data represents instantaneous values of the 8th dynode current sampled at intervals of 83 seconds. To gain some physical idea of the electron intensities involved, a crude analysis shows that at 19:45 U.T. the differential electron spectrum could be approximated by a curve of the form $E^{-\gamma}$ where E is the electron energy and $\gamma = 3.7$. The integral intensity of electrons for $E > 20$ kev is 4×10^6 electrons (cm^2 sec ster)$^{-1}$. This number is accurate to better than a factor of 2.

The plot of the proton data was made for particles with energies $E > 140$ kev and $E > 200$ kev. The proton intensities are obtained from data accumulated over a time period of 0.3 seconds. During that time the satellite turns about its axis through an angle of about 58°. Thus the 90° pitch angle intensity is an average value covering also other than locally mirroring particles.

The magnetometer data corresponds to an average of ten successive telemetry samples taken at intervals of 50 km. The field strength is expressed in gammas, and the direction is indicated in spherical satellite centered coordinates mentioned earlier.

The graph in Figure 2 is divided into three parts: Region I represents the proton and current intensities in the outer belt. Region II is characteristic of the space outside the trapping region. In this case the current output of the detector consists only of the dark current and the pulse output merges into the omnidirectional background. Region III shows a sudden increase in the electron and proton intensity at 17:31 U.T. which lasted for about one minute.

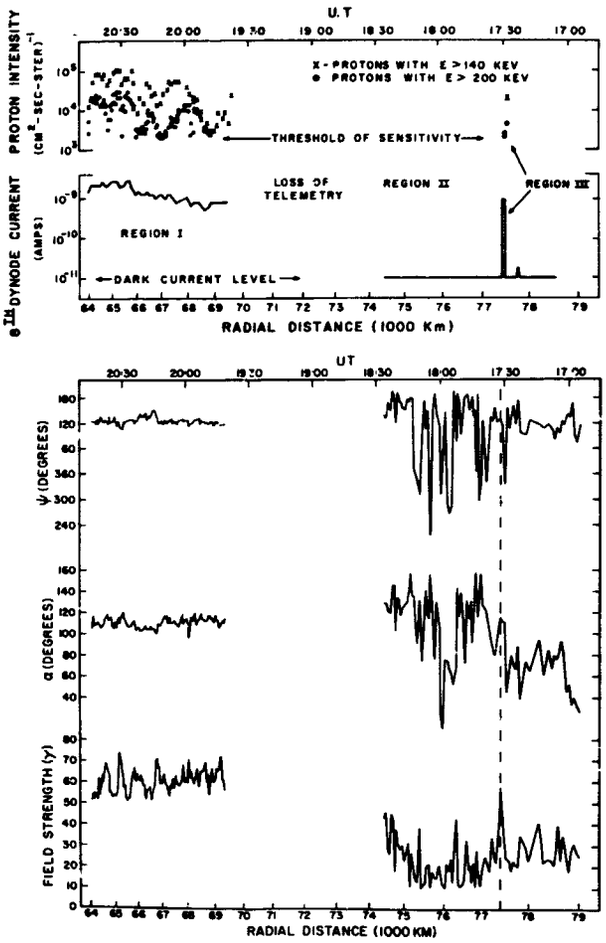

FIGURE 2.—Inbound pass of September 25, 1961. The upper two curves represent the unidirectional proton intensity for particles with 90° local pitch angle and the 8th dynode current corresponding to electrons with E > 20 kev and 90° pitch angle respectively. The lower three curves show the strength and directions of the magnetic field. Angles α and ψ were previously defined by Cahill and Amazeen (1963). The left side is a typical response for the trapping region (Region I). The right side (Region II) shows the usual response of the detectors outside the magnetosphere. For protons the threshold of sensitivity is the count rate corresponding to an omnidirectional flux of penetrating particles. Region III is the sudden increase in particle and magnetic field intensity which is the subject of the present study.

Similarly the magnetic field in Region I is the rather constant field encountered in the outer belt. Region II is typical of the field outside the boundary of the magnetosphere. The field is rather disorganized and shows many changes in direction.

The dashed line indicates the magnetic field in Region III. During the transition of Region III the magnetic field agreed in magnitude and in direction with the field observed in Region I. Before and after the sudden increase the magnetic field had an average value of 25 gamma. During the transition of Region III the field rose to 61 gamma. Aside from this single increase there is nothing unusual happening in the behavior of the field outside the magnetospheric boundary. It should be emphasized that in this context the word "region" is used only with reference to the graph and does not necessarily imply any physical structure in space. The increase is real and not due to faulty data processing because it appears on two completely independent data tapes acquired at Fort Myers, Florida and at South Point, Hawaii. This increase in particle and field intensity will from now on be referred to as Region III.

While the satellite was in Region III it was possible to obtain 15 data points for protons with $E > 140$ kev and 45 data points for protons with $E > 200$ kev. Figures 3 and 4 present the pitch

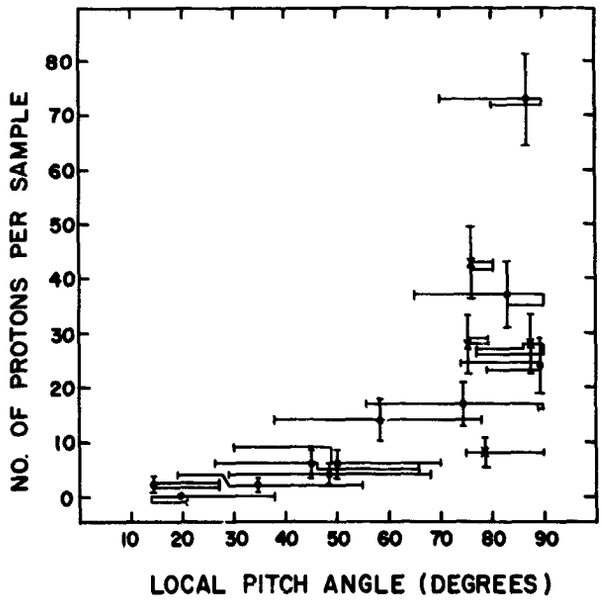

FIGURE 3.—Pitch angle distribution of protons with E>140 kev found in Region III. The vertical bars represent Poisson standard deviations. The uncertainties due to the digitization of the analog data are about half as large again. The horizontal bars represent the range of angles over which the samples were collected. The assigned p.a. corresponds to the center of the accumulation period.

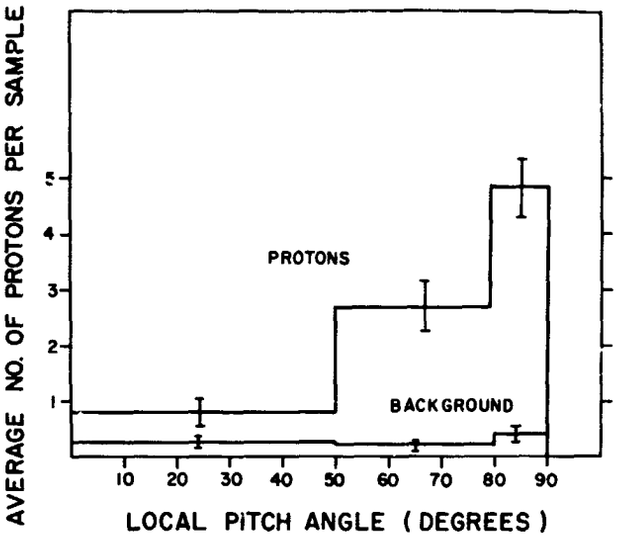

FIGURE 4.—Pitch angle distribution of protons with E>200 kev. The data points were lumped together into three groups each containing 15 points. The vertical bars represent Poisson deviations. The background count obtained with a thick plug in front of the detector aperture is given below.

angle distributions for these two cutoff energies. In both cases the pitch angles were assigned from the knowledge of the direction of the magnetic field as seen by the magnetometer. The vertical bars represent Poisson standard deviations only. The uncertainty due to the digitization of the analog data tapes is about half as large again. In Figure 3 the horizontal bars represent the ranges of pitch angles which were scanned during the accumulation period. The pitch angle assigned to each point is the value seen at the center of the accumulation period. The points represented by crosses actually have pitch angles which are supplements of the indicated pitch angles. Figure 4 is a similar diagram. In this case the number of counts per data point was small so that data points were lumped together into three groups each containing 15 points. The bars again represent Poisson standard deviations. For contrast the omnidirectional background count obtained with a thick plug in front of the detector is plotted below.

The shape of the pitch angle distributions is quite similar to those obtained for trapped particles within the magnetosphere in that the maximum intensity is found at 90° local pitch angle (Davis and Williamson, 1963). By contrast, solar protons during a sudden commencement have been observed to have maximum intensities in

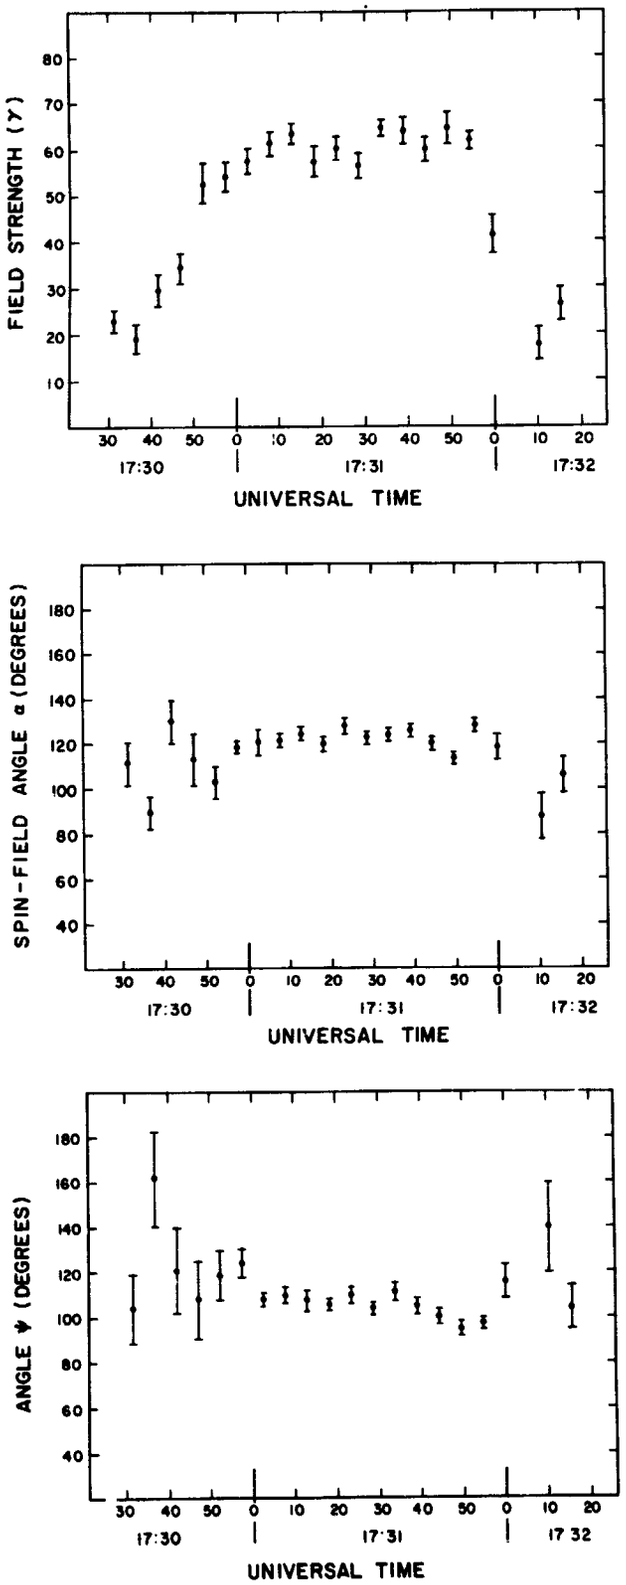

FIGURE 5.—Intensity and directions of the magnetic field in Region III. The vertical bars represent standard deviations of the mean of 16 data points each. The angles α and ψ are identical to those defined by Cahill.

directions other than 90° to the field lines (Hoffman, et. at., 1962).

Figure 5 shows the magnetic field intensity and directions during the transition of Region III. The vertical bars represent standard deviations of the mean of 16 data points each. The scatter in the original data is mostly due to the digitization of the magnetometer analog output voltage. The standard deviations increase as the field decreases in magnitude. α is the angle between the spin axis of the satellite and the magnetic field. ψ is the angle between the spin-field plane and the spin-sun plane. They are identical to those defined earlier by Cahill and Amazeen (1963). Before and after the transition of Region III the magnitude of the field was about 25 gamma. During the transition the magnitude rose to 60 gamma. There was no drastic change in either α or ψ.

Assuming for the moment that Region III is stationary an estimate of its maximum width can be made by finding the time when the particle flux was zero on the step corresponding to the lowest energy cutoff just before and after the transition of Region III and multiplying it by the velocity of the satellite. This gives the region a maximum width of 200 km. A more precise value obtained from the magnetometer data is 83 km corresponding to a width of 56 km in the radial direction from the center of the earth. It should be pointed out that the angle between the direction of the magnetic field and the velocity vector of the satellite is about 60°. This means that the angle between the velocity vector and the plane of gyration of protons with 90° pitch angle is 30°. Therefore, the width of Region III in the plane containing protons with 90° pitch angles must be close to that of Region III as measured along the velocity vector.

Table 1 shows the cyclotron radii of protons with several energies corresponding to the magnetic field encountered within Region III. It is clear from the Table that no 200 kev or 140 kev protons with pitch angles close to 90° could be trapped within a stationary Region III where the magnetic field strength is about 60 gamma. The efficiency of the detector for 310 ev protons is zero. Thus the conclusion must be drawn that Region III is a temporal rather than a spatial phenomenon.

TABLE 1.—*Cyclotron Radii of Protons*

Magnetic field strength H = 60 gamma

Proton energy	Cyclotron radius
200 kev	1075 km
140 kev	899 km
310 kev	42 km

The origin of Region III can only be conjectured. In what follows we shall try to produce convincing evidence that Region III represents a temporal extension of the outer belt.

Comparison between Region I and Region III shows that the intensities of both the 8th dynode current and of the protons are comparable in several places for particles with 90° pitch angle. The order of magnitude fluctuations of the proton flux and the somewhat smaller fluctuations of the 8th dynode current make it difficult to perform any more detailed analysis. Magnetometer data, however, provide a more quantitative comparison.

For reasons of clarity, we shall transform the angles α and ψ into the geomagnetic coordinate system.

To make a comparison with the directions of the geomagnetic field within the radiation belt, the direction of the field was obtained from experimental data at three points shown in Table 2. Region Ia occurs just after the recovery of the telemetry within the belt. Region Ib was selected to have the same increment of distance as exists between III and Ia.

Several theoretical models indicate that in the absence of a ring current and close to the equatorial plane the boundary of the magnetosphere is almost circular in the meridian plane on the day side of the earth. (Beard, 1960; Beard, 1962; Beard and Jenkins, 1962; Davis and Beard, 1962; Mead and Beard, 1964; Spreiter and Briggs, 1962; Spreiter and Alksne, 1962; Spreiter and Hyett, 1963). Assuming that this holds true the direction of the magnetic field was calculated just within the boundary of the magnetosphere at +4° geomagnetic latitude and at 10:24 hours local time.

TABLE 2

Time (U.T.)	Region	Radial distance (earth radii)
17:31	III	12.135
19:42	Ia	10.877
21:12	Ib	9.618

The results of the field calculations and observations are given in Table 3.

For comparison the satellite and sun positions were also included. A diagram of the results is given in Figure 6, where a polar projection is used to represent the field directions. To make possible the comparison between magnetic fields as observed in different regions we re-define the zero magnetic meridian to lie in the plane formed by the earth's magnetic polar axis and the radius vector of the satellite position. In this coordinate

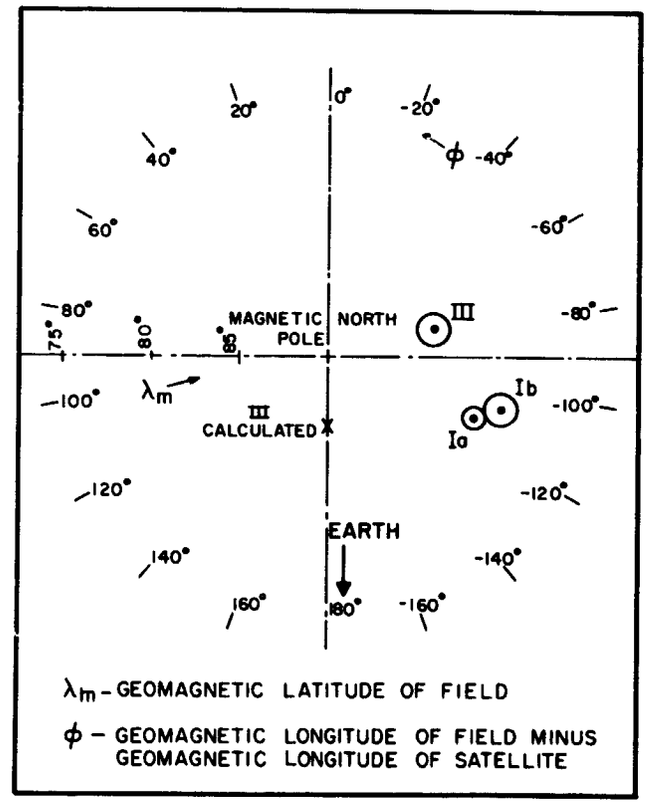

FIGURE 6.—Polar plot showing the directions of the magnetic field in Regions Ia, Ib, and III. Also shown is the direction of the magnetic field as calculated under assumption described in the text. The azimuthal variable is the difference between the geomagnetic longitudes of the field and of the satellite.

TABLE 3.—*Directions of the Magnetic Field*

Ia	19:41	2.61	−67.65	6.82	−48.77
Ib	21:12	1.77	−86.34	2.79	−71.24

system the azimuthal variable of the field direction, ϕ. is the angle whose magnitude is equal to the geomagnetic longitude of the field minus the geomagnetic longitude of the satellite position.

The points represent the directions of the magnetic field as observed in Regions III, Ia, Ib, and as calculated in Region III. The circles about the points correspond to standard deviations due to scatter of the raw data points. The lack of overlap of the data is evidence for slight temporal variations of the magnetic field. This was confirmed by taking several adjacent sets of data points in both Regions Ia and Ib. The results show a clustering of points with an average distance between the points of about two degrees.

The observed directions of the magnetic field seem to be out of phase with respect to the satellite by about −90° in the azimuthal direction rather than the expected 180° if the field is calculated under assumptions stated before.

This difference does not seem significant. Even at 20,000 and 30,000 kilometers field measurements disagree by about 7 degrees of arc with a theoretical model based on the Jensen and Cain coefficients and the Mead cavity field. (*Jensen and Cain*, 1962; *Mead*, 1964). This disagreement may be due to slight uncertainties in the calibration of the instruments or an error in the assumed direction of the satellite spin axis, or both. The problem is currently being investigated.

The significance of these results is that in spite of several systematic uncertainties in the absolute measurement of the magnetic field and other effects such as the change in the satellite's geomagnetic latitude from +3.94° at 17:31 U.T. to 1.77° at 21:12 U.T., and the unknown spatial and temporal changes in the direction of the magnetic field, the observed field directions in Regions III, Ia and Ib can be fitted into a cone with a half angle of 3°.

This means that the magnetic field in Region III points almost in the same direction as the field in the trapping region and it is, therefore, reasonable to assume that Region III is just a temporary extension of the trapping region.

It is also possible to put a lower limit on the speed with which the trapping region overtook the satellite. The initial rise in the intensity of the

magnetic field occurred at 17:30:52.9 U.T. At 17:31:04.3 U.T. the detector saw 140 kev protons. During the 5.2 sec. counting period the detector could see protons with 90° pitch angle. They were coming from directions shown in Figure 7.

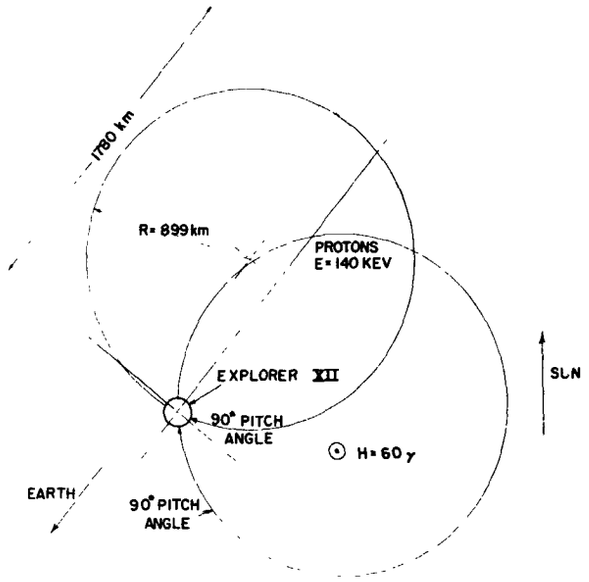

FIGURE 7.—Orbits of trapped protons with 90° pitch angle which were observed in Region III. At the time when the trapped protons were observed the boundary of the magnetosphere must have been at least at a distance of 1780 km in the radial direction away from the satellite. The interval between the first observation of the increased magnetic field and the observation of 140 kev protons was 11.4 sec. This puts a lower limit on the velocity of advance of the magnetosphere of 156 km/sec.

Since these protons were trapped their orbit could not extend beyond the boundary of the magnetic field. Thus we are led to the conclusion that during the interval of 11.4 seconds between the increase in the field and the appearance of 140 kev trapped protons the boundary must have moved through a radial distance of at least 1780 km. This puts a lower limit on its radial velocity of advance equal to 156 km/sec. A similar analysis can be performed in trying to estimate the speed of recession of the magnetosphere. The time interval between the instant when 200 kev locally mirroring protons were seen and the instant when the field strength dropped to about 25 gamma was 29 seconds. To preserve closed orbits of trapped protons, the magnetosphere must have moved in that interval at least through 2130 km. This puts a lower limit on the radial velocity of recession equal to 75 km/sec.

A survey of ground magnetograms was made. No identifiable features could be found in the records from low latitude stations. Large regular pulsation events were observed in two out of approximately twenty high latitude magnetograms which were surveyed. At Point Barrow (geomagnetic latitude 68.6°N, geomagnetic longitude 241.2) the field vector began rotating counterclockwise, as seen by an observer looking down at the earth, at about 17:31 U.T., or 0700 local time. The peak to peak amplitude was about 150 gammas and the period was 4 to 5 minutes. At Baker Lake (geomagnetic latitude 73.8°N, geomagnetic longitude 315.2°) the peak amplitude was again about 150 gammas and the period was 4 to 5 minutes, but here the wave had a roughly linear polarization and began about 17:27 U.T., or 11:00 local time.

These ground records suggest that the observed rapid expansion and probable compression of the magnetosphere were associated with the excitation of a hydromagnetic disturbance in a thin shell of the outer magnetosphere. We do not, however, believe that the nearly simultaneous observation of one event on the satellite and of an event at two out of twenty ground stations can be interpreted as conclusive evidence that the two phenomena are related.

INTERPRETATIONS

We have argued that at 17:31 U.T. the magnetosphere expanded past Explorer XII at a velocity of at least 156 km/sec. Even if the external pressure dropped to zero, the plasma in the magnetosphere would not expand at a velocity greater than

$$V = \sqrt{\frac{B^2}{4\pi mn} + \frac{2c^2}{\gamma - 1}}$$

where n is the number of protons per cm^3, c is the speed of sound, and we will use B equal to 60 gammas, m equal to the mass of a proton, and γ equal to 5/3. The speed of sound in an ideal gas is given by

$$c^2 = \frac{\gamma RT}{\mu}$$

where R is the gas constant and μ is the molecular weight of the gas. Using these expressions, the

expansion velocity is given by where T is the

$$V^2 = \frac{1.71 \times 10^6}{n} + 482T$$

temperature in electron volts and V is in km/sec.

If the magnetic energy density far exceeds the thermal energy density, the first term will dominate and an expansion velocity of 156 km/sec implies a number density of less than 70 protons per cm^3. If the magnetic field can be neglected, the second term dominates and implies a proton temperature of at least 50 ev. Several other possible combinations are listed in Table 4 where it can be seen that either the number density must be less than about 100 protons per cm^3 or the temperature must be greater than about 15 ev near the outer edge of the magnetosphere.

TABLE 4

upper limit on n(cm^{-3})	∞	341	174	117	88	70
lower limit on T(ev)	50	40	30	20	10	0

After a time interval of 69 seconds a second boundary was observed. Several interpretations are possible. The observations could be caused by an expansion and subsequent compression of the entire magnetosphere, or a small portion of the magnetosphere; they could be caused by the expansion of a small portion of the magnetosphere which breaks off and continues to move outwards; they could be caused by a wave propagating in the surface of the magnetosphere. We cannot presently determine the cause of the observation.

CONCLUSIONS

On September 25, 1961 at 17:31 U.T. Explorer XII passed through a region of enhanced proton and electron intensity which lasted for 1 minute and extended over an apparent distance of 83 km. At the same time the on board magnetometer registered an increase in the magnetic field.

Analysis of the data shows that the detected protons were trapped in the magnetic field. At the same time their cyclotron radii were much larger than the apparent width of the region. This fact points out the temporal character of the region. Similarities between the particle intensities and the strength and directions of the magnetic field in the region and in the outer belt suggest that the region comprises an impulse-like extension of the magnetosphere.

From knowing the time of the increase and the intensity of the magnetic field as well as the time when the 140 kev trapped protons were detected, a lower limit on the outward radial velocity of the magnetospheric boundary can be determined to be 156km/sec. Similarly the lower limit on the inward radial velocity of the magnetospheric boundary has been determined to be 75 km/sec.

The conclusions that can be drawn from our crude calculations are that either the proton density near the outer edge of the magnetosphere is less than about 100 per cm^3 or the temperature is greater than about 15 ev.

ACKNOWLEDGMENTS

We wish to express our appreciation to Dr. L. J. Cahill of the University of New Hampshire and to Mr. L. R. Davis and Mr. J. M. Williamson of the Goddard Space Flight Center for the use of their data from detectors flown on board Explorer XII. We also would like to thank Dr. Cahill and Mr. Davis for many helpful discussions.

MEASUREMENT OF LOW ENERGY PRIMARY COSMIC RAY PROTONS ON IMP-1 SATELLITE*

F. B. McDONALD AND G. H. LUDWIG

The first precise determination of the intensity and energy spectra of primary cosmic ray protons in the 15–75 MeV interval has been made with a three element energy vs. energy-loss telescope aboard the IMP–1 (Explorer XVIII) satellite. This spacecraft had an apogee of 193,000 km and only data obtained well beyond the effects of the earth's magnetosphere are considered. The measurements reported here cover the time interval 8 December 1963 to 6 May 1964 and are considered to be representative of the period just prior to solar minimum. The proton intensity in the range 15–75 MeV was observed to be 19 proton/m^2-sec-ster or approximately 1 percent of the total primary cosmic ray intensity and to exhibit a steeply falling energy spectrum toward lower energies, decreasing by a factor of 5 over this interval. One point for helium was obtained in the range 65–75 MeV/nuc.

The E vs dE/dx telescope (Figure 1a) provides a means of studying this low energy component in the presence of higher energy cosmic rays.[1] Because of the background and low flux in this energy interval, significant measurements cannot be obtained by balloon or rocket techniques but are dependent on satellite measurements. The principal of operation of the telescope is shown in Figure 1. For each particle which traverses the ΔE counter and stops in the E crystal (as defined by the plastic scintillator anticoincidence cup) measurements of ΔE and E—ΔE are made by 512 channel pulse height analyzers and transmitted over the satellite telemetry systems. As shown in Figure 1b, this provides a measure of mass, charge and energy resolution for $Z = 1, 2$ particles. The electron data are discussed in an accompanying paper. Saturation effects prevented the alpha particles data from being extended to lower energies. This does not affect the H or e data. Mass histograms have been obtained in the proton region for six energy intervals of about 10 MeV

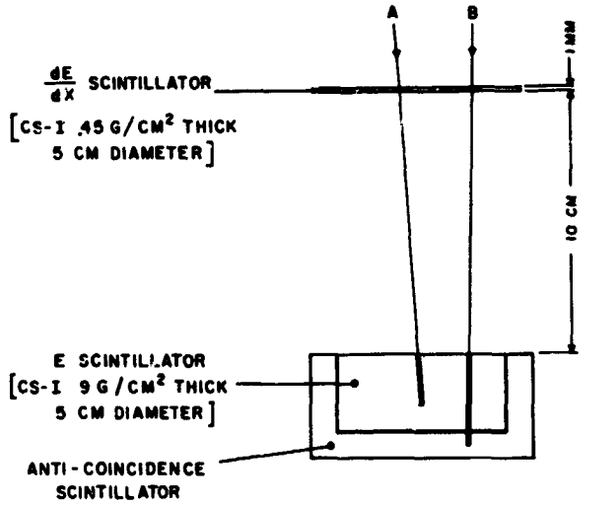

FIGURE 1a.—Schematic drawing of E vs dE/dx telescope. Particles which stop in the lower scintillator (A) are accepted for analysis while those which enter the anti-coincidence cup (B) are rejected.

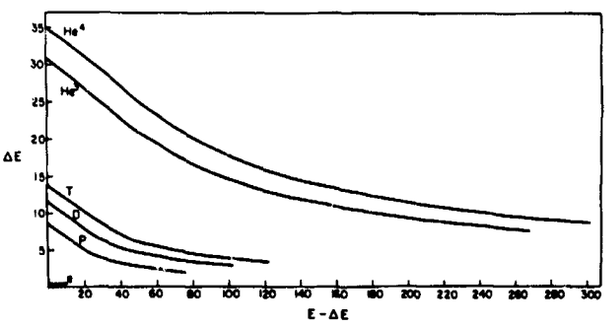

FIGURE 1b.—Mass and energy response of E[~(E-ΔE)] and dE/dx (~ΔE) telescope.

*Published as *Goddard Space Flight Center Document X-611-64-363*, November 1964.

each by summing the data in 11 channels constructed parallel to and centered about the proton line of Figure 1b. These six energy intervals for H are shown in Figure 2. The clean resolution of

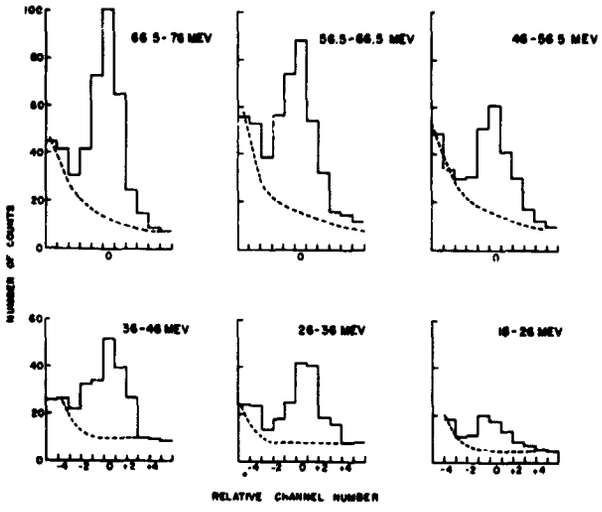

Figure 2—Mass histogram for 6 energy intervals in proton region.

the proton distribution at all energies is striking. The background correction (illustrated by the dashed line of Figure 2) has been applied using the experimental proton distribution obtained from the small solar cosmic ray event of 16 March 1964. The rigidity and energy spectra obtained from the mass histogram data of Figure 2 along with the single α point is shown in Figure 3.

To search for long term variations, the data were divided into two intervals covering the period 8 December 1963—14 March 1964 and 22 March 1964—6 May 1964. Except at the lowest energy point, the data are consistent with a change of less than 10 percent in the proton flux in the 15–75 MeV region between these two periods. The increase on the low energy point may be due to an increase in the galactic flux or, most probably, to the small solar proton event of 16 March 1964. We cannot rule out large short time variations since the long times required to obtain meaningful statistics preclude the possibility of observing variations occurring over a shorter time scale. Proton and helium data obtained at higher energies from the balloon data of Balasubrahmanyan and McDonald,[2] and Fichtel et. al.[3] are shown for comparison. It is observed that at this period of the solar cycle just prior to solar minimum there is a sharp decrease is a sharp decrease in both spectra toward lower energies that extends to the lowest observed energy.

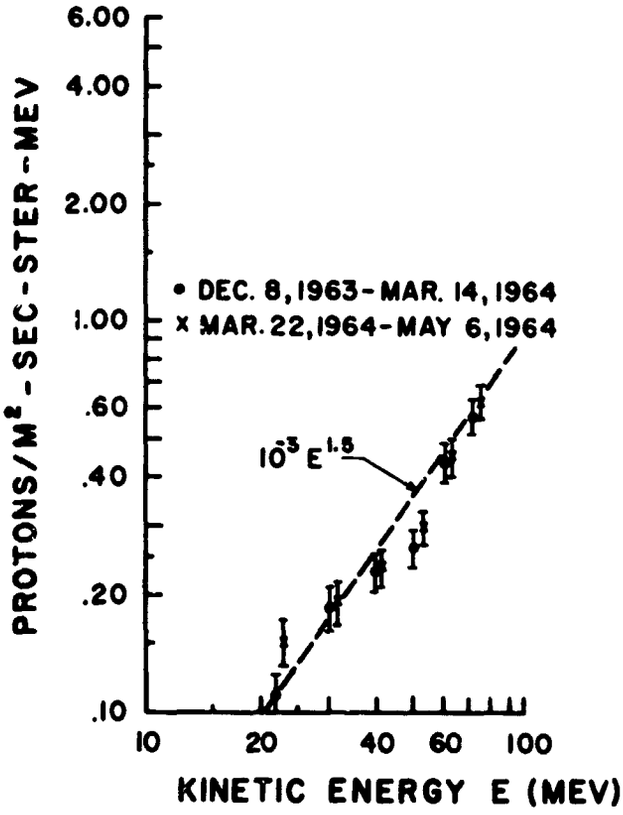

FIGURE 3a.—Cosmic ray proton energy spectra for two different time periods. The dotted line indicates an empirical fit to the data of the form $10^{-3}E^{1.5}$.

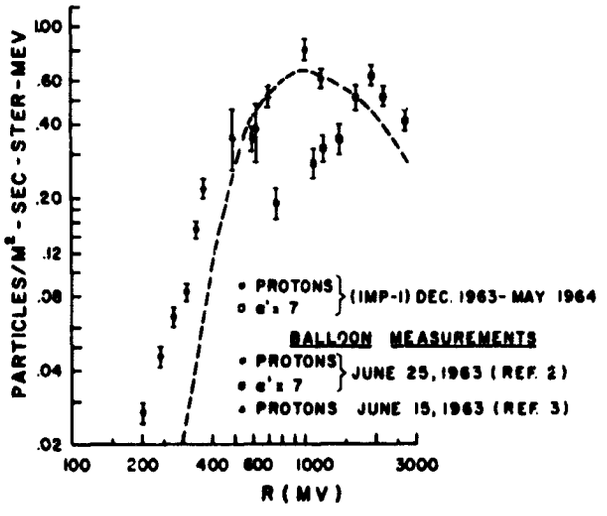

FIGURE 3b.—IMP proton and α rigidity spectra. Shown for comparison is the balloon data of Fichtel et. al.[3] and Balasubrahmanyan et. al.[2].

The flux of deuterium could not be resolved from the background and an upper limit of 8 percent of the proton flux over the corresponding energy interval was placed on its abundance.

During the last solar minimum an arctic latitude survey by Meredith, et. al.[4] using a rocket borne single Geiger counter had indicated the cosmic ray intensity did not increase strongly at low energies. The ionization chamber data of Neher [5] at balloon altitude suggested a strong variation in the low energy range >100 MeV anti-correlated with solar activity.

The only previous satellite measurements in this region were made by Stone [6] in late 1961 on a polar orbiting satellite. This study was based on 12 counts in the energy interval 11–125 MeV. They were consistent with a flat energy spectrum and served to place an upper limit of about 1 proton/m^2-sec-MeV on the proton flux since an active anticoincidence device was not used. The data in Figure 3 show the highest energy point of the IMP data reported here is in general agreement with the lowest energy point obtained in the June 1963 balloon flight by Balasubrahmanyan and McDonald [2] and Fichtel,[3] et. al. It is also consistent with the upper limit of $dJ/dE<.49$ protons/m^2-sec-MeV obtained on a high latitude flight of Brunstein in 1962 [7] and with the lowest energy points obtained by Freier and Waddington[8] and Ornes and Webber [9] from 1963 balloon flights. Further confirmation of the splitting of the normalized low rigidity spectra is also obtained.

The proton and alpha spectra as observed in interplanetary space result from a superposition of three processes—initial acceleration, diffusion through the galaxy and solar modulation. To illustrate these processes assume

(1) Energy spectra at injection are of the form

$$\mu(E)=\frac{10^4}{w(1+E)^{2.5}} \text{ protons/M}^2\text{-ster-Bev}$$

(2) Traversal of 2.5 gm/cm^2 of hydrogen before reaching the solar system; and

(3) The solar modulation is of the form

$$\frac{dj}{dE}=\frac{dj_0}{dE}\exp\left(-\frac{\text{const}}{w}\right)$$

where $\mu(E)$ is the density of cosmic rays with kinetic energy E, and dj/dE is the observed differential energy spectrum while dj_0/dE is the unmodulated or stellar spectrum and w is the particle velocity. Assumption (1) is based on an extrapolation to low energies of observations above 4 Bev [10]. The 2.5 gm/cm^2 of H is implied by the relative abundance of *Li*, *Be*, and *B* in the primary beam [11] and the solar modulation function is a diffusion model proposed by Parker [12]. In this model an equilibrium state is established between diffusion inward through irregular magnetic fields and removal by outward convection. The solar modulation effects have been obtained by normalizing at 200 MeV. These calculations are shown by the dotted curve of Figure 3b. While it can be concluded that either the injection spectra are steeper than a simple power law (as one might hypothesize from solar cosmic ray studies) or that the effects of solar modulation are not as strong at low energies (in agreement with the lack of significant long term time variations), the primary effect of these admittedly crude assumptions is to show that indeed the production of the observed steep proton energy spectrum is not unexpected on the basis of other cosmic ray observations. It is to be expected that further observations over the period of solar minimum coupled with low energy measurements of multiply charged primaries will permit more accurate determinations of the source spectra and the solar modulation mechanism.

The authors wish to thank S. Paull, C. A. Cancro and P. J. Janniche of the Goddard Space Flight Center for designing and testing the spacecraft electronics for the IMP experiment, and to A. P. Flanick and D. Clark of Goddard for testing and calibrating the detector system. The support of Paul Butler and the IMP project team is greatefully acknowledged.

SECULAR AND NON-SECULAR BEHAVIOR FOR THE COLD PLASMA EQUATIONS*

N66 37962

DAVID MONTGOMERY AND DEREK A. TIDMAN†

The origin of "secular" behavior for the nonlinear cold electron plasma equations is studied. The equations involved are closely related to the Klein-Gordon equation with a small nonlinear term. A method is developed for arriving at perturbation theoretic solutions of this equation, and the method is then applied to the case of the higher order effects of an electromagnetic wave propagating in the cold electron plasma. An explicit expression for the second order frequency shift is calculated.

INTRODUCTION

When attempts are made to calculate the behavior of nonlinear mechanical systems in perturbation theory which goes beyond the linearized approximation, the difficulty of "secular" behavior often (though by no means always) appears. The higher orders contain, in addition to trigonometric terms, time-proportional or "secular" terms. The unbounded character of these terms soon invalidates the perturbation theoretic assumptions of smallness on which they were derived.

A systematic program for doing a type of perturbation theory that is free of secular terms in the case of the harmonic oscillator equation with a "small" nonlinear term was given some time ago by Krylov and Bogolyubov (Reference 1), and later refined and mathematically justified by Bogolyubov and Mitropolskii (Reference 2).** Recently, considerable interest has arisen in modifying these techniques to deal with partial differential and differentio-integral equations, especially in connection with the work of Frieman (Reference 3) and Sandri (Reference 4). Earlier calculations, which are more closely related to this work, were made by Jackson (Reference 5) and Sturrock (Reference 6).‡

The system treated here, a partial differential equation, is considerably simpler than those described in References 3 and 4. It is nonetheless believed to be of value in that it illuminates, in a relatively uncluttered way, some new features which emerge as a consequence of its being a partial differential, rather than an ordinary differential, system.

The equation treated by Bogolyubov and Mitropolskii is

$$\left(\frac{d^2}{dt^2} + \omega^2\right) x(t) = \epsilon F\left(x, \frac{dx}{dt}\right) \qquad (1)$$

where ϵ is a formal expansion parameter (eventually to be set equal to one) written to indicate the relative "smallness" of the right hand side; F(x, dx/dt) is a known nonlinear functional of x and dx/dt; and ω^2 is a constant.

We shall examine the equation

$$\left(\frac{\partial^2}{\partial t^2} - c^2 \frac{\partial^2}{\partial x^2} + \lambda^2\right) f(x,t) = \epsilon F\left(f, \frac{\partial f}{\partial t}, \frac{\partial f}{\partial x}\right) \qquad (2)$$

where ϵ is again the formal expansion parameter; F is again a known function (which depends on the problem under consideration); and c^2 and λ^2 are non-negative real constants.

The immediate motivation for studying Equation 2 was that the equations of motion for a "cold" electron plasma in a uniform positive background may be put in this form, component by component. But it also has the value of being sufficiently simple that explicit zeroth order

*Published as *NASA Technical Note D-2305*, June 1964; also published in *Physics of Fluids*, 7(2); 242-249, February 1964.

**A quite similar technique was put forward independently by M. V. Lighthill: "A Technique for Rendering Approximate Solutions to Physical Problems Uniformly Valid," *Phil. Mag. Series* 7, 40(311):1179-1201, December 1949.

($\epsilon = 0$) solutions of it can be constructed which *both do and do not* lead to secular behavior when a straightforward attempt is made to extend them to higher order in ϵ. This simple example makes clear one difference between Equation 1 and an equation of the type 2. In general, for a given F, any $\epsilon = 0$ solution of Equation 1 will give rise to secularity when extended to higher order, whereas the conditions under which Equation 2 gives rise to secular behavior beyond the first order *depend sensitively upon which* $\epsilon = 0$ *solution it is that one wishes to extend to higher order in* ϵ, *even for a given* F.

We shall first give an example of both secular and non-secular behavior for Equation 2, and show how the difficulties may be remedied in the secular case. Then we shall give a simple physical example, that of the second order behavior of a nonlinear electromagnetic wave in a "cold" electron plasma.

THE KLEIN-GORDON EQUATION WITH A SMALL NONLINEAR TERM

A Single Monochromatic Wave

We shall first consider perturbations about the following $\epsilon = 0$ solution to Equation 2:

$$f = a \cos (K_0 x - \omega_0 t + \phi) \tag{3}$$

where

$$\omega_0^2 = c^2 K_0^2 + \lambda^2 \tag{4}$$

and, for $\epsilon = 0$, the quantities K_0, ω_0, a, and ϕ are constants.

This happens to be a situation for which secularity arises, so we shall set up the necessary formalism for handling it from the beginning. Following Reference 2, we seek a solution to Equation 2 of the form

$$f = a \cos \psi + \epsilon u_1(a, \psi) + \epsilon^2 u_2(a, \psi) + \cdots , \tag{5}$$

where the amplitude a is now determined as a "slowly-varying" function of x and t by the relations

$$\frac{\partial a}{\partial t} = \epsilon A_1(a) + \epsilon^2 A_2(a) + \cdots , \tag{6a}$$

$$\frac{\partial a}{\partial x} = \epsilon D_1(a) + \epsilon^2 D_2(a) + \cdots . \tag{6b}$$

Here, ψ is a new "phase" variable, to be chosen to coincide with the phase of Equation 3 for $\epsilon = 0$:

$$\frac{\partial \psi}{\partial t} = -\omega_0 + \epsilon B_1(a) + \epsilon^2 B_2(a) + \cdots , \tag{7a}$$

$$\frac{\partial \psi}{\partial x} = K_0 + \epsilon C_1(a) + \epsilon^2 C_2(a) + \cdots . \tag{7b}$$

The (as yet undetermined) functions A_1, A_2, $\cdots$, B_1, B_2, $\cdots$, C_1, C_2, $\cdots$, D_1, D_2, $\cdots$, are to be *chosen* so as to render the solution (5) free from secular terms. Here, "secular" must be interpreted to mean ψ-proportional; i.e., solutions can break down because of linear growth in x as well as in t. The functions u_1, u_2, $\cdots$, are to be *peroidic* in ψ.

The program is to express the various terms in Equation 2, by means of the relations (5), (6), and (7), in terms of the u's, A's, B's, C's and D's, as functions of a and ψ. For brevity's sake, we shall first only go to $0(\epsilon)$, though in principle the method may be carried to any order in ϵ. Generally, the algebra becomes prohibitive beyond $0(\epsilon^2)$. Hereafter, the notation "+ $\cdots$" will mean "of higher order in ϵ".

The result of differentiating f with respect to x and t and using (6) and (7) is:

$$\begin{aligned} \frac{\partial^2 f}{\partial t^2} - c^2 \frac{\partial^2 f}{\partial x^2} + \lambda^2 f &= a \cos \psi \left(-\omega_0^2 + c^2 K_0^2 + \lambda^2\right) \\ &+ \epsilon \left\{ \lambda^2 \left(\frac{\partial^2 u_1}{\partial \psi^2} + u_1 \right) + 2\left(\omega_0 A_1 + c^2 K_0 D_1\right) \sin \psi \right. \\ &\left. + 2a\left(\omega_0 B_1 + c^2 K_0 C_1\right) \cos \psi \right\} \\ &+ 0\left(\epsilon^2\right) . \end{aligned} \tag{8}$$

The zeroth order part of (8) vanishes identically, by virtue of (4). The coefficient of ϵ is to be equated to $F(f, \partial f/\partial t, \partial f/\partial x)$, with the arguments replaced by their zeroth order values:

$$f \to a \cos \psi ,$$

$$\partial f/\partial t \to \omega_0 a \sin \psi ,$$

$$\partial f/\partial x \to -K_0 a \sin \psi .$$

For the purpose of finding u_1, it is most convenient to write F as a Fourier series in ψ:

$$F(a\cos\psi,\ \omega_0 a\sin\psi,\ -K_0 a\sin\psi)$$

$$= g_0(a) + \sum_{n=1}^{\infty}\left(g_n(a)\cos n\psi + f_n(a)\sin n\psi\right) . \quad (9)$$

The $f_n(a)$ and $g_n(a)$ are *known* functions of the amplitude a, determined by the functional form of F. We shall make the assumption—always satisfied in practice—that the $f_n(a)$ and $g_n(a)$ go to zero, as a goes to zero, at least as fast as 0 (a^2).

The equation for u_1 may be written as:

$$\lambda^2\left(\frac{\partial^2}{\partial\psi^2}+1\right)u_1 = g_0(a)$$

$$+\left[f_1(a) - 2\omega_0 A_1 - 2c^2K_0D_1\right]\sin\psi$$

$$+\left[g_1(a) - 2a\omega_0 B_1 - 2ac^2K_0C_1\right]\cos\psi$$

$$+\sum_{n=2}^{\infty}\left(g_n(a)\cos n\psi + f_n(a)\sin n\psi\right) . \quad (10)$$

This is, effectively, an ordinary differential equation in ψ of a standard type. Its solution contains terms proportional to $\psi\sin\psi$ and $\psi\cos\psi$ *unless* the coefficients of $\sin\psi$ and $\cos\psi$ on the right hand side of (10) vanish. *If* they vanish, then the general solution may be found in the form

$$u_1 = v_0(a) + \sum_{n=1}^{\infty}\left(v_n(a)\cos n\psi + w_n(a)\sin n\psi\right) . \quad (11)$$

Our objective is to find a solution free from ψ-proportional terms. This impels us to choose A_1, B_1, C_1, D_1, so that

$$2\left(\omega_0 A_1 + c^2K_0D_1\right) = f_1(a) , \quad (12a)$$

$$2a\left(\omega_0 B_1 + c^2K_0C_1\right) = g_1(a) .$$

Two more relations may be deduced from the conditions

$$\frac{\partial^2\psi}{\partial t\,\partial x} = \frac{\partial^2\psi}{\partial x\,\partial t}$$

and

$$\frac{\partial^2 a}{\partial t\,\partial x} = \frac{\partial^2 a}{\partial x\,\partial t} .$$

Reference to (6) and (7) shows that, to lowest significant order, these become

$$A_1\frac{dC_1}{da} = D_1\frac{dB_1}{da} , \quad (13a)$$

$$A_1\frac{dD_1}{da} = D_1\frac{dA_1}{da} . \quad (13b)$$

Equations 12 and 13 are four relations for the four unknowns A_1, B_1, C_1, D_1, and once they have been obtained, (10) can be solved in a straightforward way by means of (11), and u_1 will contain no ψ-proportional terms. The function B_1 can be interpreted as a "frequency shift" and C_1 as a "wave number shift."

However, it is impossible to solve (12) and (13) completely without specifying the physical problem in more detail. For instance, if we wish to work a *boundary value* problem in which f is required to oscillate sinusoidally at a given x for all t, we do not expect a or ψ to vary with t, and B_1 and A_1 may be set equal to zero. This leaves

$$C_1 = \frac{g_1(a)}{2c^2K_0a} \quad (14a)$$

as the "wave number shift" and

$$D_1 = \frac{f_1(a)}{2c^2K_0} . \quad (14b)$$

If we are interested in an *initial value* problem in which a pure sine wave is given for all x at t = 0, we may correspondingly set C_1 and D_1 equal to zero and solve for A_1 and B_1. Other choices are necessitated by still other problems. (Note in passing that in both cases, the corrections approach zero as a approaches zero, as they must in order to make physical sense.

All this has been for a completely general F, imagined to contain all harmonics in ψ. In practice, it often happens that F contains only a few harmonics. Observe that secularity may *not* arise for some forms of the nonlinear term. Thus, if F is proportional to $(f)^2$ or $f\partial f/\partial x$, say, then $f_1(a)$ and $g_1(a)$ will both vanish; and in this order, we may set A_1, B_1, C_1, D_1, all identically zero, which is equivalent to a completely straightforward kind of perturbation theory. On the other hand, if we were to have F proportional to $(f)^3$, $f_1(a)$ is still zero, but $g_1(a) = 3a^3/4$ and straightforward perturbation theory no longer works. The occurrence of secularity thus depends, in a given order, on the particular form of the nonlinear term. In the following sub-section, we shall show that, for a given F secularity likewise may or may not appear, depending on the choice of the $\epsilon = 0$ solution.

To close this discussion, we give the full solution for $u_1(a,\psi)$ of Equation 11. If we make the (arbitrary) choice that all the first harmonic shall be collected in lowest order, we may choose $v_1(a) = w_1(a) = 0$. Then for $n \neq 1$,

$$\left.\begin{aligned} v_n(a) &= \frac{g_n(a)}{\lambda^2(-n^2+1)} , \\ w_n(a) &= \frac{f_n(a)}{\lambda^2(-n^2+1)} , \end{aligned}\right\} \qquad (15a)$$

$$\begin{pmatrix} f_n(a) \\ g_n(a) \end{pmatrix} = \frac{1}{\pi} \int_0^{2\pi} \begin{pmatrix} \sin n\psi \\ \cos n\psi \end{pmatrix} F\left(a\cos\psi,\ \omega_0 a \sin\psi,\ -K_0 a \sin\psi\right) d\psi . \qquad (15b)$$

When the phenomenon of secularity occurs, one must go to one higher order in ϵ to get corrections to f which are uniformly valid through terms of $0(\epsilon)$ for changes in x and t of $0(1/\epsilon)$, and so the solution (15) is not of great interest by itself (Reference 2). However, the expressions such as (14) for frequency and wave number shifts *are* accurate to $0(\epsilon)$, and are usually more accessible to measurement than the expression for u_1, in any case.

Two Coupled Monochromatic Waves of Differing Frequencies

We now proceed to the case in which Equation 2 has the $\epsilon = 0$ solution

$$f = a\left[\cos\left(K_1 x - \omega_1 t + \phi_1\right) + \cos\left(K_2 x - \omega_2 t + \phi_2\right)\right] , \qquad (16)$$

where

$$\omega_1^2 - c^2K_1^2 - \lambda^2 = \omega_2^2 - c^2K_2^2 - \lambda^2 = 0 , \qquad (17)$$

but where there is not necessarily any other relationship between ω_1, K_1 and ω_2, K_2. If we were to do a straightforward perturbation theory, assuming

$$f = f^{(0)} + \epsilon f^{(1)} + \epsilon^2 f^{(2)} + \cdots , \qquad (18)$$

with $f^{(0)}$ given by (16), it is clear that we can always find a secularity-free perturbation theoretic solution to (2) of the form

$$f^{(n)} = \sum_{r,s=-\infty}^{\infty} f_{rs}^{(n)}(a) \exp i\left[r\left(K_1 x - \omega_1 t + \phi_1\right) + s\left(K_2 x - \omega_2 t + \phi_2\right)\right] \qquad (19)$$

except when there happen to exist two integers $\bar{r}$, $\bar{s}$ such that

$$\lambda^2\left(-\bar{r}^2 - \bar{s}^2 + 1\right) - 2\bar{r}\bar{s}\left(\omega_1\omega_2 - c^2K_1K_2\right) = 0 . \qquad (20)$$

When (20) is fulfilled $f^{(1)}$, like the u_1 of Equation 10, will in general contain terms proportional to the phases, as well as trigonometric terms.

For a randomly selected pair of values ω_1, K_1 and ω_2, K_2, there will exist no integers $\bar{r}$, $\bar{s}$ which

fulfill (20), and there is no necessity for the Bogolyubov techniques. When, on the other hand, two such integers $\tilde{r}$, $\tilde{s}$, do exist [the relation (20) will also hold for $-\tilde{r}$, $-\tilde{s}$, of course], then the Bogolyubov techniques are called for. One method of introducing them is the following, though it is not the only method.* Seek a solution of the form

$$f = a(\cos\psi_1 + \cos\psi_2) + \epsilon u_1(a, \psi_1, \psi_2) + \cdots$$

where now the amplitude a and the phases ψ_1 and ψ_2 develop according to:

$$\left.\begin{aligned}
\frac{\partial a}{\partial t} &= \epsilon A(a, \psi_1, \psi_2) + \cdots, \\
\frac{\partial a}{\partial x} &= \epsilon B(a, \psi_1, \psi_2) + \cdots, \\
\frac{\partial \psi_{1,2}}{\partial t} &= -\omega_{1,2} + \epsilon C_{1,2}(a, \psi_1, \psi_2) + \cdots, \\
\frac{\partial \psi_{1,2}}{\partial x} &= K_{1,2} + \epsilon D_{1,2}(a, \psi_1, \psi_2) + \cdots.
\end{aligned}\right\} \quad (21)$$

The left hand side of (2) may again be computed, by using the relations (21), to give

$$\begin{aligned}
\frac{\partial^2 f}{\partial t^2} - c^2\frac{\partial^2 f}{\partial x^2} + \lambda^2 f = {} & a\left[\left(-\omega_1^2 + c^2K_1^2 + \lambda^2\right)\cos\psi_1 + \left(-\omega_2^2 + c^2K_2^2 + \lambda^2\right)\cos\psi_2\right] \\
& + \epsilon\Bigg\{\sin\psi_1\left[2\omega_1 A + a\omega_1\frac{\partial C_1}{\partial\psi_1} + a\omega_2\frac{\partial C_1}{\partial\psi_2}\right. \\
& \left. + 2c^2K_1B + ac^2K_1\frac{\partial D_1}{\partial\psi_1} + ac^2K_2\frac{\partial D_1}{\partial\psi_2}\right] + \sin\psi_2\left[2\omega_2 A\right. \\
& \left. + a\omega_1\frac{\partial C_2}{\partial\psi_1} + a\omega_2\frac{\partial C_2}{\partial\psi_2} + 2c^2K_2B + ac^2K_1\frac{\partial D_2}{\partial\psi_1} + ac^2K_2\frac{\partial D_2}{\partial\psi_2}\right] \\
& + \cos\psi_1\left[2a\omega_1C_1 - \omega_1\frac{\partial A}{\partial\psi_1} - \omega_2\frac{\partial A}{\partial\psi_2} + 2ac^2K_1D_1 - c^2K_1\frac{\partial B}{\partial\psi_1}\right. \\
& \left. - c^2K_2\frac{\partial B}{\partial\psi_2}\right] + \cos\psi_2\left[2a\omega_2C_2 - \omega_1\frac{\partial A}{\partial\psi_1} - \omega_2\frac{\partial A}{\partial\psi_2} + 2c^2aK_2D_2\right. \\
& \left. - c^2K_1\frac{\partial B}{\partial\psi_1} - c^2K_2\frac{\partial B}{\partial\psi_2}\right]\Bigg\} + \epsilon\left\{\lambda^2\left[\frac{\partial^2 u_1}{\partial\psi_1^2} + \frac{\partial^2 u_1}{\partial\psi_2^2} + u_1\right]\right. \\
& \left. + 2\left[\omega_1\omega_2 - c^2K_1K_2\right]\frac{\partial^2 u_1}{\partial\psi_1\partial\psi_2}\right\} + 0(\epsilon^2) \qquad (22)
\end{aligned}$$

The zeroth order part of (22) vanishes identically. The first order part now must be equated to $\epsilon F[a(\cos\psi_1+\cos\psi_2), a(\omega_1\sin\psi_1+\omega_2\sin\psi_2), -a(K_1\sin\psi_1+K_2\sin\psi_2)]$. It is most convenient to write this as a complex Fourier series,

$$F = \sum_{m,n=-\infty}^{+\infty} F_{mn}(a)\, e^{i(m\psi_1+n\psi_2)} \qquad (23)$$

where $F_{mn}^* = F_{-m-n}$, since we deal only with real quantities. Calling everything in the first set of braces in Equation 22 "$G(a, A, B, C_{1,2}, D_{1,2})$," we may finally write the equation for u_1 as

$$\lambda^2\left(\frac{\partial^2 u_1}{\partial\psi_1^2} + \frac{\partial^2 u_1}{\partial\psi_2^2} + u_1\right) + 2\left(\omega_1\omega_2 - c^2K_1K_2\right)\frac{\partial^2 u_1}{\partial\psi_1\partial\psi_2} = -G(a, A, B, C_{1,2}, D_{1,2}) + \sum_{m,n=-\infty}^{+\infty} F_{mn}(a)e^{i(m\psi_1+n\psi_2)}. \qquad (24)$$

*For simplicity, we assume only one independent pair of such integers, $\tilde{r}$, $\tilde{s}$, exists.

This equation, analogously to (10), has a readily obtainable secularity-free solution of the form

$$u_1(\psi_1, \psi_2, a) = \sum_{m,n=-\infty}^{+\infty} u_{mn}(a) e^{i(m\psi_1 + n\psi_2)} \tag{25}$$

if and only if the functions A, B, $C_{1,2}$, $D_{1,2}$ *are chosen to depend on* ψ_1 *and* ψ_2 *in such a manner that:*

$$\oint d\psi_1 \oint d\psi_2 \, e^{-i(\vec{r}\psi_1 + \vec{s}\psi_2)} G(a, A, B, C_{1,2}, D_{1,2}) - F_{\vec{r}\,\vec{s}}(a) = 0 . \tag{26}$$

Since (26) involves complex numbers, it really amounts to two real equations upon A, B, $C_{1,2}$, $D_{1,2}$, which are linear partial differential equations with periodic coefficients.* We need not write them down in full detail, since they are most cumbersome, and not of interest for our purposes here.

From the requirements that

$$\partial^2 a/\partial x\,\partial t = \partial^2 a/\partial t\,\partial x , \quad \partial^2 \psi_{1,2}/\partial x\,\partial t = \partial^2 \psi_{1,2}/\partial t\,\partial x ,$$

three additional conditions may be adduced. They are:

$$K_1 \frac{\partial A}{\partial \psi_1} + K_2 \frac{\partial A}{\partial \psi_2} = -\left(\omega_1 \frac{\partial B}{\partial \psi_1} + \omega_2 \frac{\partial B}{\partial \psi_2}\right) , \tag{27a}$$

$$K_1 \frac{\partial D_1}{\partial \psi_1} + K_2 \frac{\partial D_1}{\partial \psi_2} = -\left(\omega_1 \frac{\partial C_1}{\partial \psi_1} + \omega_2 \frac{\partial C_1}{\partial \psi_2}\right) , \tag{27b}$$

$$K_1 \frac{\partial D_2}{\partial \psi_1} + K_2 \frac{\partial D_2}{\partial \psi_2} = -\left(\omega_1 \frac{\partial C_2}{\partial \psi_1} + \omega_2 \frac{\partial C_2}{\partial \psi_2}\right) \tag{27c}$$

Satisfaction of these five relations on the six quantities A, B, $C_{1,2}$, $D_{1,2}$, then, will guarantee that the solution shall be secularity-free. It is clear that considerable latitude is left to choose the functions conveniently for whatever problem is under consideration. The point to be emphasized, however, is that secularity is by no means inherent in the equation to be studied, or in the form of the interaction term. Nor does its origin necessarily have a simple physical interpretation as it does for Equation 1, where the presence of secular terms is simply interpreted as a *resonance* between one of the frequencies present in the nonlinear coupling term and one of the natural frequencies of the system. It would take considerably more insight to apprehend the physical meaning of Equation 20, or any connection it might have with the secularity condition for Equation 10.

*We may consider A, B, · · · · as being expressed as Fourier series in ψ_1, ψ_2, in which case (26) leads to algebraic conditions on the Fourier coefficients.

THE COLD ELECTRON PLASMA

Suppose we consider a cold (no thermal motions) electron plasma of equilibrium number density n_0, moving in a uniform positive background, assumed immobile. If we make a perturbation about a uniform, field-free equilibrium, the appropriate variables for describing the system are:

$\vec{v}$ = electron velocity,

$-e(n_0 + n(\vec{x}, t))$ = electron charge density,

$+en_0$ = positive background charge density,

$\vec{E}$, $\vec{B}$ = electric and magnetic fields.

All these will be treated as perturbations—i.e., as first order in the amplitude—except for n_0.

The dynamical equations are well known:

$$\frac{\partial n}{\partial t} + \frac{\partial}{\partial \vec{x}} \cdot (n\vec{v}) + \frac{\partial}{\partial \vec{x}} \cdot (n_0 \vec{v}) = 0 , \tag{28a}$$

$$\frac{\partial \vec{v}}{\partial t} + \vec{v} \cdot \frac{\partial}{\partial \vec{x}} \vec{v} = -\frac{e}{m}\left(\vec{E} + \frac{1}{c}\vec{v} \times B\right) , \tag{28b}$$

$$\frac{1}{c}\frac{\partial \vec{B}}{\partial t} = -\frac{\partial}{\partial \vec{x}} \times \vec{E} , \tag{28c}$$

$$\frac{1}{c}\frac{\partial \vec{E}}{\partial t} = \frac{\partial}{\partial \vec{x}} \times \vec{B} + \frac{4\pi e}{c}(n_0 + n)\vec{v} , \tag{28d}$$

$$\frac{\partial}{\partial \vec{x}} \cdot \vec{E} = -4\pi en \,, \tag{29a}$$

$$\frac{\partial}{\partial \vec{x}} \cdot \vec{B} = 0 \,. \tag{29b}$$

Equations 29 can be regarded as initial conditions; once fulfilled, they are preserved by Equations 28.

A small amount of algebraic juggling shows that Equations 28 lead to

$$\frac{\partial^2}{\partial t^2}\vec{E} + c^2 \frac{\partial}{\partial \vec{x}} \times \left(\frac{\partial}{\partial \vec{x}} \times \vec{E}\right) + \omega_{pe}^2 \vec{E} = -\epsilon\, 4\pi e\left[n_0\left(\vec{v} \cdot \frac{\partial}{\partial \vec{x}}\vec{v} + \frac{e}{mc}\vec{v} \times \vec{B}\right) - \frac{\partial}{\partial t}(n\vec{v})\right], \tag{30a}$$

$$\frac{\partial^2}{\partial t^2}\frac{\partial \vec{B}}{\partial t} + c^2 \frac{\partial}{\partial \vec{x}} \times \left(\frac{\partial}{\partial \vec{x}} \times \frac{\partial \vec{B}}{\partial t}\right) + \omega_{pe}^2 \frac{\partial \vec{B}}{\partial t} = \epsilon\left[4\pi e n_0 c \frac{\partial}{\partial \vec{x}} \times \left(\vec{v} \cdot \frac{\partial}{\partial \vec{x}}\vec{v} + \frac{e\vec{v}}{mc} \times \vec{B}\right) - 4\pi ec \frac{\partial}{\partial \vec{x}} \times \frac{\partial}{\partial t}(n\vec{v})\right]. \tag{30b}$$

The formal expansion parameter ϵ has been written on the right hand side of Equations 30 only to remind us that these terms are "small" in the sense of being second order in the amplitude. The quantity ω_{pe}^2 is $4\pi n_0 e^2/m$, the plasma frequency.

If we now restrict ourselves to disturbances which are function of only one spatial dimension (x, say), we may write the expression (30a) in the form

$$\left(\frac{\partial^2}{\partial t^2} - c^2\frac{\partial^2}{\partial x^2} + \omega_{pe}^2 + c^2\delta_{1,i}\frac{\partial^2}{\partial x^2}\right)E_i = \epsilon \mathfrak{F}_i \,, \tag{31}$$

where $\delta_{1,i} = 0$ unless $i = 1$, and $\delta_{1,1} = 1$; $\mathfrak{F}_i$ represents the i^{th} component of the right hand side of (30a). Since (30b) is just the curl of (30a), it is not necessary to write it in the form of (31). It matters not at all that we have not bothered to express the right hand side of (30a) as a function of $\vec{E}$ alone, since we always need the values of the quantities which enter in $\mathfrak{F}_i$ to one lower order than those under consideration on the left hand side of (30a); and those will be shown to be obtainable in each order directly from (28).

The $\epsilon = 0$ solution to (31) is just the standard cold-plasma set of field-free normal modes, which is well understood (Reference 7). It will be apparent that each component of (31) has the form of Equation 2 and is therefore immediately susceptible to the methods already discussed. Equation 31 represents a generalization of the equation treated by Jackson (Reference 5), which, however, does not exhibit all the features of (31) because of the absence of x-derivatives on the left hand side in the purely electrostatic case, and of the fact that the x and t dependences separate.

The number of possibilities from (31) is very large, due to the wide range of choices for the $\epsilon = 0$ solution. The simplest case—beyond that of a pure electrostatic oscillation (Reference 5)—is that of a pure transverse, linearly polarized, electromagnetic wave. We shall extend this solution to the next two orders above the linear approximation in the following paragraphs.

Calling our base vectors $\hat{e}_x$, $\hat{e}_y$, $\hat{e}_z$, the appropriate zeroth order solution is

$$\begin{aligned} \vec{E} &= E_0 \hat{e}_y \cos(k_0 x - \omega_0 t) \,, \\ \vec{B} &= \frac{ck_0}{\omega_0} E_0 \hat{e}_z \cos(k_0 x - \omega_0 t) \\ \vec{v} &= \frac{eE_0}{m\omega_0} \hat{e}_y \sin(k_0 x - \omega_0 t) \\ n &= 0 \end{aligned} \tag{32}$$

where

$$\omega_0^2 = \omega_{pe}^2 + c^2 k_0^2 \tag{33}$$

This zeroth order solution for $\vec{E}$ is conveniently written:

$$E_i = a\left[\phi_i e^{i(k_0 x - \omega_0 t)} + \phi_i^* e^{-i(k_0 x - \omega_0 t)}\right]$$

where ϕ is a column vector

$$\phi = \begin{pmatrix} 0 \\ \frac{1}{2} \\ 0 \end{pmatrix} \tag{34}$$

and $a = E_0$ is the amplitude.

The results of Section II suggest that we seek a solution of the form

$$E_i = a\left(\phi_i e^{i\psi} + \phi_i^* e^{-i\psi}\right) + \epsilon u_i^{(1)}(a,\psi) + \epsilon^2 u_i^{(2)}(a,\psi) + \cdots \tag{35}$$

where now the amplitude a and phase ψ are to vary in x and t according to

$$\left.\begin{aligned} \frac{\partial a}{\partial t} &= \epsilon A_1(a) + \epsilon^2 A_2(a) + \cdots , \\ \frac{\partial a}{\partial x} &= \epsilon D_1(a) + \epsilon^2 D_2(a) + \cdots , \\ \frac{\partial \psi}{\partial t} &= -\omega_0 + \epsilon B_1(a) + \epsilon^2 B_2(a) + \cdots , \\ \frac{\partial \psi}{\partial x} &= k_0 + \epsilon C_1(a) + \epsilon^2 C_2(a) + \cdots , \end{aligned}\right\} \tag{36}$$

with the functions $A_1, B_1, \cdots$, as yet undetermined.

The left hand side of (31), expressed in terms of these functions, becomes, for i = 1,

$$\left(\frac{\partial^2}{\partial t^2} + \omega_{pe}^2\right) E_1 = \epsilon\left\{\omega_0^2 \frac{\partial^2 u_1^{(1)}}{\partial \psi^2} + \omega_{pe}^2 u_1^{(1)} + 2\left(-i\omega_0 A_1 + a\omega_0 B_1\right)\phi_1 e^{i\psi} + 2\left(i\omega_0 A_1 + a\omega_0 B_1\right)\phi_1^* e^{-i\psi}\right\} + 0(\epsilon^2) ; \tag{37}$$

and for i = 2 or 3,

$$\left(\frac{\partial^2}{\partial t^2} - c^2\frac{\partial^2}{\partial x^2} + \omega_{pe}^2\right) E_i = \epsilon\left\{\omega_{pe}^2\left(\frac{\partial^2 u_i^{(1)}}{\partial \psi^2} + u_i^{(1)}\right) + 2\left(-i\omega_0 A_1 + a\omega_0 B_1 - ic^2 k_0 D_1 + ac^2 C_1 k_0\right)\phi_i e^{i\psi} + 2\left(i\omega_0 A_1 + a\omega_0 B_1 + ic^2 k_0 D_1 + ac^2 C_1 k_0\right)\phi_i^* e^{-i\psi}\right\} + 0(\epsilon^2) . \tag{38}$$

These three expressions are to be equated to the three components of the right hand sides of (31), with the quantities $\vec{v}$, $\vec{E}$, $\vec{B}$, n replaced by their values (32), and with the substitution $E_0 \to a$. The result can be conveniently written as a Fourier series

$$\mathfrak{F}_i = \sum_{m=-\infty}^{+\infty} \Phi_i(m,a)\, e^{im\psi} , \tag{39}$$

where the Φ_i (m, a) are *known* functionals of a.

Suppose we now consider whether secular terms can arise. We seek the solution for $u_i^{(1)}$ in the form

$$u_i^{(1)} = \sum_{m=-\infty}^{\infty} u_i^{(1)}(m,a)\, e^{im\psi} \tag{40}$$

The equation for $u_i^{(1)}$ then becomes

$$\sum_{m=-\infty}^{\infty}\left[\left(-m^2+1\right)\omega_{pe}^2 + m^2\delta_{1,i}\left(\omega_{pe}^2 - \omega_0^2\right)\right] u_i^{(1)}(m,a)\, e^{im\psi} = -2\left(-i\omega_0 A_1 + a\omega_0 B_1 - ic^2 k_0 D_1 + ac^2 C_1 k_0\right)\phi_i e^{i\psi} - 2\left(i\omega_0 A_1 + a\omega_0 B_1 + ic^2 k_0 D_1 + ac^2 C_1 k_0\right)\phi_i^* e^{-i\psi} + \sum_{m=-\infty}^{\infty}\Phi_i(m,a)\, e^{im\psi} , \tag{41}$$

(we have made use of $\phi_1 = 0$).

We may always solve (41) for $u_i^{(1)}$ (m, a) with the absence of ψ-proportional terms, except when a coefficient of $u_i^{(1)}$ (m, a,) on the left hand side of (41) vanishes for some m. Since $\omega_0^2 > \omega_{pe}^2$ it is clear that this can only occur when $m = \pm 1$, and only in the components i = 2 or 3. However, a term-by-term inspection of Φ_i (m, a) reveals that for i = 2 or 3, the quantities Φ_i (m, a) vanish identically for the choice (33) of the zeroth order values. Thus a result emerges which would have been hard to guess from the original set of equations

(28). Secular behavior cannot arise in second order for this case, and we may set $A_1 = B_1 = C_1 = D_1 = 0$, and solve in a completely straightforward way for $u_i^{(1)}(m, a)$:

$$u_i^{(1)}(m,a) = \frac{\Phi_i(m,a)}{\left(-m^2+1\right)\omega_{oe}^2 + m^2\delta_{1,i}\left(\omega_{pe}^2 - \omega_0^2\right)}, \quad m \neq \pm 1,$$

$$u_i^{(1)}(\pm 1, a) = 0. \tag{42}$$

The calculation of the coefficients of the Fourier coefficients is a matter of simple algebra, and we may write down in full the first correction to the linear solution (32):

$$\vec{u}^{(1)} = \vec{E}^{(1)} = E_0^2 \frac{ek_0\omega_{pe}^2}{2m\omega_0^2} \frac{\sin 2\left(k_0x - \omega_0 t\right)}{\left(3\omega_{pe}^2 + 4c^2k_0^2\right)} \hat{e}_x ,$$

$$\vec{B}^{(1)} = 0 ,$$

$$n^{(1)} = -E_0^2 \frac{e^2n_0k_0^2}{m^2\omega_0^2} \frac{\cos 2\left(k_0x - \omega_0 t\right)}{\left(3\omega_{pe}^2 + 4c^2k_0^2\right)} ,$$

$$\vec{v}^{(1)} = -E_0^2 \frac{e^2k_0}{m^2\omega_0} \frac{\cos 2\left(k_0x - \omega_0 t\right)}{\left(3\omega_{pe}^2 + 4c^2k_0^2\right)} \hat{e}_x \tag{43}$$

The only qualitatively new feature which shows up in $0(\epsilon)$, then, is a *longitudinal* electric field. It is only in $0(\epsilon^2)$ that secularity manifests itself and it becomes necessary to use the Bogolyubov methods. Making use of the $0(\epsilon)$ solution we have just computed, we may write down the $0(\epsilon^2)$ part of the left hand side of (31) in terms of the A's, B's, etc. We shall need:

$$\left\{\frac{\partial^2 E_i}{\partial t^2} - c^2\frac{\partial^2 E_i}{\partial x^2} + \omega_{pe}^2 E_i\right\}_{0(\epsilon^2)_{part}}$$

$$= \epsilon^2\Big[\left(\omega_0^2 - c^2k_0^2\right)\frac{\partial^2 u_i^{(2)}}{\partial\psi^2} + \omega_{pe}^2 u_i^{(2)}$$

$$+ \left(-2i\omega_0A_2 + 2a\omega_0B_2 - 2ik_0c^2D_2 + 2ak_0C_2\right)\phi_i e^{i\psi}$$

$$+ \left(2i\omega_0A_2 + 2a\omega_0B_2 + 2ik_0c^2D_2 + 2ac^2k_0C_2\right)\phi_i^* e^{-i\psi}\Big]. \tag{44}$$

It is also a simple matter to compute the $0(\epsilon^2)$ part of the right hand side of (31) from (43) and (32). The result expressed in terms of a and ψ, is

$$\mathcal{F}_i\Big]_{0(\epsilon^2)_{part}} = \frac{\omega_{pe}^2k_0^2e^2a^3\delta_{i,2}}{4\omega_0^2m^2\left(3\omega_{pe}^2 + 4c^2k_0^2\right)}\left\{3\left(e^{3i\psi} + e^{-3i\psi}\right) - \left(e^{i\psi} + e^{-i\psi}\right)\right\}. \tag{45}$$

Since the only nonvanishing component of (45) is in the 2-direction (y-direction), the only nonvanishing component of $u_i^{(2)}$ will also be $u_2^{(2)}$. The equation to be solved in the $0(\epsilon^2)$ approximation is, therefore:

$$\left(\omega_0^2 - c^2k_0^2\right)\frac{\partial^2 u_2^{(2)}}{\partial\psi^2} + \omega_{pe}^2u_2^{(2)} =$$

$$-\left(-2i\omega_0A_2 + 2a\omega_0B_2 - 2ik_0c^2D_2 + 2ak_0c^2C_2\right)\phi_2 e^{i\psi}$$

$$-\left(2i\omega_0A_2 + 2a\omega_0B_2 + 2ik_0c^2D_2 + 2ac^2k_0C_2\right)\phi_2^* e^{-i\psi}$$

$$+\frac{\omega_{pe}^2k_0^2e^2a^3}{4\omega_0^2m^2\left(3\omega_{pe}^2 + 4c^2k_0^2\right)}\left[3\left(e^{3i\psi} + e^{-3i\psi}\right) - \left(e^{i\psi} + e^{-i\psi}\right)\right]. \tag{46}$$

We may find a solution to (46) of the form

$$u_2^{(2)}(a,\psi) = \sum_{m=-\infty}^{\infty} u_2^{(2)}(a,m)e^{im\psi} . \tag{47}$$

which is free of ψ-proportional terms, if and only if the coefficients of $e^{i\psi}$ and $e^{-i\psi}$ on the right hand side of (46) vanish. This gives us two conditions on A_2, B_2, C_2, D_2, which are algebraic relations. Two more, analogous to Equations 13, are given by the requirements that

$$\frac{\partial^2 a}{\partial t\partial x} = \frac{\partial^2 a}{\partial x\partial t}$$

and

$$\frac{\partial^2\psi}{\partial t\,\partial x} = \frac{\partial^2\psi}{\partial x\,\partial t} \ ;$$

they are:

$$D_2 \frac{dA_2}{da} = A_2 \frac{dD_2}{da} \ , \qquad (48a)$$

$$D_2 \frac{dB_2}{da} = A_2 \frac{dC_2}{da} \ . \qquad (48b)$$

Let us now specialize the problem to one in which the spatial periodicity and amplitude are given and we are to calculate the "frequency shift." This means setting $C_2 = D_2 = 0$. The condition that the coefficients of $e^{i\psi}$ and $e^{-i\psi}$ on the right hand side of (46) vanish reduces to the equation

$$(i\omega_0 A_2 - a\omega_0 B_2) = \frac{\omega_{pe}^2 k_0^2 a^3}{4m^2\omega_0^2\left(3\omega_{pe}^2 + 4c^2k_0^2\right)} \qquad (49)$$

and its complex conjugate relation. We may therefore find $A_2 = 0$, and the frequency shift $\Delta\omega$ becomes (substituting E_0 for the amplitude a):

$$\Delta\omega = -B_2 = \frac{e^2k_0^2\,\omega_{pe}^2}{4m^2\omega_0^3}\,\frac{E_0^2}{\left(3\omega_{pe}^2 + 4c^2k_0^2\right)} \qquad (50)$$

It does not seem worthwhile to write down the $0(\epsilon^2)$ corrections to $\vec{E}$, $\vec{B}$, $\vec{v}$, and n, though it would be easy to do so. In any experiment one might imagine, Equation 50 would probably be the easiest quantity to measure.

It is possible to calculate the frequency shift of a *standing* electromagnetic wave of given periodicity as well. One assumes a linearly polarized standing wave solution for (31) in lowest order and writes

$$E_i = a_i \sin k_0 x \cos\psi + \epsilon u_i^{(1)}(a, \psi, x) + \epsilon^2 u_i^{(2)}(a, \psi, x) + \cdots$$

Then, only the t-dependence of the phase variable and amplitude are expanded:

$$\frac{da}{dt} = \epsilon A_1(a) + \epsilon^2 A_2(a) + \cdots$$

$$\frac{d\psi}{dt} = \omega_0 + \epsilon B_1(a) + \epsilon^2 B_2(a) + \cdots$$

In lowest significant order, the frequency shift turns out to be exactly one eighth of the result given in Equation (50).

DISCUSSION

We have given a technique for obtaining uniformly valid, perturbation theoretic solutions to the Klein-Gordon equation with a small nonlinear term. The method has been applied to calculate the second order frequency shift of an electromagnetic wave in a cold electron plasma. The smallness of the expression (50) for attainable parameters is an indication of just how good an approximation the linear theory is at these frequencies.

It is not to be inferred, however, that the method adapts itself readily to all partial differential equations. For instance, the reader can easily convince himself that it fails for a nonlinear sound wave described by the Euler equations. (It appears to fail in all situations for which the $\epsilon = 0$ equation is a wave equation, $(\partial^2/\partial t^2 - c^2\partial^2/\partial x^2)f = 0$). The real reason is that, due to a steepening of the exact nonlinear wave front—obtainable from the Riemann invariants—a vertical tangent develops after a time of 0(1/ the amplitude). This destroys any regularity properties which may have existed in the original wave profile. Since the exact solution does not remain "close" to the $\epsilon = 0$ solution in *any* sense, after a time of order $1/\epsilon$, it is not surprising that perturbation theory is of little use beyond this time.

INITIAL RESULTS OF THE IMP–I MAGNETIC FIELD EXPERIMENT*

NORMAN F. NESS, CLELL S. SCEARCE AND JOSEPH B. SEEK

The Interplanetary Monitoring Platform, IMP–I, or Explorer XVIII launched on November 27, 1963 has provided the first accurate measurements of interplanetary magnetic fields. The initial apogee of the satellite was located 197,616 kilometers on the Sunlit side of the Earth, with an apogee-Earth-Sun angle of 33°. Detailed measurements of the interplanetary magnetic fields and the interaction of the solar wind with the geomagnetic field have been performed. This paper presents the initial results of the magnetic field experiement.

The strength of the interplanetary magnetic field is found to vary between 4 and 7 gammas with extreme values as low as 1 and as high as 10 gammas. The magnitude, however, is extremely stable over time scales of hours, although direction changes are significant. The general configuration of the interplanetary magnetic field is slightly below the plane of the ecliptic and approximately along the streaming angle predicted for a steady state solar wind. A significant feature of the magnetic field measurements is the discovery of fields pointed diametrically opposite the streaming angle indicating filamentary structure of interplanetary fields. Associated with the fields of opposite direction are null surfaces between the filaments and in the overall field structure.

The complex interaction of the solar wind and geomagnetic field shows a variety of significant magnetic field fluctuations and transition characteristics. The discovery of the collisionless magnetohydrodynamic shock wave at 13.4 R_e at the stagnation point associated with the super Alfvenic flow of solar plasma is one of the major results of this experiment. Details of the fluctuations are discussed as well as the gross structure and shape of the magnetospheric surface (10.2 R_e at the subsolar point) and the shock wave from the subsolar point to the nighttime geomagnetic tail. The transition region between the shock wave and the magnetopause is one of high turbulence in the magnetic field.

A unique aspect of the magnetic field data is the detection of the magnetohydrodynamic wake of the Moon during the fifth orbit when the satellite was eclipsed by the Moon's magnetosphere while in interplanetary space. The implications of this experimental discovery are discussed in view of other pertinent geophysical and astrophysical data.

1.0 INTRODUCTION

The Interplanetary Monitoring Platform, IMP–I, or Explorer XVIII, was launched from the Atlantic Missile Range, Cape Kennedy, Florida on November 27, 1963 at 0230:01.07 Universal Time. The 63 kilogram spacecraft shown in Figure 1. was placed into a highly elliptical orbit by a three stage Thor-Delta vehicle with an initial orbital period of 93.5 hours, inclination to the Earth's equator of 33.33° and eccentricity of 0.937. The initial apogee was on the Sunlit side of the Earth at an angle to the Sun of 32.7° and at a geocentric distance of 197,616 kilometers (initial perigee = 192 kilometers). The spacecraft was spin stabilized at an initial rate of 22.27 rpm with an initial spin axis-satellite-Sun angle measured by the spacecraft optical aspect sensor of 111°. The right ascension and declination of the spacecraft spin axis were initially 116.6° and −23.5° respectively. An important physical force acting on the dynamically spin stabilized satellite and its solar paddles is solar radiation pressure. This force, or more properly, the torque effects associated with this force have led to both a gradual increase of the satellite spin rate and a precessional motion of the spin axis in celestial inertial coordinates. When the spacecraft aspect to the Sun decreases below 90° the net effect of the solar radiation

*Published as *Goddard Space Flight Center Document X-612-64-95*, April 1964; also published in *Journal of Geophysical Research*, 69(17):-3531-3569 September 1, 1964.

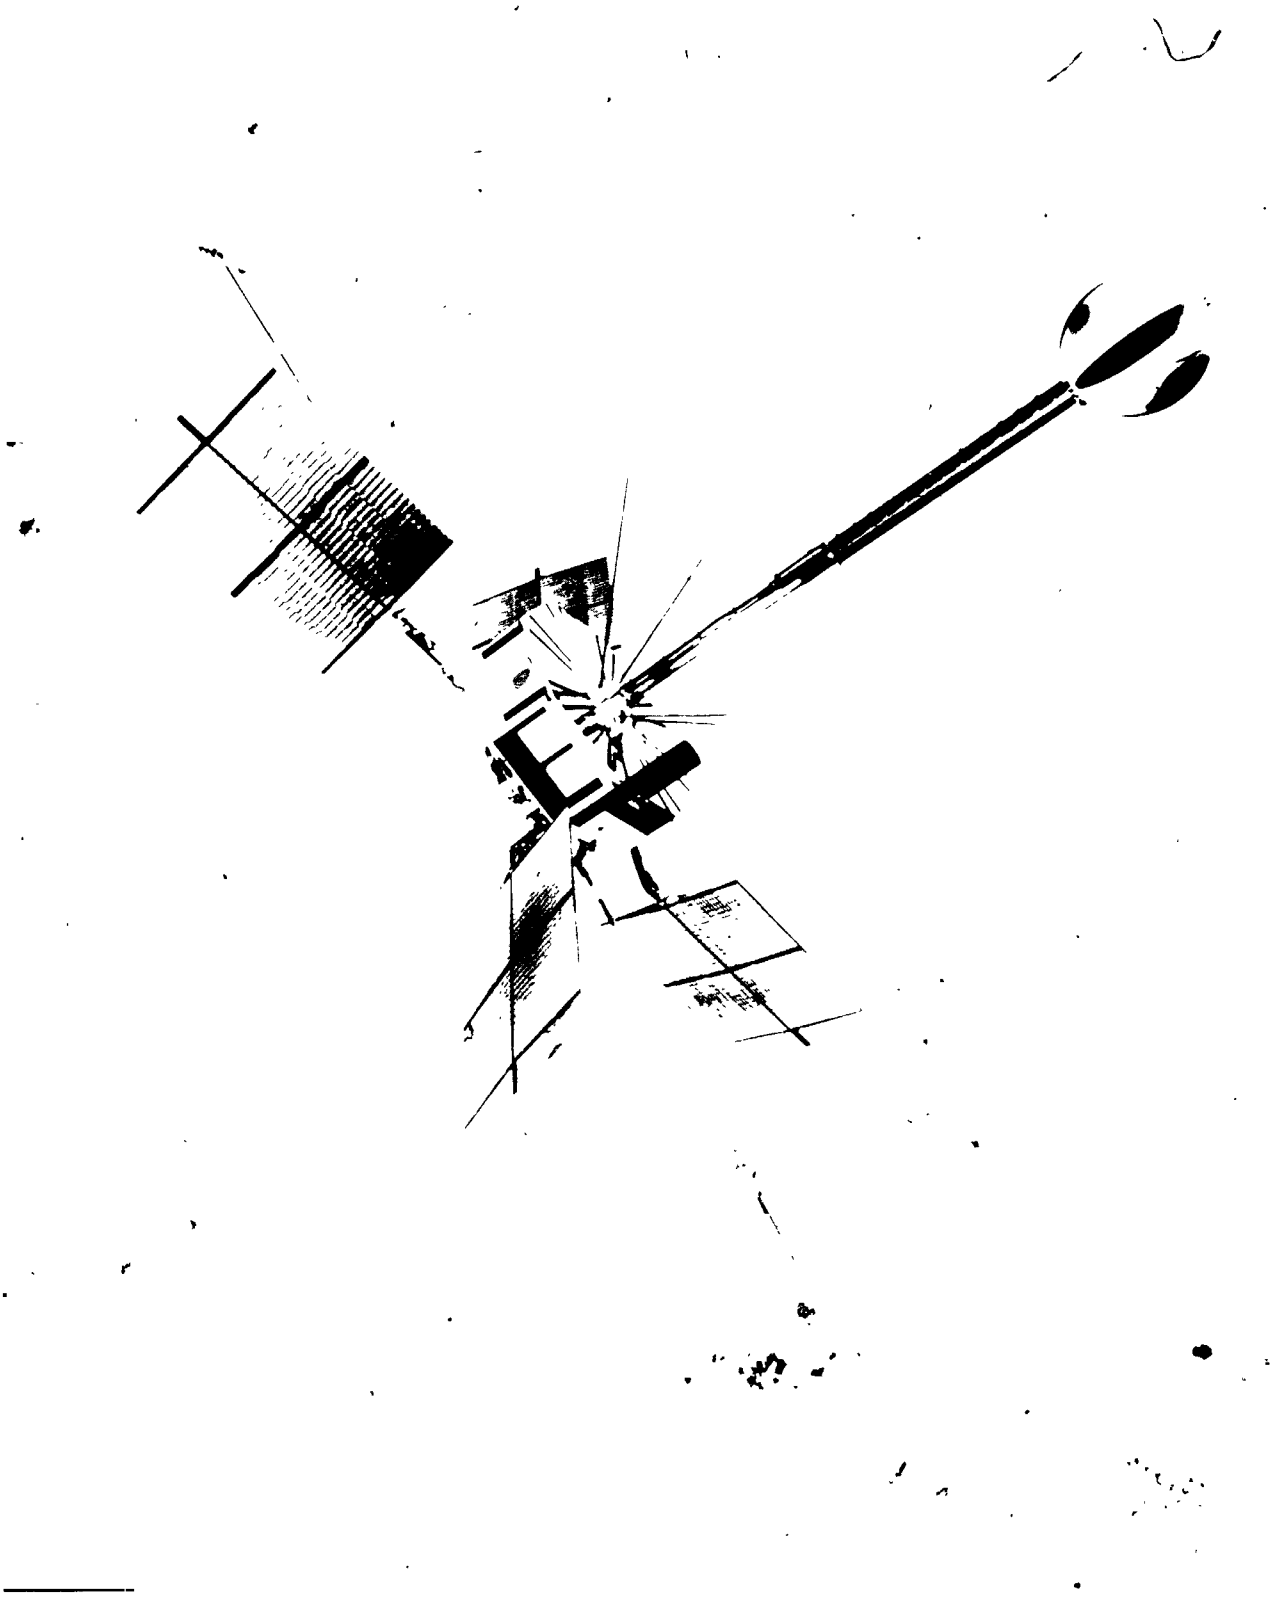

FIGURE 1.—IMP-I spacecraft in flight configuration with all appendages (solar paddles, fluxgate magnetometer booms and Rubidium vapor magnetometer tube) fully deployed.

pressure torque will be to decrease the spin rate. After 70 days in orbit the spin rate was 24.30 rpm at an aspect angle of 125° to the Sun with the location of the spin axis given by a right ascension of 111.1° and declination of −30.6°. The maximum solar aspect was 129° after 47 days in orbit. The lifetime of the satellite is expected to be at least 160 days and may well be 360 days or longer.

It is the purpose of this paper to discuss primarily the results of the magnetic field experiment on board the IMP–I spacecraft. At this early date approximately 70 days of data collected by the spacecraft has been acquired, processed and analyzed. It is important to note that our initial impressions of the significance of certain features of the data and their interpretations may be changed as the quantity of information returned from the satellite is increased and as our overall statistics and characteristics of the magnetic fields and associated phenomena become better understood.

The primary mission of the magnetic field experiment was four-fold; the investigation of:

1. The *interplanetary magnetic field*, its magnitude, direction and temporal variations as correlated with solar and terrestrial phenomena,
2. The *transition region* associated with the interaction of the solar wind with the geomagnetic field which leads to the study of two characteristic boundary surfaces, namely:
3. The *collisionless magnetohydrodynamic shock wave* surface separating the undisturbed interplanetary medium from the transition region, and
4. The *magnetopause boundary* separating the transition region from the magnetosphere, that region of space containing the geomagnetic field and encompassing the Earth in the classical concept of the Chapman-Ferraro geomagnetic cavity.

These four major phenomena have been investigated in considerable observational detail thus far by this experiment but shall be treated from a summary viewpoint at this time. Future publications concerning the IMP–I magnetic field experiment will treat substantially more detailed results of the magnetic fields in space and their solar-terrestrial correlations and also the correlations with other sensing elements carried on board the same spacecraft measuring importantly related phenomena such as the low energy proton flux "solar wind" and the higher energy proton-electron particle fluxes.

An additional feature investigated by the spacecraft has been associated with the magnetohydrodynamic wake of the Moon, as it interacts with the solar wind. This was an unexpected event during December, 1963 which placed the satellite in an approximately lunar eclipsed position with respect to solar plasma propagation from the general direction of the Sun. An even more fortuitous event studied during the lifetime of the satellite occurred near the apogee of orbit No. 2 during which time a geomagnetic sudden commencement storm occurred on December 2, 1963 at 2117 UT. This was the fifth in a series of recurrent M-region storms and such events frequently appear as a sudden commencement.

A clearly unique event was observed to occur in the interplanetary magnetic field data three minutes prior to the terrestrial magnetic field event.

2.0 HISTORICAL BACKGROUND

The existence, general description and temporal behavior of the interplanetary magnetic field have been deduced in the past from a variety of terrestrial observations notably the analysis of energetic particle trajectories impacting the Earth energetic particle trajectories impacting the Earth. An analysis by McCracken (1962) is indicative of the most recent efforts in this respect. Direct measurements in space by Pioneer V (Coleman, Davis and Sonett, 1960) with a search coil magnetometer were initially interpreted as consistent with a steady field component of 2.5 gammas normal to the ecliptic plane. In addition it was also reported that fluctuations as large as 50 gammas were detected during times of magnetic disturbance (Coleman, Sonett and Davis, 1961). Recent efforts to re-analyze and re-interpret the Pioneer V data by Greenstadt (1963, 1964) have yielded results inconsistent with the initial findings in that the fields are now found to have been much nearer to being in the plane of the ecliptic with a magnitude of 5–10 gammas.

A steady field normal to the plane of the ecliptic is inconsistent with a number of models of the interplanetary magnetic field in which solar magnetic lines of force are stretched out away from the Sun by the highly conducting streaming solar plasma (Parker, 1958a). The low energy proton flux detected by Explorer X (Bonetti, Bridge, Lazarus, Rossi and Scherb, 1963) was directed at all times away from the sun but fluctuated in magnitude and energy spectra as a function of time. Measurements by the Mariner spacecraft (Neugebauer and Snyder, 1962; Snyder and Neugebauer, 1964) have indicated that the flux of low energy plasma from the Sun presents a spectrum with considerable temporal and energy structure but in general is in agreement with the extrapolated results of Explorer X.

Measurements of the interplanetary magnetic field by Explorer X (Heppner, Ness, Skillman and Scearce, 1963) were distorted by a strong interaction between the streaming plasma and the magnetic field of the Earth which led to the formation within the plasma stream of a cavity containing the geomagnetic field. The magnetometer measurements on the Mariner spacecraft (Coleman, Davis, Smith and Sonett, 1962) are incomplete for total vector information, because of unknown spacecraft magnetic fields and do not provide accurate vector data on the interplanetary magnetic field. The data is consistent with an interplanetary field in the plane of the ecliptic with a strength of approximately 5 gammas normal to a Sun-satellite direction. The magnitude of this field component compares somewhat favorably with Pioneer V but the direction is different by 90°. Recent data on galactic fields (Davies, Verschuor and Wild, 1962) indicate that they are on the order of 0.5 gammas and may be up to 2.5 gammas in interstellar space.

In summary the interplanetary magnetic field has been estimated by various methods to be approximately 1–10 gammas average value, although steady periods might be infrequent. The variability of the interplanetary magnetic field and the extreme variations expected during solar disturbances indicated a wide dynamic range was required as well as precise and accurate measurements in order to achieve the desired scientific objectives of this experiment.

3.0 INSTRUMENTATION

The IMP–I satellite experiment complement included two types of magnetic field instruments: A Rubidium 87 vapor magnetometer and two monoaxial fluxgate magnetometers. The purpose of the Rubidium vapor magnetometer was to allow extremely accurate measurements of the interplanetary magnetic field to be performed and also to provide a wide dynamic range for magnetic field measurements within the magnetosphere and near its boundary, the magnetopause. The two monoaxial fluxgate magnetometers were employed to delineate precisely the vector characteristics of the interplanetary magnetic field. Their zero levels were calibrated inflight on the spacecraft through a combined use of the Rubidium vapor magnetometer data. The dynamic range of the fluxgates is ± 40 gammas with a sensitivity of $\pm \frac{1}{4}$ gamma while the dynamic range of the Rubidium vapor magnetometer is 3–500 gammas with a sensitivity dependent upon the magnitude of the field; the 0.1 percent precision of the ground digitization system leading to maximum errors of ± 0.5 gammas at the upper limit.

The Rubidium vapor magnetometer measures the absolute scalar intensity of the magnetic field by measuring the Zeeman splitting of the sublevels in the ground state of the atom (Bloom, 1962). For the Rubidium 87 isotope the separation between adjacent levels is 6.99592 cycles per sec. per gamma. In order to detect these separations, a technique known as optical pumping is employed to selectively populate one of these sub-levels. As the vapor in the absorption cell is "pumped" by a spectral lamp it absorbs the light until a final state is reached in which the cell becomes transparent. The application of a weak AC magnetic field at the frequency corresponding to the separation of the Zeeman sublevels (which is the Larmor frequency) then results in the redistribution of the population to all the levels and hence re-absorption of the incident light. It is possible to couple the modulated light produced and subsequently detected by a silicon photocell to the coil producing the AC magnetic field. Such a feed-back loop with the appropriate phasing of signals operates the magnetometer as an atomic self-oscillator with the resonant frequency being the Larmor frequency.

A "flashlight" configuration (Ruddock, 1961) of one lamp and absorption cell has been employed in the particular configuration on the IMP spacecraft (see Figure 2).

Although the Larmor frequency is dependent only upon the magnetic field intensity the inherent signal-to-noise ratio depends upon the angle (α) between the optical axis of the system (along the spin axis in IMP–I) and the magnetic field as approximately sin 2α. This leads to the formation of two null regions of field orientation, polar and equatorial relative to the spin axis, in which

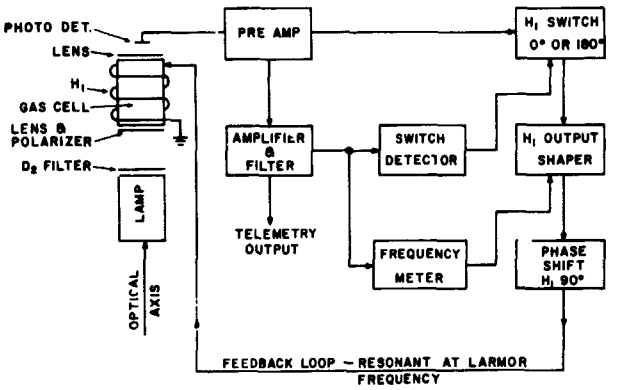

FIGURE 2.—Functional block diagram of single absorption cell self-resonant Rubidium vapor magnetometer instrumented for IMP–I.

the magnetometer will not self-oscillate with sufficient signal-to-noise ratio for accurate quantization by the ground digitization system. The fluxgate magnetometers however do measure the magnetic field vector at an extended range (see below) when in the null regions of the Rubidium vapor magnetometer and thus provide complete coverage of the magnetic field in interplanetary space over the range 0.25 to 40 gammas or more.

It is possible to convert the scalar Rb^{87} magnetometer to a vector instrument by application of a sequence of known triaxial bias magnetic fields. On a spin stabilized spacecraft, the rotation of the structure reduces the complexity of the bias coil system so that only one set of coils and one bias vector field is required. By a proper choice of the orientation and magnitude of the bias field the instrument will measure vector magnetic fields with an accuracy dependent upon the unknown vector field magnitude and orientation. An additional purpose of the bias coil system is to provide a means for in-flight calibration of the fluxgate magnetometer zero field levels since it is possible to measure the unknown vector field simultaneously with two vector instruments.

Let F = magnitude of unknown magnetic field

α = polar angle of F to spin axis

B = magnitude of bias magnetic field

θ = polar angle of B to spin axis

R = magnitude of resultant field measured

ω = spin frequency of spacecraft

Then:

$$R = \sqrt{F^2+B^2+2FB\cos\alpha\cos\theta \overline{+2FB\sin\alpha\sin\theta\cos\omega t}} \quad (3.1)$$

The analysis of $R(t)$ will yield values of F and α assuming B and θ are known.

A major problem associated with the utilization of a Rubidium vapor magnetometer in satellite applications is the necessity to maintain both the lamp used for optical pumping and resonance observation as well as the absorption cell employed at optimum temperatures. These unfortunately range over only limited values and for the gas cell an optimum temperature is approximately $42.5° \pm 50°$C. The temperature at the lamp bulb base support structure is optimumly $110° \pm 10°$C. The development of the IMP Rubidium 87 vapor magnetometer was predicated upon the necessity to include active thermal control circuits and heating coils on the lamp and gas cell. Because of the difference in optimum temperatures required it was necessary to operate three completely independent temperature control systems: one for the lamp and two for the gas cell. Figure 3. illustrates the results of the active thermal control system on the spectral lamp from telemetered temperatures of the lamp bulb. It is seen that shortly after launch the temperature of the bulb begins to rise until it reaches the critical value of 120°C at which time the heat source is turned off. When the temperature reaches the lower limit of 100°C the active thermal control once again begins to heat the bulb to raise its temperature and this cycle

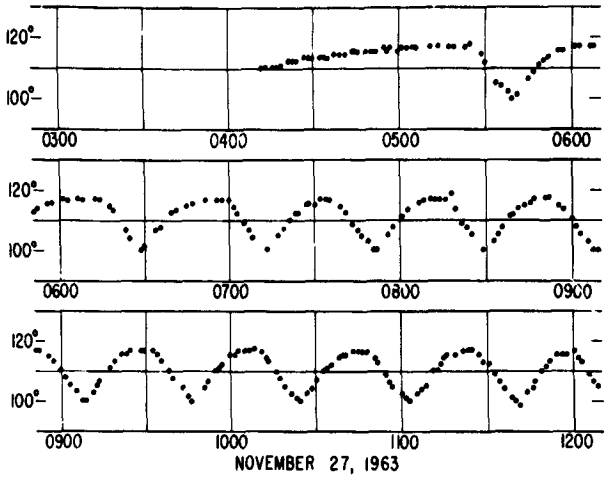

FIGURE 3.—Representative cycling of active thermal control on spectral lamp of Rubidium[87] vapor magnetometer following launch of IMP–I.

has continued since launch stabilizing at a periodicity of approximately 32 minutes. This is indicative of the thermal time constants of the lamp bulb housing and the radiative properties of the support structures enclosing the Rubidium spectral lamp. The temperature of the gas cell has always been above its lower limit and has not cycled thus far. It maintains temperature at approximately 47°C being heated by the thermal losses from the physically adjacent spectral lamp. The IMP–I Rubidium magnetometer is completely transistorized. The additional power required for controlling the environmental temperatures of these elements is a fraction of the total power required by the system (approximately 4.5 watts).

The characteristics of the fluxgate magnetometers are considerably less sensitive to temperature and their operation is proper and within the specified limits over a very wide temperature range. Thus no measurement of the temperatures of the fluxgates was required and their operation has proceeded normally. Standard calibrations on the sensitivity of the fluxgates are conducted in-flight and have been within the desired range. The operation of the instrumentation for the magnetic field experiment on the IMP–I spacecraft has been excellent since date of launch and no failures have been experienced to date.

In order to provide a uniform environment for the Rubidium magnetometer system, a spherical enclosure with a 13 inch diameter encompasses the lamp and gas cell mounted on top of the spacecraft (see Figure 1.). This sphere, appropriately surface coated for passive thermal control, provides a uniform temperature regime in which thermal equilibrium of the sensing elements can be maintained with minimum power. In addition this sphere supports a set of McKeehan (1936) coils for generating the known bias fields. The strength of the magnetic bias field employed on the IMP–I spacecraft was 20 gammas at an angle of 54° 45′ to the spin axis. These values were chosen to optimize the directional sensitivity of the resulting vector magnetometer for interplanetary magnetic fields. The output frequency from the magnetometer was used to directly phase modulate the 136 megacycle carrier of the satellite telemetry system. Subsequent digitization of the signal on the ground via a period count procedure was employed using a multiplied reference frequency recorded on the raw analog data tape as the counter. This eliminated to first order the wow and flutter errors associated with record and playback of data.

The fluxgate magnetometer measures the relative magnetic field intensity along the axis of the sensing element. The fluxgate sensor consists essentially of a saturable magnetic core which is driven at a high rate (10Kc) from positive to negative saturation by a solenoidal drive coil. Any second harmonic signal generated is due to the presence either of an ambient field component along the axis of the element or to permanent magnetization of the core material. The voltage output (0 to +˜) represents the discriminated second harmonic output which is calibrated to yield the magnitude of the field component parallel to the sensor axis while the phase indicates the direction, parallel or antiparallel. Figure 4. presents a block diagram of the fluxgate magnetometers used on IMP–I.

The PFM (pulsed frequency modulation) telemetry system employed on IMP–I encoded the fluxgate data by applying it to a voltage controlled oscillator whose frequency output, 333 cps to 938 cps, modulated the 136 mc. carrier. The fluxgate signals were digitized on the ground through the combined use of a contiguous set of narrow bandpass filters specifically designed for the PFM telemetry scheme and commonly referred to as a

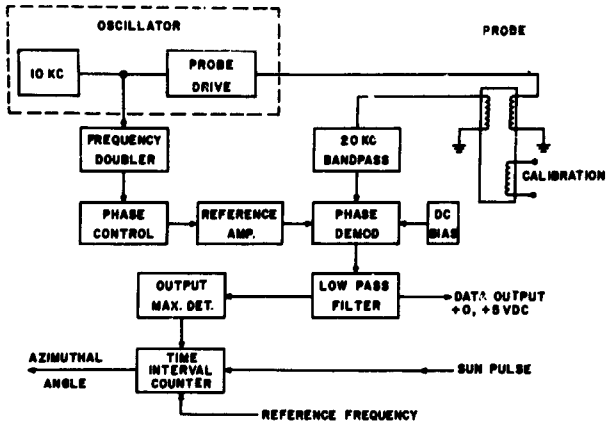

FIGURE 4.—Functional block diagram of monoaxial fluxgate magnetometer and on-board data processor of azimuthal angle instrumented for IMP-I.

"comb filter." This led to a precision in the digitization of ± 0.4 gamma associated with the precision of the comb filters (±1 percent of full scale range).

4.0 SPACECRAFT STRUCTURE AND MAGNETIC CLEANLINESS

In order to insure the success of the magnetic field experiments on the IMP spacecraft it was absolutely essential that permanent or induced magnetic fields associated with the structure and/or the electronics and instrumentation be kept to an absolute minimum. In the design and fabrication of all sub-systems, components that were highly magnetic were replaced by non-magnetic equivalents and all circuit leads and welding material were chosen to be non-magnetic or minimally magnetic. Considerable care was taken in the design and wiring of the spacecraft harness and power distribution system so that no net circulating currents and/or ground loops existed. In some instances this necessitated complex wiring techniques between and within subsystems. In addition, each solar cell module (8 x 15 series—parallel individual cell arrangement) was back wired within the paddle structure for compensation so that cell and module degradation did not change the compensating currents required. All power leads between subsystems and within subsystems at current levels above 20 ma were bifilar or twisted pair wound.

Extensive tests of individual subsystems and illuminated solar paddles at the Goddard Space Flight Center Magnetic Test Facility and finally the entire spacecraft in flight configuration at the Naval Ordnance Laboratory Magnetic Ship Modeling Facility in White Oak, Maryland and the U.S. Coast and Geodetic Survey, Fredericksburg Magnetic Observatory in Corbin, Virginia provided confidence that minimum magnetic fields would be enjoyed on the satellite after launch. Mapping of the actual spacecraft magnetic fields due to permanent, induced and stray magnetic fields indicated contamination levels at the fluxgate sensors of less than 0.6 gamma and contamination levels at the Rubidium vapor magnetometer of less than 1 gamma. These limits were set by the natural ambient magnetic field variations at the two facilities since it was not possible to completely cancel out the normal geomagnetic field fluctuations. In addition extensive tests were performed on the effects of vibration of ferro-magnetic materials in the Earth's magnetic field to evaluate the potential "perming" which might result from the vibration of the satellite during the launch maneuver. These tests indicated contamination fields which were significantly less than the sensitivity of the experiment. The in-flight measurements (see Section 5.0) show that the spacecraft fields actually achieved by the IMP-I were less than ±0.25 gamma representing one of the "cleanest" satellites carrying magnetometers launched to date.

Figure 5. illustrates a schematic cross section of the IMP satellite showing the geometrical

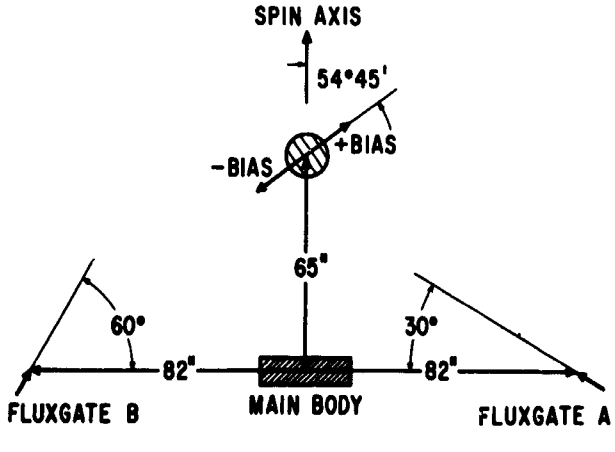

FIGURE 5.—Schematic cross section of the IMP Satellite illustrating location and orientation of sensors for magnetic field measurements.

configuration and positional location of the three magnetic field sensing elements. In spite of all the precautions taken to restrict spacecraft magnetic fields to an absolute minimum it was still necessary to place the magnetometer sensors at as remote a distance from the spacecraft as possible. The Rubidium vapor magnetometer was contained within the spherical enclosure mounted on top of a telescoping two section boom. This was erected at the same time the spacecraft was separated from the third stage ABL–258 rocket motor during the launch maneuver. This placed the Rb^{87} magnetometer resonance gas cell at a distance of 1.65 meters (65″) from the center of the spacecraft. The two monoaxial fluxgate magnetometers were mounted at the extremities of double sectioned folding booms. These were also erected at 3rd stage separation and placed the sensors 2.1 meters (82″) from the center of the spacecraft. The use of two booms was part of the experiment design to yield a spacecraft structure that was both statically and dynamically stable. Their axes were oriented so as to both lie in the same meridian plane containing the spin axis of the satellite but at different angles to the spin axis. The purpose of the two angles was to allow the sampling of magnetic fields larger than 40 gammas by either one of the two sensors depending upon the orientation of the unknown field to the spin axis. This is illustrated in Figure 6. in which the allowable magnitude as a function of polar angle (α) is shown for the θ angles $\theta_A = 30°$ and $\theta_B = 60°$ chosen for the two sensors. It is seen that by use of the two angles whose sum equals 90° the sensors tend to compliment each other in their capability to accurately and in an undistorted manner measure fields of intensities greater than 40 gammas. It was the intent of the experiment by these means to extend the effective range of the fluxgate magnetometers beyond 40 gammas and thereby compliment the Rubidium vapor magnetometer for field orientations that were nearly parallel or perpendicular to the spin axis of the spacecraft because of its signal-to-noise degradation at these orientations.

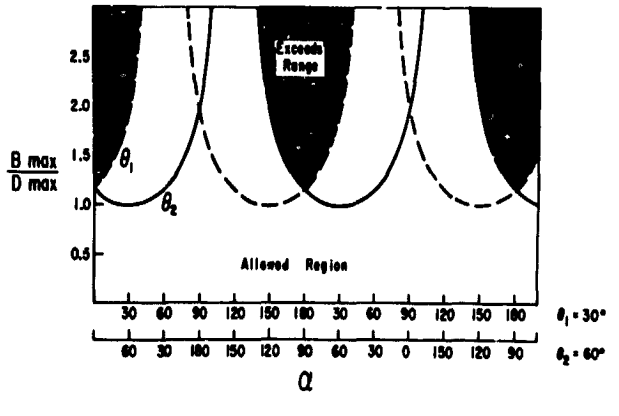

FIGURE 6.—Dynamic range of IMP-I fluxgate magnetometers as a function of sensor and field orientation. Allowed region is defined to be such that the detected output of the sensor is linearly related to the component of the field parallel to the sensor axis.

5.0 DATA SAMPLING AND ANALYSIS PROCEDURES

Magnetic field data is transmitted by the satellite sequentially in a format which time multiplexes the magnetic field information with the other scientific sensors and spacecraft performance parameters in a predetermined time shared manner. Figure 7. illustrates on a linear time scale four sequences of 16 frames containing fluxgate and Rubidium vapor magnetometer data extending over a time interval of 327.65 seconds. Each normal telemetry sequence is 81.9144 seconds in length and contains four samples of real time fluxgate magnetometer data consisting of continuous transmissions for 4.8 seconds at intervals of 20.5 seconds. Four such samples per sequence are shared between the two fluxgates,

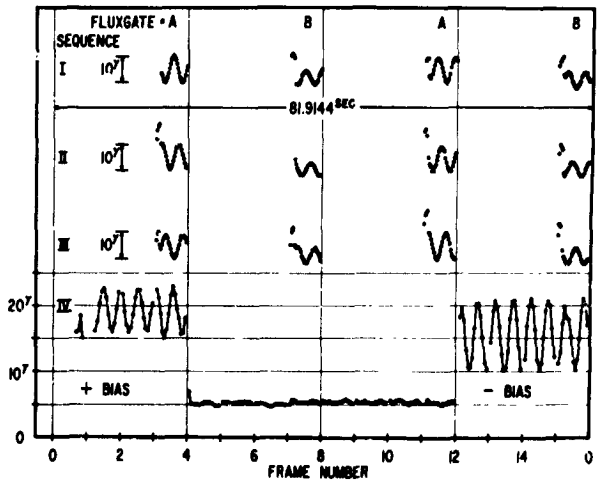

FIGURE 7.—Sample telemetry data format for IMP-I taken at a distance of 100,000 kilometers illustrating inerlacing of fluxgate and Rubidium vapor magnetometer data.

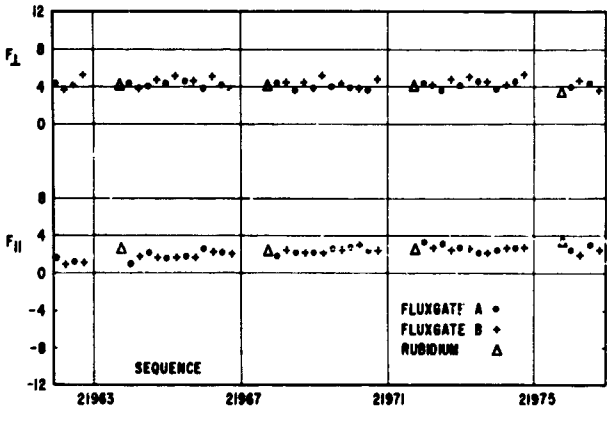
A and B, previously referred to in the description of the location of sensors on board the spacecraft. This procedure is repeated for the next two sequences in identical fashion. Every fourth sequence transmitted, however, is uniquely different from the previous three in that it contains only Rubidium vapor magnetometer data continuously transmitted for a period of 81.91 seconds with gaps associated with the synchronization time channels required by the PFM telemetry format every 5.12 seconds.

Figure 7. illustrates the effects due to the different θ angles of the monoaxial fluxgate sensors as indicated by the difference in amplitude of the spin modulated sine wave for fluxgates A and B. In addition during the first few samples of each fluxgate a sensitivity calibration is performed which linearly adds a field of 10 gammas to the measured field. By measuring the difference in the recorded fields, and taking into account the rotation of the spacecraft, the verification of the sensor's sentitivities can be performed.

The programming of the Rubidium vapor magnetometer bias coil system is also evident. During the first four frames of the 4th sequence the Rubidium bias field is in a positive direction pointing forward relative to the spin axis. During the next eight frames the bias coil is programmed off and during the last four frames the current through the bias coils is directed in the reverse sense so as to yield a bias vector which points aft of the spacecraft.

The design of the experiment was contingent upon a measurement of interplanetary magnetic fields ranging between 1 and 10 gammas. Utilization of a bias magnetic field of 20 gammas and the illustrated programming sequence allows a unique and a complete determination of the vector magnetic field characteristics through the use of mathematical procedures to analyze the resultant fields given in equation 3.1. This data was obtained at an elevation of approximately 10^5 kilometers during the first month's operation of the satellite and is representative of the general characteristics of magnetic field data obtained in interplanetary space on the IMP-I spacecraft.

A principal problem with the use of fluxgate magnetometers is the fact that they are relative devices whose absolute zeros can only be calibrated by physically reversing the sensor in a stationary magnetic field. Although the spacecraft rotates about its spin axis and thereby allows a unique determination of the magnetic field component perpendicular to the spin axis $F_\perp$, the component parallel to the spin axis, $F_\parallel$, is not capable of unique and absolute determination from the fluxgate data alone. Thus it has been necessary to calibrate the fluxgate magnetometer zero levels through the use of the absolute Rubidium vapor magnetometer data while in flight.



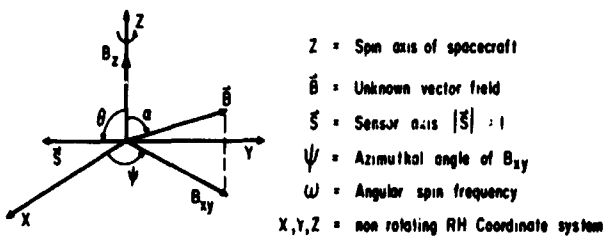


FIGURE 8.—Results of calibration of fluxgate magnetometer zero levels with Rubidium vapor magnetometer data obtained while IMP-I was in orbit.

Figure 8. illustrates the comparison of the fluxgate magnetometer data and the Rubidium vapor magnetometer data when viewed in a coordinate system in which magnetic field data is represented by perpendicular and parallel component values.

In this representation the magnetometer data from Fluxgate A has been used without any adjustment of its zero level. The data from Fluxgate B has been adjusted taking into account a zero offset of -2.1 gammas. Throughout the 70 day life of the satellite thus far, the fluxgate magnetometer data and the Rubidium vapor magnetometer data have compared very well with the zero offset for Fuxgate A remaining constant at 0 ± 0.25 gammas which is equal to the sensitivity of the analysis and the noise level of the instrument. The zero offset for Fluxgate B has changed from approximately -2.1 gammas to -2.5 gammas. The fluxgate magnetometers were manufactured by the Schonstedt Instrument Corporation, Silver Spring, Maryland. The Rubidium spectral lamp and absorption cell were

manufactured by Varian Associates, Palo Alto, California. The ancillary electronics for Fluxgate A and the complete electronics for the Rubidium vapor magnetometer were fabricated at Goddard Space Flight Center.

A natural coordinate system to use in the initial reduction of magnetic field data on a spin stabilized spacecraft is associated with the spin axis of the satellite and the satellite-Sun direction. A payload coordinate system is defined in Figure 9. in which the Z-axis is coincident with the spin axis of the spacecraft, the X-Z plane contains the satellite-Sun vector and the Y-axis is chosen to form a right-handed coordinate system. The analysis of the monoaxial fluxgate data has proceeded through the use of numerical filters designed to extract from the spin modulated magnetometer signal the first harmonic and the first and second time derivatives of the magnetometer signal at a particular instant of time. As illustrated in Figure 9. it is possible to combine the first and second time derivatives to determine both the component of the magnetic field perpendicular to the spin axis $B_{xy}=B \sin \alpha$ and also the azimuthal angle of the magnetic field ψ. These two quantities and the first harmonic then determine the component of the magnetic field parallel to the spin axis $=B \cos \alpha$. These three quantities: parallel, perpendicular and azimuthal angle completely specify the vector magnetic field $\vec{B}$.

$$\text{Detector Output} = D = \vec{B}\cdot\vec{S} = B\cos\alpha\cos\theta + B\sin\alpha\sin\theta\cos(\omega t-\psi)$$

$$\frac{\partial D}{\partial t} = -\omega B_{xy}\sin\theta\sin(\omega t-\psi)$$

$$\frac{\partial^2 D}{\partial t^2} = -\omega^2 B_{xy}\sin\theta\cos(\omega t-\psi)$$

$$B_{xy}^2 = \left[\left(\frac{\partial D}{\partial t}\right)^2\omega^2 + \left(\frac{\partial^2 D}{\partial t^2}\right)^2\right]\Big/\omega^4\sin^2\theta$$

$$\psi = \tan^{-1}\left[\omega\frac{\partial D}{\partial t}\Big/\frac{\partial^2 D}{\partial t^2}\right]$$

FIGURE 9.—Payload coordinate system and analysis procedure to obtain vector fields with monoaxial fluxgate magnetometers on a spin stabilized spacecraft

A similar procedure is used to deduce the vector fields from the Rubidium magnetometer data.

A limited amount of on-board processing of the Fluxgate A magnetometer data was performed on IMP-I as shown in the block diagram of Figure 4. A signal peak detector was developed to provide a pulse in time coincident with the maximum field value which occurred each spin period. A counter using the optical-aspect Sun pulse to open a gate and start a 100 cps count rate was terminated by this peak pulse. By this means an on-board measure of the azimuthal angle ψ was made once each telemetry sequence and provided an accurate check on the numerical procedures used to *de*-modulate the spin modulated magnetometer data. Angle accuracies are more precisely determined for azimuth because of this and are accurate to $\pm 2°$. The angular error of the polar angle α is dependent upon direct measurements of $B_\perp$ and $B_\parallel$ and thus can be large for certain ratios of $B_\perp$ and $B_\parallel$. This angular error is not significant in the transformation of the data from the initial payload coordinate system to another coordinate system by using a rotation matrix since one uses $B_\perp \sin\psi$, $B_\perp \cos\psi$ and $B_\parallel$ directly. The uncertainties in the field values and azimuth angle combine so that an estimate of the general directional accuracy of $\pm 5°$ is conservative.

Each fluxgate magnetic field vector measurement is obtained from a sample of data 4.8 seconds in length containing 30 discrete samples of the magnetic field with a sensitivity of 0.4 gammas. The bandpass of the magnetometer sensors is flat with negligible phase shift from 0 to 5 cps and falls off at 6 db per decade for higher frequencies. The analysis procedure employed to obtain a vector measurement from the sampling of the magnetic field limits the final information band width in the analysis to approximately 0 to 0.1 cycles per second. As is shown in Figure 7. the field samples from the fluxgates are obtained once every twenty seconds.

It is important to note from Figure 7. that during the interval when the Rubidium vapor magnetometer bias coil was off the spin modulation observed on the total magnetic field output is less than ± 0.25 gamma. During this particular time interval the magnetometer is sensitive to contamination fields which are perpendicular to the spin axis of the satellite at the position of the

Rubidium vapor sensor. The fluxgates always measure the component of the magnetic field perpendicular to the spacecraft spin axis accurately, independent of spacecraft contamination fields and zero offsets of the sensors. The agreement of the fluxgate and *Rb* magnetometer fields (F.) shown in Figure 8. combined with the absence of spin modulation in the Rb^{87} data gives assurance that the magnetic field data being discussed is accurate to ± 0.25 gammas and is not affected by spacecraft fields.

6.0 COORDINATE SYSTEM FOR RESULTS

The primary mission of the IMP magnetic field experiment was the delineation of the characteristics and statics of the interplanetary magnetic field. However, the particular satellite chosen for these measurements was Earth-orbiting so that all data collected was obtained in the near vicinity of the Earth. A geocentric solar ecliptic coordinate system has been defined which reflects both the interplanetary nature of the data and takes into account the motion of the Earth around the Sun. This is identical to the coordinate system used previously in the Explorer X data analysis and interpretation (Heppner et al., 1963). In this coordinate system shown in Figure 10. the origin is at the center of the Earth, the X_{se} axis points to the Sun, the Z_{se} axis is normal to the ecliptic plane and Y_{se} is chosen to form a right-handed coordinate system. These coordinates have proven extremely successful in the analysis and interpretation of the magnetic field data.

The vector magnetic field will be presented as a magnitude F and two angles: θ represents the latitude of the magnetic field being positive above the plane of the ecliptic and negative below and ϕ the longitude, being 0° when it points to the Sun and 180° when it points away from the Sun. As will become evident from studying the results of this experiment, the choice of a magnitude and two angle representation of the vector magnetic field appears to have more clearly elucidated its unique characteristics rather than the alternate representation using three components of the magnetic field. It should be noted that the coordinate system is not stationary in inertial coordinates but rotates about two principal axes and maintains its orientation as shown in Figure 10. at all times. Viewed from a non-rotating

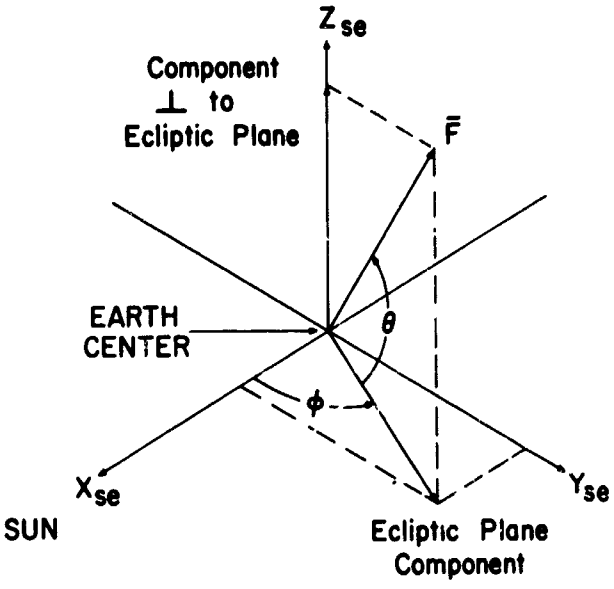

FIGURE 10.—Solar ecliptic coordinate system and associated parameter nomenclature and definitions.

solar-centric position the coordinate system moves around the Sun once each year following the orbital motion of the Earth.

In addition to its utility in the investigation of the interplanetary magnetic fields, the solar ecliptic coordinate system is also useful for studying the magnetic field phenomena associated with the interaction of the solar wind with the geomagnetic field. Since this interaction leads to the formation of a geomagnetic cavity which is strongly solar oriented the coordinate system chosen is particularly meaningful in presenting the magnetic field data in a frame of reference which illustrates the intimate solar-terrestrial phenomena being studied.

The magnetic field results herein presented represent the time average of the 12 fluxgate measurements occurring in the telemetry transmission in sequences I, II and III, yielding a sampling interval of 5.46 minutes. The solar ecliptic components for these 12 measurements are averaged by simple addition and no special numerical filters are employed. For the X_{se} component, if X^i_{se} represents the i^{th} value of the magnetic field in the sample set possible:

$$\overline{X}_{se} = \frac{1}{N} \sum_{i=1}^{N} X^i_{se} \qquad (6.1)$$

where N is less than or equal to 12 depending

upon the percentage of missing data points in the original 30 point data samples. If the number of missing points due to either digitization errors or transmission errors is greater than 10 percent, the corresponding vector field sample is not used in the analysis to determine the 5.46 minute average.

These average values for the three components are used to compute the magnitude $\bar{F}$ and the two angles θ and ϕ. In addition the average value for the components is used in computing estimates of the variance of the magnetic field for the 12 sample data set. The variance is defined as

$$\delta Y_{se}=\sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(X_{se}^{i}-\bar{X}_{se}\right)^{2}} \qquad (6.2)$$

for the X_{se} component and similarly for Y_{se} and Z_{se}. The Rubidium vapor magnetometer data has not been included in this field averaging initially because its directional sensitivity for magnetic fields is not as high as the fluxgate magnetometers.

In summary, the magnetic field data is represented by the following six parameters sampled at 5.46 minute intervals:

1. $\bar{F}$ = the magnitude of the average components
$$=(\bar{X}_{se})^2+(\bar{Y}_{se})^2+(\bar{Z}_{se})^2$$
2. θ = the latitude of the field direction
$$=\tan^{-1}\{\bar{Z}_{se}/[(\bar{X}_{se})^2+(\bar{Y}_{se})^2]^{1/2}\}$$
3. ϕ = the longitude of the field measured in the plane of the ecliptic
$$=\tan^{-1}[\bar{Y}_{se}/\bar{X}_{se}] \qquad (6.3)$$
4. δX_{se} = variance of the field in the X_{se} direction
5. δY_{se} = variance of the field in the Y_{se} direction
6. δZ_{se} = variance of the field in the Z_{se} direction

7.0 ORBIT CHARACTERISTICS

The orbit of the IMP–I is highly eccentric with an apogee of approximately 31.7 R_e (Earth radii).

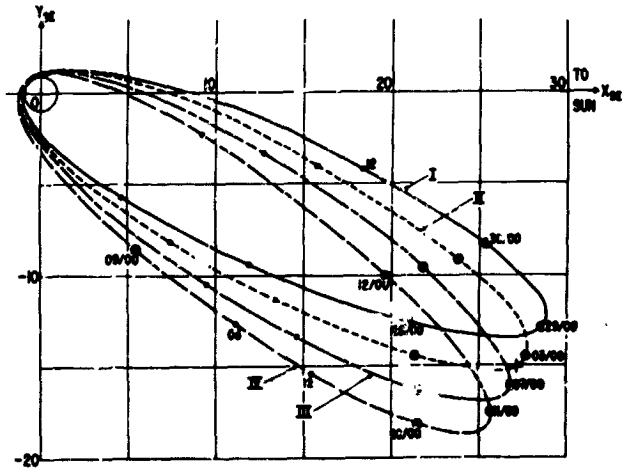

FIGURE 11.—Projection on solar ecliptic XY plane of orbits 1 through 4. Cross indicates location of satellite at time of December 2 sudden commencement geomagnetic storm.

The projection of the first four orbits as a function of time on the plane of the ecliptic or X-Y solar ecliptic plane is shown in Figure 11. The figures placed on the projection of the trajectory reference the date of the month and/or the time of the day measured in hours (UT) at which the satellite is located at the particular position shown. The location of the satellite at the time of the sudden commencement geomagnetic storm on December 2 is indicated by a cross on orbit No. 2. The data from this particular orbit will be presented later and discussed in detail with regard to the propagation of magnetic storms in interplanetary space.

A unique feature of highly eccentric orbits is related to the basic dynamics of satellites orbiting the central force field of the Earth. At apogee the satellite moves very slowly in longitude so that with IMP–I the spacecraft is located for 66 percent of its orbital period beyond 20 R_e. Thus the measurements of properties of interplanetary space is enhanced with respect to total time of possible observations. However, because of the high eccentricity of the IMP–I orbit it is severely affected by the gravitational field of the moon. The selection of an appropriate "launch window" for the IMP must take into account the multiplicity of spacecraft requirements for favorable solar aspect for power and thermal control as well as lifetime in orbit before lunar perturbations lead to a perigee which intersects the Earth's surface.

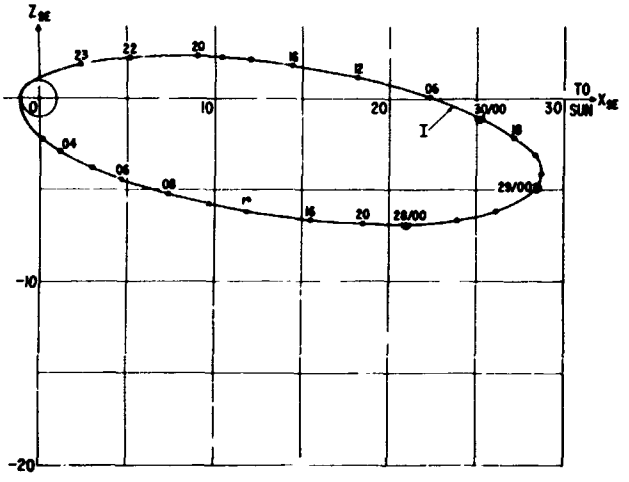

FIGURE 12.—Projection on solar ecliptic XZ plane of orbit No. 1

IMP–I has a lifetime on this basis of approximately two years.

The highly elliptical orbit does not place the satellite far above nor below the ecliptic plane as seen in Figure 12. Here a projection of orbit No. 1 is made on a plane perpendicular to the ecliptic plane passing through the Earth and the Sun, which is the X-Z plane in solar ecliptic coordinates. As time has progressed since launch the projection becomes foreshortened on this particular plane as the Earth moves about the Sun until the apogee eventually occurs behind the Earth, 160 days after launch. Figure 13. illustrates the predicted variation of the apogee-Earth-Sun angle as a function of lifetime of the satellite.

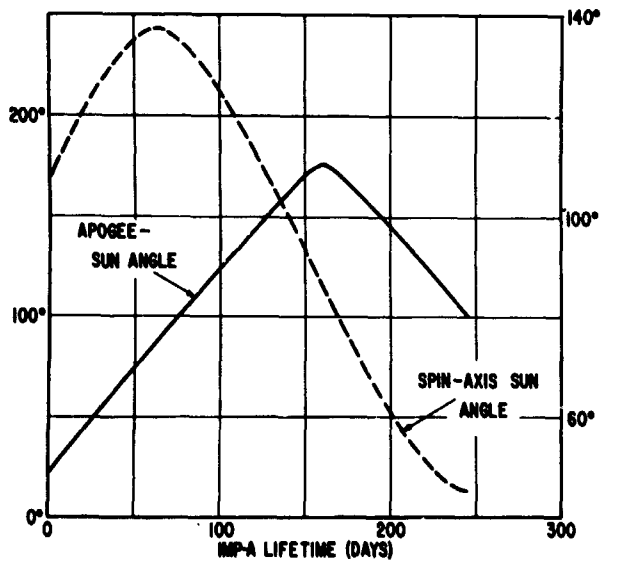

FIGURE 13.—Predicted variation of apogee Sun-angle and solar aspect angle for IMP–I.

The fact that the apogee-Earth-Sun angle never is 180° or 0° is due to the inclination of the line of apsides to the ecliptic plane. The magnitude of the inclination is determined from this figure to be 5°. The spacecraft spin axis-Sun angle shown is important for certain of the directional sensors on board the spacecraft such as the two plasma probes, whose response is principally associated with solar originating and radially directed plasma flux. The solar aspect angle is also important in determining the effects of solar radiation pressure on the spin period of the satellite since the four solar paddles were all pitched in the same sense and at the same angle and a spin up or spin down of the spacecraft occurs dependent upon whether the Sun is below or above the equatorial plane of the satellite.

8.0 MAGNETIC FIELD RESULTS

A selection of one particular orbit of the available and already analyzed 19 orbits of the IMP satellite has been made to illustrate the characteristics of the data obtained and the format in which the data will be presented. The initial studies reported herein are preliminary only in the sense that detailed correlations of magnetic fields with other sensors on board and certain other solar and terrestrial phenomena have yet to be completed. The data themselves are final as no other changes, corrections or calibrations are necessary since all have been included in this presentation.

However, as the data are further studied certain characteristic features may become more evident than they are at the present time. The study of long term statistics of the interplanetary fields and the quantitative descriptions of the shock wave and magnetopause boundaries statistically are subjects for future studies.

The magnetic field data obtained on an outbound portion of orbit No. 11 on January 5, 1964 is presented in Figure 14. As previously indicated the data is presented in a magnitude and two angle representation. The RMSE or variance of the solar ecliptic components is indicated in the lower three curves. The numerical values at the bottom refer to UT (hours) on the date

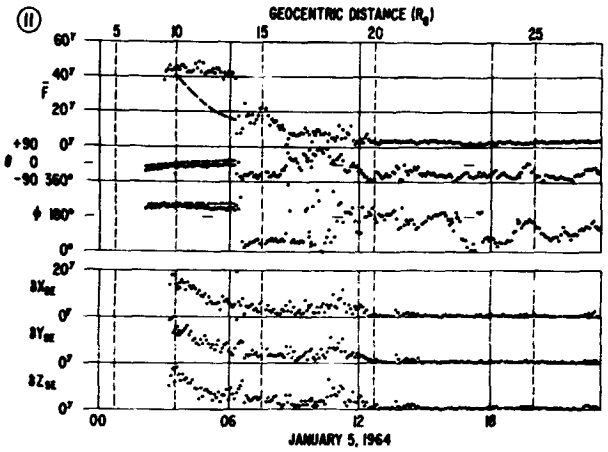

FIGURE 14.—Magnetic field data from orbit No. 11 January 5, 1964, illustrating outbound traversal of magnetopause boundary at 13.6R_e and shock wave boundary at 19.7R_e.

indicated while the values at the top indicate the geocentric distance of the satellite in Earth radii. By inspection of the data and reference to previous results on Explorer X (Heppner, Ness, Skillman and Scearce, (1963)), and Explorer XII, (Cahill and Amazeen (1963); Freeman, Van Allen and Cahill (1963)) it is clear that the magnetopause boundary has been traversed by the IMP–I satellite at a distance of 13.6 R_e at 0630 on January 5, 1964.

As the satellite moved away from the Earth the measured magnetic field began to increase above the predicted value at about 10 R_e, and proceeded to increase to more than twice that expected on the basis of the Finch and Leaton (1957) coefficients for spherical harmonic expansion of the Earth's terrestrial fields. In addition there were slight but regular angular deviations of the magnetic field increasing in importance until at 13.6 R_e there was an abrupt change in the character of the magnetic field in both magnitude and direction. The direction of the magnetic field appears to reverse by 180° while the magnitude simultaneously and just as suddenly decreases to less than 50 percent of its original value. The magnetic field then begins to fluctuate appreciably in its average magnitude and direction as the satellite continues moving further away. Although the direction of the field remains roughly stable pointing generally back toward the Sun and below the ecliptic plane, the magnetic field continues to display large deviations in the three solar ecliptic components which indicate a turbulent characteristic until a distance of 19.7 R_e is achieved. At this point in space the magnetic field becomes stable both in magnitude and direction as evidenced in the F, θ, ϕ presentation but shown much more dramatically in the presentation of the variance results. This sudden decrease in the variance from several gammas to less than 0.4 gammas is a consistently remarkable feature of the IMP–I data. This value is equivalent to the noise level of the instrument and the analysis procedure. For the next twelve hours the magnetic field is approximately 4 to 5 gammas in magnitude and pointed about 30 to 40 degrees below the ecliptic plane while directed either away or generally towards the Sun. The change in character and quantitative values describing the field at 19.7 R_e is identified as the collisionless shock wave suggested by Zhigulev (1959), Axford (1962), Gold (1962), Kellogg (1962) and Rossi (1963), associated with the standing bow wave due to the super Alfvénic streaming velocity of the solar wind impacting the geomagnetic field. Theoretical aspects of these data will be discussed later in this paper.

Continuing through orbit No. 11, Figure 16. illustrates data taken on January 6, 1964 immediately following that shown in Figure 15. In this case it is seen that the interplanetary field remains very steady at a level of 4 to 7 gammas and in general is below the plane of the ecliptic by 10° to 20° although the sense of the field is to point either away from the Sun at approximately the streaming angle associated with steady state models of coronal expansion or towards the Sun

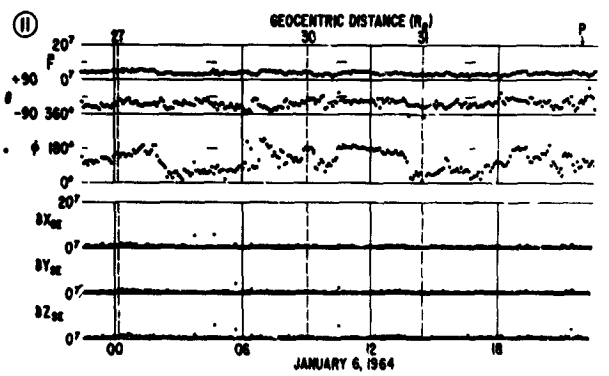

FIGURE 15.—Magnetic field data from orbit No. 11 January 6, 1964, illustrating interplanetary magnetic field.

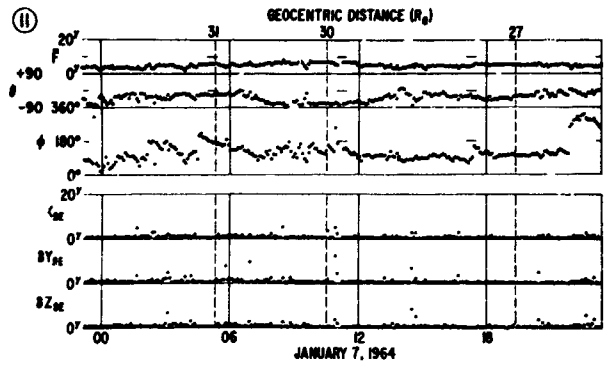

FIGURE 16.—Magnetic field data from orbit No. 11 January 7, 1964, illustrating interplanetary magnetic field and null surface separating filaments.

at the streaming angle. A significant feature in Figure 16. is the occurrence of a reversal of field direction at 2300 UT on January 7. At the same time as the field changed from being along the streaming angle to 180° opposite the streaming angle, the magnitude abruptly decreased to 10 minutes. Detailed inspection of the data at this time shows that the field went to zero as the field changed directions indicative of a *neutral surface* in interplanetary space.

The variance of the field remains quite low and clearly indicates a relatively stable magnetic field configuration somewhat in contrast to those results previously reported on Mariner 2 by Coleman et al., (1962). Figures 17. continues the presentation of data from orbit No. 11 on January 7, 1964 and supports the general statements of the stability of magnitude of the interplanetary field

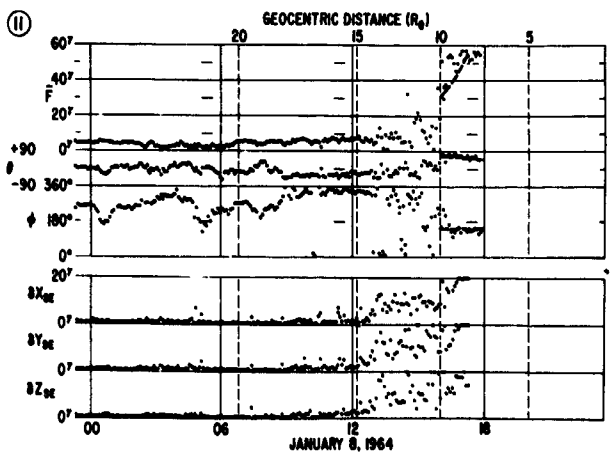

FIGURE 17.—Magnetic field data from orbit No. 11 January 8, 1964, illustrating inbound traversal of magnetopause boundary at 9.7R_e and shock wave boundary at 16.0R_e.

between 4 and 7 gammas while the directional changes in general are slow, on time scales of hours to several hours, and average directions correspond to pointing towards and away from the Sun at the streaming angle.

The inbound pass on orbit No. 11 is shown in Figure 17. presenting the magnetic field data obtained on January 8, 1964. The presentation of data is such that time always increases from left to right and the satellite is identified as being either on the inbound or outbound portion of its orbit by the sense in which the geocentric distance increases. Figure 17. illustrates two more traversals of the boundaries characteristically found throughout the lifetime of the IMP satellite. The shock wave identified as before on the basis of the increased turbulence in the magnetic field shows in this sample as an abrupt and very distinct increase in magnetic field strength at 16.0 R_e. The magnetopause boundary at which the field jumps rapidly to very large values more than twice those theoretically predicted, at the same time as its direction abruptly changes, is found to occur at 9.7 R_e. These data very briefly summarize the salient features of the 19 orbits which have been studied to date on the IMP–I satellite.

The general characteristics of all the orbital passes have been as shown in orbit No. 11, namely: traversals of two characteristic boundaries twice in each orbit. As the satellite orbit has progressed around from the Sun-Earth line the distance at which the magnetopause boundary and the shock wave boundary have been found to occur has changed. These changes have been correlated with a number of phenomena and will be discussed shortly. However, the most unique aspect of the boundary crossings in general has been their consistent and readily identifiable occurrence on all of the orbits.

The most important feature of the interplanetary magnetic field results has been in general the finding that the interplanetary magnetic field magnitude is quite steady and varies only over fractions of a gamma on the relatively long time scale of hours. This stability of the field magnitude but the variability of the direction may lend support to the studies by Dessler and Walters (1964) and Walters (1964) as to the effects of the streaming magnetized plasma on terrestrial magnetic activity and magnetospheric geometry.

The correlation between directional changes of the interplanetary magnetic field and the associated terrestrial activity as indicated by various indices, including K_p and A_p, is currently being investigated in detail. Previous studies experimentally by Snyder, Neugebauer and Rao (1963), Greenstadt (1964) and Maer and Dessler (1964) have not been completely consistent although they have generally indicated a definite correlation between K_p or (A_p) and solar wind velocity. These results are in some contradiction to the theoretical suggestions by Dessler and Fejer (1963) which deduce a correlation between K_p and changes in the solar wind velocity. It is important to note that the time variations of the interplanetary magnetic field observed reflect mainly the structural variations within the interplanetary medium. This is because the proper frame of reference moves with the bulk velocity of the solar plasma.

Although the statistics are not as yet complete it appears that in general there is a preference for the interplanetary magnetic field over this portion of time in the solar cycle to lie generally below the plane of the ecliptic by approximately 10° to 20°. At the same time the projected vector on the ecliptic plane appears to have three preferred orientations to which it returns and near which it is observed most of the time. In order of duration these three directions are:

1. Anti-solar,
2. At the streaming angle associated with the theoretical models of the solar wind,
3. At the anti-streaming angle, meaning exactly 180° opposite to the streaming angle theoretically predicted.

These results of the IMP-I magnetic field experiment suggest very strongly the existence of filamentary structure in the interplanetary medium associated with unique and separate sources of solar associated magnetic fields. These fields are stretched out away from the Sun by the highly ionized streaming solar plasma as modeled and discussed by Parker (1958). In between these streaming filamentary elements evidence has been found for magnetic field magnitudes decreasing abruptly to zero so as to essentially be in consonance with the idea of a null surface separating regions of interplanetary magnetic fields which are oppositely directed. Throughout the lifetime of the satellite thus far approximately 12 such readily identifiable filamentary structures have been observed.

A comparison of the observed streaming angle with those predicted by steady models assuming an axially symmetrical expanding solar plasma flux is shown in Figure 18. The observed interplanetary magnetic field is close to $\phi = 130$ to 150°

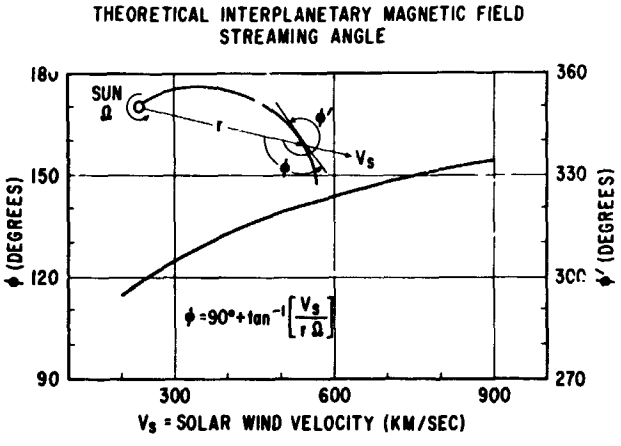

FIGURE 18.—Theoretical direction of interplanetary magnetic field ϕ as a function of solar wind velocity V_s.

or 310 to 330° for the streaming or anti-streaming angles. These directions are consistent with velocities of the solar wind of 300–700 km/sec, values found by the Mariner II probe, (Snyder and Neugebauer, (1963)). The detailed characteristics of the angular deviations of the interplanetary magnetic field are currently being studied and in the future detailed correlations with the plasma probes on board the satellite as well as additional solar and terrestrial indices will be made.

At the present time it appears that the results of the IMP magnetic field experiment have indicated an impressive consistency with the theoretical models proposed mainly by Parker, but also by Gold (1959, 1963). Those of Parker are substantiated on the basis of the interplanetary field direction dependence upon plasma velocity which compares very favorably with observation. The general directions of the field lines empasize the principal fact that a rotating Sun continuously emitting plasma will lead to a gross superposed spiral field structure under most circumstances. The filamentary structures appear to indicate specific sources as proposed by Gold (1963) as

must be considered in the modeling of realistic solar coronal phenomena. It is also possible that the data are consistent with the magnetic "bottle" ideas of Gold (1962) in which cutting of lines of force near the Sun generates field topologies which do not include the Sun.

Additional data from the magnetic field experiment is shown in Figure 19. from orbit No. 15 on

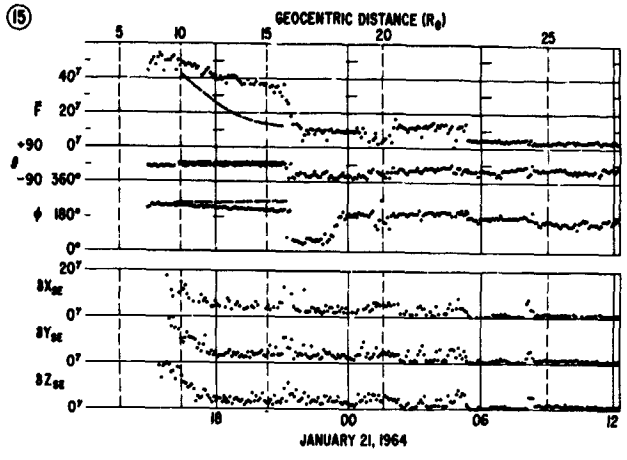

FIGURE 19.—Magnetic field data from orbit No. 15 January 21, 1964, illustrating outbound traversal of magnetopause boundary at 15.7 R_e, shock wave bound. at 22.7 R_e and precursor at 24.5 R_e.

January 21 1964. Again the presentation is in the same form as previous results and clearly illustrates the crossing of the magnetopause at 15.7 R_e while the shock wave traversal is not observed to occur until 22.7 R_e

A particularly significant feature of the outbound traversal of the shock wave on this orbit is the appearance at 24.5 R_e of an increased variance for 10–30 minutes. Not in evidence on every orbit although clearly indicated here, this feature of the IMP–I magnetic field data is very important. This limited increase in variance is also spatially associated with the position of the shock wave and when observed is usually found to be several Earth radii beyond the shock wave. This is identified as a precursor to the shock and is suggested to be indicative of characteristic plasma instabilities or particle resonances whereby the presence of the shock wave can be communicated "upstream" to the plasma by a mechanism that depends upon the individual particle dynamics of the plasma rather than the continuum dynamics of the collective particles. Continuing

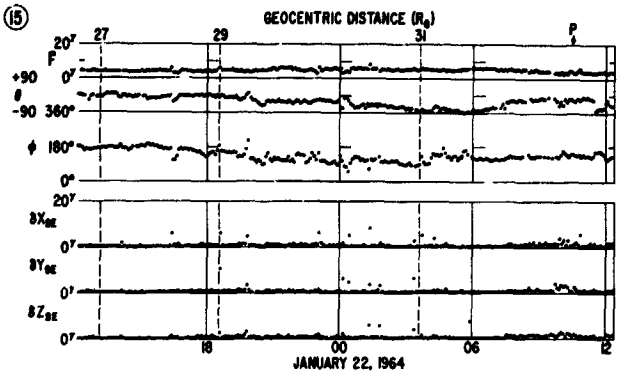

FIGURE 20.—Magnetic field data from orbit No. 15 January 22, 1964, illustrating interplanetary magnetic field.

in orbit No. 15, the interplanetary field is shown in Figure 20. on January 22, 1964. The characteristics of the data are quite similar to those shown for orbit No. 11 although the positions of the boundary are considerably beyond those observed in orbit No. 11 and correspondingly the positions of the boundary detected during orbit No. 11 occur at larger distances than originally detected during the early orbits of the spacecraft. An important feature of the turbulent field structure now is that fluctuations occur about a specific orientation so that there is an appreciable sense of directionality to the magnetic field, even though it is not stable in magnitude.

The data from orbit No. 6 inbound is being investigated in detail since it followed an interval of time during which the interplanetary field was disturbed because of the interaction of the Moon's magnetosphere with the solar wind (see Section 13.). It is clear from Figure 21. that the characteristic boundaries observed on all 37 other traversals are not evidenced here in the same manner. Principally the variance remains at the instrument noise level until a distance of 10.8 R_e is reached. Secondly, the abrupt directional changes in magnetic field are not coincident with abrupt changes in the magnetic field strength. The data strongly suggest the absence at this time of the collisionless shock wave probably due to the increased field strengths and possibly low plasma densities leading to Alfvén velocities sufficiently high that a shock situation does not exist. These data are also consistent with the study by Alfvén, Danielsson, Falthammer and Lindberg (1963) on the direct entry of solar

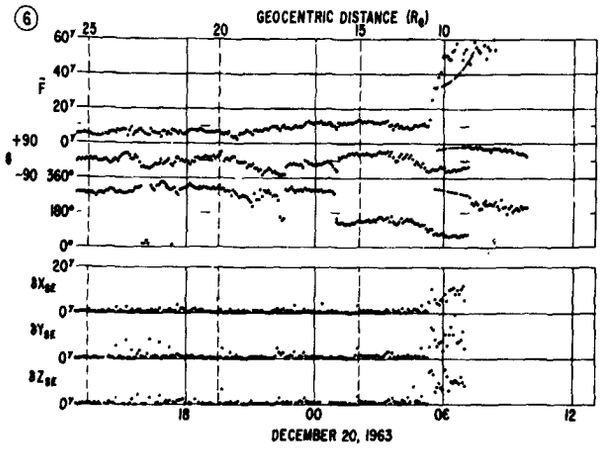

FIGURE 21.—Magnetic field data from orbit No. 6 December 20, 1963, illustrating inbound traversal of magnetopause boundary at 10.8 R_e and questionable shock wave boundary at 16.3 R_e.

plasma into the geomagnetic field when fields external to the cavity are parallel to internal fields.

9.0 SUMMARY CHARACTERISTICS OF MAGNETIC FIELD PHENOMENA

It is appropriate to summarize the many details of the interplanetary magnetic field data and the characteristics of the magnetic field at the shock wave and the magnetopause boundaries as well as the characteristics of the data for the transition region. Certain features are clear and have been already stated. The omission of certain characteristics which may become obvious to the reader should not be taken to indicate their dismissal by the authors as insignificant aspects of the data. It is quite impossible to discuss in this first publication all of the results which have been obtained from this particular experiment.

The orbit of the IMP–I satellite and the data obtained is such that it suggests logically separating the region of space surrounding the Earth into three physical regions for discussions:

1. The *Magnetosphere*, that region of space including the Earth and its radiation belts and enclosed by the magnetopause boundary from region 2. This geomagnetic cavity corresponds to a persistent containment of the geomagnetic field along the concepts initially developed for magnetic storm theory by Chapman and Ferraro (1931, 1932, 1933); Ferraro (1952, 1960a,b) and reviewed by Chapman (1960, 1963).
2. The *transition region* which extends from the magnetosphere to the interplanetary medium or more appropriately the interaction region between the streaming solar plasma and the geomagnetic field which is separated by the collisionless magnetohydrodynamic shock wave from region 3.
3. The *interplanetary medium* in which the plasma flux and magnetic fields are undisturbed and undistorted by the presence of the Earth in interplanetary space. This region of space and its physical characteristics represent the principal region of interest for the IMP–I measurements.

The physical characteristics of the magnetic fields in these three regions and the description and discussion of the boundary properties is given in the following paragraphs.

The dynamics of charged particle motion in the magnetosphere region is dominated by the magnetic field of the Earth. Measurements on the IMP–I show that deviations of direction and magnitude of the observed magnetic field when compared with theory do not become significant until an elevation of 7–10 R_e is reached. The deviations beyond this distance are consistent with the characteristics of a contained geomagnetic field with the strength increasing to at least a factor of two greater than normally expected without the formation of a magnetopause.

The directional distortion is consistent with the fields being oriented approximately tangential to the magnetopause surface. Although it requires further investigation in the future it is possible to state that the magnetic fields near the boundary on the Sunlit hemisphere interior to the magnetopause are not stable as argued by Dessler (1961, 1962) and that appreciable energy must be transmitted into the magnetosphere in the form of magnetohydrodynamic waves. The fluctuations observed are generally smaller than could have been detected by Explorer XII, because of its limited sensitivity of ± 12 gammas (Cahill and Amazeen, 1963) and show characteristic values of 10 gammas RMS or less and corresponding values of $\delta\vec{F}/\vec{F}$ of 0.05 to 0.3.

The magnetopause, reviewed by Hines (1963) is identified by the abrupt discontinuity in the character and quantitative description of the magnetic field as the satellite passes from Region

1 to Region 2. Near the subsolar point this is found to occur at approximately 10 R_e (see Section 10). The magnetic field rapidly de creases from values of 30–60 gammas to 5–20 gammas and corresponding variances from small $\delta\bar{F}/\bar{F}$ to large $\delta\bar{F}/\bar{F}$, being approximately 0.5 to 2.0. The thickness of the magnetopause is difficult to determine unambiguously but upper limits can be placed assuming that the boundary is stationary on a time scale such that the total time for motion of the satellite across the magnetopause is small. At distances of $10R_e$ the satellite radial velocity from the Earth is approximately 2.7 km/sec.

In general the analysis procedures and definitions currently employed to determine the location of the magnetopause are such that ± 2.5 to ± 15 minutes is a good measure of the uncertainty in precisely specifying where the boundary is traversed. Folding the spacecraft velocity and this time uncertainty together yields thicknesses of 810 km to 4860 km. This is quite reasonable since the proton Larmor radius for a 1 kev proton in a magnetic field of 10 gammas is 450 km and should be a reasonable scale length to consider in estimating the magnetopause thickness since all plasma flux is presupposed to be reflected and excluded by the geomagnetic field from entering the magnetosphere (Grad, 1961).

The direction of the fields at the magnetopause boundary strongly suggest that both internally and externally to the magnetopause, the fields are tangential to the magnetopause surface at least locally, i.e., not far from the boundary. Furthermore the directional changes suggest that although the magnetic fields are oppositely directed on either side of the magnetopause for a number of the crossings studied thus far, there are cases in which the fields appear to be crossed perpendicular with respect to each other on opposite sides of the boundary.

The *transition region* is one of great instability of the magnetic field suggesting that turbulent phenomena occur in this region and that statistical descriptions of the field will be most appropriate in their study. The vector field fluctuates rapidly in magnitude and direction with $\delta\bar{F}/\bar{F}$ ranging from 0.5 to 2.0. At times however the magnetic field direction and magnitude stabilize for time scales of 20 to 60 minutes with values corresponding to those of Regions 1 or 3. Although suggested by the interpretation of Explorer XII results, this is not considered to be representative of the general characteristics of Region 2. It is not interpreted to be indicative of rapid spatial movements of the mangetopause as it expands and contracts. Actually in a region of turbulence there is a finite probability that the field orientations will equal those of other Regions. The region of high turbulence encompassing and enclosing the magnetosphere is well established by the IMP data and quantitative statistical descriptions of the magnetic field and its topology in the vicinity of the magnetopause will be presented in future publications.

The collisionless shock wave boundary separates the interplanetary region 3 from the turbulent region 2, and is observed experimentally at 13.4 R_e at the subsolar point. The identification of its position as the satellite traversed it in space is based upon the striking physical differences between Regions 2 and 3. The abruptness of the changes in character of the fields at the outer boundary of the turbulent region is not always as sharply defined as at the inner boundary. In general, the interplanetary fields are very stable and characteristically show very small variances, less than 0.4 gammas for extended times yielding $\delta\bar{F}/\bar{F} < 0.1$. Interior to the shock wave boundary the field is observed to be randomized in direction and the total energy density in the magnetic field increases: both the DC value, as measured by $B^2/8\pi$ and the fluctuating field as measured by the variances δX_{se}, δY_{se}, and δZ_{se}. This means that the total energy of the magnetic field increases by factors of 5–10 and can play an important role in the flow of plasma around the cavity. It should be noted that although the identification of the shock wave boundary is generally unique based upon the above physical criteria, certain samplings of the shock region show a precursor in the Region 3 which stands off from the shock wave by several R_e. This *precursor* does not show the characteristic of larger fields but does display larger variances, up to 5 gammas, in each component for time scales of ≤ 40 minutes. At these distances, the satellite is moving radially outward at approximately 1.8 km/sec. Thus the spatial width of the precursor is ≤ 4000 km. Since the satellite is moving more

slowly when it traverses the shock wave, the longer times required do not indicate a more diffuse boundary than is the case of the magnetopause.

The existence of the collisionless magnetohydrodynamic shock wave was anticipated on the basis of theoretical analyses relying principally on the analogy with high speed aerodynamic flow. Various aspects of this general approach have been reviewed by Levy, Petschek and Siscoe (1963). Their specific interest and results were mainly to deduce certain aspects of the overall plasma flow around the geomagnetic cavity. Analytical studies on the structure of collisionless shocks in magnethydrodynamics have proceeded in some work by modification of the appropriate form of the Rankine-Hugoniot conditions derived by De Hoffman and Teller (1950). Theoretical studies by Adlam and Allen (1958); Auer, Hurwitz and Kilb (1961, 1962); Fishman, Kantrowitz and Petschek (1960); Morawetz (1961, 1962) and Morton (1962) have attempted to treat in varying degree, the detailed description of the shock characteristics and sufficient conditions for its existence. The present situation appears to be one in which the characteristics of the plasma flow are grossly described, at least in the location of the shock and magnetopause, on a basis of the analogy with fluid dynamics. However, the physical structure of the fields and plasmas in the observed three dimensional case of the Earth are not immediately derived by such simplifying considerations. In particular the discovery of the shock precursor is obviously indicative of the necessity to treat the flow of plasma more specifically as a two stream flow of non-cold electrons and protons (Bernstein, Fredricks and Scarf (1964) and Morton (1964)). A more detailed study of the observed shock wave with regard to the theoretical descriptions is presently in progress. However, it is reasonably certain that the IMP-I satellite and its experiment complement has provided the first physical measurements of the physical structure of a collisionless magnetohydrodynamic shock which heretofore has never been observed because of the "scaling problems" in laboratory research.

The interplanetary region 3 is defined most readily by the stability of the magnetic field as measured by the variances δX_{se}, δY_{se}, and δZ_{se}. These are observed to be less than 0.4 gammas with corresponding magnitudes of 4 to 7 gammas although excursions to values as low as 1 and to as high as 10 gammas for extended time intervals have been observed. The extreme stability of the magnitude of the field is in contrast to the more variable directional characteristics of the field. In general the fields lie on average slightly below the plane of the ecliptic ($\theta = 10°$ or $20°$) and at the streaming angle of 130°–150° or anti-streaming angle 310°–330°. The gross structure of the interplanetary field is in remarkably good agreement with the general concepts of spiral field configurations originally proposed by Parker (1958a). Associated with the two preferred orientations of the field, along or opposing the traces of the plasma flux, are regions of abrupt change to low values on time scales of less than 5 minutes. These are identified as neutral surfaces of zero field strength separating magnetic field filaments oppositely directed.

10.0 LOCATION AND GEOMETRY OF MAGNETOPAUSE AND SHOCK WAVE

A summary of the positions of shock wave and magnetopause traversals as a function of time associated with preliminary K indices from the Fredericksburg, Virginia magnetic observatory are shown in Figures 22–25. In addition, the geomagnetic latitude of the subsolar point, χ_{ss},

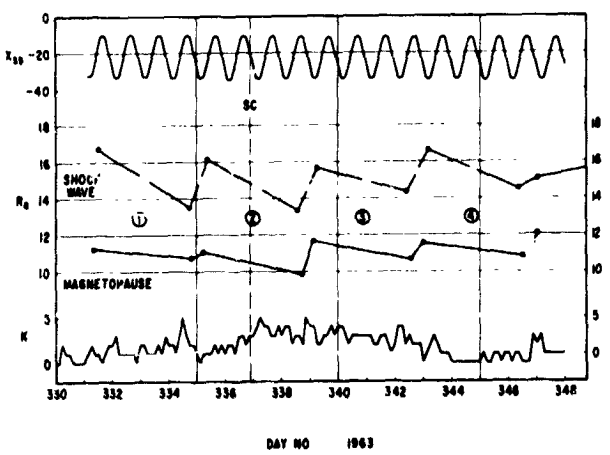

FIGURE 22.—Time characteristics of geomagnetic latitude of subsolar point χ_{ss}, magnetopause and shock wave boundary locations and K indices for days 330 to 348, 1963.

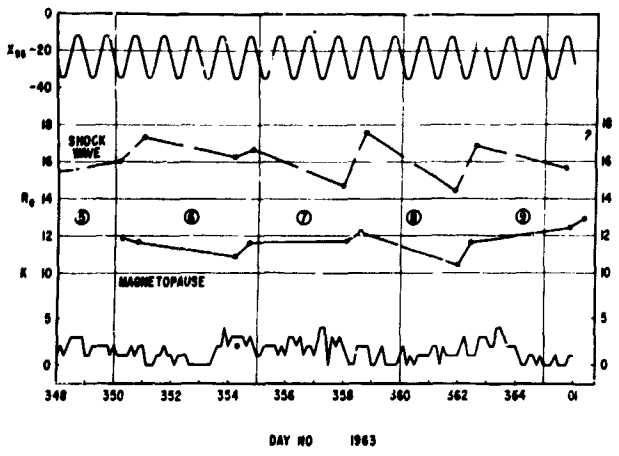

FIGURE 23.—Time characteristics of geomagnetic latitude of subsolar point x_{ss}, magnetopause and shock wave boundary locations and K indices for days 348, 1963, to day 01, 1964.

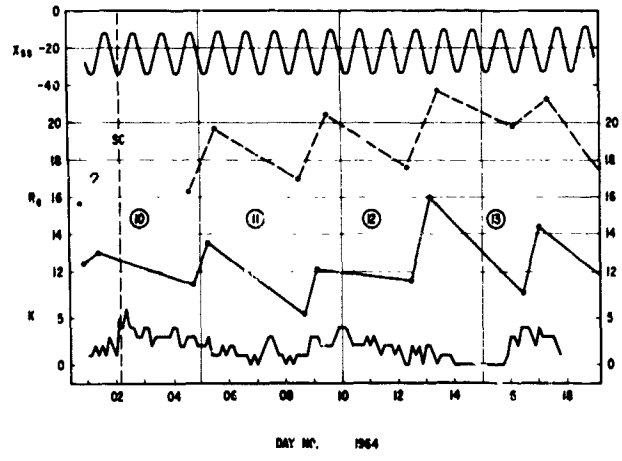

FIGURE 24.—Time characteristics of geomagnetic latitude of subsolar point x_{ss}, magnetopause and shock wave boundary locations and K indices for days 01 to 19, 1964.

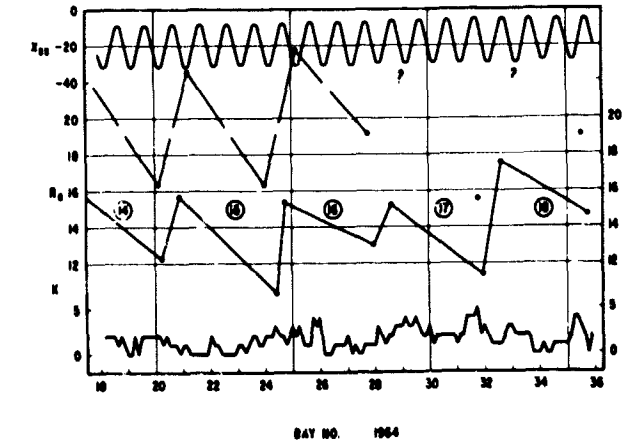

FIGURE 25.—Time characteristics of geomagnetic latitude of subsolar point x_{ss}, magnetopause and shock wave boundary locations and K indices for days 18 to 36, 1964.

has been included since it is an important factor in the interpretation of the position of the boundary crossings and the manner in which they relate to theoretical models of the magnetopause and the shock wave surfaces. In these Figures the orbit number is enclosed in a large circle while the boundary crossings are indicated by small circles. These are connected from inbound to outbound passes by straight lines if successive boundary crossings are uniquely identifiable. In some cases the position of the boundary is not sufficiently clear, as for example on the outbound portion of orbit 5, to uniquely specify its position and a question mark is displayed. This is related to the difficulty associated with the definition of the characteristics of the boundaries as deduced from the magnetic field data alone.

Certain aspects of the position of the boundary crossings are immediately evident upon inspection of these data. Principally seen is the periodic difference in position of the boundary crossings associated with outbound and inbound passes of the satellites. Characteristically the outbound pass shows the position of both boundaries to be greater than that associated with the next successive inbound pass. On a more detailed investigation it is found that following the sudden commencement storm in December 1963, indicated in Figure 22., the magnetopause and shock wave boundaries were located at smaller distances than normally to be expected on the basis of previous passes. Also over the 70 day interval covered by this data presentation, it is clear that the position of the magnetopause boundary and shock wave boundary increase as the satellite moves away from the Earth-Sun line. The two boundaries do not increase by the same amount. The shock wave increases more rapidly implying a wider transition region away from the subsolar point. It is noted that the satellite motion is roughly normal to these surfaces for early orbits, but becomes more oblique for later orbits.

Superimposed upon this spatial variation of the boundaries is the fact that the position of the boundary must be sensitive during successive crossings to the varying geomagnetic latitude of the subsolar point. That this is so is seen by inspecting the condition for balance of magnetic and particle pressure at the boundary. Originally

developed by Chapman and Ferraro (loc. cit.) the recent work by Beard (1960), Davis and Beard (1962), Spreiter and Briggs (1962) has led to agreement of the proper form. The location of the boundary at the stagnation point is given by

$$\frac{B_t^2}{8\pi} = 2mn\, V_s^2 \qquad (10.1)$$

where m is proton mass, n is proton density, V_s is solar wind velocity, and B_t is the net magnetic field tangential to the magnetopause boundary. This is commonly taken to be given by

$$B_t = 2fB_e \qquad (10.2)$$

where f is a factor ≤ 1 (usually taken as unity) and B_e is the theoretical and undisturbed geomagnetic field. However,

$$B_e = B_0 \frac{R_e^3}{R_c^3}\sqrt{1+3\sin^2\chi_{ss}} \qquad (10.3)$$

where χ_{ss} = geomagnetic latitude at the stagnation point where the flow velocity is normal to the surface and B_0 is the terrestrial equatorial field strength.

Combining 10.1, 2 and 3 yields

$$R_c = R_e\left[\frac{B_0^2\,(1+3\sin^2\chi_{ss})}{4\pi\, mn\, V_s^2}\right]^{1/6} \qquad (10.4)$$

where χ_{ss} is the geomagnetic latitude of the subsolar point. Clearly the distance at which the magnetopause is predicted depends upon the angle of the Earth's dipole to the solar plasma.

This concept has been included in the final data summary and has been employed to rectify the position of the boundary crossings to a geometry which allows comparison with the simplified theoretical treatments. In these analyses the solar stream is assumed normally incident upon the axis of the magnetic dipole, implying coincidence of the geomagnetic equatorial plane and the ecliptic plane.

A summary of the location of the magnetopause and shock wave traversals rotated into the ecliptic plane as a function of position of the satellite is presented in Figure 26. The effect of motion of the line of apsides of the satellite relative to the Sun-Earth line is evident. Presented

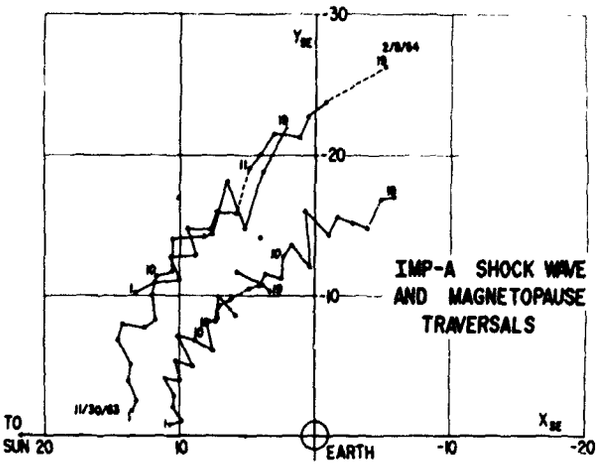

FIGURE 26.—Location of magnetopause and shock wave boundary traversals rotated onto ecliptic XY plane.

in this figure are all boundary crossings which have been uniquely identified on the basis of magnetic field information alone. These data do not include any corrections for time variations of the solar wind, the planetary indices of the geomagnetic field, nor the geomagnetic latitude of the subsolar point, χ_{ss}. These boundary crossing positions have been rotated from their actual position to the ecliptic plane in a meridian plane through the Z_{se} axis. This essentially assumes a constant radius of curvature in each meridian plane. An alternative procedure, not employed, is to rotate the positions into the ecliptic plane about the X_{se} axis which presumes cylindrical symmetry about the X_{se} axis.

Clearly evident in this figure is the fact that the magnetopause is not spherical, but actually on the nightside hemisphere of the Earth, the boundary flares out in consonance with the ideas originally resulting from measurements on the Explorer X satellite (reviewed by Bridge (1963) and Ness (1963)). In addition, it is seen that the shape of the shock wave boundary when projected on the ecliptic plane is approximately hyperbolic. The angle which the hyperbola asymptotically approaches is referred to as the Mach angle and if measured could indicate the velocity of solar wind propagation relative to the interplanetary magnetic field strength and plasma density by defining the Mach number of the super Alfvénic flow of the solar wind.

In order to make a first order correction for the variation of the geomagnetic latitude of the

sub-solar point and thereby take into account the variable magnetic field strength which the solar wind meets at the stagnation point, an expansion factor K has been computed. This is dependent upon the geomagnetic latitude of the sub-solar point and the strength of the magnetic field of an assumed dipole at the center of the Earth. From Equation 10.4, K is defined as:

$$K=[1+3\sin^2\chi_{ss}]^{1/6} \qquad (10.5)$$

The maximum inclination of the Earth's magnetic dipole axis to the solar wind direction is 35.1° being the sum of 11.7°, the tilt of the magnetic axis to the rotation axis, and 23.4°, the obliquity of the rotation axis to the ecliptic. The maximum

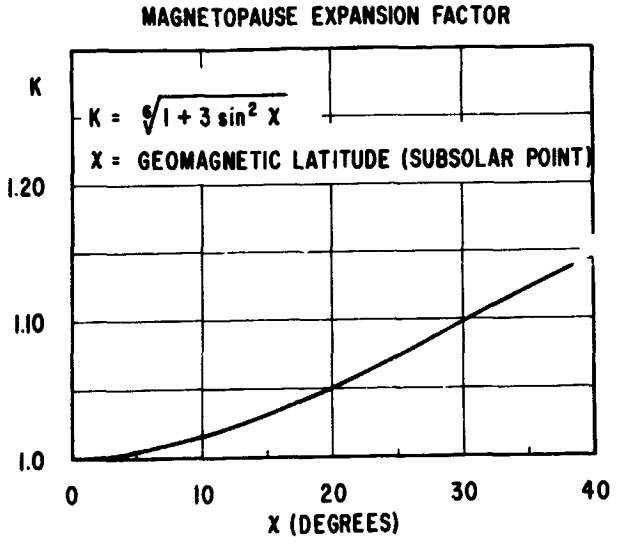

FIGURE 27.—Magnetopause expansion factor K to compensate for variable tilt of Earth's magnetic field axis to "angle-of attack" of solar wind.

expansion is seen in Figure 27. to be 12 percent assuming a constant pressure of the solar wind. The time of launch of IMP–I is such that the maximum inclination was achieved during the first month of operation of the satellite, being winter solstice and since that time the Earth's rotational axis has approached perpendicularity to the Earth-Sun line. This is seen in Figures 22 thru 25 in which the diurnal variation of χ_{ss} is seen to become more negative, reaching a maximum in December 1963 and then becoming less negative as time progresses. The average values of χ_{ss} over one day indicates the angle between the normal to the Earth-Sun line (X_{se} axis) and the direction of the Earth's rotation axis.

In comparing theoretical and observed boundary geometries, it has been assumed that the only model currently available is that provided by the provided by the computations of Spreiter and Jones (1963) using a blunt body profile representing the Earth's magnetosphere to determine the shape of the shock wave surface based upon a strict analogy with high speed aerodynamic flow.

The blunt body profile used is that which has been obtained by rotating about the X_{se} axis the trace of the magnetopause in the geomagnetic equatorial plane. The shape has been determined by a number of workers Beard (1960); Hurley (1961); Midgley and Davis (1962); Slutz (1963); Spreiter and Briggs (1962); Mead and Beard (1964), and all results are in generally good agreement as long as the region near the null points in the polar regions is not considered. None of these analyses have included an interplanetary magnetic field in determining the shape nor physical characteristics of the magnetopause boundary, particularly in view of the importance of the collisionless shock wave. This omission has been partially rectified in the work of Lees (1964) in inclusion of the interplanetary magnetic field. The ramification of the shock on the field configuration external to the magnetopause has been considered by Beard (1964). The results for the particular model which Spreiter and Jones (1963) utilized have been slightly adjusted to match the actual observation of stand-off distances of the geomagnetic cavity boundary and the shock wave boundary at the subsolar point. In addition all boundary crossings have been rectified by dividing the observed distance by the appropriate value of the expansion factor K so as to reduce all distances to a geometry in which the solar wind is normally incident upon the axis of the Earth's magnetic dipole. The results of these rectifications and the adjustment of the theoretical models is compared in Figure 28. with the theoretical results indicated as the solid curves through the experimental data. The theoretical magnetopause geocentric distance at the subsolar point is taken to be 10.25 R_e while that of the shock wave is taken as 13.4 R_e. It has been necessary to rotate the theoretical model by 5° about the Z_{se} axis to obtain the demonstrated

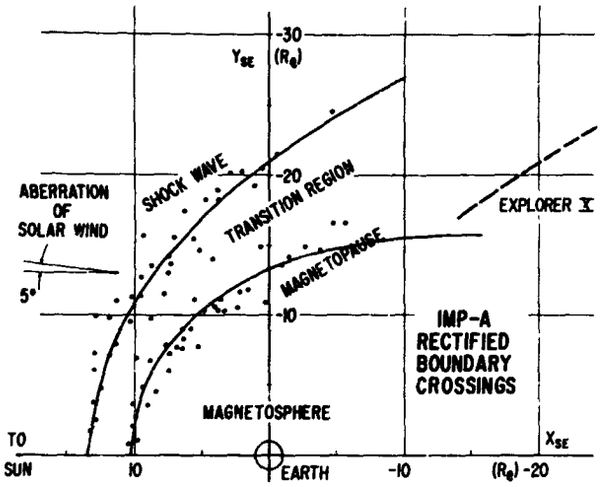

FIGURE 28.—Summary of location of rectified shock wave and magnetopause boundary crossings and comparison with theoretical predictions using analogy with supersonic fluid flow.

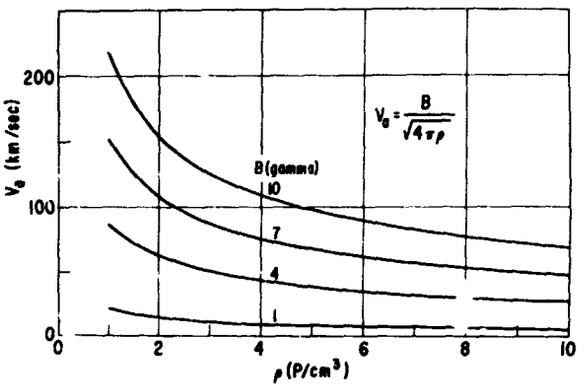

FIGURE 29.—Alfvén magnetohydrodynamic phase velocity of wave propagation as function of magnetic field strength and plasma density.

agreement. This is comparable with the aberration effect due to the Earth's orbital motion of 30 Km/sec when compared to the solar wind velocities. For values of V_s between 300 and 400 Km/sec the aberration effect changes from 5.7° to 4.6° and the value of 5° is taken to be a representative average.

An important parameter describing the flow of the solar plasma and its interaction with any planetary object is the velocity at which disturbances can be propagated. In the highly ionized magnetized plasma being studied, the appropriate modes of propagation are the magneto-acoustic modes. Considering the important mode to be the simple Alfvén transverse magnetohydrodynamic mode, the relevant velocity is given by

$$V_A = \frac{B}{\sqrt{4\pi\rho}} \tag{10.6}$$

This is shown in Figure 29. covering the range of parameters observed in space. Since in general representative values of these parameters are

$$4 \leq B \leq 7 \text{ gammas}, \tag{10.7}$$

$$3 \leq \rho \leq 10 \text{ protons/cm}^3$$

$$\text{then } 25 \leq V_A \leq 90 \text{ Km/sec}$$

Now the directed stream velocity of the solar wind is observed to be

$$300 \leq V_s \leq 700 \text{ km/sec}$$

Thus the ratio of directed velocity to Alfvén velocity measures the super Alfvénic ratio, or Mach number corresponding to the gas dynamic analogy, is

$$3.3 \leq M_A \leq 28 \tag{10.8}$$

and a mean value of

$$\overline{M_A} = 5\text{–}10 \tag{10.9}$$

A general review of the applicability of the gas-dynamic analogy used in treatments of the flow of plasma around the geomagnetic field has been given by Levy, Petschek and Siscoe (1963).

The comparison between theory and observation of the position of the shock wave surface is good. It is clear however that the comparison is possible at the present time only near the stagnation point. Here the shape of the surface is not critically dependent upon Mach number or equivalent gas specific heat ratio used. The experimental data however does suggest an outward flaring of the magnetopause, first observed on Explorer X and is seen to be consistent with the present observations on IMP. The portion of the Explorer X trajectory over which the magnetopause boundary was observed is indicated in Figure 28., having been rotated about the X_{se} axis into the ecliptic plane ahead of the Earth. The extrapolation of the IMP observations coincides reasonably well with these previous measurements. It indicates a fundamental discrepancy between theory and observation in that all theoretical models using a real, thermalized

plasma lead to a closure of the magnetopause at distances of 30–50 R_e on the dark side of the Earth. However, the observations indicate that an outward flaring of the magnetopause surface at a half-cone angle of 10–15° occurs. The magnetic fields interior to the magnetopause for orbits numbered 11 and beyond are directed at $\phi = 205$–215° which is consistent with an outward flaring if the fields are tangential to the bounding geomagnetic cavity surface.

The relative position of the subsolar geocentric distance to the shock wave, R_s, and the magnetopause boundary, R_c, is presented as a function of the Alfvén Mach number in Figure 30. The

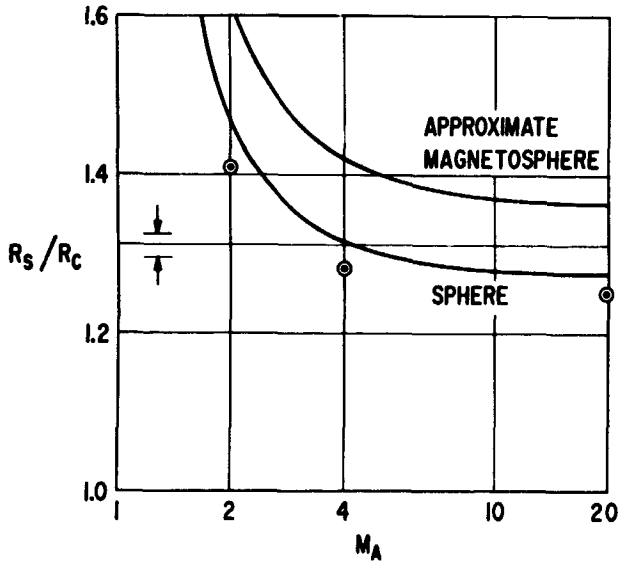

FIGURE 30.—Theoretical stand-off ratio R_s/R_c of shock wave surface to magnetopause boundary and comparison with observations.

solid lines indicate the theoretical models for a sphere and blunt body as predicted by Spreiter and Jones (1963). The circled data represent the values deduced by Kellogg (1962) in his analysis using the analogy of supersonic flow in gasdynamics and the theoretical results of Hida (1953) for a spherical object. The observed value of the ratio of R_s/R_c is shown as a horizontal solid line, experimentally determined to be 1.31 ± 1 percent. The correspondence between theory and observation is very good and although the use of the blunt body profile does not yield the proper ratio, it is increased in the proper sense. The present discrepancy between theory and observation can be readily resolved through use of $\gamma < 2$ and slightly altering the magnetopause shape.

The totality of IMP observations on the location and geometry of the magnetopause and collisionless shock wave boundary are in generally good agreement with theoretical models using the analogies between supersonic fluid flow and the super Alfvénic flow of the solar wind with the interplanetary magnetic field acting to couple the particles together as described by Axford (1962) and Kellogg (1962) rather than direct particle collisions. Obayashi (1964) has reviewed all previous satellite measurements with respect to their significance in the detection and identification of the magnetopause and shock wave boundary positions.

Since the satellite has yet to completely map the nighttime magnetospheric tail, it is not possible to definitely state that an extended flaring of the cavity far behind the Earth is the only possible interpretation of the data. It appears a reasonable assumption to make, however, and it is anticipated that during orbits 20–40 the IMP satellite will provide extremely important data on the actual geometry and physical characteristics of the magnetopause boundary and the magnetic field topology within the geomagnetic tail. Studies on the magnetopause tail magnetic field topology have been performed by Axford and Hines (1961); Harrison (1962); Hones (1963) and Johnson (1960). Quantitative estimates of the field characteristics in the magnetopshere near the stagnation point have been performed by Mead (1964). In the traversals of the magnetopause boundary the direction of the magnetic fields appear to be tangent to the apparent magnetopause surface within $\pm 10°$. At present one of the major theoretical uncertainties is the reason for the outward flaring shape of the cavity boundary on the nightside of the Earth.

11.0 SOLAR TERRESTRIAL TRANSIENTS

The general level of terrestrial magnetic activity throughout the lifetime of the IMP satellite has been extremely low as seen by the K values in Figures 22–25. This is associated with the decrease of solar activity which will meet its absolute minimum within the next eighteen months. Fortunately, however, there have been a few specific isolated magnetic disturbances

associated with the limited solar activity and these have been observed definitively on the IMP satellite in interplanetary space. In particular, the December 2, 1963 sudden commencement storm beginning at 2117 UT occurred at a very favorable time in the second orbit of the satellite. At this time, as shown in Figure 11., the satellite was approaching apogee and essentially was stationary in space except for its motion through the interplanetary medium at the heliocentric orbital velocity of the Earth.

The regular run magnetograms from a number of standard observatories in the U.S. Coast and Geodetic Survey net are presented in Figure 31.

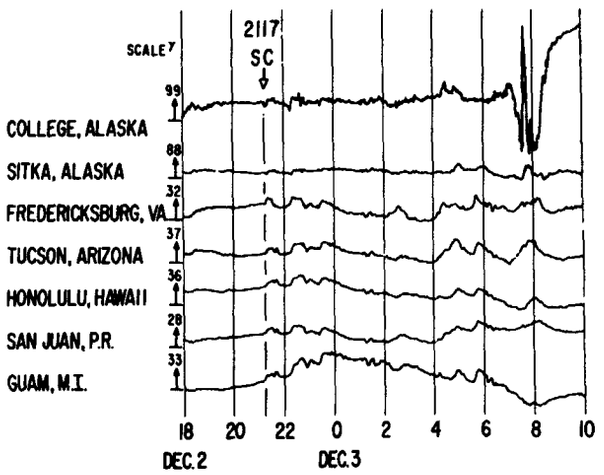

FIGURE 31.—Regular-run observatory H component magnetograms for December 2, 1963 sudden commencement storm period.

for the time interval preceding and following the sudden commencement storm. It is clear from inspection of the records that this sudden commencement showed similar characteristics at a number of stations for several hours after the initial onset. In order to accurately establish the time of occurrence of the sudden commencement at terrestrial stations, the rapid-run magnetograms from certain of these same stations are illustrated in Figure 32. in which the time scale is considerably expanded. It is seen that the onset time of 2117 is easily identifiable as there is no discrepancy in its unique characteristic.

The magnetic field data obtained on the outbound portion of the orbit No. 2 on December 1, 1963 is shown in Figure 33. At this time the boundary of the magnetopause was observed at

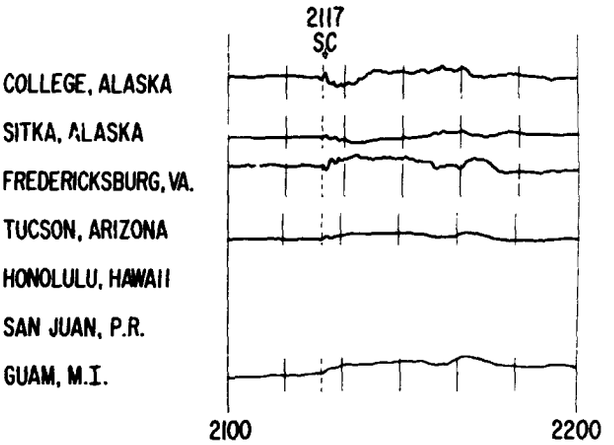

FIGURE 32.—Rapid-run observatory H component magnetograms for December 2, 1963, sudden commencement storm period.

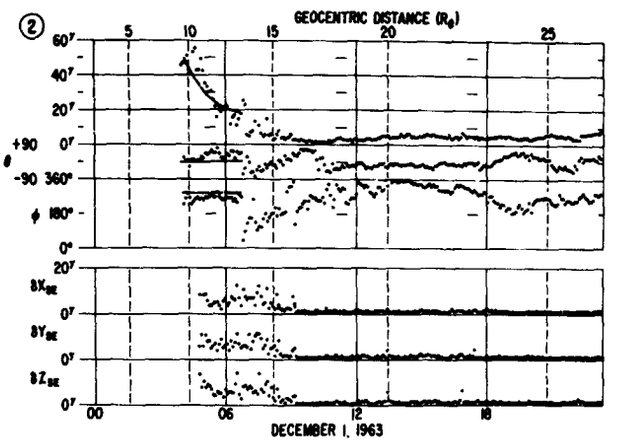

FIGURE 33.—Magnetic field data from orbit No. 2 December 1, 1963 indicating traversal of magnetopause boundary at 11.1 R_e and shock wave boundary at 16.2 R_e.

11.1 R_e while the shock wave was observed at 16.2 R_e. In general the interplanetary magnetic field conditions were quiet although the field was somewhat larger than previously observed, approximately 6 gammas, varying somewhat in direction and illustrating the filamentary structure previously referred to in the summary of the overall characteristics of the interplanetary magnetic field. Data from the portion of the second orbit during which the storm occurred is shown in Figure 34. The interplanetary magnetic field was undisturbed prior to the occurrence of the sudden commencement, although the magnitude increased gradually. Shortly before the terrestrial observations of the sudden commencement

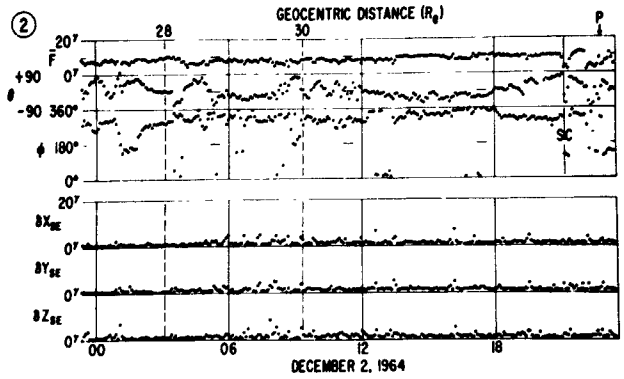

FIGURE 34.—Magnetic field data from orbit No. 2 December 2, 1963, illustrating interplanetary magnetic field at time of sudden commencement storm.

The field decreased very rapidly, and varied somewhat for several hours, eventually returning to a configuration similar to that prior to the storm. An expanded time scale presentation of the interplanetary magnetic field is presented in Figure 35.

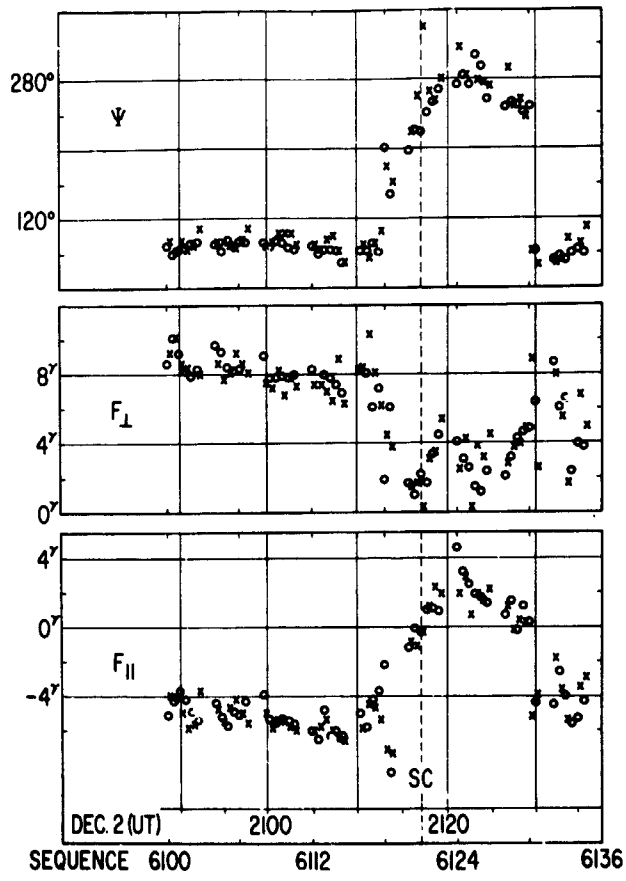

FIGURE 35.—IMP-I magnetic field data on expanded time scale in payload coordinates at time of December 2, 1963, sudden commencement storm. Circles refer to fluxgate *A* data while crosses reference fluxgate *B*.

in a payload coordinate system. Instead of 5.46 minute averages, the 12 sample values in that interval are presented separately with a time spacing of 20 seconds. It is clear that the occurrence of the sudden commencement indicated by the initial onset of the magnetic field disturbance occurs at 2114 on December 2 at the satellite. Assuming radial propagation of the plasma front and the associated magnetic field distortions to the surface of the Earth yields a propagation velocity of 700 kilometers per second. This velocity is an apparent value of velocity of propagation since it does not include the physical propagation of the storm transient itself to the surface of the Earth, assumes the direction of propagation of the storm front and that the magnetic field disturbance and the plasma disturbance occur at the same place in the solar plasma stream. This value of 700 kilometers, however, is consistent with the transit time associated with the projected solar region responsible for the storm, and is equivalent to particle energies of 2.5 kev. On the assumption of a propagation velocity of 700 kilometers per second and observing the time interval during which the magnetic field is disturbed and presumed to be associated with the propagation of the shock front surface, the thickness is 0.005 AU. This is consistent with particle measurements yielding scale lengths of scattering centers in interplanetary space at the time of magnetic disturbances.

Another important feature of the storm is that there is a null surface observed during the transit of the storm front surface across the spacecraft. The structure may well be consistent with Parker's "blast wave" model of sudden commencement storms if one includes the fact that if the compressed interplanetary fields are filamentary in their topology, then null surfaces must occur. This suggests that magnetic field annihilation as proposed by Petschek (1963) may be the mechanism whereby acceleration of particles in the shock front occurs. The present sample of magnetic fields associated with SC's in interplanetary space does not show the large fields, up to 50 gammas, previously reported by Coleman et al., (1961) for Pioneer V results. Indeed the experimental results appear to be in the main contradictory since Pioneer V did not measure a

null surface either. At the present time, it is suggested that these differences only reflect the great variability in storm characteristics and intensities.

12.0 INTERPRETATIONS OF SOLAR STREAM PROPERTIES

The location of the magnetopause and shock wave boundaries as observed by the magnetic field experiment permit an extrapolation to the characteristics of the streaming solar plasma. The streaming angles indicated by the magnetic fields are used in computing the characteristics of the solar stream. The interpretation assumes that the streaming angle provides a reasonable estimate of the particle velocity. Figure 36. gives

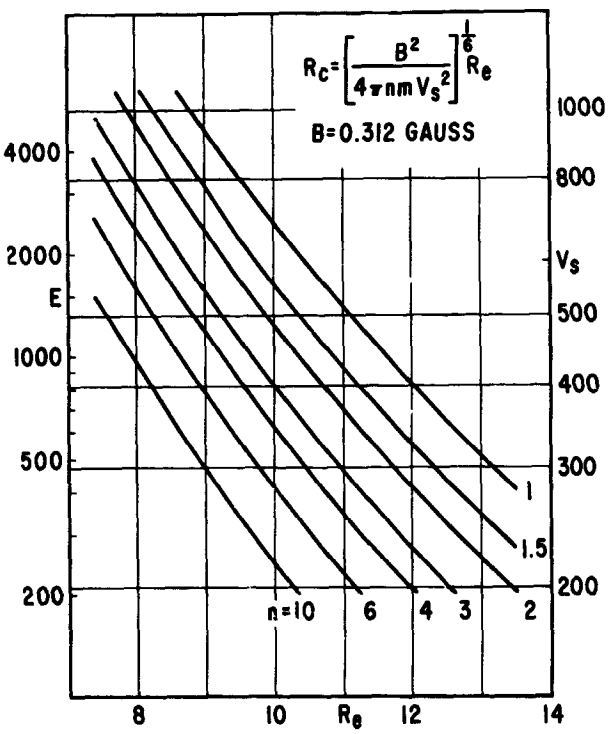

FIGURE 36.—Theoretical stagnation point distance R_c of magnetopause boundary as function of particle velocity (or energy) and plasma density.

the particle density and velocity that would be consistent with the observed location of the magnetopause if the plasma were directly incident upon the magnetopause. This density and velocity represent an effective description of the plasma flux pressure, being balanced by the magnetic field pressure. The actual solar wind velocity and density must be adjusted in terms of the boundary conditions which exist at the shock wave. On the assumption of particle velocities between 300–700 kilometers per second and the observed location of the magnetopause boundary of 10.25 R_e, it is seen that the corresponding proton density is between 1 and 5 protons/cc. This yields a flux value of 0.7 to 1.5×10^8 protons/cm^2/sec, which is in good agreement with previous plasma results extrapolated from Explorer X, (Bonetti et al., 1963) and the direct measurements on the Mariner II spacecraft (Snyder and Neugebauer, 1962).

13.0 MAGNETOHYDRODYNAMIC WAKE OF THE MOON

A unique phenomena occurred in interplanetary space during the fifth orbit of the satellite. At that time the interplanetary magnetic field was observed to fluctuate much more so than had been previously observed or was subsequently observed and also to reach a maximum value of 14.6 gammas for a period of 4 hours on December 14, 1963. This high value of both the magnitude and the variance had never been observed throughout the previous 4 orbits of the spacecraft when in the interplanetary medium and some concern was expressed initially as to whether or not the operation of the instrument and/or the telemetry digitization system was proper at the time. The integrity of the operation of the telemetry system and the sensor has been verified and the conclusion is irrevocably that the basic data is valid. At this time the satellite was located between 28 to 31 R_e from the Earth at approximately an angle of 40° to the Sun-Earth line and far beyond the shock wave location.

Investigation of solar conditions prior to the anomalous field behavior, extending from 0100 UT, December 14 to 1000 UT Decmber 15, has not revealed any significant features that might have led to disturbed conditions in interplanetary space. The characteristics of the fluctuations are quite unlike those of the magnetic fields associated with the sudden commencement storm on December 2, 1963. Indeed the characteristics are similar to those observed when sampling the transition region associated with the solar wind impacting the geomagnetic field.

The explanation offered is that the relative location of the Sun, Moon and satellite was unique and that the interaction of the solar wind with the Moon and its magnetosphere formed a magnetospheric tail which IMP-I traversed. This extended far behind the Moon much in the manner of cometary tails (Biermann 1951) and as may be the case of the Earth's tail. An inspection of the ephemerides of the Moon, Sun and IMP-I satellite has shown that this is a reasonable interpretation. Thus it provides the first direct measurements of magnetic field phenomena associated with the Moon and indeed may provide quantitative estimates of the lunar field strength upon subsequent detailed analysis.

The projected locations of the relevant celestial objects on the ecliptic plane is shown in Figure 37. Included is the location of the magnetopause

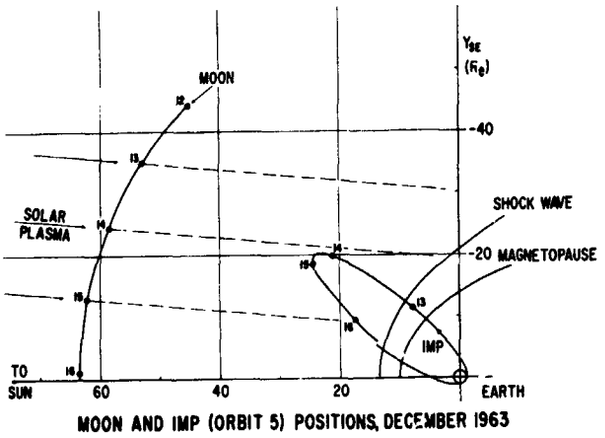

FIGURE 37.—Relative location of IMP-I Satellite, earth and moon during period December 12-16, 1963, when lunar magnetospheric wake was detected by the magnetic field experiment.

and the shock wave boundaries to illustrate the fact that the satellite was not sampling the region of interplanetary space influenced by the presence of the Earth. The numbers on both the IMP-I and Moon orbits indicate the location of the respective object at 00 hours UT on the particular day in December 1963. The projected view of the same days on the solar ecliptic YZ plane is shown in Figure 38. Certain physical parameters important in specifying the relative location of the Sun, Moon and IMP-I are

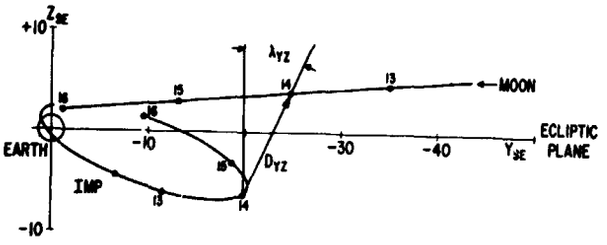

FIGURE 38.—Relative location of IMP-I Satellite, earth and moon projected on plane perpendicular to earth-sun direction, the solar-ecliptic, YZ plane during period December 12-16, 1963.

defined as follows:

$\vec{D}$ = vector distance from satellite to Moon

$$\vec{D} = D_x\vec{i}_x + D_y\vec{i}_y + D_z\vec{i}_z$$

$$D_{sm} = |\vec{D}| = [D_x^2 + D_y^2 + D_z^2]^{\frac{1}{2}}$$

$$D_{xy} = [D_x^2 + D_y^2]^{\frac{1}{2}}$$

= projected distance in XY plane (11.1)

$$D_{yz} = \left[D_y^2 + D_z^2\right]^{1/2} = \text{projected distance in } YZ \text{ plane}$$

cosine $\lambda_{xy} = D_y/D_{xy}$ = cosine of angle between $\vec{D}$ and $\vec{i}_x$ projected into XY plane

cosine $\lambda_{yz} = D_z/D_{yz}$ = cosine of angle between $\vec{D}$ and $\vec{i}_z$ projected into YZ plane

The distance D_{yz} and the angle λ_{yz} are illustrated in Figure 38. For an optical occultation $D_{yz} = 0$, while when $\lambda_{yz} = 0$ it implies that the Sun-Moon-IMP-I define a plane that is perpendicular to the ecliptic plane.

A summary of the above critical parameters as a function of time in December is shown in Figure 39. as well as the indication of where traversals of the shock wave boundary occurred. The parameter D_{yz} refers to the projected distance on a plane rotated by 5° from the YZ plane to take into account the aberration of the solar wind. The "closest" distance from the satellite to the Moon is seen to be 7.9 R_e in the YZ plane while the satellite is 38 R_e from the Moon. Converted to lunar radii, R_m while the apparent diameter of the tail at that distance is at least 30 R_m. These values indicate a magnetospheric wake with a half-cone angle of approximately 11°, a value consistent with the Mach angle associated with the solar wind interaction with a Moon possessing a weak magnetic field.

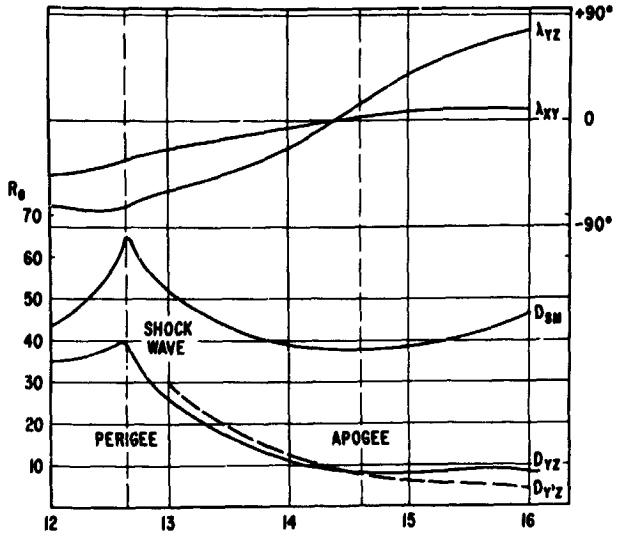

FIGURE 39.—Critical parameters related to "shadowing" by moon's magnetosphere on IMP–I magnetic field measurements during December 12–16, 1963.

The direct measurement of the lunar magnetic field and a precise determination of its geometrical properties is of vital importance in the study of the origin of the Earth-Moon system. The interpretation of terrestrial data suggests the nonexistence of a lunar magnetic field similar in origin to the Earth's in which a dynamo system of currents circulates in a fluid core. The presence of a lunar magnetic field may be indicative of a permanent state of magnetization which reflects an ancient field at the time of origin of the Moon. It has been suggested by Gold (1962) that the streaming magnetized solar plasma may provide a mechanism whereby the interplanetary magnetic field is captured by the finite electrical conductivity of the Moon. This would then lead to a magnetic field configuration which would be interpreted as a lunar magnetic field.

Russian measurements of the lunar magnetic field on the second Cosmic rocket (Dolginov, Eroshenko, Zhugov, Pushkov and Tynrmina, 1960) indicate a surface field of less than 50 to 100 gammas corresponding to a magnetization intensity less than 0.25 percent of the Earth's. The streaming solar plasma is sufficiently strong that it will greatly distort a lunar magnetic field regardless of its origin (Neugebauer, 1960). Thus it can reasonably be expected that a cavity and geomagnetic tail similar to that observed on Explorer X (in the anti-solar direction behind the Earth) and thus far suggested by IMP–I, will also develop around the Moon.

The detailed measurement and accurate vector mapping of such a lunar magnetic field and associated magnetospheric tail can only be accomplished with a spacecraft orbiting the Moon. The present IMP–I measurements may provide information sufficient to indicate the nature of the lunar magnetic field. A detailed study of the magnetic field results in currently being conducted and a future publication will treat the lunar wake separately.

14.0 CONCLUSIONS

The IMP–I satellite has provided the first direct measurements of interplanetary magnetic fields with high accuracy. The spacecraft fields are found by analysis of in-flight data to be less than ± 0.25 gamma. The observed field strengths in the interplanetary medium range generally from 4 to 7 gammas with temporary excursions to values as low as 1 and as high as 10 gammas. The magnitude is impressively steady although directional changes occur fairly frequently on time scales of several hours. The steady magnitudes are a feature of the fields which has not been anticipated.

A significant feature of the vector field and the inferred interplanetary field configuration is the gross feature of spiral structure associated with the rotation of the Sun, in directions consistent with observed solar plasma velocities. At times the field reverses directions on a time scale of 5–20 minutes, going through zero rapidly, indicating neutral surfaces separating filamentary elements of magnetic fields. The overall Archemedian spiral structure imbedded in which are the distinctive filaments strongly suggests a merging of theoretical field topologies principally discussed by Parker (1958) and Gold (1959). However, the fields have only been recently sampled and further analysis will be required to determine whether the "magnetic bottles" of Gold (1959) are also consistent with the data. Indeed with only one sample point in space in space it may not be possible to delineate between such features.

Our observations of the solar wind interactions have experimentally confirmed the existence of the collisionless shock wave predicted by theoretical analogies with supersonic gas dynamics.

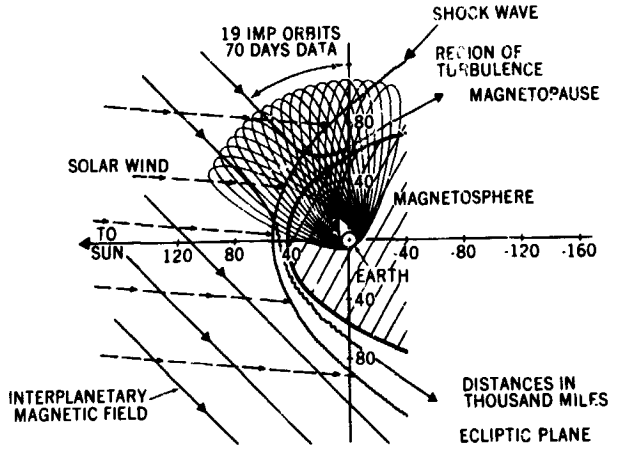

FIGURE 40.—Illustration of IMP—I magnetic field data interpretation showing solar wind, interplanetary fields collisionless shock wave and magnetopause locations on ecliptic plane.

Indeed the position of the shock wave is impressively consistent with the theoretical models showing a departure of only a few percent. The magnetosphere boundary, the magnetopause, is clearly observed and found to be separated from the shock wave by a region of high turbulence in the magnetic field. An interpretive graphical summary of the initial results of interaction of the solar wind with the Earth is shown in Figure 40. The geocentric distance to the magnetopause is found to be 10.25 R_e at the stagnation point. The distance to the shock wave is 13.4 R_e yielding a stand-off ratio of 1.31 ± 1 percent.

The detection of the extended lunar magnetospheric wake into interplanetary space at least

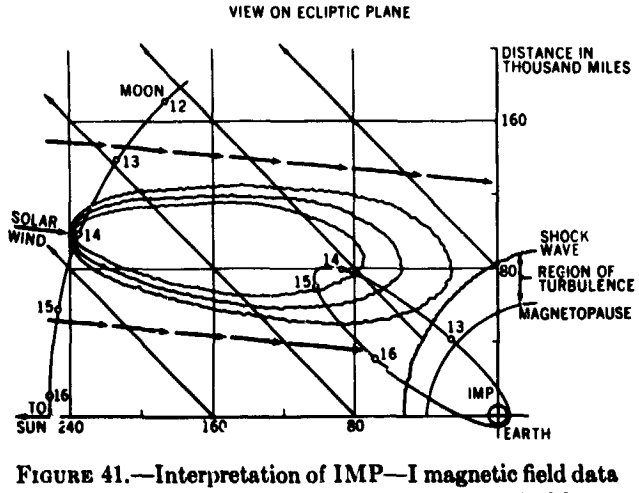

FIGURE 41.—Interpretation of IMP—I magnetic field data indicating characteristics of interplanetary and cislunar space and *MHD* wake of moon at time of lunar magnetosphere detection.

150 lunar radii behind the Moon is important evidence in confirming the general aspects of our understanding of the solar wind interactions with planetary objects. The field strengths and directions are indicative of the magnetohydrodynamic interaction of the solar wind with the Moon's magnetosphere and may provide evidence on the lunar magnetic field strength. The lunar wake geometry is illustrated in Figure 41.

ACKNOWLEDGEMENTS

The success of the magnetic field experiment is due in large part to the outstanding effort by the technical staff at Goddard Space Flight Center, the other experimenters and the IMP project staff in restricting the spacecraft fields to an absolute minimum. We are particularly indebted to those individuals without whose cooperation and contributions the final cleanliness of the spacecraft could not have been achieved. In addition the contributions of additional individuals too numerous to separately mention in the overall IMP spacecraft mission is hereby gratefully acknowledged.

THE MAGNETOHYDRODYNAMIC WAKE OF THE MOON*

NORMAN F. NESS

The possible detection of the lee wake of the magnetohydrodynamic interaction of the solar wind with the Moon as observed by the IMP-1 satellite is discussed. The interplanetary magnetic field was found to fluctuate very rapidly and reach anomalously large values when the satellite was approximately eclipsed by the Moon in December 1963. Later data on the interplanetary field in February 1964 suggest that a detached lunar shock wave analogous to that observed by IMP-1 associated with the Earth may not be a permanent feature of the lunar environment. The approximate length of the wake region behind the Moon is 150 lunar radii at which distance the diameter of the region is about 70 lunar radii. A review of related studies on 29.5 day periodicities of K_p is presented. The solar wind interaction with the geomagnetic field extends the magnetosphere far behind the Earth. Hence, lunar synodic periodicities in K_p may reflect the interaction of the Moon with the Earth's magnetic tail rather than the moon's wake with the Earth.

1.0 INTRODUCTION

Lunar associated terrestrial phenomena have been studied extensively for many years in a wide range of scientific disciplines including geomagnetism (Chapman and Bartels, 1940). The principal geophysical effects which have been observed are due primarily to the direct or indirect influence of the Moon's gravitational field. The rotation of the Earth coupled with the elliptic orbit of the Moon introduces characteristic time modulations and fluctuations of geophysical phenomena with frequencies which can be accurately ascribed to a lunar gravitational influence. The various "tidal" phenomena with semi-diurnal to monthly periods occurring in both the solid and fluid Earth contain important lunar constituents (Melchior, 1957; Doodson, 1958; Siebert, 1960). Recently attention has been directed to a study of the expansion of the solar corona into interplanetary space. This can lead to a somewhat different and more complex lunar as well as solar influence on the immediate terrestrial environment. Fejer (1964) has suggested that at least a portion of the classical "tidal" variations in geomagnetism may be directly related to this phenomenon.

Subsequent to the early suggestion by Biermann (1951) that an adequate explanation of cometary tail structures required a substantial and continuous solar corpuscular flux, Parker (1958, 1960) developed the hydrodynamic theory of the coronal expansion, referring to this plasma flow as the "solar wind." Direct measurements by satellite and space probes since 1959 have confirmed experimentally the existence of a solar plasma flowing approximately radially from the Sun with a positive ion flux between 10^7 to 10^8 particles/cm^2/sec and energies between 200ev to 10 Kev (Gringauz, 1961; Bonetti et al, 1963; Snyder and Neugebauer, 1964; Bridge et al, 1964). A direct consequence of the radial solar wind velocity, the highly ionized coronal gases, and the rotation of the Sun is that the photospheric magnetic fields are extended in the plane of the ecliptic and twisted into the form of an Archimedes spiral (Parker, 1963). Accurate measurements of the interplanetary magnetic field have recently been made on the IMP-1 satellite (Ness et al, 1964) confirming certain of the theoretical predictions on the direction of the field and determining the average magnitude to be close to 5 gammas (Ness and Wilcox, 1964).

The interaction of the solar wind with planetary objects is an important factor in determining

*Published as *Goddard Space Flight Center Document X-612-64-333*, October 1964; also published in *Journal of Geophysical Research*, 70(3):517-534, February 1, 1965.

their space environment. The principal result of the solar wind impacting a planetary magnetic field is to confine the field to a region of space surrounding the planet. The existence of a quasi-static Chapman-Ferraro cavity (reviewed by Chapman (1963)) which excludes the direct penetration of solar plasma into the geomagnetic field has been demonstrated by the recent satellite experiments of Bonetti et al (1963), Heppner et al (1963), Cahill and Amazeen (1963), Freeman et al (1963), Ness et al (1964), Anderson et al (1964), Bridge et al (1964), and Freeman (1964). An important feature of the interplanetary medium, with respect to its interaction with planetary objects, is that it is a magnetized plasma and thus supports magnetohydrodynamic wave propagation. In this sense the plasma flow is super-Alfvénic since the velocity of magnetohydrodynamic wave propagation is less than 90 km/sec while the solar plasma velocity is between 300–900 km/sec. This leads to Alfvén Mach numbers usually greater than 4.

This paper is concerned with an expanded discussion of possible direct experimental evidence of the magnetohydrodynamic interaction of the solar wind with the Moon as obtained by the IMP–1 magnetic field experiment (Ness et al, 1964). During the month of December 1963 the IMP–1 satellite appears to have been located within the downstream wake region of the Moon as it interacts with the solar wind. This interpretation of the data as well as the data itself will be discussed in the following sections.

2.0 MAGNETIC FIELD OF THE MOON

The existence or absence of an intrinsic lunar magnetic field is important in the development of adequate theories to explain planetary magnetism and the origin of the solar system. The presently accepted theory for the origin of the geomagnetic field is based upon a fluid core sustaining a regenerative dynamo system of electrical currents (Elsasser, 1950; Inglis, 1955). The possibility of a lunar magnetic field maintained by such fluid motion has been theoretically investigated by Zharkov and Ulinich (1960) concluding that surface fields of 0.1 to 1.0 gauss are possible. The internal constitution of the Moon is not well known (MacDonald, 1961) but the possibility of a dense fluid core analogous to the Earth's seems highly unlikely. Another possibility is that sometime in the ancient past the Moon cooled down through its Curie point while in the presence of an external magnetic field thus acquiring thermoremanent magnetization. This latter suggestion requires that the Moon was at one time nearly entirely molten whether it accreted from a large number of smaller masses or was formed from one large mass. At the present time this hypothesis cannot be conclusively argued (Levin (1960), MacDonald (1963)).

The only direct evidence of the state of a lunar magnetic field has been provided by the Soviet space probe Lunik II (Dolginov et al, 1961). Measurements with a sensitivity of about 30 gammas were performed along an impact trajectory to within a distance of 55 km from the lunar surface. No lunar magnetic field larger than the noise level was detected. The conclusion reached by these authors on the basis of a simple dipole model of the lunar magnetic field was that the effective lunar magnetic moment must be less than 10^{-4} that of the Earth's. As pointed out by Vestine (1957) and Neugebauer (1960) however, the solar wind is sufficiently strong to confine the magnetic field of the Moon to a region very close to or even below its surface. In the latter case the solar wind directly impacts the lunar surface. On the assumption that

(1) the Moon possesses a dipolar magnetic field with equatorial field strength $= B_0$,
(2) the dipole axis is perpendicular to the solar wind velocity and
(3) the solar plasma flows on around to the back side of the Moon rather than to be specularly reflected

then the radius of the lunar magnetic cavity boundary at the subsolar or stagnation point is given by:

$$R_c = R_m \left[\frac{B_0^2}{2\pi m n V_s^2} \right]^{1/6} \qquad (2.1)$$

where V_s = velocity of solar wind (km/sec)
n = proton density (p/cm^3)
m = proton mass (gms)

This is illustrated in Figure 1 and clearly shows that for the observed values of the solar wind any such lunar magnetic field will be compressed rather close to the surface of the Moon.

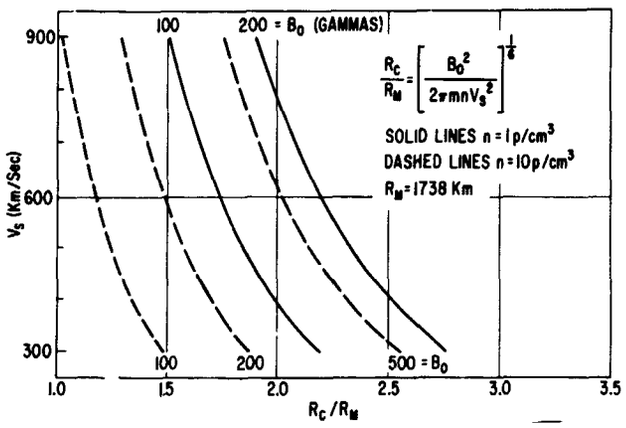

FIGURE 1.—Lunar magnetic cavity radius or curvature (R_c) in units of lunar radius (R_m) as a function of the solar wind flux and equatorial field stenrgth (B_0) of assumed lunar dipole.

Gold (1964) has suggested an origin of a lunar field which incorporates the interaction of the magnetized solar plasma with the lunar body. The finite electrical conductivity of the Moon provides a mechanism for the trapping of the interplanetary magnetic field. The model proposed has not been quantitatively developed. It depends critically upon the magnetic Reynolds number of the Moon, requiring that the interplanetary field be obstructed in its motion through the lunar body so that lines of force are accumulated and compressed on the sunlight hemisphere. This must occur for a time interval sufficiently long that a quasi-static field configuration can develop in spite of the rotation of the Moon and the observed variability of the direction of the interplanetary magnetic field.

3.0 LUNAR SHOCK WAVE

The presence or absence of a lunar magnetic field is important in determining the detailed characteristics of the solar wind interaction with the Moon. Far downstream it is not as clear how important any lunar field may be in determining the characteristics of the resultant interactions in the solar wind as it resumes a free stream flow. The overall situation may well resemble more closely the interaction of the solar wind with comets (Marochnik, 1963) rather than its interaction with the geomagnetic field. For the present study, the most pertinent feature of the solar wind interaction is the distance behind the Moon to which observable effects of such magnetohydrodynamic phenomena would persist. Various authors (Beard, 1960; Johnson, 1960; Piddington, 1960; Harrison, 1963; Lees, 1964; Axford et al, 1964 and Dessler, 1964) have presented qualitative arguments on the length of the geomagnetic "tail" behind the Earth. This region of the magnetosphere has yet to be experimentally probed and existing theoretical treatments are limited in their scope. The best efforts thus far have utilized the analogy with supersonic gas dynamics representing the solar wind as a viscous fluid and translating the particle characteristics of the plasma to a continuum property of the fluid.

The suggestion that a detached collisionless magnetohydrodynamic shock wave encloses the Earth's magnetosphere has been presented by Axford (1962) and Kellogg (1962) among others. Spreiter and Jones (1963) have applied classical supersonic flow theory to determine the location and geometry of the shock wave surface. The agreement between theory and observation is very good, requiring only a minor modification in the choice of equivalent specific heat ratio used in the fluid dynamic analogy to yield improved comparisons with the observations. The most critical point in these studies being the ratio at the stagnation point of the shock wave radius to the geomagnetic cavity radius. The success of this similitude argument has been verified experimentally only near the stagnation point of the solar wind interaction with the Earth's magnetic field. However this suggests its consideration for conditions far from the stagnation point, i.e., the tail region of the solar wind interaction with the geomagnetic field. This has been done by Lees (1964) who showed that a secondary shock or tail shock would develop in the wake of the plasma flow around the earth. Data obtained by the IMP–1 satellite which have yet to be analyzed will partially answer these important questions about the magnetic field topology within the geomagnetic tail.

In the absence of more definite knowledge about a lunar magnetic field the argument for a lunar shock wave is not on as firm a basis as in the case of the Earth. In the relatively weak interplanetary magnetic field the radius of gyration of a solar wind proton is comparable to the lunar radius. Table 1 presents representative values for the proton Larmor radius as a function of

TABLE 1.—*Proton Larmor radius (in Kilometers) as function of particle Energy (or velocity) and magnetic field strength (gammas).*

Magnetic Field Strength (γ)		10	5	2
Proton Energy	Velocity			
4 Kev	876 Km/sec	914	1828	4572
2 Kev	619 Km/sec	646	1292	3232
1 Kev	438 Km/sec	457	914	2286
500 ev	310 Km/sec	323	646	1616
250 ev	219 Km/sec	229	457	1143

field strength and plasma energy (or velocity).

The Larmor radius is equal to or greater than the stand off distance of 550 km. of the shock wave at the stagnation point that is obtained using the value of $R_s/R_c=1.31$ as measured in the case of the Earth (Ness et al, 1964). For the case of a sphere Kellogg (1962) using Hida's (1953) analysis of a shock surrounding a spherical object determined the stand off ratio to be approximately 1.25 for Mach values greater than 4. It may well be that in the case of the moon a collisionless shock wave analogous to the Earth's may not develop at all times, if indeed at all. Whether or not such a shock develops depends very critically upon the physical parameters in the interplanetary medium and the state of the lunar magnetic field. This point has also been discussed by Gold (1964) with regard to the direct penetration of the solar plasma into the lunar body.

The detailed characteristic of the lunar surface and atmosphere are strongly dependent upon whether or not the surface is shielded from direct impact of the solar wind by either a lunar field or a shock wave. Studies on these and related lunar surface characteristics have been performed by Bernstein et al (1963), Wehner et al (1963), Hapke (1964), Hinton and Taeusch (1964) and Kopal and Rackham (1964).

4.0 OBSERVATIONS OF A LUNAR MAGNETOHYDRODYNAMIC WAKE

The IMP–1 magnetic field experiment has been described in an earlier publication (Ness et al, 1964) which should be consulted for a detailed description of the satellite, its orbit, the instrumentation and telemetry system and the general characteristics of the interplanetary magnetic field. In addition the interaction of the solar wind with the geomagnetic field is discussed. In the following presentation the positions of the satellite, earth and moon are initially presented in the solar ecliptic coordinate system defined as: X_{se} is the axis from the Earth to the Sun, Z_{se} is the axis normal to the ecliptic plane and in the same sense as the Earth's angular momentum and Y_{se} which forms a right handed coordinate system. All distances are given in units of an Earth radius ($R_e=6378.4$ Km) although in the final interpretation of the data a translation will be made to a lunar associated coordinate system using a scale in Moon radii ($R_m=1738$ Km).

The positions of the Moon and IMP–1 during December 1963 are shown in Figure 2 as projected

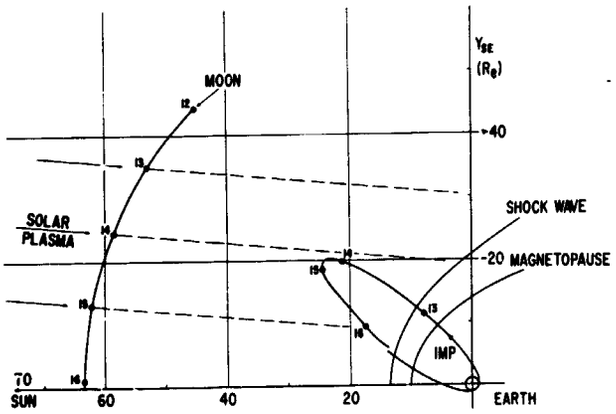

FIGURE 2.—Relative positions of IMP–1 satellite, earth and moon projected on ecliptic plane during period December 12–16, 1963, when the wake of the moon was detected in interplanetary space.

on the plane of the ecliptic. The solar wind direction has been adjusted to appear to come from 5° west of the Sun in order to represent the aberration effect due to the heliocentric motion of the Earth. The orbital velocity of the Earth is 30 Km/sec and for a solar wind velocity of approximately 330 Km/sec the angular displacement is 5°. Ness and Wilcox (1964) have determined from a correlation of the solar photospheric magnetic field and the interplanetary field as measured on IMP–1 that the average solar wind velocity was approximately 385 Km/sec during the time interval November 27, 1963 to February 19, 1964.

Thus the correction for a 5° aberration is slightly larger than would be justified on the basis of experimental data. The projected traces of the average position of the magnetopause and shock wave boundaries are also included in the figure in order to show when the satellite was outside of these boundaries and within the relatively undisturbed interplanetary medium. It is seen that on December 14 the satellite was close to apogee and approximately in line with the Moon with respect to the propagation of the solar wind. This is a measure only in the XY plane however, and does not include the distance of the satellite either above or below the Sun-Moon line.

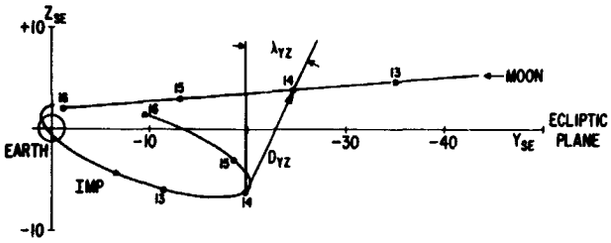

FIGURE 3.—Relative positions of IMP–1 satellite, earth and moon projected on solar ecliptic Y-Z plane during period December 12–16, 1963, when the wake of the moon was detected in interplanetary space.

In Figure 3 the positions of the satellite and the Moon during the same time interval are shown projected onto the plane perpendicular to the X_{se} axis. The satellite was several Earth radii below the Moon during the entire period of interest, December 14–15. The location of the satellite with respect to the Moon as a function of time is summarized in Figure 4. The two angles λ_{xy} and λ_{yz} are introduced as a measure of the apparent angular displacement of the Moon with respect to the satellite as projected onto the XY and YZ planes respectively. The quantity D_{yz} measures the projected distance in the YZ plane, D_{sm} measures the distance from the satellite to the Moon and $D_y'_z$ measures the distance projected onto a YZ plane which has been rotated by 5° West so as to be perpendicular to the aberrated solar wind. These parameters show that on December 14 at approximately 0915 the satellite was close to being immediately behind the Moon. At this time the satellite was 37.8 R_e from the Moon and 8.7 R_e below the Sun-Moon line. The aberration of the solar wind by 5° leads

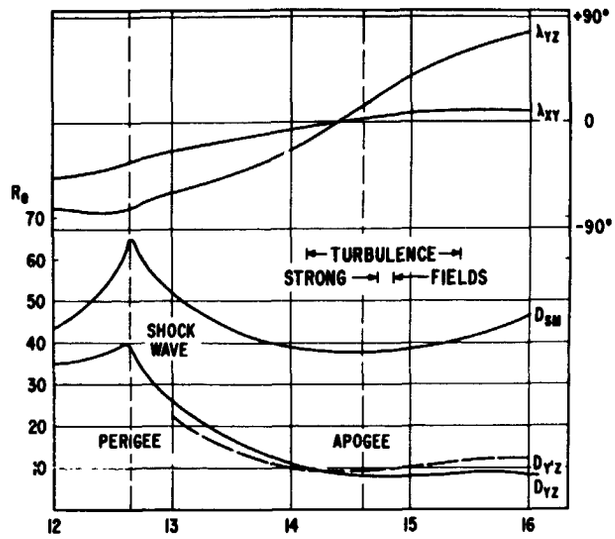

FIGURE 4.—Variation of relevant earth, moon and IMP–1 satellite position parameters during period December 12–16, 1963. The wake of the moon was detected between 0130 December 14 to 0900 December 15. The time intervals of turbulence and of unusually strong fields are indicated.

to a change in the alignment of the satellite with regard to the Moon and solar wind as shown by the dashed curve in Figure 4. The time at which the satellite is closest to being aligned with the Moon-Sun direction occurs several hours in advance of the non-aberrated case although the distance is approximately the same. On the basis of these data the most probable time for the observation of solar wind interactions with the lunar body would be centered around 0900 December 14, on the assumption that the lunar wake extended in the general flow direction behind the Moon.

The 5.46 minute averages of the magnetic field obtained by this experiment for the time interval 1600 December 13 to 1600 December 15 are shown in Figures 5 and 6. The format for the presentation is identical to that used by Ness et al (1964). The two angles θ and ϕ measured the latitude and longitude respectively of the magnetic field vector in the solar ecliptic coordinate system. In figure 5 the first 9 hours of data show the characteristic behavior of the interplanetary magnetic field with a stable orientation and magnitude. At this time the magnetic field was directed approximately in the plane of the ecliptic ($\theta = 0 \pm 30°$) and pointed back toward the Sun

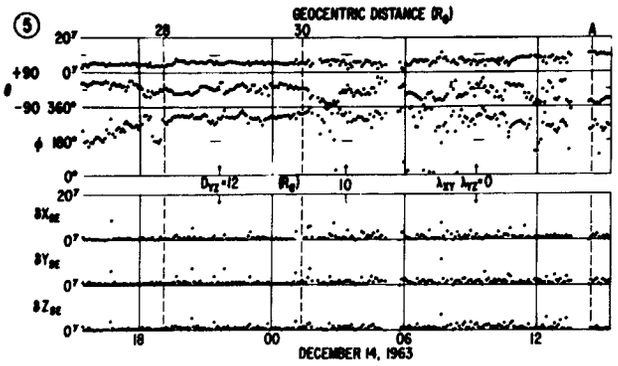

FIGURE 5.—Magnetic field data from orbit No. 5 December 14, 1963, illustrating IMP–1 entry into lunar magnetohydrodynamic wake from relatively undisturbed interplanetary space at 0130.

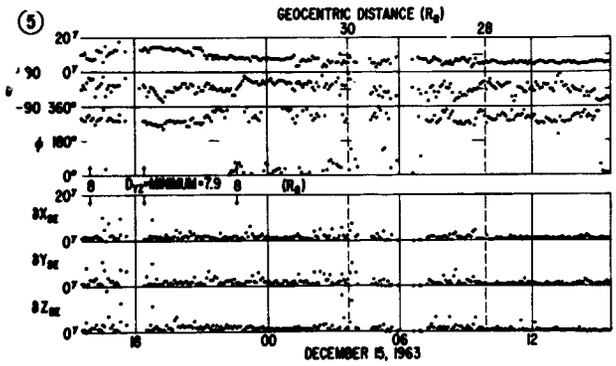

FIGURE 6.—Magnetic field data from orbit No. 5 December 15, 1963, illustrating IMP–1 exit from lunar magnetohydrodynamic wake into relatively undisturbed interplanetary space at 0900 with large field magnitudes observed between 1800 to 2100 December 14.

along the Archimedian spiral angle predicted for the interplanetary field ($\phi = 315° \pm 20°$). During this time the satellite is close to apogee (geocentric distance = 31.7 R_e), and far removed from any direct effects of the solar wind interaction with the Earth. As time progresses the field becomes variable in both magnitude and direction. The onset of this turbulence occurs at approximately 0130 December 14, and persists until 0900 December 15. Midway in this time interval the field magnitude reaches the anomalously large value of about 15 gammas for more than 3 hours, from 1800–2100 December 14, while the turbulent characteristics of the field as measured by the angle ϕ noticeably decreases. Following 0900 December 15 the magnetic field again resumes its characteristic stable configuration although it is not as stable as it was prior to these events.

Superimposed on the time plots are specific values of parameters related to the position of the satellite with respect to the Moon. It should be noted that when the satellite is closest to being in line ($\lambda_{xy} = 0$) the distance D_{yz} is not necessarily at a minimum. Indeed the minimum value of D_{yz} occurs at 1830 December 14 and is approximately the same time as the midpoint of the time interval during which the turbulent magnetic field observations were made. The closest aberrated distance, $D_{y'z} = 9.3\ R_e$, occurs at 0840. The characteristics of the magnetic field during this time interval are unlike those during other occasions on which the satellite was in the interplanetary medium. The turbulence and large field values, as well as the orientation during the time of large field magnitudes suggest that the IMP–1 satellite passed through the turbulent lee wake of the Moon in the solar wind. The strong fields observed correspond to the magnetosphere of the Moon and the turbulent fields to the transition region between the lunar magnetosphere and the undisturbed interplanetary medium.

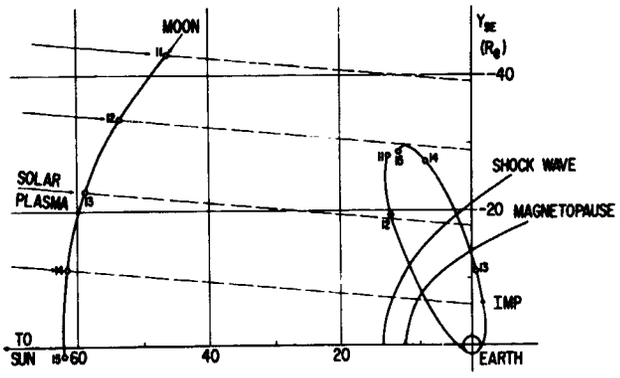

FIGURE 7.—Relative positions of IMP–1 satellite, earth and moon projected on ecliptic plane during period January 11–15, 1964.

In Figure 7 the positions of IMP–1 and the Moon during January 1964 are shown as projected onto the ecliptic plane. This presentation is identical to that for December as shown in Figure 2. Here, however, the relative positions of the satellite and the Moon are seen to be quite different. The time at which IMP–1 is roughly aligned with the Moon occurs at 0730 January 13 but at this time the satellite is enclosed within the Earth's shock wave. Figure 8 presents the relative positions of IMP–1 and the Moon as projected onto

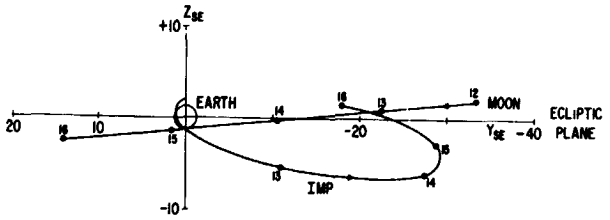

FIGURE 8.—Relative positions of IMP–1 satellite, earth and moon projected on solar ecliptic *Y-Z* plane during period January 12–16, 1964.

the *YZ* plane. The satellite is about in the same position relative to the plane of the ecliptic as in December but the Moon is considerably lower. A summary of the relevant position parameters related to the relative positions of IMP–1 and the Moon is given in Figure 9. The format is identical to that of Figure 4 and illustrates that during the 13th orbit when the satellite was in the lee of the Moon it was also within the region of space surrounding the Earth enclosed by the shock wave surface. The time at which the Earth's shock wave was traversed by the satellite is indicated by the solid vertical line. It occurred several hours after the satellite was aligned with the Moon and the Sun. The situation with respect to the aberrated solar wind direction does not favor the observation of a lunar wake since the satellite is seen to spend a longer time within the region of space associated with the solar wind interaction with the geomagnetic field. Thus the

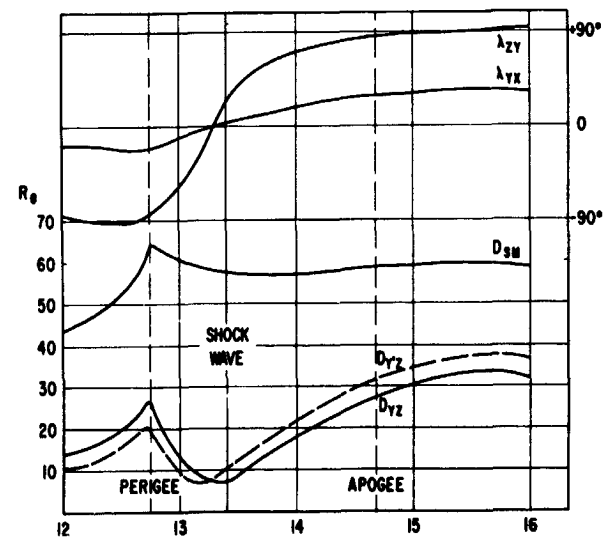

FIGURE 9.—Variation of relevant earth, moon and IMP–1 satellite position parameters during period January 12–16, 1964.

satellite motion in the month of January 1964, was such as to preclude being in a favorable position with respect to observation of the lunar wake. In spite of this the interplanetary magnetic field data for January 13 and 14 has been inspected in detail since the December observation extended over a time period of more than one day. It has not disclosed any characteristics which are suggestive of a lunar wake, either in turbulence or field magnitude.

The last opportunity for observation of the lunar wake with IMP–1 occurred in February 1964 during orbit. 20. On the succeeding opportunities for wake observations during the next six months, the IMP–1 satellite was enclosed completely within the interaction region of the solar wind with the geomagnetic field. The steady precessional motion of the IMP–1 orbit in the solar ecliptic coordinate system is evident by comparing Figure 10 for February 1964 with that of Figure 2 for December 1963. The relative positions

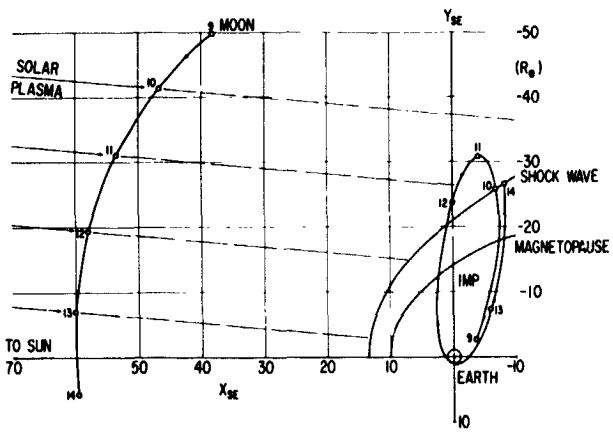

FIGURE 10.—Relative positions of IMP–1 satellite, earth and moon projected on ecliptic plane during period February 9–14, 1964, when a weak wake of the moon was possibly observed.

of IMP–1 and the Moon in February are such that they are approximately aligned at 0020 February 11. The position of these two objects in February projected onto the *YZ* plane is shown in Figure 11. Both the elongation of the IMP–1 orbit relative to Figures 3 and 8 and the location of the Moon below the ecliptic plane are a result of the heliocentric motion of the Earth about the Sun. It can be seen from this figure, however, that the two objects are very close to being in

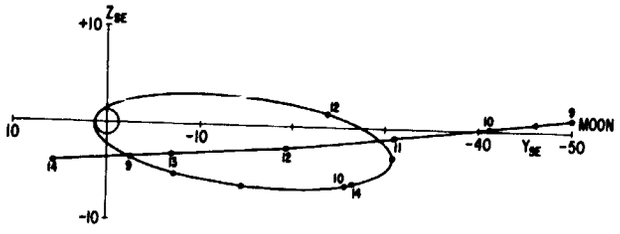

FIGURE 11.—Relative positions of IMP-1 satellite, earth and moon projected on solar ecliptic *Y-Z* plane during period February 9–14, 1964, when a weak wake of the moon was possibly observed.

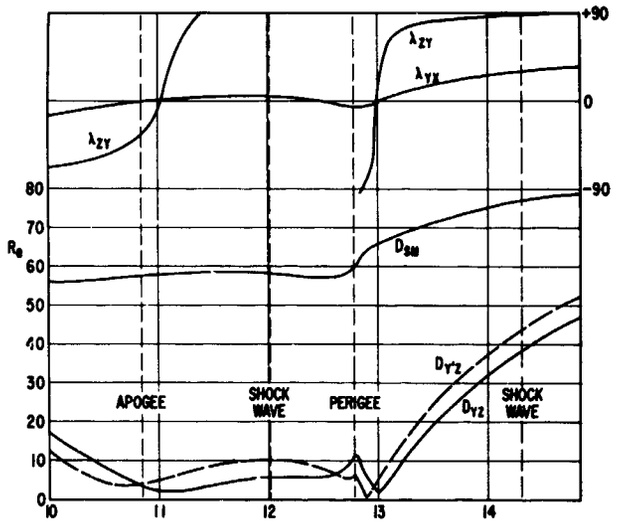

FIGURE 12.—Variation of relevant earth, moon and IMP-1 satellite position parameters during period February 10–15 when a weak wake of the moon was possibly observed between 0400 to 1200 February 10.

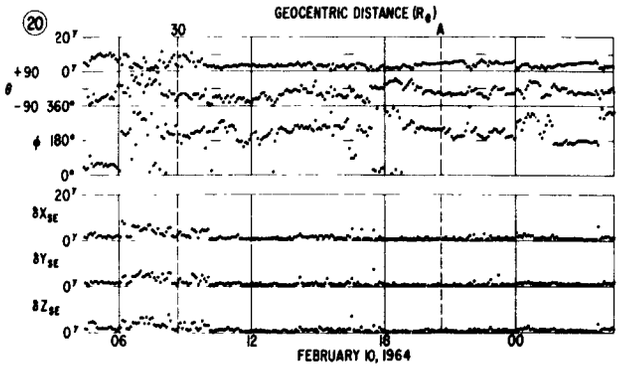

FIGURE 13.—Magnetic field data from orbit No. 20, February 10, 1964, illustrating IMP-1 sampling of the interplanetary magnetic field and possible lunar magnetohydrodynamic wake after exit from transition region of the solar wind interaction with the geomagnetic field. The Earth's shock wave was traversed at a geocentric distance of 30.3 R_e.

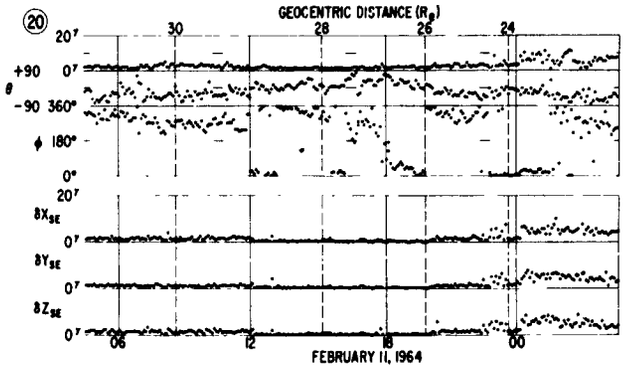

FIGURE 14.—Magnetic field data from orbit No. 20, February 11, 1964, illustrating IMP-1 sampling of the interplanetary magnetic field and possible lunar magnetohydrodynamic wake before entry into transition region of solar wind interaction with geomagnetic field. The earth's shock was traversed at a geocentric distance of 23.6 R_e with a possible "precursor" detected at 24.2 R_e.

precise alignment. Figure 12 summarizes the relative positions of IMP-1 and the Moon as a function of time in a format identical to that used for Figures 4 and 9. The distance from the satellite to the Moon is seen to have increased now to 57.9 R_e while the minimum value for the distance in the *YZ* plane is 1.7 R_e. For the aberrated solar wind the closest distance $D_{y'z}$ of 3.7 R_e occurs at 1640 February 10.

The magnetic field data for the time interval 0430 February 10 to 0430 February 12 is shown in Figure 13 and 14. The data in Figure 13 illustrates the outbound traversal of the shock wave associated with the Earth's magnetosphere at a distance of 30.3 R_e at 0958 February 10. The characteristic of large turbulent fields in the transition region is clearly evidenced. Also shown and to be discussed in a future separate publication on the magnetic field characteristics in the transition region is the compressed and reasonably well aligned magnetic field such as were first observed by Explorer X (Heppner et al, 1963). The abruptness of the shock boundary, as shown by the variance plot, is a persistent feature of the shock phenomena in which the thickness is small and comparable with the ion gyro-radius. Subsequent to the outbound shock wave traversal the magnetic field in interplanetary space is somewhat variable in direction as measured by θ and ϕ but is not turbulent in the same sense as in the transition region as measured by the variance characteristics. However, during the time interval 0400 to 1200 February 11 there is a small

increase above the noise level in the turbulence as measured by the variance. At the same time the variability between successive values of θ and ϕ is increased. However, during the time interval while the variance is higher than the noise level, the field is at its lowest value, less than 3 gammas, during this sample of the interplanetary medium on orbit No. 20.

Figure 14 contains the remainder of the interplanetary magnetic field data observed on orbit 20 and also illustrates the inbound traversal of the Earth's shock wave by the IMP–1 satellite. Again the characteristics of the transition region on the inbound pass are quite similar to those observed on the outbound traversal although they occur at a different geocentric distance, 23.6 R_e, with a suggestion of a "precursor" at 24.3 R_e. The nonspherical symmetry of the shock wave surface enclosing the Earth coupled with the fact that the satellite traverses these boundaries at considerably different satellite-earth-sun angles on successive transits leads to these differences. Throughout the time interval during which the interplanetary medium was sampled, features similar to the December 1963 observation can not be seen. At this time it is suggested that the February 1964 data show characteristics which are similar in some respects but are not as conclusive an evidence of a lunar wake as observed in December 1963.

5.0 FLUID DYNAMIC CONSIDERATIONS

The classical magnetohydrodynamic problem of the interaction of a spherical object with a conducting fluid in the presence of a magnetic field has been treated by Stewartson (1956), Imai (1960) and Ludford and Murray (1960) among others. For the case of either compressible or incompressible fluid flow a downstream wake always develops for large or small magnetic Reynolds numbers as long as the magnetic field strength is small (Sears (1960)). This is measured by the ratio of free stream velocity (V_s) to the pure Alfvén velocity (V_a) or the geometric mean (V_a^*) of the Alfvén and sound velocities. This ratio, Vs/Va or Vs/V_a^*, must be greater than unity in order that a lee wake develop and effectively determines whether or not the presence of the body in the flow field can be communicated upstream by magnetohydrodynamic wave propagation. A major limitation in the quantitative use of the presently available analytical treatments is that they employ restrictive assumptions which are not justified in the case of the interaction of the solar wind with the Moon. In general these include one or all of the following: infinitely conducting fluid, magnetic fields aligned with the flow velocity, nonconducting or infinitely conducting body, and collision mean free paths much smaller than other lengths characteristic of the flow. The case of the Moon in the solar wind satisfies few of these assumptions and thus direct comparisons are not possible. Further development of analytical studies on collisionless magnetohydrodynamic shocks (see review by Kantrowitz and Petschek (1964)) is required for application to the present problem.

In the case of the interaction of the solar wind with the geomagnetic field rather successful results, at least near the stagnation point, have been obtained through use of a pure fluid dynamic analogy. A general review of the use of the aerodynamic similitude and its application to the solar wind interaction with the Earth's magnetic field has been given by Levy et al (1964) and Lees (1964). On this basis an important aspect of the interpretation of the magnetic field data on IMP–1 is that the free stream Mach number can provide a measure of the angular width of the shock surface associated with the interaction. (Michel (1964) has treated this problem assuming complete magnetohydrodynamic flow of the solar wind.)

However, the detailed characteristics within the interaction region and more importantly the wake region may not be completely specified. The Mach number in the case of the solar wind is measured by the ratio of the plasma bulk velocity (V_s) to the magnetohydrodynamic wave phase velocity (V_a). In the interplanetary medium the velocity V_a is approximately given by the Alfvén velocity so that the Mach number is given by

$$M_a = \frac{V_s}{V_a} = \frac{V_s\sqrt{4\pi mn}}{B} \qquad (5.1)$$

where B is the strength of the interplanetary field.

A plot of the Alfvén velocity as a function of the plasma density and magnetic field strength is shown in Figure 15. From classical supersonic

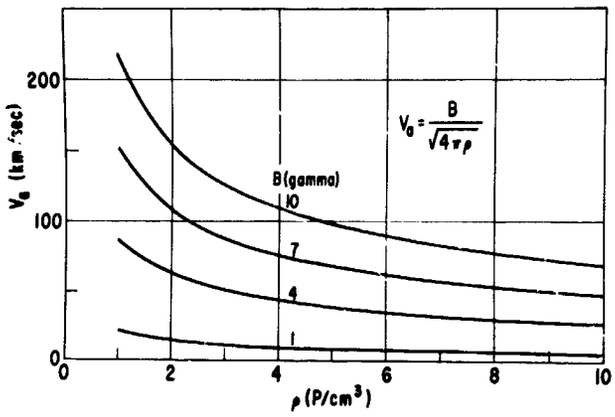

FIGURE 15.—The Alfvén velocity as a function of the interplanetary magnetic field strength and solar plasma flux parameters. The average magnetic field in interplanetary space was 5 gammas with limits of 1 to 10γ.

flow (Hayes and Probstein (1959)) the Mach angle β associated with a specific Mach number is given by

$$\beta = \sin^{-1}\left(\frac{1}{M_a}\right) \tag{5.2}$$

and represents the asymptotic direction of the shock surfaces far downstream from the obstruction. The Mach angle is plotted in Figure 16 as a function of the Mach number.

The average magnetic field in the interplanetary medium has been determined by the IMP–1 measurements to be 5.0 gammas. The average solar wind velocity has been estimated to be approximately 385 Km. Using these average values for the magnetic field and solar wind velocity and

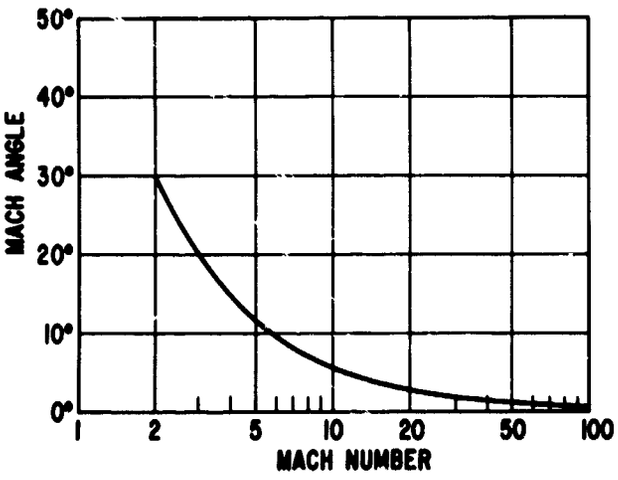

FIGURE 16.—Mach angle as function of the corresponding Alfvén mach number.

assuming a plasma density between 1.5 to 35 p/cm^3 yields a Mach number between 4 and 20. For these two values of Mach number the limits on the Mach angle are 14.5° and 2.8° respectively.

Obayashi (1964), in a review of previous satellite measurements related to the solar wind interaction, has adapted classical hydrodynamic equations for approximating the geometry of the shock surface surrounding a spherical object. Defining:

R_s = the radial distance to the shock from the center of the sphere at the stagnation point

R = the radial distance to the shock surface

ϕ = the angle between R and R_s, then he deduces that:

$$R = R_s\left[\frac{1+\sec\beta}{1+\sec\beta\cos\phi}\right] \tag{5.3}$$

A translation of the position of the IMP–1 satellite to a lunar set of coordinates has been made for the pertinent time periods in December 1963 and February 1964. The position of the satellite in these lunar associated coordinates is

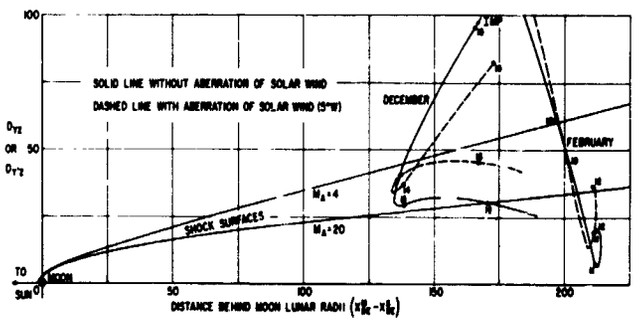

FIGURE 17.—Relative position of IMP–1 satellite and moon in lunar associated corrdinates illustrating envelopment within lunar shock wave assuming aerodynamic similitude during December 1963 and February 1964.

shown in Figure 17 with the abscissa being given by D_{xy} or D_{xy}' where

$$D_{xy} = \sqrt{(D_{sm})^2 - (D_{ys})^2}$$
$$D_{xy}' = \sqrt{(D_{sm})^2 - (D_{y's})^2} \tag{5.4}$$

and the ordinate by D_{yz} or $D_{y'z}$. This presentation essentially assumes that far down stream from the Moon the lunar wake region is cylindrically symmetrical about the solar wind flow direction. Superimposed on these trajectory positions

are the two shock surfaces corresponding to Mach numbers 4 and 20. These surfaces assume that the lunar magnetic field strength is inherently less than a few hundred gammas and that the shock stand off ratio $R_s/R_m=1.25$. It is seen that if the flow is such that the Mach number is less than about 10 then the position of the satellite in December 1963 is well within the shock region of the lunar wake. If the Mach number of the flow is less than about 40 then the satellite is within the shock for February 1964.

The detection of a lunar wake is definitely consistent with supersonic flow theory for the orbit No. 5 observation and with the orbit 20 observation. However, even though the wake was possibly observed in December 1963, the interaction of the solar wind with the Moon is probably so variable that appropriate interplanetary conditions in the vicinity of the Moon are required in order to initiate the formation of a collisionless magnetohydrodynamic shock. Indeed using the average velocity of 385 km/sec and the average field strength of 5 gammas leads to a proton Larmor radius of 830 Km. This implies that on average the shock wave radius assumed for the Moon, 2175 Km, is only 2.6 times this critical value. The stand off distance is about 340 Km so that as previously noted it is somewhat questionable whether a lunar shock can develop that is similar to the case of the Earth. In the case of the Earth the values of the parameters are such that the radius of the shock surface at the stagnation point is more than 100 times the proton Larmor radius. If one considers the field internal to the magnetosphere the radius of the magnetosphere is some 500 times the proton gyro radius since the magnetic field is 50 gammas or greater at the magnetopause boundary.

6.0 *Kp* AND RELATED STUDIES

During the three month interval, December 1963 to February 1964, solar conditions were reasonably undisturbed. A geomagnetic storm observed on December 2, 1963, at 2117 UT was also measured in interplanetary space by the magnetic field experiment (Ness et al, 1964). During the remainder of the interval however, terrestrial magnetic activity as measured by the planetary index K_p was generally low. Because the solar-terrestrial conditions were relatively quiescent those disturbances which were observed and identified as the lunar wake have not been associated with any solar origin that might cause these variable properties of the interplanetary medium.

Recent studies (Bell and Defouw, 1964; Davidson and Martyn, 1964; Michel et al, 1964; Stolov and Cameron, 1964) on K_p have been directed to a resolution of the important question raised by the work of Bigg (1963a, b; 1964) on lunar influences on geomagnetic activity with a synodic period of 29.53 days. The original work was based on the physical supposition that any lunar magnetic field would shield the Earth from propagation of solar particles and thereby affect the level of terrestrial magnetic activity. The specific result of this paper is that a turbulent lunar wake associated with a magnetohydrodynamic interaction of the solar wind with the Moon does exist. If such turbulence in the magnetic field implies equivalent turbulence in the interplanetary plasma it suggests further that fluctuations of magnetic activity could possibly be enhanced at about the time of new Moon.

The statistical significance of the early work has come under severe criticism, although the use of K_p as a quantity obeying the normal laws of algebra is inherently presumed by all participants in these discussions. In spite of this, separate but very similar correlative studies by two groups using identical data have been interpreted quite differently. Stolov and Cameron (1964) have concluded that a lunar effect exists but with the interesting result that the phase corresponds to a full Moon disturbance. Michel et al (1964) on the contrary state that their results are not statistically significant. Bell and Defouw (1964) using a superposed epoch method however concluded a lunar effect at full moon does exist statistically.

Davidson and Martyn (1964) using a superposed epoch and harmonic dial analyses on A_p conclude that no statistically significant effect exists. These authors conducted "a simple statistical experiment" to illustrate their case. A major problem in the analysis of a dimensionless index such as K_p or A_p is whether or not the statistical signifiance tests are based on valid statistical properties of the variable being investigated. In the case of these indices it is by no means clear that definitive answers can be obtained. Davidson

and Martyn (1964) also state that smoothing the data such as done by Bigg can introduce spurious periodicities. This is not true for the weighting function used by Bigg (running average by three's) and is in general not true for most classical numerical filtering procedures. The general situation with regard to statistical studies on K_p or A_p is definitely not yet resolved concerning lunar periodicities. Finally a very recent study by Dodson and Hedeman (1964) indicated an anomalous periodicity of 29.5 days in solar cosmic ray data. This latest result is certain to contribute to our apparent lack of understanding of possible lunar related phenomena.

If the geomagnetic tail extends far behind the Earth to the distance of or beyond the Moon, that is at least 60 R_e, then the Moon will interact with the tail and this may lead to temporal variations in the characteristics of the magnetospheric fields and particle populations independent of solar activity. Indeed such an extended magnetospheric tail has recently been proposed by Dessler (1964). A more pertinent discussion with respect to the magnetic field topology interior to the tail has been given by Axford et al (1964). Detailed studies on the IMP-1 data obtained while in the geomagnetic tail region are presently being conducted to determine the possible lunar effects during March, April and May of 1964, as well as the detailed topological characteristics of the field. On the basis of these IMP-1 results and others obtained on the Explorer X satellite (Heppner et al (1963) and Explorer XIV (Cahill (1964) it appears certain that the geomagnetic field and its tail extend far away from the Earth in an anti-solar direction. Thus, interaction of the Moon with the Earth's magnetic tail can be reasonably anticipated. The studies of Stolov and Cameron (1964) and Bell and Defouw (1964) lend support to such a conclusion.

Howard et al (1964) have suggested that variations in the electron density in the cislunar medium during a solar eclipse are related to a shadowing effect in the lee of the Moon as it interacts with the solar wind. Although the maximum change in solar wind density required to explain the observations is rather high, 100 p/cm^3, there is considerable difficulty in accurately removing changes caused by the ionsphere and magnetosphere. This propagation experiment on lunar associated changes in the cislunar medium may indicate a separate technique for the investigation of the magnetohydrodynamic wake of the moon during the time of new moon.

SUMMARY AND CONCLUSIONS

During the period in which the IMP-1 satellite was located in interplanetary space beyond the direct effects of the solar wind, interaction with the geomagnetic field a unique disturbance was observed. This was characteristic of the transition region and magnetosphere tail associated with the solar wind interaction with the geomagnetic field. This temporal disturbance showed turbulent magnetic fields and enhanced magnetic flux values well above the normal interplanetary condition. This event is identified as the magnetohydrodynamic wake of the Moon's interaction with the solar wind. The use of an aerodynamic analogy, which has proven so successful in studying the Earth's interaction with the solar wind, shows that the satellite was within the primary shock region associated with a super Alfvénic solar wind flow. A second opportunity to investigate the lunar wake in January 1964 was obscured by the location of the satellite within the shock region of the solar wind interaction with the geomagnetic field. A third opportunity in February 1964, possibly detected a wake but it did not demonstrate the same characteristic features. At this time the satellite was some 200 lunar radii from the Moon.

The great distance at which the lunar wake is observed and the lack of quantitative descriptions regarding the Earth's magnetic tail preclude an estimate of the strength of any lunar magnetic field. However, the fact that a lunar wake was observed during December 1963 is suggestive of a lunar magnetic field at the equatorial surface of several hundred gammas or more.

A major question raised by this paper is whether or not a shock wave due to the moon is expected to develop at all times in the interplanetary medium unless an intrinsic lunar magnetic field is present. It would appear that the absence of a strong field, and the small size of the Moon preclude a condition analogous to that in the case of the Earth in which a shock wave is usually expected to occur. The Larmor radius of the average solar wind proton is of the same order of

magnitude as the lunar radius and thus the analogy with fluid dynamics is probably not justified.

The Russian measurements on the Lunik II spacecraft impacting the lunar surface indicate that the magnetic field of the Moon is not sufficiently strong to produce field strengths larger than 100 gammas at a distance of 55 Km. This can be understood on the basis of a compression of a lunar magnetic field by the solar wind. However, at the same time that this data was obtained scintillation counter data (Vernon et al, 1960) obtained at a distance of less than 1000 Km from the lunar surface indicated energetic particle flux values 100 times those found typically in interplanetary space. This value of 1000 Km is tantalizingly close to the lunar shock wave stand off distance. Indeed the magnetic field data for distances less than 1000 Km are also larger and more variable also. This may indicate that shock region characteristics similar to that observed surrounding the Earth may have been present surrounding the Moon at that time.

The fact that the Earth's magnetospheric tail does extend far behind the Earth may well lead to lunar associated variations of K_p or A_p at full moon as the Moon sweeps through the Earth's tail.

ACKNOWLEDGEMENTS

I am indebted to C. S. Scearce and J. B. Seek for their important participation in the IMP–1 magnetic field experiment. Stimulating discussions of the lunar wake with Drs. E. K. Bigg, A. G. W. Cameron and T. Obayashi are hereby acknowledged. The comments of Dr. J. M. Wilcox are particularly appreciated.

THE MAGNETOSPHERE AND ITS BOUNDARY LAYER*

NORMAN F. NESS

The sun is an ubiquitous source of the Earth's energy input. More than 30 years ago in an attempt to explain the characteristic storm-time fluctuations of the geomagnetic field, a solar origin was postulated by Chapman and Ferraro (1933). It was suggested that the sun, at times of solar disturbances such as flares, emitted a neutral but ionized gas referred to as a plasma. When this plasma reached the earth it compressed the earth's magnetic field and contained it in a region of space surrounding the earth. The cavity in the solar plasma thus formed has been termed Chapman-Ferraro cavity and the mechanism of its formation has been reasonably successful in explaining the temporal characteristics of various geomagnetic sudden commencement and other storm phenomenon. A naive representation of the interaction of the solar plasma with the earth's magnetic field is shown in Figure 1. Here the individual particles are assumed to be specularly reflected at the boundary of the earth's magnetic field. The region within the boundary the geomagnetic cavity has been referred to as the *magnetosphere* since the dominant factor influencing charged particle motion within this region of space is the earth's magnetic field. In the remainder of this paper the terminology will utilize magnetosphere rather than the Chapman-Ferraro cavity.

In an attempt to explain the fluctuations and characteristics of type I cometary tails, Biermann (1951) early in the 1950's suggested that a continual flux of solar plasma was required. This was similar to that postulated by Chapman and Ferraro (1933) in their theoretical studies. Subsequent to this, Parker (1958) developed his hydrodynamic theory of the expansion of the solar corona referring to the phenomena as the "solar wind." This was predicted to consist of ionized

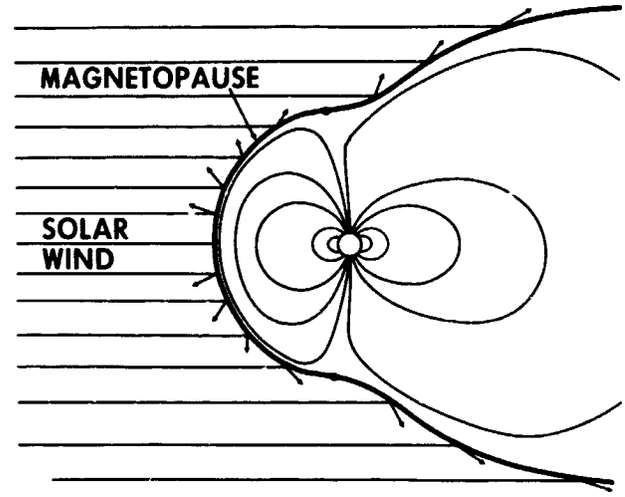

FIGURE 1.—Naive representation of the interaction of the solar plasma with the geomagnetic field. Direct impact of the plasma with the magnetic field is shown as being specularly reflected from the geomagnetic or Chapman-Ferraro boundary. The distance to the boundary at the subsolar point on this basis is given by $R_c = \left[\frac{B_0^2}{4\pi m n V_s^2}\right]^{1/6} R_e$ where R_e is the radius of the Earth, B_0 the equatorial magnetic field strength, V_s the velocity of the solar plasma and n, the plasma density (m being proton mass). See Figure 8.

gas with the principal constituent being hydrogen and flowing radially from the sun with flux values of 10^7 to 10^{10} particles/cm^2/sec. The energy of the particles was assumed to be approximately 1 Kev. Direct measurements of this solar wind or plasma have recently been performed by means of satellite measurements conducted both by this country (Bonetti et al, 1963; Snyder and Neugebauer, 1963) and by the USSR (Gringauz, 1962). As a part of the overall NASA program investigating the characteristics of the interplanetary medium on a continuing basis, a series of interplanetary Explorer satellites has been developed. Figure 2 presents a photograph of the IMP-1 satellite, the first Interplanetary Monitoring Platform in this series which was successfully launched

*Published as *Goddard Space Flight Center Document X-612-64-356*, November 1964.

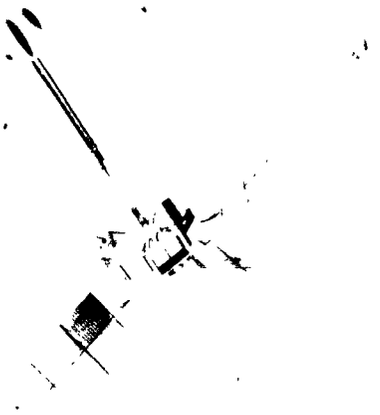

FIGURE 2.—Photograph of the first Interplanetary Monitoring Platform, IMP–1, launched Nobemver 27, 1963. The unique appendages extending from the spacecraft octagonal body support magnetometers at remote distances so that the magnetic fields of the electronic components do not contaminate the low field measurements. The satellite weighs 140 lbs and measures 14 ft from tip to tip of the fluxgate magnetometer booms.

1	Cosmic Rays	Range / Energy Loss	100 kev < P < 200 mev
2	Cosmic Rays	Total Energy / Energy Loss	Energy, Charge Spectra
3.	Cosmic Rays	Neher Ionization Chamber	Total Ionization
4	Cosmic Rays	Orthogonal Geiger–Counter Telescope	Spatial Isotropy CR Events
5	Magnetic Fields	Rubidium Vapor Scaler Mag.	$\|\vec{B}\|$ < 2000 Gammas
6.	Magnetic Fields	Fluxgate Vector Sensor Mag.	$\vec{B}$ < 40 Gammas
7.	Solar Wind	Proton Flux — Electrostatic	200 ev < P < 20 kev
8.	Solar Wind	Proton Flux — Faraday Cup	10 k/s < V_p < 1000 k/s
9.	Solar Wind	Thermal Ion–Electrons (Charged–Particle Trap)	few ev < electrons, ions

FIGURE 3.—Experiment repetoire on the IMP–1 satellite. The separate experiments were provided by both NASA and University laboratories including: Goddard Space Flight Center, Ames Research Center and the Universities of Chicago, California and MIT. Details of the various energy ranges and sensor techniques are included.

November 27, 1963. It transmitted information on the characteristics of magnetic fields, plasmas and energetic particles in the region surrounding the earth for a period of more than six months. The apogee of the satellite was 31.7 R_e (earth radii) or 197,616 km with an orbital period of 93 hours. The interaction of the solar wind with the earth's magnetic field leads to a distortion of the earth's magnetic field as well as creating a disturbance in the flow field of the solar wind. This paper is concerned principally with the distortion of the earth's magnetic field and the resultant boundary layer region between the magnetosphere and the undisturbed interplanetary medium as measured by the IMP–1 satellite.

A broad compliment of experiments in the measurement of energetic particles, low energy plasmas and magnetic fields was instrumented for flight on the IMP–1 satellite. Figure 3 presents a summary of the various instruments, their measurement range and energy characteristics. Figure 4 presents the solar-ecliptic coordinate system appropriate for studying the interaction of the solar wind with the earth's magnetic field. In this coordinate system the X-axis is directed at all times from the earth's center to the sun, the Z-axis is chosen to be perpendicular to the ecliptic plane and the Y-axis forms a right handed co-

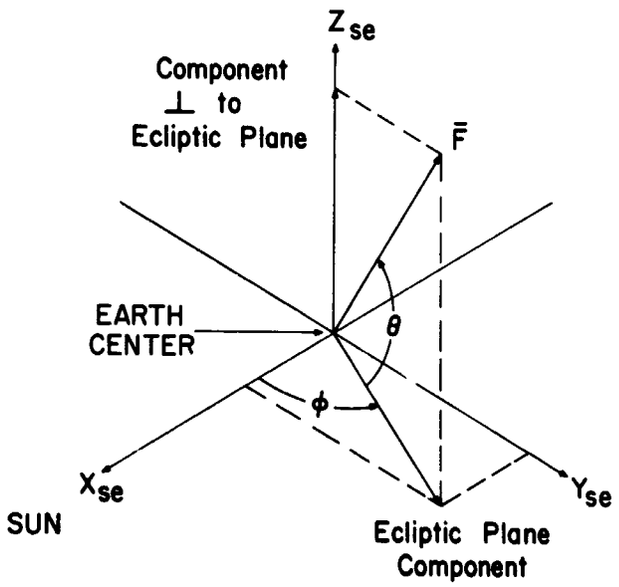

FIGURE 4.—Illustration of the solar-ecliptic coordinate system employed to study the characteristics of the interaction of the solar wind with the geomagnetic field. See text for an explanation of the specific parameters X_{se}, Y_{se}, Z_{se}, θ and ϕ.

ordinate system. In addition two angles are defined to represent a vector field: θ being the latitude, positive about the plane of the ecliptic and negative below and Φ the longitude, being 0° directed to the sun and 180° when pointed away from the sun. The characteristics of the highly eccentric IMP–1 orbit are shown in Figure 5 as projected on the ecliptic plane. The first four

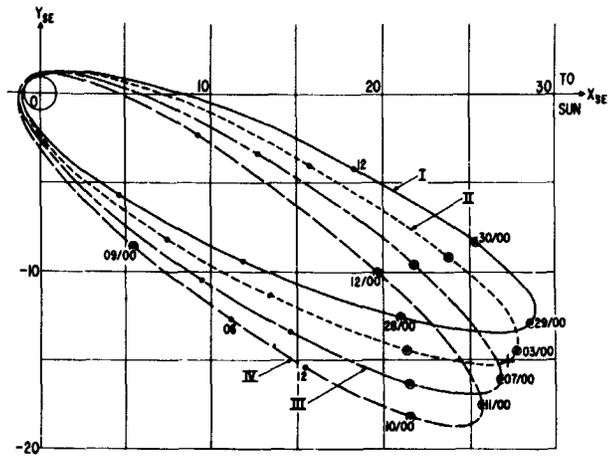

FIGURE 5.—Projection of the first four orbits of IMP–1 satellite as viewed on the $X_{ss}-Y_{ss}$ plane, the ecliptic plane. The values adjacent each trajectory orbit refer to the date and/or time in hours when the satellite was located at the indicated points.

orbits are shown with the figures adjacent to the trajectory indicating the time at which the satellite was at a particular position in space. Upon inspection of this figure it is noted that for approximately 60 percent of each orbit the satellite is well beyond 20 R_e distance from the center of the earth. A corresponding view of the orbit projected on a plane perpendicular to the ecliptic plane is shown in Figure 6. It is seen from these two figures that the orbit of IMP–1 is a very elongated ellipse. This paper shall utilize the experimental results obtained from the magnetometers (Ness et al, 1964) and the plasma probe

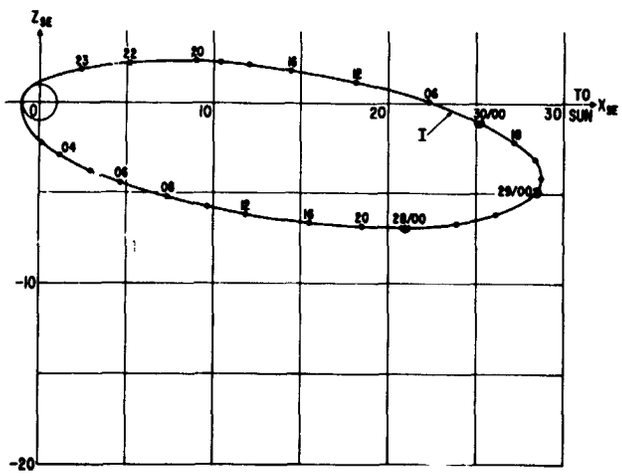

FIGURE 6.—Projection of the first orbit of the IMP–1 satellite as viewed on the $X_{ss}-Z_{ss}$ plane. The positive Z_{ss} axis points towards the north ecliptic pole.

(Bridge et al, 1964) to illustrate the characteristics of the magnetosphere and its boundary region.

The results of the magnetic field measurements on the inbound portion of orbit 1 are shown in Figure 7. The experimental data is presented as

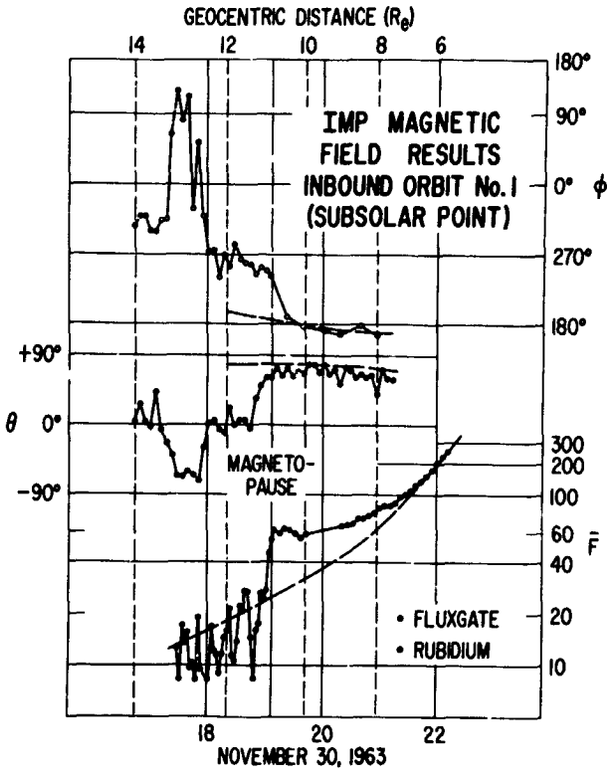

FIGURE 7.—Magnetic field measurements of the boundary of the magnetosphere from IMP–1 inbound orbit No. 1. The abrupt discontinuity in magnitude and direction of the field at 10.7 R_e is identified as the boundary. Theoretical values for F, θ and ϕ are shown as dashed curves and do not include any compression of the earth's field by the solar plasma.

a magnitude F and two angles θ and Φ. Each data point represents the average of the vector magnetic field over a time interval of 5.46 minutes. The satellite is moving approximately 2 km/sec in this region of space so that over this time scale the satellite traverses a radial distance of approximately 660 kilometers. The measurements at geocentric distances beyond 10.7 R_e are seen to be highly variable in both magnitude and direction of the magnetic field. However, at a distance of 10.7 R_e the magnetic field abruptly increases in magnitude to a value of 60 gammas and assumes a stable configuration. The theoretical magnetic field to be measured in space, extrapolated by spherical harmonic analysis from

surface measurements, is shown as dashed lines in this figure. The abruptness in both magnitude and direction as well as the temporal characteristics of the magnetic field at and beyond 10.7 R_e are identified as the boundary of the magnetosphere. It is seen that the observed magnitude is approximately twice that which would be theoretically predicted by considering the magnetic field in space to be only that due to the earth's magnetic field.

The containment of the earth's field by the solar plasma essentially doubles the magnetic field strength at the boundary surface. This can be understood simply by viewing the plasma impacting the geomagnetic field as being represented by a plane boundary across which the normal component of magnetic field must be zero. This is related to the phenomenon that in a highly conducting plasma, such as the solar wind, the magnetic field is "frozen into" the plasma motion. Hence as a plasma stream interacts with a magnetic field it does so by compressing the lines of force ahead of it. Mathematically this can be represented by placing an image dipole on the sunward side of the earth at an equal distance from the boundary and thus the normal component of the field is zero. This can explain both the magnitude increase of the observed magnetic field as well as the preservation of its direction. This simplified viewpoint is not completely correct but is substantially valid as long as the discussion refers only to the boundary near the subsolar or stagnation point.

Utilizing this simplified theoretical model of the solar plasma directly impacting the earth's magnetic field permits an interpretation of the solar stream properties on the basis of the size of the earth's magnetosphere. On the assumption that the subsolar radial distance to the magnetosphere boundary is 10.7 R_e it is seen in Figure 8 the plasma density ranges from 1 to 10 protons per cubic centimeter for velocities between 200 and 600 km/sec. These plasma values are representative of those which have been measured on previous satellites and space probes. Thus, it would appear that the general characteristics of the bounding of the earth's magnetic field by the solar plasma and the distance at which it occurs can be reasonably well understood on the elementary individual particle basis.

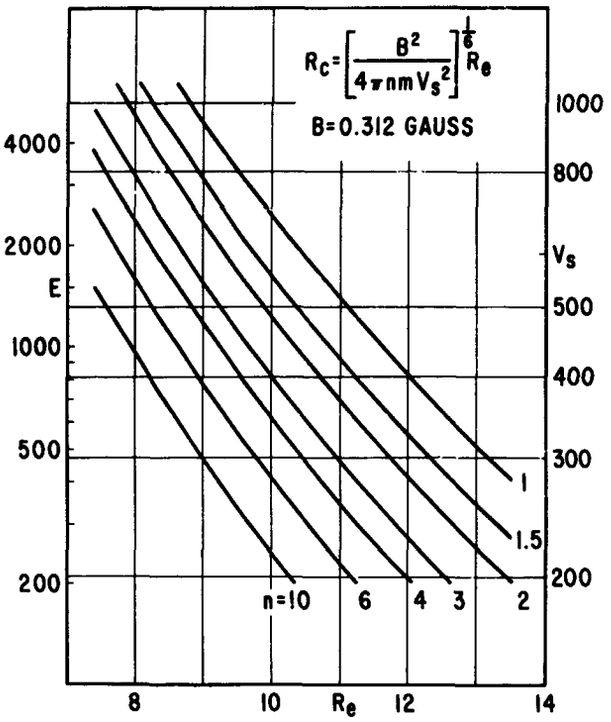

FIGURE 8.—Theoretical size of the magnetosphere at the subsolar point assuming normal impact of the solar plasma on the geomagnetic field. For a magnetosphere of 10.7 R_e and assumed velocity of 400 km/sec the deduced plasma density is found to be 2 p/cm^3.

However, this is not the complete story on the characteristics of the magnetosphere and its boundary region. A correlated set of data from the MIT plasma probe and the GSFC magnetic field experiment is shown in Figure 9. This included the same interval shown in greater detail in Figure 7. The important feature of the MIT plasma detector, a Faraday cup, is that it is directionally sensitive to the flow of plasma. As the satellite rotates, the acceptance aperture of the detector scans the celestral sphere and includes orientations directly toward and away from the sun. Shown on this figure are the plasma flux values when the detector is pointed almost directly toward the sun and directly away from the sun. The difference between these two measurements is a measure of the anisotropy of the plasma flow. It is seen that at very large distances from the earth, greater than 16 R_e, the plasma flow is principally from the sun. However, at a distance of 13.6 R_e the flow of plasma suddenly comes apparently from all directions, i.e. the flux is isotropic. It is also at this point that the fluctuations in the magnetic

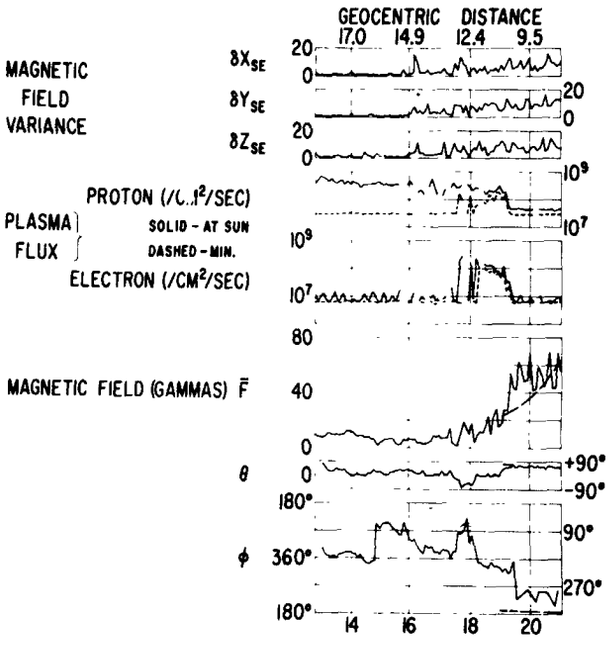

FIGURE 9.—Time correlated MIT plasma and GSFC magnetic field measurements on IMP–1 inbound orbit 1. The root-mean-squared deviation or variance estimate is of the magnetic field is shown as SX_{se}, SY_{se} and SZ_{se}. The plasma flux values in both a solar and antisolar direction are shown for the plasma probe. Isotropic fluxes immediately outside the magnetosphere boundary terminate at 13.7 R_e. Directional fluxes are observed beyond this boundary, which is identified as a collisionless magnetohydodynamic shock wave.

field increase appreciably. This is measured by the root-mean-squared deviations shown in the top most three curves illustrating the Z, Y, Z, components of the deviation of the magnetic field over the 5.46 minute time intervals. The fluctuating magnetic field and the isotropic plasma are observed until the distance at which the magnetic field abruptly increases to a very large value. This region of space surrounding the earth's magnetosphere in which a thermalized or isotropic plasma flux is observed to be correlated with fluctuating magnetic fields is termed the transition region of the magnetosphere boundary layer. It is this boundary layer which this paper studies, discusses its characteristics and attempts to present the current concepts related to its formation.

The first measurements clearly suggesting a continual containment of the earth's magnetic field were provided on the leeward side of the solar wind plasma flow by the Explorer X satellite in March, 1961 (Heppner et al, 1963). Over an interval of 48 hours the magnetic field and plasma was observed in a characteristic pattern in which strong fields directed radially from the earth were exchanged with periods during which radial plasma flow from the sun and fluctuating magnetic fields were observed. Conclusive experimental evidence for the bounding of the geomagnetic field by the solar wind was provided by the Explorer XII satellite measurements of the magnetic field and trapped particle fluxes as reported by Cahill and Amazeen (1963) and Freeman, Van Allen and Cahill (1963). Subsequent to the Explorer XII, the Explorer XIV satellite provided additional information on these characteristics. Thus far only limited summaries of the magnetic field in these regions have appeared although detailed discussions of the particle flux measurements have been presented in numerous articles. The plasma probes on board the Explorer XII and XIV did not reveal the isotropic fluxes observed on IMP–1.

Although the purpose of the IMP–1 satellite was primarily to investigate the characteristics of the interplanetary medium, the fact that the satellite is gravitationally anchored to the earth implies a traversal of the magnetosphere boundary region twice each orbit. The results of the IMP–1 satellite obtained in these traversals have substantially confirmed and extended our knowledge of the magnetosphere boundary layer. Our overall interpretation of the results is based upon an analogy with high speed aerodynamic flow. It is assumed that the magnetosphere acts as a blunt body which deflects the flow of the solar plasma. An important aspect of the rarefied solar plasma flow is that it contains a magnetic field. The average interplanetary magnetic field value has been accurately established by the IMP–1 satellite (Ness and Wilcox, 1964). For the average solar proton of 1 Kev energy this leads to a Larmor radius of approximately 500 kilometers. This small characteristic length permits the use of a fluid continuum approximation. This is also about the spatial resolution with which the boundaries of both the magnetosphere and the transition region are sampled. In this magnetized plasma the propagation of disturbances is by magnetohydrodynamic waves as contrasted to the supersonic gas dynamic case when propagation is by acoustic waves. The appropriate propagation velocity, the Alfvén mode is presented

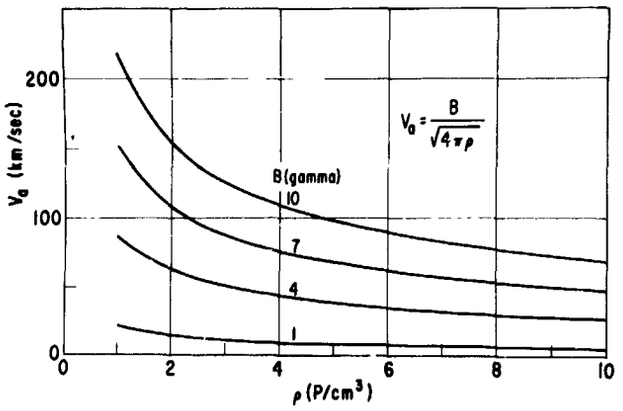

FIGURE 10.—The characteristic velocity of propagation of disturbances in the interplanetary medium is the Alfven velocity. This magnetohydrodynamic mode is shown as a function of magnetic field strength B and plasma density, ρ.

in figure 10 as a function of plasma density and magnetic field strength. The important feature of this diagram is that it shows that for the interplanetary medium the Alfvén velocity is characteristically less than 100 Km/sec. The estimated velocity of the solar plasma is 385 Km/sec from the interpretations of solar magnetic fields and the interplanetary magnetic field (Ness and Wilcox, 1964). Thus, the flow of the solar wind is supersonic in the magnetohydrodynamic sense. Actually the flow is hypersonic since the equivalent Mach number or more appropriately the Alfvén number is greater than 4. Under such conditions the well known phenomenon of a detached shock wave develops in the gas dynamic case which encloses the disturbing body in a region of space with a boundary across which discontinuous changes in parameter values occur. At the present time the detailed quantitative study of the physical properties of the boundaries as observed by the IMP-1 satellite have yet to be completed. A particular limitation to their detailed study will be the spatial and time resolution limitations inherent in the spacecraft orbit and telemetry system. The detached shock wave which is observed in gas dynamics has characteristics which closely resemble that of the earth's magnetic field interacting with the flow of the solar wind. The termination of the turbulent transition region observed as the satellite moves radially away from the earth is interpreted to be the collisionless magnetohydrodynamic shock wave associated with the interaction of the solar wind with the geomagnetic field. The IMP-1 data has provided the first accurate measurements of this phenomenon and indeed have mapped in detail its position relative to the earth sun line. This is a most important feature of the boundary of the magnetosphere since it may provide mechanisms for acceleration of charged particles.

Within and adjacent to the transition region, satellite detectors have shown transient fluxes of energetic electrons having energies greater than 45 Kev and total fluxes of $10^6/cm^2/sec$ an order of magnitude greater than background (Anderson et al, 1964; Fan et al, 1964). The IMP results suggest these observations are related to the formation of the magnetosphere and the shock wave boundary. The experimental evidence is very recent and the full theoretical significance of these data has yet to be completely evaluated. The particle fluxes which are observed are substantially less than those observed within the trapped particle belts within the earth's magnetic field. Hence it is not possible to consider these as hazards to manned space flight travel or to satellite hardware systems when one considers the more important contributions due to the Van Allen Radiation Belts.

A summary of the observed positions of the shock wave boundary and the magnetosphere boundary is shown in Figure 11. In this presen-

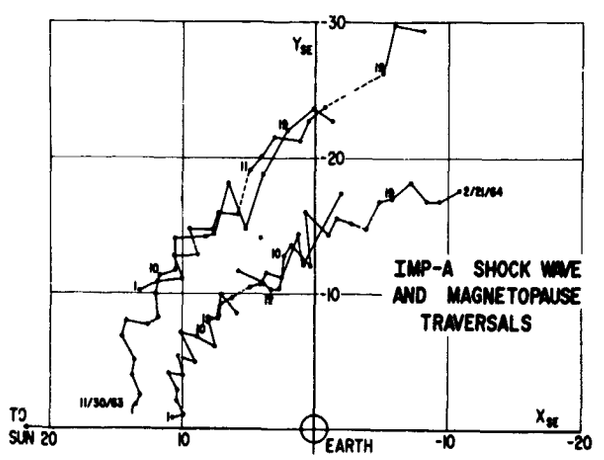

FIGURE 11.—Summary of the observed positions of the magnetosphere boundary and shock wave as determined by the magnetic field experiment on IMP-1. Successive traversals of the boundaries are connected by straight line segment. Orbits number 1 through 23 are shown and are seen to be approximately parabolic in shape.

tation the boundaries of the magnetosphere and transition region as detected by the magnetic field experiment are illustrated. It is seen that the geocentric distance to the shock wave at the stagnation point is approximately 13.4 R_e but this distance increases away from the subsolar or stagnation point. This indicates an increase in the thickness of the transition region. The data also indicates that the magnetosphere is not closed, at least to the distance of 10 to 20 R_e behind the earth. The data are suggestive that the magnetosphere trails out far behind the earth in the fashion analogous to cometary tails. On this basis it is reasonable to expect the moon to intersect the earth's magnetosphere once each month (Ness, 1964).

A comparison of the theoretical shape and position of the shock wave boundary and magnetosphere boundary with observations is shown in Figure 12. Using a gas dynamic ratio of less than 2 but more than 5/3 permits exact comparison of the data. The small scatter in the position of the boundary crossings is related to the variability of the solar plasma flow. The comparison with theory (Spreiter and Jones, 1963) is very good and indicates a fundamental characteristic of the interplanetary plasma near the stagnation point and on the scale on which the observations are made. The standoff ratio between the shock

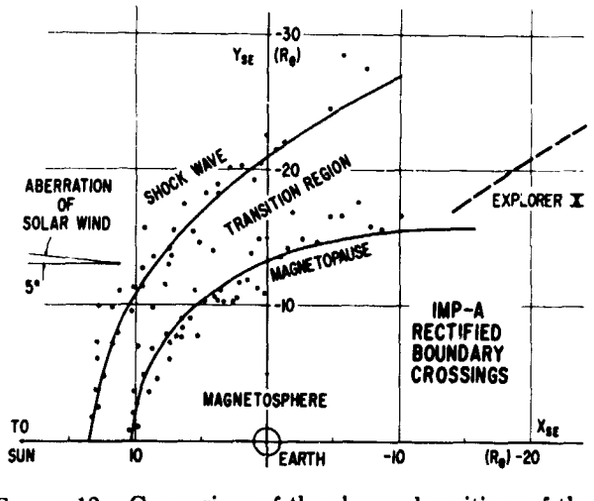

FIGURE 12.—Comparison of the observed positions of the boundary of the magnetosphere and shock wave with the theoretical positions according to Spreiter and Jones (1963). Very good agreement is obtained by slightly modifying their treatment to accommodate the values of magnetosphere radius (10.25 R_e) and shock wave radius (13.4 R_e) actually observed.

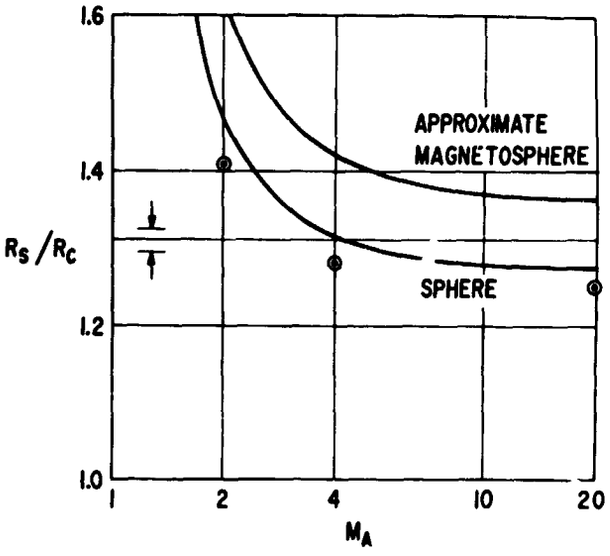

FIGURE 13.—Theoretical standoff ratios (R_s/R_c) for the magnetosphere assuming it to be a sphere or an extended blunt object as a function of Mach number. The observed values 1.31 shown intermediate to these two cases.

wave distance and the magnetosphere boundary is shown in Figure 13 as a function of Mach number for two models of the shape of this magnetosphere. One is that of a sphere utilizing the theoretical results by Hida (1953) and the other utilizes the various models in generally good agreement as represented by Beard (1960) and Spreiter and Jones (1963). The observed value of 1.31 ± 1 percent is seen to be between the two limits. For the observed Mach numbers the standoff ratio is reasonably insensitive to the exact value of Mach number. Hence time variations in the characteristics of the solar plasma do not affect to first order the standoff ratio, as do the magnetosphere shape and specific heat ratio used in the gas dynamic analogy.

A summary of the description of the magnetosphere and its boundary layer as projected on the plane of the ecliptic is shown in Figure 14. In this figure the interplanetary magnetic field is shown at an angle of 135 degrees to the Earth Sun line and in a sense which is positive with respect to flux lines extending from the sun into interplanetary space. The projected positions of the IMP satellite are shown for the first 19 orbits and the positions of the magnetosphere boundary and shock wave are shown as average positions. Within the transition region is a turbulent plasma

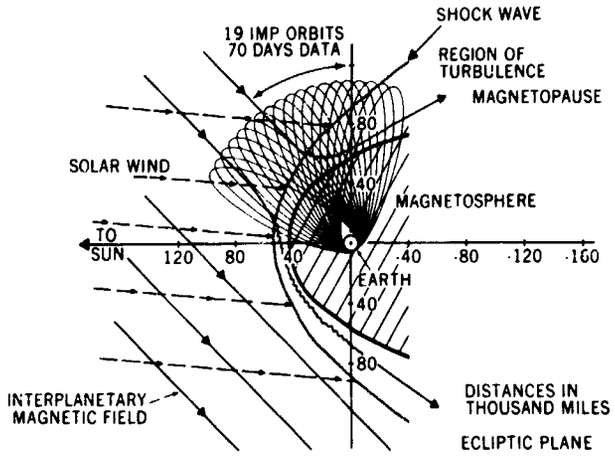

FIGURE 14.—Summary schematic illustration of the magnetosphere shape and boundary layer thickness as deduced from magnetic field measurements on the IMP-1 satellite. The flow of solar plasma, the solar wind, is taken to be aberated by 5° west of the sun due to the heliocentric orbital motion of the earth.

flow of very high temperatures with fluctuating magnetic fields. Within the magnetosphere a distorted geomagnetic field is observed, dependent upon the strength of the earth's magnetic field and the strength of the solar wind containing it. Present measurements do not indicate a termination of the magnetosphere on the leeward side of the solar wind flow. It is very possible that the earth's magnetic field trails out 100 R_e or more behind it, intersecting the orbit of the Moon (Ness, 1964).

ACKNOWLEDGMENTS

I acknowledge the contribution of the other experimenters on the IMP-1 satellite, in addition to my own co-experimenters, Mr. C. S. Scearce and Mr. J. B. Seek.

ON THE SOLAR ORIGIN OF THE INTERPLANETARY MAGNETIC FIELD*

NORMAN F. NESS AND JOHN M. WILCOX†

Direct measurements of the interplanetary magnetic field at 1 A.U. have recently been made by an experiment[1] conducted on the Interplanetary Monitoring Platform (IMP-1). The 63 kg spin stabilized satellite was launched on Nov. 27, 1963 into a highly eccentric orbit with a geocentric apogee of 197,616 km. and an orbital period of 93.5 hours. The Sun-Earth-apogee angle was initially 25° west of the Sun and increased approximately 1°/day due to the Earth's helicoentric motion. Successful transmission of scientific data continued for 180 days until May 30, 1964 when the Sun-Earth-apogee angle had increased to 201°. The interplanetary data is based on the average magnetic field computed every 5.46 minutes using 12 successive data transmissions at 20.5 second intervals. The absolute uncertainty of the data is less than 0.25 γ ($1\gamma = 10^{-5}$ gauss). This letter presents the initial results of a detailed comparison of these interplanetary magnetic field measurements with solar magnetograph observations of the photospheric magnetic fields as measured at the Mt. Wilson Observatory.

Previous space probe measurements[2] of the interplanetary magnetic field by Pioneer V in 1960 were interpreted as evidence of a 2.5 γ field normal to the ecliptic plane. A recent reanalysis[3] of this data has yielded the result that the direction of the interplanetary field was nearly parallel to the plane of the ecliptic and that the magnitude was between 5–10 γ. The measurements[4] of the solar plasma efflux in 1962 by the Mariner II Venus probe have confirmed the initial restricted results[5] of the Explorer X satellite obtained in 1961 and the Lunik II[6] moon probe in 1960. The Mariner II results showed that a continual flow of plasma, the solar wind[7], existed with an average streaming velocity of 504 km/sec.

The interaction of the solar wind with the geomagnetic field disturbs the interplanetary medium in the immediate vicinity of the Earth and spatially confines the Earth's field. Thus measurements of the relatively undisturbed interplanetary medium by IMP/1 are restricted to times centered about the satellite apogee and outside the interaction region. This region is limited to about 85,000 km at the subsolar point, but is not spherically symmetrical[1] and instead broadens out away from the stagnation point and eventually trails out behind the Earth. Hence as the orbit of IMP-1 precessed in the solar-ecliptic coordinate system[1] the maximum length of time possible for measurements of the interplanetary medium decreased from about 3 days during Orbit 1 to 1 day on Orbit 22. The interplanetary magnetic field data obtained during this portion of the IMP-1 lifetime were distributed over the time interval Nov. 27, 1963 to Feb. 17, 1964 covering the three solar rotations 1784 to 1786.

The initial results of these measurements are consistent with the general model[8] of an interplanetary field of solar origin in which the effects of a radial solar wind velocity and the solar rotation combine to produce magnetic lines of force which are twisted in the plane of the ecliptic in the form of an Archimedes spiral. Figure 1 summarizes the orientation histograms for the interplanetary magnetic field data. The angular distribution of the field component in the ecliptic plane is shown on the left-hand side with an angular increment of 20° selected on the basis of an uncertainty of direction of less than 5° for each 5.46 minute average. A total of 12,510 data points were obtained during the 83 day interval

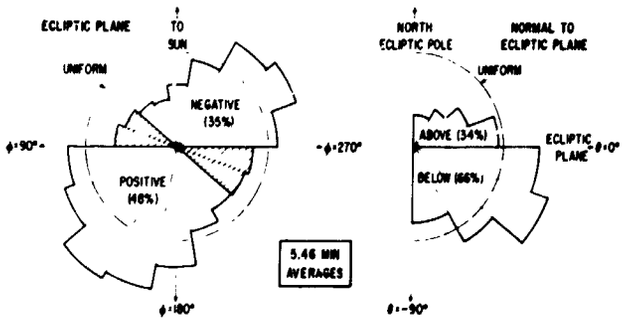

FIGURE 1.—Distribution of the interplanetary magnetic field direction in the plane of the ecliptic and normal to the ecliptic. Both histograms show the field angular distribution per unit solid angle; the dashed circles would correspond to an isotropic distribution of the same number of vectors.

covered by this data. The decided tendency of the field to be oriented parallel or anti-parallel to the theoretical angle (~135°) proposed by Parker[8] is clearly indicated. The asymmetry between the oppositely directed fields is presently being investigated. The figure also identifies those sectors in which the direction of the field is predominantly away from the Sun ($\phi = 90°$ to 230°, "positive" direction) and those in which the field is predominantly towards the Sun ($\phi = 270°$ to 50°, "negative" direction). Also shown in Figure 1 is the angular distribution of the field component perpendicular to the ecliptic plane. This illustrates the tendency of the neaby interplanetary field to be directed nearly parallel to the ecliptic plane, although a slight but distinct southward directed component is apparent. These facts suggest that magnetic field filaments exist in the interplanetary medium. The average field magnitude is close to 5γ and ranges principally between 3–6γ.

For direct comparison with the solar magnetograph data the IMP–1 data has been averaged over a 12 hour interval. Each such interval was divided into 4 subintervals which were assigned a polarity on the basis of the direction of the most frequent occurrence of the initial 5.46 minute averages. If 3 or 4 of the subintervals were of the same polarity the 12 hour interval was assigned that polarity. Other possible results including incomplete data coverage were considered too ambiguous and were not assigned any polarity. The purpose of this procedure was to obtain the large scale polarity distribution of the interplanetary magnetic field. These IMP–1 data were first examined for evidence of a 27 day recurrence period, on the assumption that this would be a measure of the solar influence on the measured interplanetary field. A prominent peak with an amplitude of 0.55 ± 0.05 in the auto-correlation[9] curve was observed at a lag of about 27 days. It was observed that if the first 8 days of IMP observations (including the magnetic storm of Dec. 2, 1963) were omitted, the remaining data yielded a 27 day auto-correlation peak with an amplitude of about 0.85 ± 0.10. Therefore this 75 day interval of data was selected for further analysis on the assumption that this represented a period of time in which the large scale features of the interplanetary magnetic field were quasi-static.

Dr. Robert Howard of the Mt. Wilson Observatory kindly made available the daily solar magnetograms that were obtained with the solar magnetograph.[10] With this instrument the photospheric magnetic field is measured utilizing the longitudinal Zeeman effect. The minimum detectable field was 2 gauss (averaged over an area on the Sun of 4 x 10^8 km^2) in the observations used in this note. Each magnetic region occupied an appreciable portion of the visible disk (i.e. this note is not directly concerned with the much stronger but much more localized fields associated with sunspots; discrete events such as flares also do not enter into this analysis). The direction (out of or into the Sun) of the photospheric field at the center of the visible disk was assigned a polarity (plus or minus) during the three solar rotations of interest. An increment of 6.7° in longitude (corresponding to the solar rotation in 12 hours) and of 10° in latitude was chosen. Occasionally the field direction in an increment of area was ambiguous and such an area was omitted in the analysis. There are also gaps in the photospheric data for about 25 days caused by weather conditions at Mt. Wilson. A cross-correlation between the IMP–1 field direction and the solar field direction was then computed. The computation was repeated at 5° intervals for latitudes from 25°N to 25°S of the center of the visible disk.

Three such cross-correlations are shown in Figure 2 as a function of the time lag from central meridian passage of the photospheric field area to the time the field was measured by IMP–1. The prominent positive peak at a lag of approximately

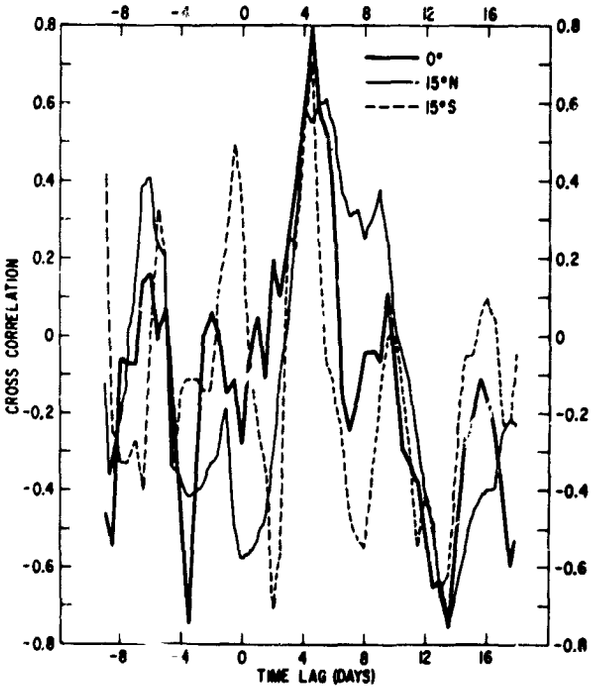

FIGURE 2.—Cross-correlation between IMP magnetic field direction (toward or away from the sun) and the photospheric field direction (into or out of the sun) for three latitudes on the sun. The positive peak at about 1½ days would correspond to a uniform radial solar wind velocity of about 385 km/sec. The negative peaks at −3½ days and +13 days can be understood in terms of a quasiperiodicity in the data. The latitudes are measured from the center of the visible disk.

4½ days is common to all of the latitudes examined. Because several of the photospheric field regions have a considerable extent in latitude the limited data sample available does not permit a statistically significant determination of the solar latitude at which the best correlation with IMP is obtained. The peak in the correlation at a lag of $4\frac{1}{2}\pm\frac{1}{2}$ days would correspond to an average radial solar wind velocity of 385 ± 45 km/sec. The average radial solar wind velocity over the first seven IMP orbits measured by the MIT plasma detector experiment[11] was 398 km/sec.

The latitude of the photospheric source of the interplanetary magnetic field has been investigated by means of the differential rotation of the photospheric magnetic field. Figure 3 shows the rotation period as a function of latitude as determined from auto-correlations of the photospheric field data previously described[12]. Also shown is the recurrence period determined from auto-correlation of the IMP data. This comparison suggests that the latitude of the photospheric source of the interplanetary field was within 10 or 15 degrees of the center of the visible disk (or of the equator; the present analysis cannot make a distinction between the two).

These results indicate that during three solar rotations near the minimum of the solar cycle, some of the magnetic field lines passing through the photosphere near the center of the visible disk tended to be dragged out by the solar wind plasma to become part of the near-by interplanetary magnetic field. The best correlation was obtained

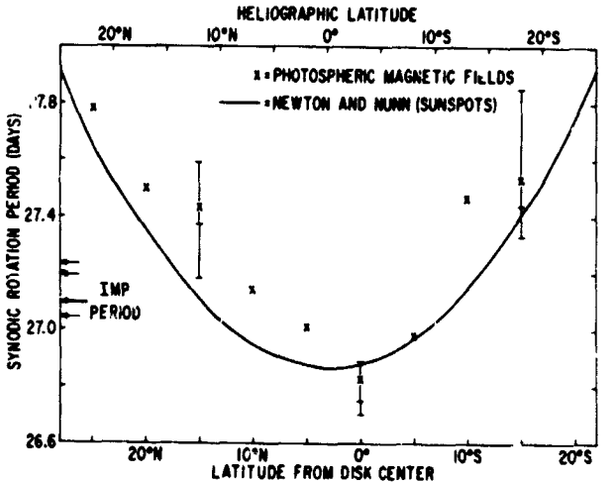

FIGURE 3.—Differential rotation periods of the photospheric magnetic field. The latitude of the photospheric observations is measured from the center of the visible disk, whose average heliographic latitude was 3°S during the time considered here. The error bars were estimated by dividing the data into three parts and analyzing each separately. The solid line is from the sunspot observations of Newton and Nunn [13]. The arrows at the left indicate the IMP recurrence period; the position of the heavy arrow was computed using all the data and the light arrows represent a division of the data into three parts.

when the photospheric field was in the same direction throughout an area corresponding to at least two or three days rotation. These conclusions are consistent with the model suggested by Ahluwalia and Dessler[13] in which the sense of the interplanetary magnetic field filaments is related to the sense of photospheric magnetic field regions.

We thank Dr. Robert Howard for making the solar magnetograms available, and Dr. Howard and Dr. V. Rumba for several valuable discussions.

One of us (JMW) thanks the director of the Mt. Wilson Observatory for guest investigator privileges at the observatory.

SPINOR FORMULATION OF MAGNETOGAS DYNAMICS*

LAWRENCE A. SCHMID

It is shown that all the variables needed for a classical description of the dynamical behavior of a fluid consisting of electrically charged particles having spin can be incorporated into two spinors having a total of four complex elements. The particle spin is included, not because it plays any significant role in magnetogas-dynamical problems, but because it is needed to account for all the degrees of freedom of the spinors.

The link between the spinors and the familiar quantities that describe the fluid is provided by the "particle tetrapod" consisting of one time-like and three space-like 4-vectors. These four vectors constitute an orthonormal system and are normalized to the particle density of the fluid in its local rest-frame. The time-like vector is identified with the flux density of the fluid; one space-like vector is used to specify the orientation of the particle spin axis; and the remaining degree of freedom, an angle, is postulated to be proportional to the de Broglie phase, the proportionality constant being Planck's constant.

Incorporating the de Broglie phase into the tetrapod has two consequences: First, Planck's constant is introduced into the formalism. Second, because the canonical momentum is the gradient of the de Broglie phase, the tetrapod contains all the information needed for a dynamical, as well as a kinematical, description of the fluid.

It is shown that the vectors of the tetrapod can be generated by four different bilinear forms involving the elements of two spinors and their complex conjugates. In this sense, the spinors may be regarded as the "square roots" of the tetrapod. The phase angle common to the two spinors is the only one of the eight degrees of freedom of the spinors that does not make itself felt in generating the tetrapod. This phase angle is used to specify the sign of the particle charge.

If the spinors that describe the fluid satisfy a first-order linear partial differential equation that involves the 4-vector electromagnetic potential and the particle mass, regarded as a linear function of the gravitational potential and the specific enthalpy, then it turns out that, for the case of adiabatic flow, the quantities involved in the tetrapod automatically satisfy a 4-vector equation that has the form of the relativistic Euler equation in the presence of electromagnetic, gravitational, and pressure fields. Spin-dependent forces proportional to Planck's constant also appear in this equation but, for problems on an macroscopic scale, these forces are completely negligible. It is shown that it is possible to drop the condition of adiabatic flow, and admit fluid viscosity, or energy injection or loss (e.g. through nuclear reactions or radiation, respectively), without changing the form of the spinor equation to be solved. Only the form of the equation that determines the specific enthalpy in terms of other fluid quantities is altered.

Because the spinor equation is linear for the case of gravitational, electromagnetic, and thermal fields regarded as fixed functions of the space-time coordinates, wheras the corresponding Euler equation is nonlinear, it is suggested that use of the spinor alternative to the Euler equation would facilitate the solution of the complete megnatogas-dynamical problem, involving both fluid-dynamical and field equations, by means of a straight-forward iteration procedure. This approach should be especially fruitful in the case of the self-excited dynamo problem, and it is in terms of this problem that the physical interpretation of the formalism is made.

The spinor alternative to Euler's equation has the form of the Dirac equation, except that the particle mass is regarded as a scalar function of the space-time coordinates, rather than a constant. The theory, however, except for the incorporation of the de Broglie phase into the tetrapod, is completely classical in spirit. In particular, no quantization process, and nothing corresponding to the Exclusion Principle have been introduced into the formalism. Thus the theory developed

*Published as *Goddard Space Flight Center Document X-640-64-55*, March 1964.

here could not be expected to yield valid solutions for problems in which the charged fluid should become degenerate as, for instance, at the centers of certain stars.

As a preliminary to the introduction of the particle tetrapod and the spinor equation, consideration is given to the relativistic problem of electron and proton gases interacting with the gravitational, electromagnetic, and pressure fields produced by these same charged gases. The analysis is first carried out without particle spin, and is then modified to take spin effects into account. Finally, the particle tetrapod and the spinor equation are introduced. The detailed mathematical work involving spinors is relegated to an appendix, only the results being summarized and interpreted in the body of the paper, an understanding of which requires no prior knowledge of spinor analysis.

I INTRODUCTION

Self-Excited Dynamo

The basic equations of magnetogas dynamics are composed of two categories of equations: the fluid-dynamical equations, and the field equations. It is the purpose of this paper to develop a new formulation of the fluid-dynamical equations that will simplify the problem of the simultaneous solution of the fluid-dynamical and field equations. Although this new formulation will be applicable to a wide range of problems, the problem we shall use as a guide in discussing physical questions will be that of an isolated spheroid of fully ionized plasma whose fluid and electric currents are such that it constitutes a self-excited dynamo. A discussion of this type problem and review of the literature has been given by Elsasser (1), and in a more condensed form by Cowling (2).

The only serious attempt at a quantitative solution of this problem has been the one carried out by Bullard and his collaborators (3). In this calculation the fluid dynamical half of the problem was neglected, except for imposing the continuity condition. The calculation assumes an incompressible fluid (core of the earth), and so would not be valid, excpet in a qualitative way, for a star. Because of the immense difficulty of the calculation, it was necessary to truncate the harmonic expansion of the solution after the first few terms, and for this reason the solution is only approximate and some doubt remains concerning its convergence. Finally, the calculation was carried out for only one possible flow pattern. Other patterns, possibly of great physical interest, have not as yet been attempted. Calculations [(4) and (5)] have been made, however, for two other flow patterns that do not pretend to resemble the actual flow within the earth's core. The primary purpose of these calculations was merely to demonstrate the possibility of the existence of a self-excited dynamo in a homogeneous, dissipative, conducting sphere. Accordingly, the flow patterns were chosen to facilitate the calculation rather than (as in Bullard's calculation) to resemble a possible flow pattern in the core of the earth. These calculations, like Bullard's, neglected the dynamical half of the problem except for the condition that the fluid flow be solenoidal.

The extreme difficulty of these calculations clearly illustrates the desirability of finding an alternative formulation of magnetogas dynamics that will ease the calculational burden.

Two-Fluid Formulation of the Problem

Rather than formulate the problem in terms of a single conducting fluid through which an electric current flows, we shall work with two electrically charged fluids—the electron and proton gases. (Simply by changing the particle mass, we would have a gas of positive ions, instead of a proton gas.) This two-fluid approach is more rigorous than the single-fluid approach in that it obviates the need to introduce the conductivity which under certain conditions becomes an untenable concept.

The electron and proton gases are postulated to be independent perfect gases that interact only through common gravitational and electromagnetic fields. The partial pressures of the two charged gases are taken into account, but viscosity is neglected. Each of the charged fluids must independently satisfy Euler's equation, which is just the expression of Newton's second law for the fluid.

Sources of Nonlinearity

The magnetogas-dynamical problem is intrinsically nonlinear inasmuch as the interaction of

the electron and proton gases with each other, and the self-interaction of each, means that superposability of solutions is not possible. However, even when we eliminate the interaction by requiring that the gravitational, electromagnetic, and pressure fields be fixed functions of the space-time coordinates (i.e., independent of the fluid flow solutions), we find that Euler's equation is still nonlinear because it contains terms that are quadratic in the fluid velocity. Because we know from physical reasoning that in the case of fixed fields superposability of solutions is possible, it would appear that the nonlinearity in Euler's equation caused by the terms that are quadratic in velocity must be spurious in the sense that there must exist an alternative way to formulate the fluid-dynamical problem that would be linear for the case of fixed fields.

We shall see that it is possible to replace Euler's equation by an equivalent spinor equation that is just the desired linear alternative (in the case of fixed fields). Having this linear alternative to Euler's equation, a straight-forward iteration solution of the total magnetogas-dynamical problem is now possible: we start with a zero-order solution of the linear spinor equations (one for each of the two charged fluids), for a certain choice of zero-order fields; we use this solution to determine the zero-order source terms in the field equations; we solve the field equations for the first-order corrections to the fields, which we then use in the spinor equations to calculate the first-order corrections to the fluid flow of the electron and proton gases; then the whole process is repeated as many times as needed to give the desired accuracy. Such a straight-forward iteration procedure would be impossible using Euler's equation instead of the spinor equation because the solution of the fluid flow for the case of given fixed fields would be blocked by the nonlinearity of Euler's equation arising from the terms that are quadratic in velocity.

Spinor Equations of Motion

As a prerequisite for deriving the spinor equations, we must introduce the electron and proton spin as additional degrees of freedom. Since particle spin plays no significant role in magnetogas-dynamical problems, it would seem that this is an unnecessary complication of an already too complicated problem. In actual fact, however, in the solution of a problem like the self-excited dynamo, the introduction of spin coordinates does not increase the calculational difficulty because it merely means that we work with an expansion in spinor harmonics instead of an expansion of vector harmonics.

We shall see that it is possible to regard the spinors that describe the electron gas, for example, as the "square roots" of the electron flux density 4-vector. In the same way that we find that taking the square root of a real number gives us an extra degree of freedom (the sign of the root) that must be specified by some physical condition, taking the "square root" of the flux 4-vector gives rise to extra degrees of freedom, among which are those corresponding to particle spin. Thus, the introduction of particle spin is the necessary price we must pay for the convenience of working with the linear spinor equation, rather than with the nonlinear Euler (4-vector) equation.

We shall find that the spinor equations of motion have the form of the Dirac equation in which the particle mass, instead of being a constant, is a scalar function of the space-time coordinates that includes the mass per particle associated with the gravitational and thermal energy of the fluid, as well as the constant rest-mass of the particle. In spite of the fact that the spinor equation of motion has the form of the Dirac equation, the theory developed in this paper is purely classical (except for the fact that it incorporates the de Broglie Hypothesis, which introduces Planck's constant into the theory). In particular, no quantization process is introduced. Thus the Exclusion Principle, and consequently degeneracy of the electron and proton gases at high densities, do not follow from the theory.

In recent years there has been an increased interest in the problem of finding a classical interpretation of the Dirac equation. Noteworthy in this respect is the long paper by Takabayasi (6), and the book by Halbwachs (7) in which most of the work up to 1960 is reviewed. More recent work has been done by Schiller (8) and by Grossmann and Peres (9). (The latter reference gives a bibliography for the most recent work.) All this work differs from the theory developed in this paper in that the authors cited were ultimately concerned with finding a deeper or more intuitively

appealing interpretation of quantum mechanics, rather than in the simplification of the equations of classical magnetogas dynamics. Thus, although some formal similarities exist between the present work and certain of the papers cited, vital differences also exist, with the result that any comparison must be made with great care. In any case, the present paper is intended to be self-contained and no use is made of any previous work.

Assumptions and Approximations

A realistic solution of the self-excited dynamo problems corresponding to the sun or the core of the earth would involve taking into account many detailed and complicated physical effects, some of which are not well understood. Such a detailed program would be premature. Rather, we shall aim at solving a well-defined, relatively simple idealization that, with only minor modifications can be brought into close enough correspondence with the real problems occurring in nature to afford some physical insight. We shall now discuss the assumptions and approximations that denfine this idealization.

First, we treat the electron and proton gases as fluids, rather than as distributions of particles having different velocities, spins, etc. Thus, for example, at a given point of space-time, there is only a single electron velocity, and this velocity is a continuous function of the space-time coordinates.

Further, we postulate that the electron and proton gases are perfect, classical (no degeneracy) gases.

We postulate that we have at every point of space-time a fully ionized plasma in which the electrons or protons (or positive ions) are individually conserved.

We shall neglect fluid viscosity (but not pressure). This is a valid approximation in situations such as we find in the interior of the sun and earth's core, since in such cases the magnetic forces are very large compared with the viscous forces. In the case of very tenuous plasmas, such as we find in the corona of the sun, or in interstellar space, this is no longer true, and it would be necessary to take viscosity into account. This can be done in fact, by means of a relatively minor modification of the theory, which is discussed in Appendix A. For the sake of definiteness, however, we assume throughout the body of the paper that fluid viscosity may be neglected.

We impose two different adiabatic conditions: first, we postulate that a given bubble of electron or proton gas loses or gains no heat energy. Second, we postulate that if we were to make a small adiabatic virtual displacement of a given bubble of gas into a neighboring position, then the bubble will have the same thermodynamic properties as the fluid surrounding its new position. We shall see that for quasistatic (i.e., reversible) flow, these two adiabatic conditions can be combined into the single condition that the 4-gradient of the specific entropy vanish. This means that the specific entropy is constant throughout the gas for all time.

The adiabatic condition with respect to virtual displacement of a bubble of gas is a natural one, since it corresponds to the fact that even though the macroscopic flow is well-ordered, there is always small-scale turbulence that tends to maintain the assumed adiabatic condition.

The assumption that a given bubble of gas gains or loses no heat energy as time goes by is less realistic inasmuch as it neglects energy lost through radiation and the possibility of energy injection through nuclear reactions or some other mechanism. Moreover, we are neglecting heat gained or lost by conduction. It is, in fact, not difficult to modify the theory so as to allow for energy injection or loss. The way in which this can be done is discussed in Appendix A. For definiteness, however, through the body of the paper we shall neglect the possibility of energy loss or injection. We justify this by taking the point of view that we divide the total problem into two steps: (1) Solution of the dynamical problem subject to the adiabatic condition; (2) Solution of the energy balance problem subject to the assumption that dropping the adiabatic condition has no effect on the dynamical solution other than to cause a slow change in its parameters (e.g., the slow expansion or contraction of a star). This two-step point of view is illustrated in Figure 1: On the left side is shown a possible flow pattern in the sun or the earth's core. Fluid rises from the center C in the equatorial plane, floes along the surface through a typical surface point S to the poles, where it returns to the center. On

the right side of Figure 1 is shown the pressure (P) vs. specific volume (V_1) plot for a typical bubble of fluid that goes through a complete cycle in the indicated flow pattern. The points C and S on the P-V_1 plot indicate the thermodynamic state of the bubble at the corresponding points in the pattern. Thus, assuming the adiabatic condition, we note that as the bubble moves from the center C to the surface S, on the P-V_1 plot it moves

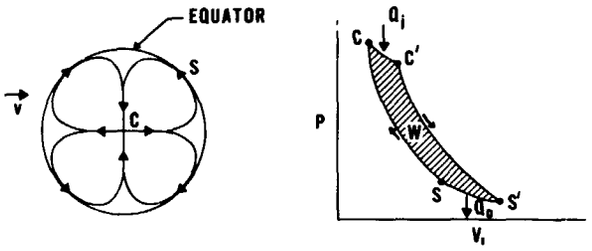

FIGURE 1.—Heat transfer associated with convection.

downward from C to S, corresponding to an expansion. The return trip to the center of the core carries it along the same path in the P-V_1 plot back to the point C. Thus, on the outward trip, the bubble performs an amount of work equal to the area under the curve C-S; that is, heat energy in this amount is converted into some other form of energy, notably electromagnetic energy. But on the return trip the bubble retrieves this energy, so there is no net transfer to electromagnetic field.

Now let us imagine that, when the bubble is at C, an amount of energy Q_i is injected isothermally by means of a nuclear reaction so that while the bubble is still at the center of the core C, it traverses the isothermal C-C'. Then it expands adiabatically reaching the surface in the thermodynamic state S'. At the surface it isothermally radiates the energy Q_o, and then traverses the path S-C back to the center. Thus we have a Carnot cycle in which the net amount of energy W is transferred to the electromganetic field to compensate losses due to Joule heating.

The two-step procedure mentioned above for solving the total problem is valid only if the Carnot cycle is very narrow. In such a case, the energy injection and loss will have no appreciable effect on the dynamics of the problem. This amounts to assuming that the energy injected and radiated during each cycle is small compared with the adiabatic work performed during the trip from the center to the surface. Obviously, this will not be the case if energy is injected too quickly. In such cases the energy injection does affect the dynamical problem, and it is necessary to modify the theory in the manner discussed in Appendix A.

As a final observation concerning the adiabatic condition, we note that, since this condition is applied to the electron and proton gases independently, it would seem that we are assuming that there is no energy transfer between the two gases; that is, we are assuming that the thermodynamic properties, in particular the temperatures, of the two gases are completely independent. We shall find, however, that it follows as a consequence of the approximate equality of the two gas densities that, if the temperatures are approximately equal at one point in space-time, then they must be approximately equal to everywhere. The approximate equality of the two charged gas densities is, of course, automatically maintained by the fact that strong electric fields cannot exist in a plasma. The approximate equality of the two temperatures at a single point, such as the center of the sun or earth's core, must be imposed as a boundary condition.

Completing the list of approximations that define our idealized model, we note that we employ a scalar theory of gravitation which, although it is a covariant theory, will not give the correct higher-order velocity dependence (such as we encounter in computing the advance of the perihelion of Mercury). This requires a theory based on a symmetric tensor, as in General Relativity, rather than one based on a scalar potential.

A scalar theory, however, is perfectly adequate for the needs of magnetogas dynamics. We shall also violate the Equivalence Principle as far as the mass associated with electromagnetic, thermal, and gravitational energy is concerned. That is, although all these contributions will be included in the inertial mass, they will not be included in either the active or passive gravitational mass, for which we use just the rest-mass. This approximation should also be adequate for the needs of almost all of the existing problems in magnetogas dynamics.

Plan of Presentation

As a preliminary to writing down the fundamental equation of motion for each of the two charged fluids (Euler's equation), it is shown in Section II that the necessary thermal properties of each fluid can be completely described in terms of the specific enthalpy of the fluid and the particle density. The great advantage of doing this is that the pressure term in Euler's equation can then be replaced by the gradient of the specific enthalpy, which then plays the role of a "thermal potential function" that is completely analogous to the scalar gravitational potential. This fact allows us to absorb both the gravitational and the thermal energy into the particle rest-mass, which is regarded as a scalar function of the space-time coordinates. In this way the particle rest-mass is made to play a dual role: It describes the inertial property of the particle, and at the same time serves as a potential function for the scalar force fields acting on the particle. In Appendix A, it is shown that this procedure has the added advantage that, when we replace the adiabatic condition by one that allows for fluid viscosity or energy injection, the form of Euler's equation (or the spinor equation that replaces it) remains unchanged. Only the form of the "thermal field equation," i.e. the equation that determines the specific enthalpy as a function of the fluid variables, is altered. This same remark is also valid if we drop the assumption that the two charged fluids are perfect gases.

After writing down Euler's equation in terms of specific enthalpy instead of pressure, the rest of Section II is devoted to showing that, if we limit ourselves to a certain subset of solutions that correspond to imposing certain physically reasonable conditions, Euler's equation can be replaced by a tensor equation that is linear except for the fact that the quadratic normalization condition for the 4-velocity must be satisfied.

In Section III, it is shown that it is this tensor equation, rather than Euler's equation, that results from the Hamilton-Jacobi formulation of the problem. In order to make the discussion more physical (as well as to simplify it), the Hamilton-Jacobi formulation is presented simply as the implementation of the deBroglie Hypothesis, reguarded as an experimental fact.

The conclusion drawn from Sections II and III is that the tensor equation is more fundamental than Euler's equation. In Section VIII it is shown that the spinor equations correspond to the tensor equation, rather than directly to Euler's equation. (Any solution of the tensor equation, of course, is a solution of Euler's equation, although the converse in general is not true.)

In Section IV the electromagnetic and gravitational field equations are presented.

In Section V the changes in the fluid-dynamical equations that result when we introduce particle spins are discussed.

Section VI is a summary of the results of the preceding sections, all of which have been derived within the framework of Special Relativity, but without any mention of spinors.

In Section VII spinors are introduced as the "square roots" of 4-vectors, and all the necessary dynamical quantities are defined in terms of spinors. The discussion is intended to be self-contained, and no prior knowledge of spinor analysis is assumed.

In Section VIII the postulated spinor equation of motion is presented, and the corresponding scalar, vector, and tensor equations that follow as direct consequences of the spinor equation and the definitions of Section VII are presented and discussed. The identification of these equations with the equations of magnetogas dynamics that were summarized in Section VI is made, and the advantages of the spinor formulation are discussed. No prior knowledge of spinor analysis is necessary to follow the discussion of this section. The detailed derivation of the results presented in this section is given in Appendix C, and here some familiarity with spinor analysis is assumed.

Choice of Metric

All the work of this paper is done within the framework of Special Relativity. The metric tensor g^{jk} that is used throughout is chosen to have the following form:

$$g^{00}=g_{00}=1;\ g^{jj}=g_{jj}=-1;\ g^{jk}=g_{jk}=0 \qquad (j,k=1,2,3)\ j\neq k \qquad (1\text{-}1)$$

This choice of metric, which is the most convenient for the transition to spinors, means that the

spatial components of the contravariant and covariant forms of a 4-vector differ by a sign. We shall always identify the *contravariant* form as being the four-dimensional generalization of the corresponding 3-vector. (The only exception is the gradient operator, discussed below.) Thus, if $\vec{v}$ is the particle 3-velocity, the 4-velocity u^j has the following form:

$$u^0=\frac{1}{\sqrt{1-\beta^2}}=u_0;\ \beta=\frac{v}{c}$$
$$u^j=\frac{u^0}{c}v^j=-u_j(j=1,\ 2,\ 3) \tag{1-2}$$

Note that this specification of u^j corresponds to a normalization to unity, rather than to c^2:

$$u^j u_j=1 \tag{1-3}$$

Because $(x^1,\ x^2,\ x^3)$ (rather than the covariant components) are identified with the coordinates $(x,\ y,\ z)$, it follows that the *covariant* form of the gradient operator ∂_j (rather than the contravariant form ∂^j) is the generalization of the 3-gradient $\vec{\nabla}=(\partial_x,\partial_y,\partial_z)$:

$$\partial_0=\frac{\partial}{c\partial t}=\partial^0$$
$$\partial_j=\frac{\partial}{\partial x^j}=-\partial^j\ (j=1,\ 2,\ 3) \tag{1-4}$$

and

$$\vec{\nabla}=(\partial_x,\ \partial_y,\ \partial_z)=(\partial_1,\ \partial_2,\ \partial_3) \tag{1-5}$$

The d'Alembertian operator $\Box$ is defined in terms of the 4-gradient ∂_j as follows:

$$\Box=\partial_j\partial^j=\frac{1}{c^2}\frac{\partial^2}{\partial t^2}-\vec{\nabla}^2 \tag{1-6}$$

We shall have occasion to use the completely antisymmetric unit tensor ϵ^{ijkl}, which is zero if any two of its indices are equal, and $+1$ or -1 if the indices are all different and their order differs from the order (0 1 2 3) by an even or odd number of transpositions respectively. The covariant form of the anti-symmetric unit tensor ϵ_{ijkl} is derived from the contravariant form ϵ^{mnpq} according to the usual rule:

$$\epsilon_{ijkl}=g_{im}\,g_{jn}\,g_{kp}\,g_{lq}\,\epsilon^{mnpq} \tag{1-7}$$

This relation has the consequence that the definition of the covariant form of the tensor differs bay sign from that of the contravariant form. Thus ϵ_{ijkl} is -1 (instead of $+1$) when the order of the indices $(ijkl)$ differs from the order (0 1 2 3)by an even number of transpositions.

Inasmuch as the definition of the contravariant form ϵ^{ijkl} is just the extension of the familiar three-dimensional antisymmetric unit tensor, whereas the definition of the covariant form differs by a sign, we see that these definitions are consistent with the general rule that it is the contravariant form of a quantity, rather than the covariant form, that we regard as the generalization to four dimensions of the corresponding three-dimensional quantity.

II EULER FORMULATION

Thermodynamic Properties

As a preliminary to writing down the Euler equation for each of the charged fluids, we shall first consider the thermodynamic properties of the fluids. All these properties will appear in duplicate, one for each fluid. This fact will be indicated by the symbol $(\pm)$ used usually as a subscript, but sometimes as a superscript when the symbol in question already has a subscript. When we have a product of quantities all referring to one of the two fluids, the symbol $(\pm)$ will be appended to the entire product instead of to each symbol in the product individually. Our notation for the necessary thermodynamic quantities is defined as follows:

$P_{(\pm)}\equiv$ pressure
$T_{(\pm)}\equiv$ absolute temperature
$m_{(\pm)}\equiv$ particle rest-mass
$\rho_{(\pm)}\equiv$ particle density in fluid rest-frame
$V_1{}^{(\pm)}\equiv$ volume per unit mass (specific volume)
$k\equiv$ Boltzmann's constant $=1.3708\times10^{-16}$ *erg/°k*
$f_{(\pm)}\equiv$ number of degrees of freedom per particle
$u_{(\pm)}\equiv$ internal thermal energy per unit mass
$h_{(\pm)}\equiv$ enthalpy per unit mass (specific enthalpy)
$s_{(\pm)}\equiv$ entropy per unit mass (specific entropy)
$c_v{}^{(\pm)}\equiv$ constant volume specific heat referred to unit mass
$c_p{}^{(\pm)}\equiv$ constant pressure specific heat referred to unit mass
$\gamma_{(\pm)}\equiv$ ratio of specific heat $=(c_p/c_v)_{(\pm)}$

We note that because $u_{(\pm)}$ and $h_{(\pm)}$ are referred to unit mass, $(mu)_{(\pm)}$ and $(mh)_{(\pm)}$ represent respectively the internal thermal energy per particle, and the enthalpy per particle.

By definition

$$h_{(\pm)} \equiv u_{(\pm)} + (PV_1)_{(\pm)} \tag{2-1}$$

PV_1 is the amount of work that could be done by the gas surrounding a bubble of unit mass of the gas if this bubble were removed (or its molecules cooled to absolute zero) and the surrounding gas allowed to move in and occupy the space that had been occupied by the bubble. (We assume, of course, that the bubble is so small compared with the surrounding atmosphere of gas that, when the surrounding gas moves in to occupy the space previously occupied by the bubble, the pressure P of the gas does not change significantly. Because the energy PV_1, as well as the energy u, is theoretically available for conversion into work, h, rather than u, is to be regarded as the potential thermal energy associated with a bubble of unit mass of the gas. (Because the energy PV_1 is really provided by the gas surrounding the bubble, rather than the gas within the bubble, it would be more accurate to say that h is the potential thermal energy to be associated with the *region of space occupied by the bubble.*)

The above argument indicates why h is often referred to as "the heat function" and is regarded as the total thermal energy content of the gas. It is not surprising that, as we shall see below, mh, rather than mu, is the thermal potential energy of the particle, analogous to the gravitational potential energy mg, where g is the gravitational scalar potential.

Further intuitive support for the idea that it is h, rather than u, that plays the role of a thermal potential comes from the fact that, for adiabatic flow of a gas through an insulated pipe in which the gas performs no work, the governing equation has the following form: kinetic energy + potential energy + enthalpy = constant. Thus the enthalpy enters the equation in the same way as potential energy. In the case of large-scale adiabatic convection flow within a fluid, we may think of the fluid as flowing in pipes whose walls are defined by the flow lines.

The above arguments are intended only to provide an intuitive understanding of the results ensuing from the formalism below, but no use will be made of them in the formalism.

We now postulate that both charged fluids are perfect gases. Thus the following relations are valid:

$$c_v^{(\pm)} = \frac{k}{2}\left(\frac{f}{m}\right)_{(\pm)} \tag{2-2a}$$

$$c_p^{(\pm)} = c_v^{(\pm)} + \frac{k}{m_{(\pm)}} = \frac{k}{m_{(\pm)}}\left(1 + \frac{1}{2}f_{(\pm)}\right) \tag{2-2b}$$

$$\gamma_{(\pm)} = (c_p/c_v)_{(\pm)} = 1 + \frac{2}{f_{(\pm)}} \tag{2-3}$$

$$u_{(\pm)} = (c_v T)_{(\pm)} \tag{2-4}$$

$$h_{(\pm)} = (c_p T)_{(\pm)} \tag{2-5}$$

$$P_{(\pm)} = k(\rho T)_{(\pm)} \tag{2-6}$$

$$s_{(\pm)} = [c_v \ln T - \frac{k}{m} \ln \rho + \text{constant}]_{(\pm)} \tag{2-7}$$

We choose $h_{(\pm)}$ and $\rho_{(\pm)}$ as our thermodynamic variables, and note that the other quantities can be expressed in terms of these variables as follows:

$$P_{(\pm)} = k\left(\frac{\rho h}{c_p}\right)_{(\pm)} = \left[\rho m h\left(1 - \frac{1}{\gamma}\right)\right]_{(\pm)} \tag{2-8}$$

$$T_{(\pm)} = (h/c_p)_{(\pm)} = \left[\frac{mh}{k(1+\frac{1}{2}f)}\right]_{(\pm)} \tag{2-9}$$

$$u_{(\pm)} = (h/\gamma)_{(\pm)} \tag{2-10}$$

$$s_{(\pm)} = \left[\frac{k}{m}(\tfrac{1}{2}f \ln h - \ln \rho) + \text{constant}\right]_{(\pm)} \tag{2-11}$$

From (2-1) we have

$$\partial_j h_{(\pm)} = \left[(\partial_j u + P\partial_j V_1) + \frac{1}{\rho m}\partial_j P\right]_{(\pm)} \tag{2-12}$$

where we have used the fact that, by definition

$$V_1^{(\pm)} = \frac{1}{(\rho m)_{(\pm)}} \tag{2-13}$$

Since $\Delta u - P\Delta V_1$ is the heat injected into unit mass of the gas during the change indicated by the

increment symbol Δ, we can interpret $(\Delta x^j)(\partial_j u - P\partial_j V_1)$ as the heat injected into unit mass of the gas during the virtual displacement (in time or space) described by Δx^j. Thus $\partial^j u - P\partial^j V_1$ can be regarded as the 4-force per unit mass caused by heat injection. Let Q^j be this force. Thus

$$Q^j{}_{(\pm)} = [\partial^j u + P\partial^j V_1]_{(\pm)} \tag{2-14}$$

We note that, using (2-8) and (2-10), we can rewrite (2-14) as follows:

$$[\rho\partial^j h - (\gamma-1)h\partial^j\rho - \rho\gamma Q^j]_{(\pm)} = 0 \tag{2-15}$$

Substituting (2-14) into (2-12), we have

$$[\rho m\partial^j h]_{(\pm)} = [\rho m Q^j - \partial^j P]_{(\pm)} \tag{2-16}$$

In order to exploit this relation, we shall introduce a variable particle mass $\breve{m}_{(\pm)}$, defined as follows:

$$\breve{m}_{(\pm)} = m_{(\pm)}(1 + g/c^2 + h_{(\pm)}/c^2) \tag{2-17}$$

where g is the gravitational potential. Thus $\breve{m}_{(\pm)}$ is the total particle mass, taking the mass associated with the gravitational and thermal energy as well as the rest-mass, into account. Because, in the situations in which we shall be primarily interested (e.g., the interior of the sun), the positive thermal energy is insufficient to overcome the negative gravitational energy, we shall refer to $\breve{m}_{(\pm)}$ as the "bound particle mass" and $\breve{m}_{(\pm)}$ as the "free particle mass."

From (2-16) and 2-17), we have

$$[\rho\partial^j(\breve{m}c^2)]_{(\pm)} = [\rho m\partial^j g + \partial^j P \cdot + \rho m Q^j]_{(\pm)} \tag{2-18}$$

The significance of this relation becomes apparent when we note that the three terms on the right are the force-per-unit-volume terms that appear in Euler's equation. (Equation (2-18) has been written in contravariant form to emphasize that this, rather than the covariant form, is the generalization of 3-force.)

Euler's equation for the charged fluids has the following form:

$$\left[\rho\frac{d(\breve{m}cu^j)}{d\tau}\right]_{(\pm)} = [\rho m\partial^j g + \partial^j P + \rho m Q^j]_{(\pm)} \pm qF^{jk}(\rho u_k)_{(\pm)} \tag{2-19}$$

where

$\tau_{(\pm)} \equiv$ proper time

$q \equiv$ magnitude of particle charge (always positive)

$F^{jk} \equiv$ Maxwell field tensor

In terms of the electric field intensity $\vec{E}$ and the magnetic flux density $\vec{B}$, the tensor F^{jk} is defined or follows:

$$(F^{10}, F^{20}, F^{30}) \equiv (E_x, E_y, E_z) = \vec{E} \text{ (statvolts/cm)}$$

$$(F^{23}, F^{31}, F^{12}) \equiv -(B_x, B_y, B_z) = -\vec{B} \text{ (Gauss)}$$

$$F^{jk} = -F^{kj} \tag{2-20}$$

where the units have been given to indicate that we shall use Gaussian units throughout. (All dynamical quantities will be expressed in *cgs* absolute units.)

Referring to (1-2), we note the following:

$$\frac{d}{d\tau} = cu^j\partial_j = u^0\left[\frac{\partial}{\partial t} + \vec{v}\cdot\vec{\nabla}\right] \tag{2-21}$$

Using (2-20) and (2-21), we can write (2-19) in the more familiar three-dimensional form:

$$\left\{(\rho u^0)\left[\frac{\partial(\breve{m}u^0c^2)}{\partial t} + \vec{v}\cdot\vec{\nabla}(\breve{m}u^0c^2)\right]\right\}_{(\pm)} = \left[\rho m\frac{\partial g}{\partial t} + \frac{\partial p}{\partial t} + \rho mcQ^0\right]_{(\pm)} \pm q(\rho u^0\vec{v})_{(\pm)}\cdot\vec{E} \tag{2-22a}$$

$$\left\{(\rho u^0)\left[\frac{\partial(\breve{m}u^0\vec{v})}{\partial t} + \vec{v}\cdot\vec{\nabla}(\breve{m}u^0\vec{v})\right]\right\}_{(\pm)} = [-\rho m\vec{\nabla}g - \vec{\nabla}p + \rho m\vec{Q}]_{(\pm)} \pm q(\rho u^0)_{(\pm)}\left(\vec{E} + \frac{1}{c}\vec{v}_{(\pm)}\times\vec{B}\right) \tag{2-22b}$$

where

$$\vec{Q}_{(\pm)} = (Q^1, Q^2, Q^3)_{(\pm)} = -(Q_1, Q_2, Q_3)_{(\pm)} \tag{2-23}$$

The physical interpretation of (2-22) is immediately evident when we recall that ρu^0 and $\breve{m}u^0$ are respectively particle density and particle mass *in the observer's reference frame.* $(\rho mcQ^0)_{(\pm)}$ obviously represents the rate at which energy is

injected per unit volume by nuclear or other reactions, and/or the heat energy generated by fluid viscosity, and $(\rho m\vec{Q})_{(\pm)}$ represents the viscous force, and/or the effective force resulting from heat injection caused by nuclear or other reactions.

The advantage of working with specific enthalpy becomes apparent when we substitute (2–18) into (2–19):

$$\left[\frac{d(\breve{m}cu^j)}{d\tau}\right]_{(\pm)} = \partial^j(\breve{m}_{(\pm)}c^2) \pm qF^{jk}u_k^{(\pm)} \quad (2\text{–}24)$$

We have assumed in writing (2–24) that $\rho_{(\pm)}$ is everywhere non-zero, so that it is permissible to divide an equation through by it.

The advantage of (2-24) over (2–19) is twofold: First, we have eliminated $Q^j{}_{(\pm)}$ from Euler's equation, and transferred it instead to (2–15) which may be regarded as a "thermal field equation" on a par with the gravitational and electromagnetic field equations. Thus, regardless of whether or not we introduce fluid viscosity or heat injection by nuclear reactions, we can always regard (2–24), with $\breve{m}_{(\pm)}$ defined by (2–17), as the governing fluid dynamical equation for each charged fluid. In fact, this is true even if we drop the postulate that the charged fluids are perfect gases. Second, $\rho_{(\pm)}$ does not appear in (2–24), which has the form of a single-particle equation. This would appear to allow us to solve first for $u^j{}_{(\pm)}$ without concerning ourselves about $\rho_{(\pm)}$ and then, knowing $u^j{}_{(\pm)}$, we would find $\rho_{(\pm)}$ from the continuity equation:

$$\partial_j(\rho u^j)_{(\pm)} = 0 \quad (2\text{–}25)$$

whose three-dimensional form is

$$\frac{\partial(\rho u^0)_{(\pm)}}{\partial t} + \vec{\nabla}\cdot[(\rho u^0)\vec{v}]_{(\pm)} = 0 \quad (2\text{–}26)$$

In actual fact, of course, $\rho_{(\pm)}$ enters into (2–24) implicitly through $h_{(\pm)}$ which, as we see from (2–15), is a function of $\rho_{(\pm)}$. In an iteration solution, however, we may regard $h_{(\pm)}$ as a specified function of the space-time coordinates. In such a case, use of (2–24) allows a separation of the solution of $\rho_{(\pm)}$ and $u^j{}_{(\pm)}$ whereas (2–19) does not.

Thus far we have not introduced the assumption that our fluid flow is reversible. If we now introduce this assumption, we have the following relation:

$$Q^j_{(\pm)} = [T\partial^j s]_{(\pm)} = \left[\frac{h}{c_p}\partial^j s\right]_{(\pm)} \quad (2\text{–}27)$$

Using this, we can integrate (2–15) to obtain the following expression for $h_{(\pm)}$:

$$h_{(\pm)} = [H(\rho/\rho_0)^{(\gamma-1)}e^{(s-s_0)/c_p}]_{(\pm)}$$

(reversible flow) (2–28)

where $\rho_0{}^{(\pm)}$ and $s_0{}^{(\pm)}$ are the density and specific entropy respectively at a certain fixed point $x^j_{(0)}$ in space-time (and hence constants). $H_{(+)}$ and $H_{(-)}$ are two constants that must be specified as part of the boundary conditions of the problem. Obviously,

$$H_{(\pm)} = [h(x^j_{(0)})]_{(\pm)} = [c_p T(x^j_{(0)})]_{(\pm)} \quad (2\text{–}29)$$

Thus, the constants $H_{(+)}$ and $H_{(-)}$ can be determined from a knowledge of the fluid temperatures at the point $x^j_{(0)}$.

The equation (2–28) may be used as the "thermal field equation" in preference to (2–15). Equation (2–15) has the advantage, however, that it is valid even when condition (2–27) is not satisfied. If, for example, we wished to introduce viscosity into the problem by requiring that Q^j be a suitable function of the derivatives of u^j, then in general (2–27) will not be satisfied. In such a case (2–28) would not be valid, whereas (2–15) would.

We have indicated the way in which viscosity or heat injection through nuclear reactions would be introduced into the problem by specifying an appropriate functional form for $Q^j{}_{(\pm)}$. We have shown that such a procedure would in no way alter our basic dynamical equation (2–24). Only the "thermal field equation" (2–15) would be altered. The ultimate purpose of this paper is to find a spinor alternative to the vector equation (2–24), and the way we choose to handle $Q^j{}_{(\pm)}$ makes no difference in the form of this equation. Both for the sake of definiteness, and because we noted in Section I that the adiabatic case was a sensible first step of a two-step process for solving the total self-excited dynamo problem, we shall now introduce the *adiabatic condition:*

$$Q^j{}_{(\pm)} = 0 \quad \text{(adiabatic condition)} \quad (2\text{–}30)$$

In Appendix A several alternatives to (2-30) are discussed, but for the rest of the body of the paper we shall assume that (2-30) holds. Thus the "thermal field equation" (2-15) becomes

$$[\rho\partial_j h-(\gamma-1)h\partial_j\rho]_{(\pm)}=0 \quad \text{(adiabatic case)} \quad (2\text{-}31)$$

and its integral is

$$h_{(\pm)}=[H(\rho/\rho_0)^{(\gamma-1)}]_{(\pm)} \quad \text{(adiabatic case)} \quad (2\text{-}32)$$

We may use either (2-31) or (2-32) as our adiabatic "thermal field equation."

Now we note that if the following relations are valid

$$\gamma_{(+)}=\gamma_{(-)} \quad (2\text{-}33a)$$

$$\rho_{(+)}\approx\rho_{(-)} \quad (2\text{-}33b)$$

$$(mH)_{(+)}\approx(mH)_{(-)} \quad (2\text{-}33c)$$

then it follows from (2-32) that

$$(mh)_{(+)}\approx(mh)_{(-)} \quad (2\text{-}34)$$

and from (2-8) and (2-9) that

$$P_{(+)}\approx P_{(-)} \quad (2\text{-}35)$$

and

$$T_{(+)}\approx T_{(-)} \quad (2\text{-}36)$$

(2-33a) is valid because the electron and proton gases are both monatomic gases. The approximate equality (2-33b) will be maintained automatically by the electrostatic screening effect. (2-33c) must be imposed as a boundary condition. From (2-2b) and (2-29) it is evident that this amounts to requiring that the electron and proton temperatures be approximately equal at a particular point in space-time (e.g., the center of the sun at $t=0$). (2-35) and (2-36) then tell us that the two pressures and temperatures are approximately equal throughout space for all time. The significance of this statement is that, even through our way of formulating the problem in terms of two independent specific enthalpies $h_{(+)}$ and $h_{(-)}$ would at first glance appear to let the electron and proton pressures and temperatures differ wildly from each other, in actual fact (if we impose the boundary condition (2-34)) the two pressures and the two temperatures are automatically constrained to remain very nearly equal to each other. This is a satisfying state of affairs since we know that because of particle collisions the two temperatures cannot differ greatly.

Tensor Alternative to Euler's Equation

Equation (2-24), which is the form of Euler's equation that we shall use throughout, is a 4-vector equation. We shall now derive an alternative equation in which all the terms are antisymmetric tensors. This is most easily done by starting with the three-dimensional form given in (2-22b) (except that the bracket on the right is replaced by $-]\rho\vec{\nabla}(\breve{m}c^2)]_{(\pm)}$ and the term $[\vec{v}\cdot\vec{\nabla}(\breve{m}u^0\vec{v})]_{(\pm)}$ on the left is transformed by means of a well-known vector identity):

$$\frac{\partial(\breve{m}u^0\vec{v})}{\partial t}_{(\pm)}+\vec{\nabla}(\breve{m}u^0c^2)_{(\pm)}-\vec{v}_{(\pm)}\times[\vec{\nabla}\times(\breve{m}u^0\vec{v})_{(\pm)}]$$

$$\pm q\left(\vec{E}+\frac{1}{c}\vec{v}_{(\pm)}\times\vec{B}\right) \quad (2\text{-}37)$$

It can be shown that (2-22a) results from the dot product of both sides of (2-37) with $\vec{v}_{(\pm)}$.

Now we note that if we impose the condition

$$\vec{\nabla}\times(\breve{m}u^0\vec{v})_{(\pm)}=\mp\frac{q}{c}\vec{B} \quad (2\text{-}38)$$

(2-37) reduces to

$$\frac{\partial(\breve{m}u^0\vec{v})_{(\pm)}}{\partial t}+\vec{\nabla}(\breve{m}u^0c^2)_{(\pm)}=\pm q\vec{E} \quad (2\text{-}39)$$

These two 3-vector equations can be combined into the following single tensor equation:

$$\partial^j(\breve{m}cu^k)_{(\pm)}-\partial^k(\breve{m}cu^j)_{(\pm)}=\mp\frac{q}{c}F^{jk} \quad (2\text{-}40)$$

This is the tensor alternative to Euler's equation (2-24). Regarding $\breve{m}$ and F^{jk} as fixed functions of the space-time coordinates, (2-40) is a linear equation, whereas Euler's equation is nonlinear. The linearity of (2-40) is spoiled, however, by the fact that we must maintain the normalization condition (1-3) for the 4-velocity:

$$(u^ju_j)_{(\pm)}=1 \quad (2\text{-}41)$$

Thus we must still contend with the algebraic nonlinearity of (2-41). In the case of Euler's equation, the condition (2-41) must also be satisfied. In addition, we have what we might term

a "differential nonlinearity" in Euler's equations itself because of the presence of the term $[u^l\partial_l(\mathring{m}cu^j)]_{(\pm)}$. Thus, by replacing (2–24) with (2–40), we have rid ourselves of the differential nonlinearity, but are still left with the algebraic nonlinearity (2–41).

It is evident that the tensor equation (2–40) is not exactly equivalent to Euler's equation, because it corresponds only to the subset of solutions of (2–37) that satisfy the condition (2–38). Either we regard (2–37) as more fundamental than (2–40), with the result that by working with (2–40) we are excluding physically meaningful, and perhaps important, solutions from consideration; or, we take the point of view that (2–38) is a physically necessary condition, and the solutions of (2–37) that do not satisfy (2–38) have no physical validity. In order to help convince ourselves that the latter situation is actually the case, we shall first investigate the physical meaning of condition (2–38).

To this end, we let $\mathring{\vec{B}} = [\vec{B}]_{v(\pm)=0}$ be the magnetic field in the local fluid rest-frame.

Then from (2–38) we have

$$[(\vec{\nabla}\times\vec{v})_{v=0}]_{(\pm)} = -\frac{q}{\mathring{m}_{(\pm)}c}\mathring{\vec{B}} \qquad (2\text{–}42)$$

The left-hand side is the fluid vorticity The presence of vorticity means that at the microscopic level the fluid can be regarded as rotating like a rigid body with the angular velocity $\mathring{\vec{\Omega}}_{(\pm)}$ where

$$\mathring{\Omega}_{(\pm)} = \tfrac{1}{2}[(\vec{\nabla}\times\vec{v})_{v=0}]_{(\pm)} \qquad (2\text{–}43)$$

Thus we have

$$\mathring{\vec{\Omega}}_{(\pm)} = \mp\frac{q}{2\mathring{m}_{(\pm)}c}\mathring{\vec{B}} \qquad (2\text{–}44)$$

which is just the Larmor Condition. The physical interpretation of this condition is that there can be no local vorticity, or rotation, in the charged fluid without a magnetic field to provide, via the Lorentz force, the necessary Coriolis force.

From (2–38) we note that large-scale vorticity ($\vec{v}\neq 0$) is possible even in the absence of a magnetic field, because then the gravitational force and/or the pressure gradient can provide the necessary Coriolis and centripetal forces.

Thus we see that for a charge *fluid*, (2–38) is a physically necessary condition. It must be emphasized that the Larmor Condition is necessary for a fluid, but not for a single particle. In the case of a single particle moving in a circular orbit, for example, the condition relating angular velocity and magnetic field is that the Lorentz force must provide the necessary centripetal force. This condition, which defines the so-called cyclotron frequency, is identical to (2–44) except that the factor 2 is absent in the denominator on the right. The Euler equation guarantees that this condition is fulfilled, since it is just the generalization of the condition on the Lorentz force for arbitrary particle orbits.

In the case of a fluid, we must allow for the fact that, in addition to the rotational velocity which requires a centripetal force, there is a random thermal velocity which, together with the rotation of the fluid, gives rise to a Coriolis accelcration which must also be taken into account. For given angular velocity, the required centripetal force is proportional to the size of the fluid vortex being considered, and so vanishes in the limit of zero vortex radius, which is the limit involved in the evaluation of $\vec{\nabla}\times\vec{v}$ in (2–43). The Coriolis force, however, remains finite in this limit since the thermal velocity on which it depends is independent of vortex size. This is the reason why, for a fluid, the Lorentz force must be equated to the Coriolis force alone.

We noted that, in the case of a single particle, the Euler equation itself guaranteed that the Lorentz force would have the proper value in relation to the characteristics of the particle orbit. In the case of a fluid, however, an extra side condition, namely (2–38), is needed to guarantee that the magnetic field strength will have the proper relation to the vorticity. The reason for the need for an extra side condition is that this condition arises from the presence of thermal velocity, which is not represented in the Euler equation. (Only the *energy* of thermal motion is represented via the enthalpy, but the detailed *momentum* and *force* considerations associated with thermal motion—namely the need for a Coriolis force—cannot be represented in Euler's equation.)

Thus, we conclude that the solutions of (2–37) which do *not* satisfy the condition (2–38), and hence are lost when we use (2–40) instead of

(2–37), are those corresponding to an absolutely cold fluid with no thermal motion. In such a case there is no need to impose the Larmor Condition, and the problem of calculating fluid flow is no different from that of calculating particle orbits. If, however, thermal motions are present in the fluid (i.e., $h \neq 0$), the Larmor Condition must be imposed. Except for this extra side condition, the fluid problem is still the same as the problem of calculating particle orbits (except that we must introduce the thermal potential h), since solutions of the tensor equation (2–40) are always solutions of (2–24), which has the form of a single particle equation.

We have used above a physical argument to convince ourselves that the tensor equation is more fundamental (for real fluids) than Euler's equation. In the next section we shall use a more formal argument to arrive at the same conslusion, in that we shall show that the Hamilton-Jacobian formulation of the magnetogas-dynamical problem leads to the tensor equation, rather than to Euler's equation. To simplify the discussion, as well as to lend it greater physical signifiance, we shall present the Hamilton-Jacobian formulation as the incorporation of the de Broglie Hypothesis, regarded as an experimental fact, into the formalism.

III HAMILTON—JACOBI FORMULATION

We take as our starting point the following well-known expression for the canonical particle momentum p^j in the presence of an electromagnetic field represented by the 4-vector potential A^j:

$$p^j_{(\pm)} = (\check{m}cu^j)_{(\pm)} \pm \frac{q}{c}A^j \tag{3–1}$$

The feature of the Hamilton-Jacobi formalism that is vital to our present considerations is the fact that p^j can be represented as the gradient of a scalar function Φ, which is Hamilton's Characteristic Function. Thus

$$p^j_{(\pm)} = -\partial^j \Phi_{(\pm)} \tag{3–2}$$

or, in three-dimensional form

$$p^0_{(\pm)} = -\frac{1}{c}\frac{\partial \Phi_{(\pm)}}{\partial t} \tag{3–3a}$$

$$\vec{p}_{(\pm)} = (p^1, p^2, p^3) = \vec{\nabla}\Phi_{(\pm)} \tag{3–3b}$$

From the point of view of the Hamilton-Jacobi formalism, (3–2) is part of a contact transformation that carries the Hamiltonian function over into a form that allows an easy solution. It is physically more significant, however, if we take the point of view that (3–2) is just the expression of the de Broglie Hypothesis, which we regard as an experimental fact that must be incorporated into our theory. In its usual form, the de Broglie Hypothesis states that for every *particle* there exists a scalar function whose gradient is the particle momentum. In order to adapt this statement to a *fluid*, it is necessary to impose the requirement that Φ be a *continuous* function of the space-time coordinates. Thus, in the same way that the fluid picture of a gas (as opposed to the kinetic theory picture) requires that the fluid velocity must not vary in a rapid and random way, but rather must be a smoothly varying function, we require that the phase function of the fluid must also be a smoothly varying function. This continuity postulate is implicit in (3–2).

Substituting (3–2) into (3–1), we have

$$-\partial^j \Phi_{(\pm)} = (\check{m}cu^j)_{(\pm)} \pm \frac{q}{c}A^j \tag{3–4}$$

Taking the curl of (3–4), we have

$$\partial^j(\check{m}cu^k)_{(\pm)} - \partial^k(\check{m}cu^j)_{(\pm)} = \mp\frac{q}{c}(\partial^j A^k - \partial^k A^j) = \mp\frac{q}{c}F^{jk} \tag{3–5}$$

where we have used the fact that the curl of A^j is the Maxwell field tensor F^{jk}. This equation is just the tensor alternative (2–40) to Euler's equation that was introduced in Section II. As was noted there, this equation (like Euler's) must be supplemented by the continuity and normalization conditions:

$$\partial_j(\rho u^j)_{(\pm)} = 0 \tag{3–6}$$

$$(u^j u_j)_{(\pm)} = 1 \tag{3–7}$$

If we solve (3.4) for $u^j_{(\pm)}$ and substitute into (3–7), we obtain

$$\left(\partial_j \Phi_{(\pm)} \pm \frac{q}{c}A_j\right)\left(\partial^j \Phi_{(\pm)} \pm \frac{q}{c}A^j\right) = (\check{m}_{(\pm)}c)^2 \tag{3–8}$$

which is just the well-known Hamilton-Jacobi equation.

If we regard A^j and $\check{m}_{(\pm)}$ as given space-time functions, then in principle we can solve (3–8) for $\Phi_{(\pm)}$ and use this in (3–4) to find $u^j_{(\pm)}$, which would then automatically satisfy (3–7). (It would still be necessary to impose (3–6).)

Alternatively, we could ignore (3–8), and regard (3–5) – (3–7) as our basic system of equations.

To return to the question of weighing the tensor equation (3–5) against Euler's equation (2–24), we note that if we contract (3–5) with u_j, and use the relations

$$u_j\partial^j=\frac{1}{c}\frac{d}{d\tau} \tag{3–9}$$

and

$$u_j\partial^k u^j=\tfrac{1}{2}\partial^k(u_ju^j)=0 \tag{3–10}$$

the result is

$$\left[\frac{d(\check{m}cu^k)}{d\tau}\right]_{(\pm)}=\partial^k(\check{m}c^2)_{(\pm)}\pm qF^{kj}u_j^{(\pm)} \tag{3–11}$$

which is just Euler's equation.

Thus we have seen that it is the tensor equation, rather than Euler's equation, that results from the Hamilton-Jacobi formulation of the problem, and that Euler's equation (which is nonlinear) results from the tensor equation (which is linear) by contracting the latter with u_j. It is this contraction process that introduces the term quadratic in u_j, and hence the nonlinearity, into Euler's equation. Thus the nonlinearity of Euler's equation can be regarded as physically spurious, resulting from the unnecessary contraction of the tensor equation with u_j.

IV FIELD EQUATIONS

It was noted in Section I that the purpose of this paper is to transform the dynamical half of the magnetogas-dynamical problem, replacing Euler's equation by a spinor equation. The source equations for the electromagnetic and gravitational fields will be just Maxwell's equation and the four-dimensional Poisson equation respectively. In order to define the notation and to provide a convenient reference, the relevant field equations will be briefly discussed in this section.

Electromagnetic Field

The definition for the elements of the Maxwell field tensor F^{jk} in terms of the electric field intensity $\vec{E}$ and the magnetic flux density $\vec{B}$ has been given in (2–20). The four-dimensional form of Maxwell's equations (in unrationalized Gaussian units) is

$$\partial_jF^{jk}=4\pi q[(\rho u^k)_{(+)}-(\rho u^k)_{(-)}] \tag{4–1}$$

where $q=4.802\times10^{-10}$ statcoulomb is the magnitude (always positive) of the electron and proton charge, and $(\rho u^k)_{(+)}$ and $(\rho u^k)_{(-)}$ are the flux densities of the proton and electron gases respectively. The three-dimensional form of (4–1) is

$$\vec{\nabla}\cdot\vec{E}=4\pi q[(\rho u^0)_{(+)}-(\rho u^0)_{(-)}] \tag{4–2a}$$

$$\vec{\nabla}\times\vec{B}=\frac{4\pi}{c}q[(\rho u^0\vec{v})_{(\pm)}-(\rho u^0\vec{v})_{(-)}]+\frac{1}{c}\frac{\partial\vec{E}}{\partial t} \tag{4–2b}$$

The field tensor F^{jk} is related to the 4-vector potential in the usual way:

$$F^{jk}=\partial^jA^k-\partial^kA^j \tag{4–3}$$

The vector equivalent of (4–1) is

$$\Box A^k-\partial^k(\partial_jA^j)=4\pi q[(\rho u^k)_{(+)}-(\rho u^k)_{(-)}] \tag{4–4}$$

where $\Box$ is the d'Alembertian operator defined in (1–6). The choice of gauge in (4–4) has been left arbitrary.

Let $\hat{F}^{jk}$ be the dual to F^{jk}. It is defined as follows:

$$\hat{F}^{jk}\equiv\tfrac{1}{2}\epsilon^{jkln}F_{ln}=\epsilon^{jkln}\partial_lA_n \tag{4–5}$$

where ϵ^{jkln} is the antisymmetric unit tensor defined at the end of Section I. Using (2–20) we have

$$(\hat{F}^{10},\hat{F}^{20},\hat{F}^{30})=(B_x,B_y,B_z)=\vec{B}$$

$$(\hat{F}^{23},\hat{F}^{31},\hat{F}^{12})=E_x,E_y,E_z)=\vec{E}$$

$$\hat{F}^{jk}=-\hat{F}^{kj} \tag{4–6}$$

From (4–5) we have

$$\partial_j\hat{F}^{jk}=\epsilon^{jkln}\partial_j\partial_lA_n=0 \tag{4–7}$$

Using (4–6), we have for the three-dimensional form of (4–7)

$$\vec{\nabla}\cdot\vec{B}=0 \tag{4–8a}$$

$$\vec{\nabla}\times\vec{E}+\frac{1}{c}\frac{\partial\vec{B}}{\partial t}=0 \tag{4–8b}$$

which, together with (4–2), constitute Maxwell's equations in three-dimensional form. We note that the equations (4–8) follow directly from the introduction of the 4-vector potential; that is, these equations are the justification for introducing the 4-vector potential.

We remark, incidentally, that using (4–5), it is easy to show that (4–7) can be written in the following alternative form:

$$\partial^j F^{kl}+\partial^k F^{lj}+\partial^l F^{jk}=0 \tag{4–9}$$

We note that, because of the antisymmetry of F^{jk}, the left side of this equation vanishes identically when any two indices have the same value.

Let E^{jk} be the electromagnetic stress-energy tensor. As is well-known, it has the following form:

$$E^{jk}=\frac{1}{4\pi}\left[F^{jl}F^{k}_{\ l}+\frac{1}{4}g^{jk}(F^{ln}F_{ln})\right] \tag{4–10}$$

where g^{jk} is the metric tensor specified in (1–1). Thus $4\pi E^{jk}$ may be regarded as the square (in the sense of matrix multiplication) of the field tensor F^{jk}, plus the diagonal tensor $\frac{1}{4}g^{jk}(F^{ln}F_{ln})$ where, using (2–20), we find

$$\tfrac{1}{4}(F^{ln}F_{ln})=\tfrac{1}{2}(\vec{B}^2-\vec{E}^2) \tag{4–11}$$

Using (4–10) and (2–20), we find the following well-known expressions for the elements of E^{jk}:

$$E^{00}=\frac{1}{8\pi}(\vec{E}^2+\vec{B}^2)$$
$$\equiv\text{electromagnetic energy density} \tag{4–12a}$$

$$c(E^{01}, E^{02}, E^{03})=c(E^{10}, E^{20}, E^{30})=\frac{c}{4\pi}(\vec{E}\times\vec{B})$$
$$\equiv\vec{U}_{em}\equiv\text{electromagnetic energy flux density (Poynting's vector)} \tag{4–12b}$$

$$E^{jk}=-\left[E^{00}g^{jk}+\frac{1}{4\pi}(E^jE^k+B^jB^k)\right]$$
$$=\text{electromagnetic stress tensor}$$
$$(j, k=1, 2, 3) \tag{4–12c}$$

where

$$(E^1, E^2, E^3)\equiv(E_x, E_y, E_z)$$
$$(B^1, B^2, B^3)\equiv(B_x, B_y, B_z) \tag{4–12d}$$

Using the fact that

$$g^j_{\ j}=4 \tag{4–13}$$

it is evident from (4–10) that

$$E^j_{\ j}=0 \tag{4–14}$$

Using (4–1), (4–9), and (4–10), we find the following well-known relation:

$$\partial_l E^{kl}=-gF^{kl}[(\rho u_l)_{(+)}-(\rho u_l)_{(-)}] \tag{4–15}$$

The time-like part of this, which is the statement of the conservation of energy, can be written as follows:

$$\frac{\partial E^{00}}{\partial t}+\vec{\nabla}\cdot\vec{U}_{em}=-q\vec{E}\cdot[(\rho u^0\vec{v})_{(+)}-(\rho u^0\vec{v})_{(-)}] \tag{4–16}$$

The expression on the right side represents the energy transferred per unit time per unit volume *from* the charged fluids *to* the electromagnetic field.

Gravitational Field

We postulate the following source equation for the scalar gravitational potential g:

$$\Box g=-4\pi\Gamma[(\rho m)_{(+)}+(\rho m)_{(-)}] \tag{4–17}$$

where $\Gamma=6.668\times10^{-8}$ dyne cm^2/gm^2 is the gravitational constant.

For the time-independent case in which the mass on the right is distributed with spherical symmetry, we find for $(-\vec{\nabla}g)$, which is the gravitational force per unit mass, the following:

$$-\vec{\nabla}g=-\frac{\Gamma m_s}{r^2}\vec{r}_1 \tag{4–18}$$

where $\vec{r}_1$ is the unit radial vector, and m_s is the total mass contained within the sphere of radius r. This, of course, is just the familiar Newtonian gravitational force. Thus (4–17) corresponds to a suitably covariant extension of Newtonian gravitation.

Because we are employing scalar theory, however, rather than a tensor theory as in General Relativity (in which the symmetric metric tensor effectively plays the role of a gravitational potential), we must expect to find that the velocity dependence of the gravitational force on a moving mass is not correct to higher orders of v/c. Moreover, since only the rest-mass appears on the right side of (4–17), our scalar theory neglects the gravitational effect of the mass arising from the thermal, electromagnetic, and gravitational energy of the electron and proton gases. However, these errors are negligible in most magnetogasdynamical problems of physical interest.

Let G^{jk} be the stress-energy tensor of the scalar gravitational field. It has the following form:

$$G^{jk}=\frac{1}{4\pi\Gamma}\left[(\partial^j g)(\partial^k g)-\frac{1}{2}g^{jk}(\partial^l g)(\partial_l g)\right] \tag{4–19}$$

That this is indeed the correct expression for G^{jk} can be verified by calculating $\partial_j G^{jk}$:

$$\partial_l G^{kl}=\frac{1}{4\pi\Gamma}[(\partial_j\partial^j g)\partial^k g+(\partial_j g)(\partial^j\partial^k g)-(\partial_l g)(\partial^k\partial^l g)]=\frac{1}{4\pi\Gamma}[(\Box g)(\partial^k g)]$$
$$=-[(\rho m)_{(+)}+(\rho m)_{(-)}]\partial^k g \tag{4–20}$$

The right side of (4–20) is just the negative of the gravitational force density acting on the two fluid fields. This is completely analogous with (4–15) in which the right side is the negative of the electromagnetic force density acting on the two charged fluid fields.

From (4–19) we find the following expressions for the elements of G^{jk}:

$$G^{00}=\frac{1}{8\pi\Gamma}\left[\frac{1}{c^2}\left(\frac{\partial g}{\partial t}\right)^2+(\vec{\nabla}g)^2\right] \tag{4–21a}$$
$\equiv$ gravitational energy density

$$c(G^{01}, G^{02}, G^{03})=c(G^{10}, G^{20}, G^{30})=-\frac{1}{4\pi\Gamma}\left(\frac{\partial g}{\partial t}\right)(\vec{\nabla}g)$$
$\equiv \vec{U}_{gr} \equiv$ gravitational energy flux density 4(–21b)

$$G^{jk}=\frac{1}{4\pi\Gamma}\left\{\frac{1}{2}\left[(\vec{\nabla}g)^2-\frac{1}{c}\left(\frac{\partial g}{\partial t}\right)^2\right]g^{jk}+(\partial^j g)(\partial^k g)\right\}$$
$(j, k=1, 2, 3) \equiv$ gravitational stress tensor (4–21c)

From (4–13) and (4–19) we find

$$G^j=-\frac{1}{4\pi\Gamma}(\partial^l g)(\partial_l g)=\frac{1}{4\pi\Gamma}\left[(\vec{\nabla}g)^2-\frac{1}{c^2}\left(\frac{\partial g}{\partial t}\right)^2\right] \tag{4–22}$$

Finally, we note that the time-like component of (4–20), which is the statement of conservation of energy, can be written as follows:

$$\frac{\partial G^{00}}{\partial t}+\vec{\nabla}\cdot\vec{U}_{gr}=-[(\rho m)_{(+)}+(\rho m)_{(-)}]\frac{\partial g}{\partial t} \tag{4–23}$$

where the right-hand side is just the energy transferred per unit time per unit volume *from* the two fluids *to* the gravitational field.

V SPIN EFFECTS

As was noted in Section I, we must take particle spin into account, not because it is physically significant in magnetogasdynamical problems, but rather because it is the price we must pay for the benefits of using the spinor formulation of the problem.

Magnetic Moment

Spin makes itself felt in two ways: through its magnetic moment, and through its angular momentum. We shall consider first the effects of the magnetic moment.

Let the direction of the magnetic moment of a particle in its rest-frame be specified by the 3-vector $\vec{\mu}_{(\pm)}$, which can be generalized to the 4-vector $\mu^j{}_{(\pm)}$ by specifying that the time-like component be zero in the particle rest-frame. We specify the magnitude of the magnetic moment of a particle by the scalar $\mu_{(\pm)}$. (We allow the possibility that $\mu_{(\pm)}$ is not a constant, but rather a function of the fluid and field variables. In Sector VIII we shall see that the functional form of $\mu_{(\pm)}$ is automatically specified by the spinor equations.)

The magnetic moment of a particle may also be described in terms of the antisymmetric tensor $(\mu s^{jk})_{(\pm)}$ where $s^{jk}{}_{(\pm)}$ is derived from $\mu^j{}_{(\pm)}$ and the particle 4-velocity $u^j{}_{(\pm)}$ as follows:

$$s^{jk}{}_{(\pm)} \equiv \epsilon^{jklm}(\mu_l u^n)_{(\pm)} \tag{5–1}$$

Thus

$$[\rho\mu(s^{23}, s^{31}, s^{12})]_{(\pm)}=[(\rho u^0)(\mu\dot{\vec{\mu}})]_{(\pm)} \tag{5–2a}$$

$$[\rho\mu(s^{10}, s^{20}, s^{30})]_{(\pm)}=\left\{(\rho u^0)\left[\frac{1}{c}\vec{v}\times(\mu\dot{\vec{\mu}})\right]\right\}_{(\pm)} \tag{5–2b}$$

where in (5–2b) we have made use of the fact that $\vec{v}x\vec{\mu}=\vec{v}x\dot{\vec{\mu}}$, which follows directly from the form of the Lorentz transformation.

Since ρu° is just the particle density in the observer's frame, (5–2a) tells us that the space-space part of $\rho\mu s^{jk}$ is just the magnetization of the fluid. We note that the cross-product inside the brackets on the right side of (5–2b) is just the well-known electric dipole associated with a moving magnetic dipole. Thus, even though electrons and protons have no electric dipole moment at rest, a spin-dependent electric polarization of the fluid is possible when there is motion.

Now we know that in a magnetized body there is an effective current density given by the curl of the magnetization. By analogy, we would expect a 4-momentum density to be associated with the angular momentum density arising from particle spin. If $\delta p^j{}_{(\pm)}$ is this extra 4-momentum density divided by ρ, i.e. the extra momentum per particle, than (3–4) must be replaced by

$$-\partial^j\Phi_{(\pm)}=(\tilde{m}cu^j)_{(\pm)}\pm\frac{q}{c}A^j+\delta p^j_{(\pm)} \qquad (5\text{–}3)$$

The form of this equation indicates that it should be possible to absorb $\delta p^j{}_{(\pm)}$ into the 4-potential, i.e., to express the spin effects as a small correction to the electromagnetic field. In order to be thorough about this, we must keep in mind that every particle has a contribution to its rest-mass $\Delta m_{(\pm)}$ arising from the interaction of the magnetic field and the magnetic dipole moment. If $\dot{\vec{B}}$ and $(\dot{\vec{\mu\mu}})_{(\pm)}$ are respectively the magnetic field and the magnetic dipole moment in the particle rest-frame, then the magnetic contribution to the particle rest-mass is

$$\Delta m_{(\pm)}=-\frac{1}{c^2}(\dot{\vec{\mu\mu}})_{(\pm)}\cdot\dot{\vec{B}}=\frac{1}{2c^2}(\mu s^{jk})_{(\pm)}F_{jk} \qquad (5\text{–}4)$$

where, in the second step, we have made use of (2–20) and (5–2).

If we wish to express the spins effects in terms of a small correction $a^j{}_{(\pm)}$ to the 4-vector potential A^j, then we must introduce a corresponding correction $f^{jk}{}_{(\pm)}$ to the field tensor F^{jk} where, in analogy, to (4–3), we have

$$f^{jk}{}_{(\pm)}=\partial^j a^k{}_{(\pm)}-\partial^k a^j{}_{(\pm)} \qquad (5\text{–}5)$$

Analogous to (2–20), we can define corrections $\vec{e}_{(\pm)}$ and $\vec{b}_{(\pm)}$ to the electric and magnetic field intensities $\vec{E}$ and $\vec{B}$ as follows:

$$\begin{aligned}&(f^{10}, f^{20}, f^{30})_{(\pm)}\equiv(e_x, e_y, e_z)_{(\pm)}=\vec{e}_{(\pm)}\\&(f^{23}, f^{31}, f^{12})_{(\pm)}\equiv-(b_x, b_y, b_z)_{(\pm)}=-\vec{b}_{(\pm)}\\&f^{jk}{}_{(\pm)}=-f^{jk}{}_{(\pm)}\end{aligned} \qquad (5\text{–}6)$$

If $f^{jk}{}_{(\pm)}$ is to be regarded as completely analogous to F^{jk}, then it should produce a contribution $\delta m_{(\pm)}$ to the particle rest-mass having the form of (5–4) with F_{jk} replaced by $f_{jk}{}^{(\pm)}$:

$$\delta m_{(\pm)}=-\frac{1}{c^2}[(\dot{\vec{\mu\mu}})\cdot\dot{\vec{b}}]_{(\pm)}=\frac{1}{2c^2}(\mu s^{jk}f_{jk})_{(\pm)} \qquad (5\text{–}7)$$

Let $\tilde{m}_{(\pm)}$ be the total magnetic contribution to the particle rest-mass. Then

$$\begin{aligned}\tilde{m}_{(\pm)}=\Delta m_{(\pm)}+\delta m_{(\pm)}&=-\frac{1}{c^2}[(\dot{\vec{\mu\mu}})\cdot(\dot{\vec{B}}+\dot{\vec{b}})]_{(\pm)}\\&=\frac{1}{2c^2}(\mu s_{jk})_{(\pm)}(F^{jk}+f^{jk}{}_{(\pm)})\end{aligned} \qquad (5\text{–}8)$$

If we regard $u^j{}_{(\pm)}$, $(\mu s^{jk})_{(\pm)}$, and $\delta p^j{}_{(\pm)}$ as known functions, then it is evident from (5–3) that $a^j{}_{(\pm)}$, is determined by the condition

$$\delta p^j_{(\pm)}=(\tilde{m}cu^j)_{(\pm)}\pm\frac{q}{c}a^j{}_{(\pm)} \qquad (5\text{–}9)$$

where from (5–5) and (5–8) we see that $\tilde{m}_{(\pm)}$ is a function of the derivatives of $a^j{}_{(\pm)}$. Thus (5–9) is a first-order differential equation for $a^j{}_{(\pm)}$. In actual fact, it will not be necessary to solve such an equation since, as we shall see in Section VIII, the spinor equations give us an expression for $a^j{}_{(\pm)}$ that automatically satisfies (5–9).

If we let $M_{(\pm)}$ be the total particle rest-mass, we have from (2–17) and (5–8)

$$\begin{aligned}M_{(\pm)}=\tilde{m}_{(\pm)}+\tilde{m}_{(\mp)}&=m_{(\pm)}(1+g/c^2+h_{(\pm)}/c^2)\\&+\frac{1}{2c^2}(\mu s_{jk})_{(\pm)}[F^{jk}+f^{jk}_{(\pm)}]\end{aligned} \qquad (5\text{–}10)$$

Substituting (5–9) and (5–10) into (5–3), we obtain

$$-\partial^j\Phi=(Mcu^j)_{(\pm)}\pm\frac{q}{c}[A^j+a^j_{(\pm)}] \qquad (5\text{–}11)$$

This way of formulating the dynamical effects of spin gives us an immediate intuitive feeling for these effects. Moreover it provides a neat way of determining when these effects can be neglected: If we can show that $|a^{j}_{(\pm)}| \ll |A^{j}|$, then we know that the dynamical effects of spin are negligible. We shall see in Section VIII that it is very easy to estimate the magnitude of the $a^{j}_{(\pm)}$ that results from the spinor equations, and that, in all magnetogas-dynamical problems on a laboratory or astronomical scale, $a^{j}_{(\pm)}$ is completely negligible compared with the magnitudes of A^{j} encountered in such problems. If, however, we were to attempt to apply our spinor formulation of magnetogas dynamics on an atomic or nuclear scale, then it turns out that the spin effects represented by the effective potential $a^{j}_{(\pm)}$ would be far from negligible.

We note that in general $a^{j}_{(+)} \neq a^{j}_{(-)}$. This is not surprising since the correction potentials $a^{j}_{(+)}$ and $a^{j}_{(-)}$ have their origins in dynamical effects of the spin fields $(\rho\mu^{j})_{(+)}$ and $(\rho\mu^{j})_{(-)}$ which are in general different. From a purely formal point of view, the equations that follow treat $a_{(+)}{}^{j}$, for example, as an electro-magnetic field which produces a self-interaction within the proton gas, but which produces no interaction between the electron and proton gases. Similarly for $a^{j}_{(-)}$. In this respect, the effects of $a^{j}_{(\pm)}$ are analogous to the behavior of the exchange forces in quantum mechanics which act only between identical particles, and not between unlike particles.

To complete the derivation of the dynamical equations including the effects of spin, we take the curl of (5–11), and arrive at the following:

$$\partial^{j}(Mcu^{k})_{(\pm)} - \partial^{k}(Mcu^{j})_{(\pm)} = \mp\frac{q}{c}[F^{jk} + f^{jk}_{(\pm)}] \qquad (5\text{–}12)$$

This is just the generalization of the tensor equation (2–40). Contracting (5–12) with $\mu_{j}{}^{(\pm)}$, we arrive at the following generalization of the Euler equation in the form (2–24):

$$\left[\frac{d(Mcu^{k})}{d\tau}\right]_{(\pm)} = \partial^{k}(Mc^{2})_{(\pm)} \pm q[F^{kl} + f^{kl}_{(\pm)}]u_{l}{}^{(\pm)} \qquad (5\text{–}13)$$

Fluid Stress-Energy Tensor

As a preliminary to introducing the stress-energy tensor for each of the two fluid fields, we multiply (5–13) by $\rho_{(\pm)}$ and write it in the following form:

$$\left[\rho\frac{d(\tilde{m}cu^{j})}{d\tau}\right]_{(\pm)} + \left[\rho\frac{d(\tilde{m}cu^{j})}{d\tau} - \rho\partial^{j}(\tilde{m}c^{2}) \mp q\rho f^{jl}u_{l}\right]_{(\pm)} = k^{j}_{(\pm)} \qquad (5\text{–}14)$$

where $k^{j}_{(\pm)}$ is the force density acting on the proton or electron gas:

$$k^{j}_{(\pm)} = (\rho m)_{(\pm)}\partial^{j}g + \rho^{j}p_{(\pm)} \pm qF^{jl}(\rho u_{l})_{(\pm)} = \rho_{(\pm)}\partial^{j}(\tilde{m}c^{2})_{(\pm)} \pm qF^{jl}(\rho\mu_{l})_{(\pm)} \qquad (5\text{–}15)$$

We define the fluid stress-energy tensor $T_{(\pm)}{}^{jk}$ for either the proton or electron gas as follows:

$$T^{jk}{}_{(\pm)} = (\rho\tilde{m}c^{2}u^{j}\mu^{k})_{(\pm)} + t^{jk}{}_{(\pm)} \qquad (5\text{–}16)$$

where the tensor $t^{jk}{}_{(\pm)}$ contains all the spin dependences. We impose the following condition on $t^{jk}{}_{(\pm)}$:

$$\partial_{k}t^{jk}_{(\pm)} = \left[\rho\frac{d(\tilde{m}cu^{j})}{d\tau} - \rho\partial^{j}(\tilde{m}c^{2}) \mp q\rho f^{jl}u_{l}\right]_{(\pm)} \qquad (5\text{–}17)$$

(In Section VIII we shall see that the spinor equations specify the functional dependence of $t^{jk}{}_{(\pm)}$ in such a way that condition (5–17) is automatically satisfied.)

We augment (5–17) with the continuity condition:

$$\partial_{j}(\rho\mu^{j})_{(\pm)} = 0 \qquad (5\text{–}18)$$

These two conditions, together with the definitions (5–16), suffice to guarantee the validity of the following relation:

$$\partial_{l}T^{jl}{}_{(\pm)} = k^{j}{}_{(\pm)} \qquad (5\text{–}19)$$

This equation, which is identical with (5–13) when (5–17) and (5–18) are taken into account, is the justification for regarding the tensor defined in (5–16) as the fluid stress-energy tensor.

We now make the following identifications:

$$\text{fluid energy density} \equiv T_{(\pm)}{}^{00} \qquad (5\text{–}20a)$$

$$\text{fluid energy flux density} \equiv \vec{U}_{(\pm)} \equiv c(T^{01}, T^{02}, T^{03})_{(\pm)} \qquad (5\text{–}20b)$$

$$\text{fluid momentum density} \equiv \vec{G}_{\pm} = (G^{1}, G^{2}, G^{3})_{\pm} \equiv \left(\frac{1}{c}T^{10}T^{20}T^{30}\right)_{\pm} \qquad (5\text{–}20c)$$

In terms of these quantities, (5–19) can be written as follows:

$$\frac{\partial T^{00}_{(\pm)}}{\partial t}+\vec{\nabla}\cdot\vec{U}_{(\pm)}=ck^{0}_{(\pm)} \tag{5–21a}$$

$$\frac{\partial G^{j}_{(\pm)}}{\partial t}=-\partial_l T^{jl}_{(\pm)}+k^{j}_{(\pm)}(j,\ l=1,\ 2,\ 3) \tag{5–21b}$$

These equations are the justification for the identifications made in (5–20).

Fluid Angular Momentum Tensor

If the spin angular momentum density of either the proton or electron gas is designated by $S^{jkl}{}_{(\pm)}$, and the total angular momentum density of either charged gas by $M^{jkl}{}_{(\pm)}$, then

$$M^{kjl}_{(\pm)}\equiv S^{jkl}_{(\pm)}+\frac{1}{c}[x^j T^{kl}_{(\pm)}-x^k T^{jl}_{(\pm)}] \tag{5–22}$$

The intuitive significance of this definition is more apparent if it is written in the following form:

$$\vec{M}_{(\pm)}=\vec{S}_{(\pm)}+\vec{r}\times\vec{G}_{(\pm)} \tag{5–23}$$

where

$$\vec{M}_{(\pm)}=(M_x,\ M_y,\ M_z)_{(\pm)}\equiv(M^{230},\ M^{310},\ M^{120})_{(\pm)} \tag{5–24}$$

$$\vec{S}_{(\pm)}=(S_x,\ S_y,\ S_z)_{(\pm)}\equiv(S^{230},\ S^{310},\ S^{120})_{(\pm)} \tag{5–25}$$

$$\vec{r}=(x,\ y,\ z)\equiv(x^1,\ x^2,\ x^3) \tag{5–26}$$

and $\vec{G}_{(\pm)}$ is defined in (5–20c). The 3-vectors $\vec{S}_{(\pm)}$ and $\vec{M}_{(\pm)}$ are the quantities to be regarded respectively as the spin and total angular momentum densities, but the complete tensors $S^{jkl}{}_{(\pm)}$ and $M^{jkl}{}_{(\pm)}$ are necessary for a covariant formulation of the theory.

The conservation of angular momentum requires that the following condition be satisfied:

$$\partial_l M^{jkl}_{(\pm)}=\frac{1}{c}[x^j k^{k}_{(\pm)}-x^k k^{j}_{(\pm)}] \tag{5–27}$$

The integral form of this equation makes its significance more apparent. To derive this we first write the space-space part of (5–27) as follows:

$$\frac{\partial\vec{M}_{(\pm)}}{\partial t}+c\partial_l\vec{M}^{l}_{(\pm)}=\vec{r}\times\vec{k}_{(\pm)}\ (l=1,\ 2,\ 3) \tag{5–28a}$$

where

$$\vec{M}^{l}_{(\pm)}=(M^{l}_{x},\ M^{l}_{y},\ M^{l}_{z})_{(\pm)}$$
$$\equiv(M^{23l},\ M^{31l},\ M^{12l})_{(\pm)}(l=1,\ 2,\ 3) \tag{5–28b}$$

$$\vec{k}_{(\pm)}=(k_x,\ k_y,\ k_{z\,(\pm)}\equiv k^1,\ k^2,\ k^3)_{(\pm)} \tag{5–28c}$$

We integrate (5–28a) over the 3-volume V_3 contained within a large sphere of radius R. Since the term involving $\vec{M}l_{(\pm)}$ is a 3-divergence, it can be transformed by means of Gauss' theorem into an integral over the surface of the sphere. If the two charged fluids are contained completely within the sphere, or if their distribution is such that as $R\rightarrow\infty$, the magnitude of $\vec{M}^l$ on the surface of the sphere falls off faster than R^{-2} then the integral over all 3-space of the terms in (5–28a) involving $\vec{M}^l$ will vanish and we are led to the desired result:

$$\frac{d}{dt}\int_{V3}\vec{M}_{(\pm)}dV_3=\int_{V3}(\vec{r}\times\vec{k}_{(\pm)})dV_3 \tag{5–29}$$

where the integration extends over all 3-space. This equation states that the time rate of change of the total angular momentum of one of the charged gases equals the total torque acting on the gas.

Substituting (5–22) into (5–27) and using (5–19), we arrive at the following condition on $S^{jkl}{}_{(\pm)}$:

$$\partial_l S^{jkl}_{(\pm)}=\frac{1}{c}(T^{jk}-T^{kj})_{(\pm)}=\frac{1}{c}(t^{jk}-t^{kj})_{(\pm)} \tag{5–30}$$

This shows that when a fluid has spin, its stress-energy tensor cannot, in general, be completely symmetric. We shall see in Section VIII that the spinor equations specify the functional forms of $S^{jkl}{}_{(\pm)}$ and $t^{jk}{}_{(\pm)}$ in such a way that the condition (5–30) is automatically satisfied.

Total Stress-Energy Tensor

From (5–15) and (5–19) we have

$$\partial_l[T^{jl}{}_{(+)}+T^{jl}{}_{(-)}]=\partial^j[P_{(+)}+P_{(-)}]$$
$$+[(\rho m)_{(+)}+(\rho m)_{(-)}]\partial^j{}_g+qF^{jl}[(\rho\mu_l)_{(+)}$$
$$-(\rho\mu_l)_{(-)}]=\partial^j[P_{(+)}+P_{(-)}]-\partial_l G^{jl}-\partial E^{jl} \tag{5–31}$$

where we have made use of (4–15) and (4–20)

Thus

$$\partial_i T^{jl}=0 \tag{5-32}$$

where

$$\begin{aligned} T^{jl} &= T^{jl}{}_{(+)}+T^{jl}{}_{(-)}-[P_{(+)}+P_{(-)}]g^{jl}+G^{jl}+E^{jl} \\ &= (\rho\breve{m}c^2\mu^j\mu l-Pg^{jl})_{(+)}+(\rho\breve{m}c^2\mu^j\mu^l-Pg^{jl})_{(-)} \\ &\quad +t^{jl}_{(+)}+t^{jl}_{(-)}+G^{jl}+E^{jl} \end{aligned} \tag{5-33}$$

Obviously, T^{jl} is the total stress-energy tensor of the entire magnetogas-dynamical system including charged fluids and fields.

We note, incidentally, that using (2-1), (2-13$_j$, and (2-17) we have

$$(\rho\breve{m}c^2\mu^j\mu^l-Pg^{jl})_{(\pm)}=[(\epsilon+P)\mu^j\mu^l-Pg^{jl}]_{(\pm)} \tag{5-34}$$

where

$$\epsilon_{(\pm)}=[\rho(mc^2+mg+m\mu)]_{(\pm)} \tag{5-35}$$

is the energy density of the fluid in its rest-frame. The right side of (5-34) is the usual relativistic form for the stress-energy tensor of a perfect fluid (viscosity neglected).*

We now make the following identifications:

$$\text{total energy density}\equiv T^{00} \tag{5-36a}$$

$$\begin{aligned} \text{total energy flux density}\equiv \vec{U} &\equiv c(T^{01},\ T^{02},\ T^{03}) \\ &= \vec{U}_{(\pm)}+\vec{U}_{(-)}+\vec{U}_{em}+\vec{U}_{gr} \end{aligned} \tag{5-36b}$$

$$\begin{aligned} \text{total momentum density}\equiv \vec{G} &= (G^1,\ G^2,\ G^3) \\ &\equiv \frac{1}{c}(T^{10},\ T^{20},\ T^{30}) \\ &= \vec{G}_{(+)}+\vec{G}_{(-)}+\vec{G}_{em}+\vec{G}_{gr} \end{aligned} \tag{5-36c}$$

In terms of these quantities (5-32) can be written as follows:

$$\frac{\partial T^{\infty}}{\partial t}+\vec{\nabla}\cdot\vec{U}=0 \tag{5-37a}$$

$$\frac{\partial G^j}{\partial t}=-\partial_i T^{jl}\ (j,l=1,\ 2,\ 3) \tag{5-37b}$$

*See, for example, Møller (ref. 10) p. 182, eq. 104.

These equations, of course, are the justification for the identifications made in (5-36)

We can integrate the equations (5-37) in just the same way we integrated (5-28a). Doing this, we find

$$\epsilon=\int_{V_3} T^{00}dV_3=\text{constant} \tag{5-38}$$

$$\vec{p}=\int_{V_3}\vec{G}dV_3=\text{constant} \tag{5-39}$$

where ϵ is the total energy of the entire magnetogas-dynamical system, and $\vec{p}$ is the total momentum.

Total Angular Momentum Tensor

If M^{jkl} is the total angular momentum density tensor for the entire magnetogas-dynamical system, we have

$$M^{jkl}\equiv S^{jkl}_{(+)}+S^{jkl}_{(-)}+\frac{1}{c}(x^jT^{kl}-x^kT^{jl}) \tag{5-40}$$

The condition for conservation of angular momentum is

$$\begin{aligned} O=\partial_i M^{jkl} &= \partial_i[S^{jkl}_{(+)}+S^{jkl}_{(-)}]+\frac{1}{c}(T^{kj}-T^{jk}) \\ &= \left[\partial_i S^{jkl}-\frac{1}{c}(t^{jk}-t^{kj})\right]_{(+)}+\left[\partial_i S^{jkl}-\frac{1}{c}(t^{jk}-t^{kj})\right]_{(-)} \end{aligned} \tag{5-41}$$

where we have used the fact that $t^{jk}{}_{(+)}$ and $t^{jk}{}_{(-)}$ are the only parts of T^{jk} that contain any antisymmetry. Obviously, if the condition (5-30) is satisfied, conservation of total angular momentum follows automatically from the definition (5-40).

Integrating (5-41) over all 3-space in the same way we integrated (5-27), we have the following result:

$$M^{jk}=\int_{V_3} M^{jk0}dV_3=\text{constant} \tag{5-42}$$

where M^{jk} is the total angular momentum of the entire system. If we define the 3-vector momentum $\vec{M}$ as

$$\vec{M}=(M_x,\ M_y,\ M_z\equiv(M^{23},\ M^{31},\ M^{12}) \tag{5-43}$$

then from (5–42), (5–41), (5–36c) and (5–25) we have

$$\vec{M}=\int_{V_3}\vec{\mathrm{M}}dV_3=\int_{V_3}[\vec{S}_{(+)}+\vec{S}_{(-)}+\vec{r}\times\vec{G}]dV_3 \\ =\text{constant} \qquad (5\text{–}44)$$

It is possible to express the total angular momentum in terms of a 4-vector Σ^j instead of the antisymmetric tensor M^{jk} once we have defined the 4-velocity V^j of the entire system.

If $\vec{V}$ is the 3-velocity corresponding to V^j then by definition

$$V^0\equiv[1-\vec{V}^2/c^2]^{-1/2} \qquad (5\text{–}45a)$$

$$V^j\equiv\frac{V^0}{c}V^j \ (j=1,2,3) \qquad (5\text{–}45b)$$

$$V^jV_j=1 \qquad (5\text{–}45c)$$

V^j is defined in terms of ϵ and $\vec{p}=(p^1, p^2, p^3)$ as follows:

$$V^0\equiv\epsilon[\epsilon^2-c^2\vec{p}^2]^{-\frac{1}{2}} \qquad (5\text{–}46a)$$

$$V^j\equiv cp^j[\epsilon^2-c^2\vec{p}^2]^{-\frac{1}{2}} \\ (j=1,2,3) \qquad (5\text{–}46b)$$

From (5–45) and (5–46), it follows that

$$\vec{V}=\frac{\vec{p}}{(\epsilon/c^2)} \qquad (5\text{–}47)$$

where the quantity in the denominator on the right is just the total mass of the system in the observer's reference frame. The square root in the denominator of (5–46) corresponds to the rest-energy of the entire system.

Using the 4-velocity defined in (5–46), we define the 4-vector angular momentum Σ^j as follows:

$$\Sigma^j\equiv-\tfrac{1}{2}\epsilon^{jkln}V_kM_{ln} \qquad (5\text{–}48)$$

In the rest-frame of the total system ($\vec{V}=0$,) we have

$$\left.\begin{aligned}\overset{0}{\Sigma}{}^0&=0\\(\overset{0}{\Sigma}{}^1,\overset{0}{\Sigma}{}^2,\overset{0}{\Sigma}{}^3)&=\vec{M}\end{aligned}\right\}\ \text{for } \vec{V}=0 \qquad (5\text{–}49)$$

VI SUMMARY OF FOREGOING RESULTS

We have seen that the dynamical side of the magnetogas-dynamical problem can be specified by the following system of equations:

$$\left[\frac{d(Mcu^j)}{d\tau}\right]_{(\pm)}=\partial^j(Mc^2)_{(\pm)}\pm q[F^{jk}+f^{jk}_{(\pm)}]u_k^{(\pm)} \qquad (6\text{–}1a)$$

$$\partial_j(\rho u^j)_{(\pm)}=0 \qquad (6\text{–}1b)$$

$$(u_ju^j)_{(\pm)}=1 \qquad (6\text{–}1c)$$

where

$$M_{(\pm)}=\mathring{m}_{(\pm)}+\tilde{m}_{(\pm)} \qquad (6\text{–}1d)$$

$$\mathring{m}_{(\pm)}=m_{(\pm)}[1+g/c^2+h_{(\pm)}/c^2) \qquad (6\text{–}1e)$$

$$\tilde{m}_{(\pm)}=\frac{1}{2c^2}(\mu s_{jk})_{(\pm)}[F^{jk}+f^{jk}_{(\pm)}] \qquad (6\text{–}1f)$$

We impose the adiabatic condition

$$[\rho\partial j\ h-(\gamma-1)h\partial j\ \rho]_{(\pm)}=0 \qquad (6\text{–}2a)$$

or

$$h_{(\pm)}=[H(\rho/\rho_0)^{(\gamma-1)}]_{(\pm)} \qquad (6\text{–}2b)$$

where

$$\overset{0}{\rho}_{(\pm)}=[\rho(x^j{}_{(0)})]_{(\pm)};\quad \overset{0}{H}_{(\pm)}=[h(x^j{}_{(0)})]_{(\pm)} \qquad (6\text{–}2c)$$

where $x_{(0)}{}^j$ are the coordinates of a particular point in space-time. If the condition (6–2) is satisfied, then

$$[\rho\partial^j(Mc^2)]_{(\pm)}=(\rho m)_{(\pm)}\partial^j g+\partial^j p_{(\pm)} \\ +[\rho\partial^j(\tilde{m}c^2)]_{(\pm)} \qquad (6\text{–}3)$$

It is this relation which allows us to replace the force densities in Euler's equation that are associated with gravitation, pressure, and spin-field interaction by the particle density times the gradient of the total particle rest-energy $M_{(\pm)}C^2$.

The specific enthalpy $h_{(\pm)}$ is the only thermodynamic function we need know, since the other two thermodynamic functions of principal interest, $T_{(\pm)}$ and $P_{(\pm)}$, can be found from the hollowing relations:

$$T_{(\pm)}=(h/c_p)_{(\pm)} \qquad (6\text{–}4)$$

and

$$P_{(\pm)}=\left[(\rho mh)\left(1-\frac{1}{\gamma}\right)\right]_{(\pm)} \qquad (6\text{–}5)$$

We have seen that there exists a simplified alternative to the system (6–1):

$$-\partial^j \Phi_{(\pm)} = (Mcu^j)_{(\pm)} \pm \frac{q}{c}\left[A^j + a^j_{(\pm)}\right] \quad (6\text{–}6a)$$

$$\partial j\,(\rho u^j)_{(\pm)} = 0 \quad (6\text{–}6b)$$

$$(u_j\, u^j)_{(\pm)} = 0 \quad (6\text{–}6c)$$

Taking the curl of (6–9a) yields the tensor alternative to Euler's equation:

$$\partial^j (Mcu^k)_{(\pm)} - \partial^k (Mcu^j)_{(\pm)} = \mp\frac{q}{c}\left[F^{jk} + f^{jk}_{(\pm)}\right] \quad (6\text{–}7)$$

Contracting (6–7) with $u_j{}^{(\pm)}$ yields Euler's equation in the form (6–1a). Thus any solution of (6–7) or (6–6a) is also a solution of (6–1a), but the converse is not in general true. Thus (6–6a) and (6–7) correspond to a more restricted class of solutions than (6–1a). The source of this restriction can be stated in either of two ways: (1) The restriction is just the requirement that there can be no local vorticity in either charged gas without a magnetic field to provide the necessary Coriolis force arising from the random thermal motion; or (2) The restriction results from the requirement (3–2) that the generalized particle momentum must be the gradient of a scalar, which is just the incorporation of the de Broglie Hypothesis into the formalism.

Obviously a choice must be made between the systems (6–1) and (6–6), and we have chosen in favor of (6–6) which is the more fundamental formulation of magnetogas dynamics, because the added restriction it imposes is physically necessary for a charged fluid with random thermal motion.

Thus the fluid dynamical half of the problem is specified by the system (6–6). The field half of the problem is specified by the following group of equations:

$$[\rho\partial_j\, h - (\gamma-1)h\partial_j\,\rho]_{(\pm)} = 0 \quad (6\text{–}8a)$$

or

$$h_{(\pm)} = [H(\rho/\rho_0{}^{(\gamma-1)})]_{(\pm)} \quad (6\text{–}8b)$$

$$\Box\, A^j - \partial^j(\partial_k A^k) = 4\pi q[(\rho u^j)_{(+)} - (\rho u^j)_{(-)}] \quad (6\text{–}8c)$$

$$\Box\, g = -4\pi\Gamma[(\rho m)_{(+)} + (\rho m)_{(-)}] \quad (6\text{–}8d)$$

Equations (6–8a) and (6–8b) are just the equations (6–2), and have been repeated here to emphasize that we are treating $h_{(\pm)}$ as a "thermal field" on a par with the gravitational and electromagnetic fields represented by g and A^j. We have a choice between (6–8a) and (6–8b), and can use the one that is simpler for calculational purposes. We noted in (2–33) – (2–36) that if the constants $H_{(+)}$ and $H_{(-)}$ satisfy the condition

$$(mH)_{(+)} \approx (mH)_{(-)} \quad (6\text{–}9)$$

then the electron and proton temperatures are everywhere approximately equal.

The stress-energy tensor T^{jk} of the entire system, including both charged fluids and the fields, has the following form:

$$T^{jk} \equiv T^{jk}{}_{(+)} + T^{jk}{}_{(-)} - [P_{(+)} + P_{(-)}]g^{jk} + E^{jk} + G^{jk} \quad (6\text{–}10)$$

where

$$T^{jk}{}_{(\pm)} \equiv (\rho\tilde{m}c^2 u^j u^k)_{(\pm)} + t^{jk}{}_{(\pm)} \quad (6\text{–}11)$$

$$E^{jk} = \frac{1}{4\pi}\left[F^{jl}F_l{}^k + \frac{1}{4}g^{jk}(F^{lm}F_{lm})\right] \quad (6\text{–}12)$$

$$G^{jk} = \frac{1}{4\pi\Gamma}\left[(\partial^j g)(\partial^k g) - \frac{1}{2}g^{jk}(\partial^l g)(\partial_l g)\right] \quad (6\text{–}13)$$

These tensors satisfy the following divergence relations:

$$\partial_k T^{jk} = 0 \quad (6\text{–}14)$$

$$\partial_k T^{jk}{}_{(\pm)} = k^j{}_{(\pm)} \quad (6\text{–}15)$$

where

$$k^j{}_{(\pm)} = (\rho m)_{(\pm)}\partial^j g + \partial^j p_{(\pm)} \pm qF^{jk}(\rho u_k)_{(\pm)} \quad (6\text{–}16)$$

$$= [\rho\partial^j(\tilde{m}c^2)]_{(\pm)} \pm qF^{jk}(\rho u_k)_{(\pm)}$$

$$\partial_k E^{jk} = -qF^{jl}[(\rho u_l)_{(\pm)} - (\rho u_l)_{(-)}] \quad (6\text{–}17)$$

$$\partial_k G^{jk} = -[(\rho m)_{(+)} + (\rho m)_{(-)}]\partial^j g \quad (6\text{–}18)$$

Equation (6–14) justifies the following identifications:

$$\text{total energy density} \equiv T^{00} \quad (6\text{–}19)$$

$$\text{total energy flux density} \equiv \vec{U} \equiv c(T^{01}, T^{02}, T^{03}) \quad (6\text{–}20)$$

$$\text{total momentum density} \equiv \vec{G} \equiv \frac{1}{c}(T^{10}, T^{20}, T^{30}) \quad (6\text{–}21)$$

The invariant trace of the total stress-energy tensor is

$$T^{j}_{j}=(\rho\breve{m}c^2+t^{j}_{j}-4P)_{(+)}+(\rho\breve{m}c^2+t^{j}_{j}-4P)_{(-)}$$
$$+\frac{1}{4\pi\Gamma}\left[(\vec{\nabla}g)^2-\frac{1}{c^2}\left(\frac{\partial g}{\partial t}\right)^2\right]=[(\epsilon-3P)+t^{j}_{j}]_{(+)}$$
$$+[(\epsilon-3P)+t^{j}_{j}]_{(-)}+\frac{1}{4\pi\Gamma}\left[(\vec{\nabla}g)^2-\frac{1}{c^2}\left(\frac{\partial g}{\partial t}\right)^2\right] \quad (6\text{–}22)$$

where $\epsilon_{(\pm)}$ is the fluid energy density defined in (5–35).

If ϵ and $\vec{p}$ are respectively the total energy and momentum of a finite system, it follows from (6–14) that

$$\epsilon=\int_{V_3} T^{00}dV_3=\text{constant} \quad (6\text{–}23)$$

$$p=\int_{V_3}\vec{G}dV_3=\text{constant} \quad (6\text{–}24)$$

where the integration extends over all 3-space. The 4-velocity V^j of the entire system is defined as

$$U^0\equiv\epsilon[\epsilon^2-c^2\vec{p}^2]^{-1/2} \quad (6\text{–}25a)$$

$$V^j\equiv cp^j[\epsilon^2-c^2\vec{p}^2]^{-1/2}\ (j=1,2,3) \quad (6\text{–}25b)$$

which corresponds to a 3-velocity $\vec{V}$ given by

$$\vec{V}=\frac{\vec{p}}{(\epsilon/c^2)} \quad (6\text{–}26)$$

The square root in the denominator of (6–25) is the total rest-energy of the system, and the factor (ϵ/c^2) in the denominator of (6–26) is the total mass of the system in the observer's reference frame.

If $S^{jkl}{}_{(\pm)}$ is spin angular momentum density of either charged fluid, then the total fluid angular momentum $M^{jkl}{}_{(\pm)}$ is defined as follows:

$$M^{jkl}_{(\pm)}\equiv S^{jkl}_{(\pm)}+\frac{1}{c}[x^jT^{kl}_{(\pm)}-x^kT^{jl}_{(\pm)}] \quad (6\text{–}27)$$

This definition can be written in terms of 3-vectors as follows:

$$\vec{M}_{(\pm)}\equiv\vec{S}_{(\pm)}+\vec{r}\times\vec{G}_{(\pm)} \quad (6\text{–}28)$$

where

$$\vec{M}_{(\pm)}\equiv(M_x, M_y, M_z)_{(\pm)}\equiv(M^{230}, M^{310}, M^{120})_{(\pm)} \quad (6\text{–}29)$$

$$\vec{S}_{(\pm)}\equiv(S_x, S_y, S_z)_{(\pm)}\equiv(S^{230}, S^{310}, S^{120})_{(\pm)} \quad (6\text{–}30)$$

$$\vec{r}\equiv(x, y, z)\equiv(x^1, x^2, x^3) \quad (6\text{–}31)$$

Conservation of fluid angular momentum requires that

$$\partial_l M^{jkl}_{(\pm)}=\frac{1}{c}[x^jk^k_{(\pm)}-x^kk^j_{(\pm)}] \quad (6\text{–}32)$$

where $k^j{}_{(\pm)}$ is given by (6–16). This equation is equivalent to the following condition on $S_{(\pm)}{}^{jkl}$:

$$\partial_l S^{jkl}_{(\pm)}=\frac{1}{c}(T^{jk}-T^{kj})_{(\pm)}=\frac{1}{c}(t^{jk}-t^{kj})_{(\pm)} \quad (6\text{–}33)$$

The definitions for the total angular momentum density M^{jkl} for the entire magnetogas-dynamical system including fluids and fields is analogous to (6–27):

$$M^{jkl}\equiv S^{jkl}_{(+)}+S^{jkl}_{(-)}+\frac{1}{c}(x^jT^{kl}-x^kT^{jl}) \quad (6\text{–}34)$$

The condition for conservation of total angular momentum is

$$\partial_l M^{jkl}=0 \quad (6\text{–}35)$$

which is automatically satisfied if condition (6–33) is satisfied.

The integral form of (6–35) is

$$M^{jk}\equiv\int_{V_3} M^{jk0}dV_3=\text{constant} \quad (6\text{–}36)$$

or

$$\vec{M}=\int_{V_3}\vec{\mathrm{M}}dV_3=\int_{V_3}[\vec{S}_{(+)}+\vec{S}_{(-)}+\vec{r}\times\vec{G}]dV_3$$
$$=\text{constant} \quad (6\text{–}37)$$

where

$$\vec{M}=(M_x, M_y, M_z)\equiv(M^{23}, M^{31}, M^{12}) \quad (6\text{–}38)$$

It is possible to define a 4-vector total angular momentum Σ^j in terms of the antisymmetric tensor M^{jk} and the 4-velocity V^j of the total system as follows:

$$\Sigma^j\equiv-\tfrac{1}{2}\epsilon^{jkln}V_kM_{ln} \quad (6\text{–}39)$$

In the rest-frame of the total system ($\vec{V}=0$), we have

$$\left.\begin{aligned}&\dot{\Sigma}^0=0\\&(\dot{\Sigma}^1,\ \dot{\Sigma}^2,\ \dot{\Sigma}^3)=\dot{\vec{M}}\end{aligned}\right\}\ \text{for}\ \vec{V}\equiv 0 \qquad (6\text{–}40)$$

VII SPINOR DESCRIPTION OF A PARTICLE

Tetrapod Description

The particles with which we are dealing, electrons and protons, have an internal structure characterized by a symmetry axis, as evidenced by the existence of particle spin and magnetic dipole moment. They also possess a de Broglie phase, which must be regarded as an intrinsic property of the particle. Thus, for a complete description of a particle, in addition to its velocity, we must specify the orientation of its symmetry axis and the magnitude of its de Broglie phase. As illustrated in Figure 2, this can be accomplished by means of a set of four orthonormal 4-vectors—one time-like and three space-like vectors. This set of 4-vectors is called the particle tetrapod.

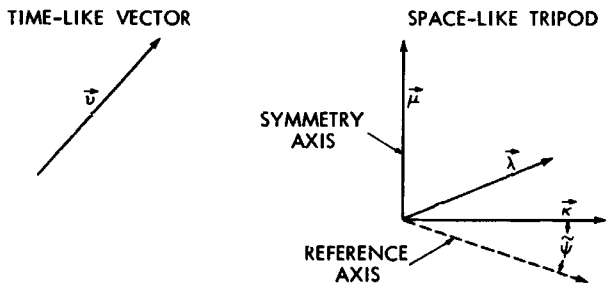

FIGURE 2.—Tetrapod representation of a particle.

The time-like vector of the tetrapod is the 4-velocity u^j (designated in the figure by the 3-velocity $\vec{v}$). One of these three space-like vectors $\vec{\mu}$ is used to specify the symmetry axis of the particle. The remaining degree of freedom, the angle $\vec{\Psi}$ needed to specify the orientation of the other two space-like vectors $\vec{k}$ and $\vec{\lambda}$ about the axis $\vec{\mu}$, is measured between $\vec{k}$ and a fixed reference axis in the observer's frame of reference. The 3-vectors $\vec{k}$, $\vec{\lambda}$, and $\vec{\mu}$ are, of course, the space-like parts of three 4-vectors, k^j, λ^j, and μ^j. In the particle rest-frame, the time-like components of these vectors are all zero.

We postulate that the angle $\vec{\Psi}$ is, to within a proportionality constant, the de Broglie phase Φ, and we postulate the proportionality constant to be $\hbar/2$ where $\hbar=1.0542\times10^{-27}$ erg-sec in Planck's constant. (The factor $\frac{1}{2}$ is necessary in order for the theory to yield a particle spin angular momentum of $\hbar/2$, which is regarded as an experimental fact with which the theory must agree.) Thus we have

$$\Phi=\frac{\hbar}{2}\tilde{\Psi} \qquad (7\text{–}1)$$

(We shall later introduce the sign of the particle charge into this relation, so that (7–1), like all the relations until (7–8), is valid only for positively charged particles. For the moment, however, we shall ignore the question of the sign of the particle charge.)

It is with (7–1) that Planck's constant is introduced into the theory. It should be emphasized, however, that in spite of the incorporation of the de Broglie Hypothesis into the theory which results from (7–1), the theory is classical, rather than quantum-mechanical, because no quantization process is introduced at any point.

From (3–2) and (7 – 1) we have

$$p^j=-\partial^j\Phi=-\frac{\hbar}{2}\partial^j\tilde{\Psi} \qquad (7\text{–}2)$$

In the particle rest-frame this becomes

$$\mathring{p}^0=\frac{\overset{0}{E}}{c}=mc+\frac{q}{c}\mathring{A}^0=-\frac{\hbar}{2c}\frac{d\tilde{\Psi}}{d\tau} \qquad (7\text{–}3a)$$

$$\mathring{\vec{p}}=\frac{q}{c}\mathring{\vec{A}}=\frac{\hbar}{2}\mathring{\vec{\nabla}}\tilde{\Psi} \qquad (7\text{–}3b)$$

where $\dot{E}$ is the particle rest-energy, $\dot{\vec{A}}$ is the space-like part of the 4-vector potential, and $\mathring{A}^\circ$ is the time-like part which, by means of a proper choice of gauge, could be made to vanish. Thus we see that the angular velocity of rotation of $\mathring{\vec{k}}$ and $\mathring{\vec{\lambda}}$ about $\mathring{\vec{\mu}}$ in the particle rest-frame determines the particle rest-energy, and the spatial rate of change in the rest-frame, when we go from one particle to another, determines the particle momentum in the rest-frame which is just $\frac{q}{c}\mathring{\vec{A}}$. Since a knowledge of the particle rest-energy at all points of space amounts to a knowledge of the function $\mathring{m}$ which determines the inertial properties of the particle as well as its scalar potentials, we see that a knowledge of $\tilde{\Psi}$ at every point of space-time

contains all the information necessary for a complete dynamical description of the particle.

Unfortunately, the function $\tilde{\Psi}$ is rather difficult to work with. In the case of a distribution of particles all at rest with respect to the observer, and having their $\mathring{\vec{\mu}}$ axes all aligned, $\tilde{\Psi}$ is easily determined. In the general case, however, $\tilde{\Psi}$ is one of three Euler angles that describe the orientation of the particle tripod in its own rest-frame, which in general is not the observer's frame. This matter is discussed at greater length in Appendix B. For present purposes, however, it is sufficient merely to appreciate the desirability of introducing a function having the essential properties of $\tilde{\Psi}$, but simpler to define and work with. From (7-2) we see that it is really the gradient of $\tilde{\Psi}$, rather than $\tilde{\Psi}$ itself, that interests us, so it will suffice to find a simply defined 4-vector ω^j that approximates the gradient of $\tilde{\Psi}$. (The choice we make for ω^j will actually approximate $-\frac{1}{2}\partial^j\tilde{\Psi}\cdot$) We define ω^j as follows:

$$\omega^j \equiv \tfrac{1}{2}\lambda_\epsilon \partial^j k^l \tag{7-4}$$

In order to see that

$$\omega^j \approx -\tfrac{1}{2}\partial^j\tilde{\Psi} \tag{7-5}$$

we note that in the particular rest-frame, ω^j can be written

$$\mathring{\omega}^j = -\tfrac{1}{2}\mathring{\vec{\lambda}}\cdot(\mathring{\partial}^j\mathring{\vec{k}}) \tag{7-6}$$

where $\partial^{\circ j}$ is the gradient operator in the particle rest-frames. Now if one pictures two neighboring tripods whose orientations are nearly the same (or a single tripod whose orientation is changing with time), it is clear that the contribution to (7-6) resulting from a difference (or a time change) in the orientation of $\mathring{\vec{\mu}}$ is very small compared with the contribution resulting from the angular displacement of $\vec{k}$ and $\mathring{\vec{\lambda}}$ about $\mathring{\vec{\mu}}$. The fact that one of the two tripods we are comparing may not be exactly at rest, but rather have a small velocity, makes only a very small difference in the right side of (7-6). Thus, the value of $\dot{\omega}^j$ is very close to what we would find in the case for which all the tripods are at rest and have their $\mathring{\vec{\mu}}$ axes aligned. This then is the basis for the approximate equality given in (7-5).

It should be emphasized, however, that this approximate equality has been introduced only to give an intuitive feeling for the physical significance of ω^j, but no use of (7-5) will be made in the development of the formalism to follow.

We conclude this discussion of the physical significance of ω^j by noting that its time-like component is essentially the de Broglie frequency of the particle, and its space-like part the de Broglie wave-vector.

Rewriting (7-3a), we have

$$\frac{d\tilde{\Psi}}{d\tau} = -\frac{2\mathring{E}}{\hbar} \tag{7-7}$$

Since the particle rest-energy $\dot{E}$ must be positive, we see from Figure 2 that the direction of rotation of $\mathring{\vec{k}}$ about $\mathring{\vec{\mu}}$ is given by the *left*-hand screw rule. ($\mathring{\vec{k}}$, $\mathring{\vec{\lambda}}$, and $\mathring{\vec{\mu}}$, in that order, constitute a right-hand system of axes.)

Now let us identify the direction of rotation of $\mathring{\vec{k}}$ about $\mathring{\vec{\mu}}$ with the sign σ ($\sigma = \pm 1$) of the electric charge of the particle. Thus our discussion has so far concerned itself only with a positively charged particle. In the case of a negatively charged particle, we assert that the direction of rotation of $\mathring{\vec{k}}$ about $\mathring{\vec{\mu}}$ is given by the *right*-hand screw rule. Thus, if the (+) and (−) subscripts or superscripts refer respectively to positively or negatively charged particles, the foregoing relations are generalized as follows:

$$\Phi_{(\pm)} = \pm\frac{\hbar}{2}\tilde{\Psi}_{(\pm)} \tag{7-8}$$

$$p^j_{(\pm)} = -\partial^j\Phi_{(\pm)} = \mp\frac{\hbar}{2}\partial^j\tilde{\Psi}_{(\pm)} \tag{7-9}$$

$$\omega^j_{(\pm)} = \tfrac{1}{2}\lambda_l^{(\pm)}\partial^j k_{l(\pm)} \tag{7-10}$$

$$\omega^j_{(\pm)} \approx -\tfrac{1}{2}\partial^j\tilde{\Psi}_{(\pm)} \tag{7-11}$$

$$\left(\frac{d\tilde{\Psi}}{d\tau}\right)_{(\pm)} = \mp\frac{2\mathring{E}_{(\pm)}}{\hbar} \tag{7-12}$$

From (7-9) and (7-11) we have

$$p^j{}_{(\pm)} \approx \pm\hbar\omega^j{}_{(\pm)} \tag{7-13}$$

and

$$\mathring{\omega}^\circ{}_{(\pm)} \approx \pm\frac{\mathring{p}^\circ{}_{(\pm)}}{\hbar} = \pm\frac{\mathring{E}_{(\pm)}}{\hbar c} \tag{7-14}$$

Thus, in contradistinction to $\dot{p}^{\circ}{}_{(\pm)}$ which is always positive, $\overset{\circ}{\omega}{}^{\circ}{}_{(\pm)}$ has the same sign as the electric charge of the particle.

We now complete our tetrapod description by normalizing the four 4-vectors to $\rho_{(\pm)}$, the invariant particle density, rather than to unity. In this way we have packed all the information we need for a complete description of a charged fluid into the particle tetrapod. Altogether this description involves seven degrees of freedom: three for $\vec{v}$, two for $\vec{\vec{\mu}}$, and one apiece for $\vec{\vec{\Psi}}$ and ρ. Since each of the 4-vectors has four elements, however, our tetrapod involves a total of sixteen elements. But it has only seven degrees of freedom. Thus the elements of the tetrapod do not represent the "normal coordinates" of the problem. This fact makes the tetrapod difficult to use in any formalism.

We shall now show that it is possible to express the four 4-vectors of the tetrapod as bilinear [illegible] of the complex elements of two spinors, each having two components. Thus the two spinors together have eight degrees of freedom. One of these degrees of freedom, the phase common to the two spinors, will be used to specify the sign of the particle charge. (It is shown in Appendix C that this identification, together with the spinor equations of motion, causes the direction or rotation of $\vec{k}$ and $\vec{\lambda}$ about $\vec{v}$ to be dependent on the sign of the particle charge, as indicated by (7–14).) If we regard the sign of the particle charge as a degree of freedom, then we can assert that the two spinors together are completely specified by eight real functions and, since the charged fluid has eight degrees of freedom, the two spinors constitute the "normal mode description" of the problem.

Spinor Description

As a preliminary to introducing the spinors that will be used to describe the charged fluids, we must introduce the irreducible form of a 4-vector. For reasons that will shortly become clear, the superscripts and subscripts used to label the elements of a 4-vector in irreducible form will not be the usual ones ($j=0, 1, 2, 3$). Rather, two indices α and $\bar{\beta}$, where $\alpha=1, 2$ and $\bar{\beta}=\bar{1}, \bar{2}$, will be used. The overhead bar in $\bar{\beta}$ indicates complex conjugation, and we shall see shortly how the need for such a notation enters the formalism.

First, we must define the irreducible vector elements in terms of the ordinary (reducible) elements. Using the 4-vector $(\rho u^j)_{(\pm)}$ as an example, and omitting for the time-being the $_{(\pm)}$ subscript, we have

$$\rho u^{1\bar{1}}=\frac{\rho}{\sqrt{2}}(u^{\circ}+u^{3})=\frac{\rho}{\sqrt{2}}e^{\nu}$$

$$\rho u^{2\bar{2}}=\frac{\rho}{\sqrt{2}}(u^{\circ}-u^{3})=\frac{\rho}{\sqrt{2}}e^{-\nu} \qquad (7\text{–}15)$$

$$\rho u^{1\bar{2}}=\frac{\rho}{\sqrt{2}}(u^{1}-iu^{2})=\frac{\rho}{\sqrt{2}}\sinh\nu\cos\hat{\theta}\,e^{-i\hat{\phi}}$$

$$\rho u^{2\bar{1}}=\frac{\rho}{\sqrt{2}}(u^{1}+iu^{2})=\frac{\rho}{\sqrt{2}}\sinh\nu\cos\hat{\theta}\,e^{i\hat{\phi}}$$

where

$$\nu=\tanh^{-1}(v/c) \qquad (7\text{–}16)$$

and $\hat{\theta}$ and $\hat{\phi}$ are respectively the polar and azimuthal angles of a system of spherical coordinates referred to the z axis as pole.

It is obvious that, for a rotation of the coordinate system through an angle $\Delta\hat{\phi}$ around the z axis, we have

$$(\rho u^{1\bar{2}})'=e^{-i\Delta\hat{\phi}}(\rho u^{1\bar{2}})$$
$$(\rho u^{2\bar{1}})'=e^{i\Delta\hat{\phi}}(\rho u^{2\bar{1}}) \qquad (7\text{–}17)$$

where the primes indicate the values of the elements after the rotation. Under this same symmetry operation, the components ρu^1 and ρu^2 are not, however, simply multiplied by a constant as in (7–17). Rather they become shuffled, i.e., the expression for $(\rho u^1)'$ involves *both* ρu^1 and ρu^2, and similarly for $(\rho u^2)'$. Thus $\rho u^{1\bar{2}}$ and $\rho u^{2\bar{1}}$ are irreducible representations of the symmetry group of rotations about the z axis, whereas ρu^1 and ρu^2 are not. Similarly, $\rho u^{1\bar{1}}$ and $\rho u^{2\bar{2}}$ are irreducible representations of the symmetry group consisting of all Lorentz transformations in the z direction, whereas ρu° and ρu^3 are not.

It is well-known that the equations of physics assume their simplest form when they are expressed in terms of irreducible quantities. For this reason, the components $\rho u^{\alpha\bar{\beta}}$ on the left side of (7–15) are to be regarded as more fundamental than the usual components ρu^j.

We now introduce the two fundamental spinors ζ^α and χ^α by means of the following relation:

$$\rho\begin{pmatrix} u^{\bar{1}1} u^{\bar{1}2} \\ u^{21} u^{22} \end{pmatrix} = \begin{pmatrix} \zeta^1 \\ \zeta^2 \end{pmatrix}(\zeta^{\bar{1}} \zeta^{\bar{2}}) + \begin{pmatrix} \chi^1 \\ \chi^2 \end{pmatrix}(\chi^{\bar{1}} \chi^{\bar{2}}) \quad (7\text{–}18)$$

where

$$\overline{\rho^\alpha} = \overline{\rho^\alpha}\ ;\ \overline{\chi^\alpha} = \overline{\chi^\alpha} (\alpha = 1, 2) \quad (7\text{–}19)$$

On the left side of (7–18) we have arranged the elements of $\rho u^{\alpha\bar{\beta}}$ in the form of a 2×2 matrix, and on the right side we have the sum of two outer products in which the pre-factor of each product is a column matrix and the postfactor is the complex conjugate of this column matrix written in row form, i.e., its Hermitean adjoint.

It is convenient, as indicated in (7–19), to designate complex conjugation of a spinor element by means of a bar over only the index(*), rather than over the entire symbol for the element. Thus, the indices $\alpha = 1, 2$ and $\bar{\beta} = \bar{1}, \bar{2}$ are regarded as entirely independent, i.e., it is not necessary in the case of $\rho u^{\alpha\bar{\beta}}$ that, for example, $\beta = \bar{1}$ when $\alpha = 1$. A 4-vector in irreducible form is characterized by one of each type of index. It can be shown that an antisymmetric world tensor of rank is characterized by either two barred or two unbarred indices. A symmetic world tensor of second rank is characterized by four indices, two of each kind. In keeping with the customary notation, vector and tensor indices ranging over the values 0, 1, 2, 3 will be designated by lower case Roman letters, whereas spinor indices will always be designated by lower case Greek letters.

In order to explain why two outer products, rather than just one, are needed on the right side of (7–18), we note that, although the spinor ζ^α (or χ^α) itself has four degrees of freedom, one of these, namely the phase factor that is common to both ζ^1 and ζ^2, is suppressed when we carry out the outer multiplication between ζ^α and its conjugate $\zeta^{\bar{\alpha}}$. Thus ζ^α by itself can be used only to represent a 4-vector with no more than three degrees of freedom, i.e., a null vector. To represent an arbitrary time-like or space-like 4-vector, two spinors are necessary.

It is in the sense of the relation (7–18) that we may think of spinors as the "square roots" of 4-vectors. In the same way that, when we take the square root of a real number, we get an extra degree of freedom, namely the sign of the square root, we find that the "square root" of a 4-vector hase xtra degrees of freedom. This is obviously the case because the 4-vector ρu^j (or $\rho u^{\alpha\beta}$) has four degrees of freedom, whereas the two spinors ζ^α and χ^α together have a total of eight degrees of freedom.

The physical significance of these extra degrees of freedom becomes clear when we note that, having the two spinors ζ^α and χ^α, it is possible to generate the complete particle tetrapod as follows:

$$\begin{aligned} \rho u^{\alpha\bar{\beta}} &= \zeta^\alpha \zeta^{\bar{\beta}} + \chi^\alpha \chi^{\bar{\beta}} \\ \rho \mu^{\alpha\bar{\beta}} &= \zeta^\alpha \zeta^{\bar{\beta}} - \chi^\alpha \chi^{\bar{\beta}} \\ \rho k^{\alpha\bar{\beta}} &= \zeta^\alpha \chi^{\bar{\beta}} + \chi^\alpha \zeta^{\bar{\beta}} \\ \rho \lambda^{\alpha\bar{\beta}} &= -i(\zeta^\alpha \chi^{\bar{\beta}} - \chi^\alpha \zeta^{\bar{\beta}}) \end{aligned} \quad (7\text{–}20)$$

Thus the extra degrees of freedom are to be associated with the particle tripod (k^j, λ^j, μ^j), and hence are the degrees of freedom specifying the orientation of the spin axis, and the de Broglie phase. The phase angle common to ζ^α and χ^α, which does not make itself directly felt in the generation of the tetrapod, will be used to specify the sign of the particle charge. (In Appendix C it is shown that this identification has the consequence that, for solutions of the spinor equations of motion, the direction of rotation of $\vec{k}$ and $\vec{\lambda}$ about $\vec{\mu}$ is dependent on the sign of the particle charge. It is only in this indirect way that the phase common ζ^α and χ^α makes itself felt—via the spinor equations of motion—in the particle tetrapod.) Finally, we note that it can be shown that the tetrapod defined by (7–20 automatically satisfies the necessary orthonormality requirements.

Equations (7–20) provide the bridge between the spinors ζ^α and χ^α, which we regard as constituting the most fundamental description of a fluid of charged particles, and the particle tetrapod in irreducible form. To complete the formalism we need a bridge that connects the spinors

*A commonly used spinor notation employs a dot, rather than a bar, over the index. This notation is appropriate when the spinor so designated, e.g. $\zeta^{\dot{\alpha}}$, transforms like $\zeta^{\bar{\alpha}}$, but is not equal to $\zeta^{\bar{\alpha}}$, i.e., it differs from $\zeta^{\bar{\alpha}}$ by a factor that is a scalar invariant. In order to emphasise that $\zeta^{\bar{\alpha}}$ not only transforms like $\zeta^{\bar{\alpha}}$, but is exactly equal to it, we use a bar over the index rather than a dot.

directly with the 4-vectors of the tetrapod expressed in the usual form, rather than with the irreducible form as in (7–20). To accomplish this, we first rewrite (7–15) in matrix form as follows:

$$\rho\begin{pmatrix} u^{1\bar{1}} u^{1\bar{2}} \\ u^{2\bar{1}} u^{2\bar{2}} \end{pmatrix} = \frac{\rho}{\sqrt{2}}\begin{pmatrix} [u^0+u^3][u^1-iu^2] \\ [u^1+iu^2][u^0-u^3] \end{pmatrix} \tag{7–21}$$

$$= \frac{\rho}{\sqrt{2}}\left[u^0\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + u^1\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} + u^2\begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} + u^3\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\right]$$

We introduce the constant matrices $\sigma_j^{\alpha\bar{\beta}}$ defined as follows:

$$\sigma_0^{\alpha\bar{\beta}} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \qquad \sigma_1^{\alpha\bar{\beta}} = \frac{1}{\sqrt{2}}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$
$$\sigma_2^{\alpha\bar{\beta}} = \frac{1}{\sqrt{2}}\begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \qquad \sigma_3^{\alpha\bar{\beta}} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \tag{7–22}$$

where, following the usual convention, the first index α indicates the row of the matrix, and the second index $\bar{\beta}$ indicates the column. The sematrices, of course, are just the Pauli spin matrices. Using these matrices, (7–15) or (7-21) can be written in the following condensed form:

$$\rho u^{\alpha\bar{\beta}} = \sigma_j^{\alpha\bar{\beta}}(\rho u^j) \tag{7–23}$$

where, as always, a repeated index means contraction.

The matrices $\sigma_j^{\alpha\bar{\beta}}$ satisfy the following important relations:

$$\sigma_j^{\alpha\bar{\gamma}}\sigma_{\gamma\bar{\beta}}^{j} = \delta_\beta^\alpha \delta_{\bar{\gamma}}^{\bar{\gamma}} \tag{7–24a}$$

$$\sigma_j^{\alpha\bar{\beta}}\sigma_{\beta\bar{\alpha}}^{k} = \delta_j^k \tag{7–24b}$$

and

$$\overline{\sigma_j^{\alpha\bar{\beta}}} = \sigma_j^{\bar{\beta}\alpha} \qquad \overline{\sigma_{\alpha\bar{\beta}}^{j}} = \sigma_{\bar{\beta}\alpha}^{j} \tag{7–24c}$$

where $\delta_\beta^\alpha \cdot \delta_\nu^\mu$, and δ_j^k are Kronecker delta functions, and the matrices $\sigma_{\alpha\beta}^j$ have the same form as the matrices $\sigma_j^{\alpha\beta}$, i.e.

$$\sigma_{\alpha\beta}^j = \begin{pmatrix} \sigma_1^j & \sigma_2^j \\ \sigma_{\bar{1}}^j & \sigma_{\bar{2}}^j \end{pmatrix} = \begin{pmatrix} \sigma_j^{1\bar{1}} & \sigma_j^{1\bar{2}} \\ \sigma_j^{2\bar{1}} & \sigma_j^{2\bar{2}} \end{pmatrix} = \sigma_j^{\alpha\beta} \tag{7–25}$$

(Note that in the case of $\sigma_{\alpha\bar{\beta}}^j$ the barred index, which designates the row of the matrix, is written first whereas, in the case of $\sigma_j^{\alpha\bar{\beta}}$, it is written second and designates the column.) Using (7–24b), it is possible to invert (7–23):

$$\rho u^j = \sigma_{\bar{\beta}\alpha}^{j}(\rho u^{\alpha\bar{\beta}}) \tag{7–26}$$

Multiplying the equations (7–20) by $\sigma_{\bar{\beta}\alpha}^{j}$ and contracting the $\bar{\beta}$ and α, we arrive at the desired bridge between the spinors and the entire tetrapod in its usual (reducible) form:

$$\begin{aligned} \rho u^j &= \sigma_{\bar{\beta}\alpha}^{j}(\zeta^\alpha \zeta^{\bar{\beta}} + \chi^\alpha \chi^{\bar{\beta}}) \\ \rho \mu^j &= \sigma_{\bar{\beta}\alpha}^{j}(\zeta^\alpha \zeta^{\bar{\beta}} - \chi^\alpha \chi^{\bar{\beta}}) \\ \rho k^j &= \sigma_{\bar{\beta}\alpha}^{j}(\zeta^\alpha \chi^{\bar{\beta}} + \chi^\alpha \zeta^{\bar{\beta}}) \\ \rho \lambda^j &= -i\sigma_{\bar{\beta}\alpha}^{j}(\zeta^\alpha \chi^{\bar{\beta}} - \chi^\alpha \zeta^{\bar{\beta}}) \end{aligned} \tag{7–27}$$

Thus far we have used only contravariant spinors, whose indices have been indicated by superscripts rather than subscripts. Knowing the contravariant form of a spinor, we can define the covariant form of this same spinor by means of the requirement that the contraction of the two must be an invariant. Furthermore, this invariant must be zero. Otherwise, as it can easily be shown, the invariant norm of the null vector that is the "square" of the spinor would have to be non-zero, and this cannot be. Thus we define the covariant spinors ζ_α and χ_α as follows:

$$\begin{aligned} \zeta_1 &= -\zeta^2;\ \zeta_2 = \zeta^1 \\ \chi_1 &= -\chi^2;\ \chi_2 = \chi^1 \end{aligned} \tag{7–28}$$

Thus

$$\zeta_\alpha \zeta^\alpha = \zeta_1\zeta^1 + \zeta_2\zeta^2 = -\zeta^2\zeta^1 + \zeta^1\zeta^2 = 0 \tag{7–29}$$

Similarly

$$\chi_\alpha \chi^\alpha = 0 \tag{7–30}$$

The contraction of ζ_α and χ^α is, however, non-zero. It follows from (7–28) that

$$\zeta_\alpha \chi^\alpha = -\zeta^\alpha \chi_\alpha \tag{7–31}$$

Thus raising one index in a contraction and lowering the other changes the sign of the result. This is to be contrasted with the fact that when

we do the same thing with the contraction of two 4-vectors, the result is unaltered. For example,

$$p_j u^j = p^j u_j \tag{7-32}$$

For a further discussion of the algebraic aspects of spinor analysis, the reader is referred to the papers of van der Waerden (11), Laporte and Uhlenbeck (12), and Bade and Jehle (13).

By means of the relations (7–27), it is possible to write the components of $\zeta^{\alpha}{}_{(\pm)}$ and $\chi^{\alpha}{}_{(\pm)}$ for each of the two charged fields in terms of the Euler angels that specify the orientation of the corresponding space-like tripod in the rest-frame of the fluid in question, and in terms of the magnitude and direction of the fluid velocity. This is carried out in Appendix B. However, for our present purposes the complete result of Appendix B is not needed. We only need to know that $\zeta^{\alpha}{}_{(\pm)}$ and $\chi^{\alpha}{}_{(\pm)}$ can be expressed in terms of two normalized spinors $\hat{\zeta}^{\alpha}{}_{(\pm)}$ and $\hat{\chi}^{\alpha}{}_{(\pm)}$ as follows:

$$\zeta^{\alpha}_{(\pm)} = \left(\frac{\rho e^{i\epsilon}}{\sqrt{2}}\right)^{1/2}_{(\pm)} e^{-i\Psi/2} \hat{\zeta}^{\alpha}_{(\pm)} \tag{7-33a}$$

$$\chi^{\alpha}_{(\pm)} = \left(\frac{\rho e^{i\epsilon}}{\sqrt{2}}\right)^{1/2}_{(\pm)} e^{i\Psi/2} \hat{\chi}^{\alpha}_{(\pm)} \tag{7-33b}$$

where

$$(\hat{\zeta}_{\alpha}\hat{\chi}^{\alpha})_{(\pm)} = 1 \tag{7-34}$$

and $\hat{\zeta}_{(\pm)}{}^{\alpha}$ and $\hat{\chi}_{(\pm)}{}^{\alpha}$ are not functions of Ψ, which means that they contain none of the high-frequency (of order of the de Broglie frequency) time or space oscillation associated with Ψ, but only the slow variation associated with changes in fluid velocity and spin orientation. From (7–33) and (7–34), it follows that

$$(\zeta_{\alpha}\chi^{\alpha})_{(\pm)} = \left(\frac{\rho e^{i\epsilon}}{\sqrt{2}}\right)_{(\pm)} \tag{7-35}$$

ϵ is the phase that is common to both ζ^{α} and χ^{α}. It is obvious from (7–27) that ϵ has no direct effect on the vectors of the tetrapod. Thus ϵ is a disposable degree of freedom that we are free to use to specify the sign of the particle charge. Thus we impose the following condition on $\epsilon_{(\pm)}$:

$$\cos \epsilon_{(\pm)} = \pm 1 \tag{7-36a}$$

which is equivalent to

$$e^{i\epsilon(\pm)} = \pm 1 \tag{7-36b}$$

Thus (7–35) becomes

$$(\zeta_{\alpha}\chi^{\alpha})_{(\pm)} = \pm \frac{\rho_{(\pm)}}{\sqrt{2}} \tag{7-37}$$

The condition (7–36) is fulfilled if we impose the following constraint on our spinors:

$$I(\zeta_{\alpha}\chi^{\alpha})_{(\pm)} = 0 \tag{7-38}$$

where I designates the imaginary part of the argument. The only constraint on the real part of $(\zeta_{\alpha}\chi^{\alpha})_{(\pm)}$ is that it have the same sign at every point of space-time.

From (7–27) and (7–35), we have the following expression for the 4-velocity u^j as a function of the spinors:

$$u^j{}_{(\pm)} = \{[2(\zeta_{\overline{\alpha}}\chi^{\overline{\alpha}})(\zeta_{\nu}\chi^{\nu})]^{-\frac{1}{2}}[\sigma^j{}_{\alpha\overline{\beta}}(\zeta^{\beta}\zeta^{\overline{\alpha}} + \chi^{\beta}\chi^{\overline{\alpha}})]\}_{(\pm)} \tag{7-39}$$

This identity is valid regardless of whether or not the constraint (7–38) is satisfied. From (7–29)—(7–31), (7–24), and (7–39) it follows automatically that

$$(u^j u_j)_{(\pm)} = 1 \tag{7-40}$$

Thus the $u_{(\pm)}{}^j$ that we calculate from the spinors is automatically normalized, and so when we work with spinors thate is no need for the troublesome nonlinear side condition that we encountered in (6–1c) or (6–6c). This is true even when the constraint (7–38) is dropped which, as we shall later show, is permissible in problems on a laboratory or astronomical scale.

Now let us estimate the magnitude of the error involved in the approximate equalities (7–11) and (7–13). To do this, we substitute the expressions for k^j and λ^j given in (7–27) into the definition of ω^j given in (7–10) which yields

$$\omega^j{}_{(\pm)} = -\tfrac{1}{2}\partial^j \Psi_{(\pm)} + \gamma^j{}_{(\pm)} \tag{7-41}$$

where

$$\gamma^j{}_{(\pm)} = I(\hat{\chi}^{\alpha}\partial^j \hat{\zeta}_{\alpha})_{(\pm)} \tag{7-42}$$

Comparing (7–41) with (7–11), we see that $\gamma^j{}_{(\pm)}$ is the amount by which (7–11) fails of being an

exact equality. It is easy to estimate the magnitude of $\gamma^{j}{}_{(\pm)}$. Let L be a length characterizing the size of the system in which we are interested. Now we have already noted that because $\hat{\zeta}^{\alpha}{}_{(\pm)}$ and $\hat{\chi}^{\alpha}{}_{(\pm)}$ are not functions of $\tilde{\Psi}$, which contains all the fast space-time oscillation associated with the de Broglie phase, they are functions only of particle velocity and spin orientation. We shall limit ourselves to solutions in which no fast precession of the spin axis is present. For such cases it is always true that appreciable changes in $\hat{\zeta}^{\alpha}{}_{(\pm)}$ and $\hat{\chi}^{\alpha}{}_{(\pm)}$ occur only over distances comparable with L and in times greater than L/c. Thus it is true that, in such cases,

$$\gamma^{j}_{(\pm)} \sim \frac{1}{L} \tag{7-43}$$

where the symbol $\sim$ is to be read "is of the order of."

Substituting (7–41) into (7–9), we have

$$p^{j}{}_{(\pm)} = -\partial^{j}\Phi_{(\pm)} = \pm\hbar(\omega^{j} - \gamma^{j})_{(\pm)} \tag{7-44}$$

which is the exact version of (7–13).

We shall now estimate the importance of $\gamma_{(\pm)}{}^{j}$ in (7–41) and (7–44). In making these estimates we shall, to simplify the notation, drop the $(\pm)$ subscript with the understanding that the results apply equally well to either charged fluid. First we note that, since the effect of γ^{j} in (7–44) is (as we shall see) small, we have

$$|\hbar\omega^{\circ}| \sim mc \tag{7-45a}$$

$$|\hbar\vec{\omega}| \sim |\vec{p}| \sim |m\vec{v}| = mv \tag{7-45b}$$

where, for order of magnitude estimates, the contribution $\frac{q}{c}A^{j}$ to p^{j} has been neglected. (The magnitude of A^{j} is, in any case, uncertain because of the arbitrariness in the choice of gauge.) From (7–43) and (7–45) we have

$$\frac{|\gamma^{\circ}|}{|\omega^{\circ}|} \sim \frac{\hbar L^{-1}}{mc} = \frac{\lambda\!\!\!^{-}}{L} \tag{7-46a}$$

$$\frac{|\vec{\gamma}|}{|\vec{\omega}|} \sim \frac{\hbar L^{-1}}{mv} = \left(\frac{\lambda\!\!\!^{-}}{L}\right)\left(\frac{c}{v}\right) \tag{7-46b}$$

where

$$\lambda\!\!\!^{-} = \frac{\hbar}{mc} \tag{7-47}$$

is the Compton wavelength of the particle. Let $O(n)$ designate "a function of the order of magnitude of the number n." Using (7–46), we can write (7–41) and (7–44) as follows:

$$\frac{\partial\tilde{\gamma}}{\partial t} = -2c\omega^{\circ}[1 + O(\lambda\!\!\!^{-}/L)] \tag{7-48a}$$

$$\vec{\nabla}\tilde{\gamma} = 2\vec{\omega}\left[1 + O\left(\frac{\lambda\!\!\!^{-}c}{Lv}\right)\right] \tag{7-48b}$$

$$p^{\circ} = \sigma\hbar\omega^{\circ}[1 + O(\lambda\!\!\!^{-}/L)] \tag{7-49a}$$

$$\vec{p} = \sigma\hbar\vec{\omega}\left[1 + O\left(\frac{\lambda\!\!\!^{-}c}{Lv}\right)\right] \tag{7-49b}$$

where $\sigma = \pm 1$ is the sign of the particle charge.

To estimate $(\lambda\!\!\!^{-}/L$ and $(\lambda\!\!\!^{-}/L)(c/v)$ we use $\lambda\!\!\!^{-} \sim 10^{-11}cm$, which is appropriate for an electron; $L \sim 10^{11}cm$, which is the order of magnitude of the sun's radius; and $v \sim 10^{5}$ cm/sec, which is the order of magnitude of the rotational velocity at the surface of the sun. For these values we have

$$\frac{\lambda\!\!\!^{-}}{L} \sim 10^{-24} \tag{7-50a}$$

$$\frac{\lambda\!\!\!^{-}c}{Lv} \sim 10^{-19} \tag{7-50b}$$

which are very small indeed. We note that, in the neighborhood of a stagnation point where $v = 0$, the contribution $\frac{q}{c}A^{j}$ to p^{j}, which we neglected in (7–45), becomes important. In such a region we should replace v in (7–45)—(7–50) by $|\frac{q}{mc}A|$. This guarantees that the ratio (7–46b) remains small, even when $v = 0$, since in general $\vec{A} \neq 0$ at such points. (In fact, we can guarantee that this is the case by an appropriate choice of gauge).

The sole purpose of these estimates has been to demonstrate that, at least for the type of problem in which we are interested, the vector ω^{j} that we introduced to replace $-\frac{1}{2}\partial^{j}\tilde{\Psi}$, which was difficult to work with in calculations, is indeed very nearly equal to $-\frac{1}{2}\partial^{j}\tilde{\Psi}$. (7–48) also provides the quantitative justification for calling ω° the de Broglie frequency and $\vec{\omega}$ the de Broglie wave-vector. When we recall that, according to (3–2), p^{j} must be the gradient of a scalar, we note from (7–48) and (7–49) that this is also very nearly the case for ω^{j}.

All of the relations presented in this section have followed directly from the definitions that provide the link between the spinors ζ^α, χ^α and the kinetic and dynamical properties described by the particle tetrapod. It is evident that any spinor equation of motion that determines the space-time behavior of ζ^α and χ^α for given electromagnetic, gravitational, and thermal fields will indirectly specify the equations of motion of the fluid quantities described by the tetrapod, in particular the equations of motion of ρ and u^j. If it should turn out that the equations so determined are just the systems (6–1) or (6–6), then the postulated spinor equations of motion for ζ^α and χ^α is the desired spinor alternative to Euler's equation.

In the next section, we shall postulate a certain spinor equation of motion, and then using the definitions of the present section we shall derive the equations of motion satisfied by the quantities described by the tetrapod. We shall find that the resulting equations are identical to the system (6–6) supplemented by an equation of motion for the particle spin, which is interesting but, for the purposes of magnetogas dynamics, not of primary importance. The spin-dependent potential $a^j{}_{(\pm)}$ in (5–1a) will be given as an explicit function of $\zeta^\alpha{}_{(\pm)}$ and $\chi^\alpha{}_{(\pm)}$, and it will be shown that, for macroscopic problems, $a^j{}_{(\pm)}$ is completely negligible compared with the potentials A^j that are encountered in such problems.

Section VIII will merely summarize results. The derivation of these results is carried out in Appendix C. For a detailed understanding of Appendix C, some prior familiarity with spinor analysis would be helpful, and for this the reader is referred to references (11), (12), and (13).

As a necessary preliminary to discussing the spinor equation of motion, we note that the 4-gradient operator ∂_j can also be written with spinor indices. Thus, analogous to (7–21), we have (7-51)

$$\begin{pmatrix} \partial_{\bar{1}1}\partial_{\bar{1}2} \\ \partial_{\bar{2}1}\partial_{\bar{2}2} \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} \left[\frac{1}{c}\frac{\partial}{\partial t}+\frac{\partial}{\partial z}\right]\left[\frac{\partial}{\partial x}-i\frac{\partial}{\partial y}\right] \\ \left[\frac{\partial}{\partial x}+i\frac{\partial}{\partial y}\right]\left[\frac{1}{c}\frac{\partial}{\partial t}-\frac{\partial}{\partial z}\right] \end{pmatrix}$$

which can also be written

$$\partial_{\bar{\alpha}\beta} = \sigma^j{}_{\bar{\alpha}\beta}\partial_j \qquad (7\text{–}52)$$

whose inverse is

$$\partial_j = \sigma_j{}^{\beta\bar{\alpha}}\partial_{\bar{\alpha}\beta} \qquad (7\text{–}53)$$

The following operator identities are also of interest:

$$\partial^{\alpha\bar{\lambda}}\partial_{\bar{\lambda}\beta} = \partial_{\bar{\lambda}\beta}\partial^{\alpha\bar{\lambda}} = \tfrac{1}{2}\delta^\alpha_\beta\partial_l\partial^l = \tfrac{1}{2}\delta^\alpha_\beta\Box \qquad (7\text{–}54)$$

$$\sigma_j{}^{\beta\bar{\gamma}}\sigma_{\bar{\gamma}\alpha}{}^k\partial^{\alpha\bar{\lambda}}\partial_{\bar{\lambda}\beta} = \tfrac{1}{2}\delta^k_j\partial_l\partial^l = \tfrac{1}{2}\delta^k_j\Box \qquad (7\text{–}55)$$

From (7–54) it follows that

$$\Box = \partial_l\partial^l = \partial_{\bar{\alpha}\beta}\partial^{\beta\bar{\alpha}} \qquad (7\text{–}56)$$

In the next section we shall work with the irreducible covariant form $A_{\bar{\alpha}\beta}$ of the 4-vector potential where

$$\begin{pmatrix} A_{\bar{1}1}A_{\bar{1}2} \\ A_{\bar{2}1}A_{\bar{2}2} \end{pmatrix} = \frac{1}{\sqrt{2}}\begin{pmatrix} [A_0+A_3][A_1-iA_2] \\ [A_1+iA_2][A_0-A_3] \end{pmatrix} = \frac{1}{\sqrt{2}}\begin{pmatrix} [A^0-A_z][-A_x+iA_y] \\ [-A_x-iA_y][A^0+Az] \end{pmatrix} \qquad (7\text{–}57)$$

where we have made use of the fact that it is the contravariant form A^j, rather than the covariant form A_j, that is regarded as the generalization to four dimensions of the 3-vector $\vec{A} = (A_x, A_y, A_z)$.

The following identity is useful for evaluating F^{jk} from $A_{\bar{\alpha}\beta}$:

$$2g^{jl}\sigma_l{}^{\beta\bar{\lambda}}\sigma_{\bar{\lambda}\alpha}{}^k(\partial^{\alpha\bar{\gamma}}A_{\bar{\gamma}\beta}) = g^{jk}(\partial_l A^l) - (\partial^j A^k - \partial^k A^j) - i\epsilon^{jkln}\partial_l A_n \qquad (7\text{–}58)$$
$$= g^{jk}(\partial_l A^l) - F^{jk} - i\hat{F}^{jk}$$

where we have used (4–3) and (4–5).

VIII SPINOR EQUATIONS OF MOTION

Spinor Equations

We postulate that the spinor equations of motion have the following form:

$$i\hbar\partial_{\bar{\alpha}\beta}\zeta^\beta_{(\pm)} = \frac{\mathfrak{m}_{(\pm)}c}{\sqrt{2}}\chi^{\bar{\alpha}}_{(\pm)} - \frac{q}{c}A_{\bar{\alpha}\beta}\zeta^\beta_{(\pm)} \qquad (8\text{–}1a)$$

$$i\hbar\partial_{\alpha\beta}\chi^\beta_{(\pm)} = \frac{\mathfrak{m}_{(\pm)}c}{\sqrt{2}}\zeta^{\bar{\alpha}}_{(\pm)} + \frac{q}{c}A_{\bar{\alpha}\beta}\chi^\beta_{(\pm)} \qquad (8\text{–}1b)$$

where

$$\mathfrak{m}_{(\pm)} = m_{(\pm)}[1+g/c^2+h_{(\pm)}/c^2] \qquad (8\text{–}1c)$$

We supplement these equations with the constraint (7-38):

$$I(\zeta_\alpha \chi^\alpha)_{(\pm)} = 0 \tag{8-1d}$$

which is equivalent to requiring that

$$\cos \epsilon_{(\pm)} = 0; \quad \sigma = \pm 1 \tag{8-1e}$$

where σ is the sign of the particle charge of the fluid under consideration.

We note that the signs preceding q in the above spinor equations are the same for both charged fluids. The reason for this is that the sign of the particle charge is treated as part of the solution of the spinor equations (the value of the phase ϵ), rather than as a parameter in the equations.

The equations (8-1) are just the spinor form of the Dirac equation with the generalization that the mass includes contributions arising from the gravitational and thermal energy.* It should be emphasized, however, that, except for the incorporation of the de Broglie Hypothesis into the theory, which introduced Planck's constant as a proportionality factor relating $\Phi_{(\pm)}$ and $\tilde{\Psi}_{(\pm)}$ (cf. (7-8)), the theory developed in this paper is completely classical in spirit. In particular, no quantization process has been introduced.

It is really not surprising that a Dirac-type equation should be the first candidate for investigation in a theory like the one developed here, since this equation is the simplest first-order linear equation that incorporates a scalar field ($\tilde{m}_{(\pm)}$) and a vector field ($A_{\alpha\beta}$), and also guarantees that the observable quantities of physical interest (ρ, u^j, μ^j, ω^j)$_{(\pm)}$ do not contain oscillatory terms with frequency of the order of the de Broglie frequency.

Derivation of the Euler System of Equations

Using the spinor equations of motion (8-1), and the definitions of Section VII that relate the observable quantities described by the tetrapod for the fluid to the spinors $\zeta^\alpha{}_{(\pm)}$ and $\chi^\alpha{}_{(\pm)}$, it is shown in Appendix C that we can arrive at the fluid equations of motion in terms of these observable quantities. In this section, we shall merely exhibit these equations, and discuss their physical significance. The most important of these equations are the following:

$$\partial_j(\rho u^j)_{(\pm)} = 0 \tag{8-2}$$

$$p^j_{(\pm)} = -\partial^j \Phi_{(\pm)} = (MCu^j)_{(\pm)} + \frac{\sigma q}{c}\left[A^j + a^j_{(\pm)}\right] \tag{8-3}$$

where

$$a^j_{(\pm)} = \frac{\hbar c}{q}(\pi^j - \gamma^j)_{(\pm)} \tag{8-4}$$

where $\gamma^j{}_{(\pm)}$ is defined by (7-42) and

$$\pi^j_{(\pm)} = \frac{1}{2\rho}\left\{\partial_k(\rho s^{jk}) - [u_k \partial_l(\rho s^{kl})]u^j\right\}_{(\pm)} \tag{8-5}$$
$$= \frac{1}{2}\left[\rho^{-1}\epsilon^{jklm}u_k \partial_l(\rho\mu_m) - s^{jk}u^l \partial_l u_k\right]_{(\pm)}$$

The $M_{(\pm)}$ that appears in (8-3) is defined as follows:

$$M_{(\pm)} \equiv \mathring{m}_{(\pm)} + \tilde{m}_{(\pm)} \tag{8-6}$$

where

$$\tilde{m}_{(\pm)} = \frac{1}{2c^2}\left[\frac{q\hbar}{2M_{(\pm)}c} s^{jk}_{(\pm)}(F_{jk} + f^{(\pm)}_{jk})\right]$$
$$= -\frac{1}{c^2}\left[\frac{q\hbar}{2M_{(\pm)}c}\vec{\mu}\cdot(\vec{B} + \vec{b})\right]_{(\pm)} \tag{8-7}$$

where

$$f^{jk}{}_{(\pm)} = \partial^j a^k{}_{(\pm)} - \partial^k a^j{}_{(\pm)} \tag{8-8a}$$

$$(f^{10}, f^{20}, f^{30})_{(\pm)} \equiv (e_x, e_y, e_z)_{(\pm)} = \vec{e}_{(\pm)} \tag{8-8b}$$
$$-(f^{23}, f^{31}, f^{12})_{(\pm)} \equiv (b_x, b_y, b_z)_{(\pm)} = \vec{b}_{(\pm)}$$

and the overhead "o" in (8-7) indicates the value of the 3-vector in question as seen in the particle rest-frame. (Note that, in general, $\vec{B}$ in the case of the proton gas is different from $\vec{B}$ in the case of the electron gas because the two rest-frames are different.)

Note that the definition for $M_{(\pm)}$ in (8-6) is implicit, rather than explicit, because $\tilde{m}_{(\pm)}$ involves $M_{(\pm)}$ itself (rather than $m_{(\pm)}$) in the denominator.

Comparing (8-7) with (6-1f), we make the following identification:

$$\mu_{(\pm)} = \frac{q\hbar}{2M_{(\pm)}c} \tag{8-9}$$

*See, for example, ref. 12, p. 1393, eq. 1. This equation does not include the factor $\sqrt{2}$ appearing in (8-1a) and (8-1b) simply because of a difference in the definition of the matrices $\sigma^j_{\alpha\beta}$.

where $\mu_{(\pm)}$ is the magnitude of the magnetic dipole moment of the particle. (8–9) is just the dipole moment that the Dirac theory yields (g-factor equals 2), with the modification that the total mass $M_{(\pm)}$, rather than the free-particle mass $m_{(\pm)}$, appears in the denominator.

The equations (8–2) and (8–3), together with the automatic normalization of the 4-velocity $\mu^j{}_{(\pm)}$ that was demonstrated in (7–40), constitute the system of equations given in (6–6). From this system we can derive, as was shown in Section VI, the Euler system of equations (6–1). Thus we have shown that a solution of the system of spinor equations (8–1) automatically yields, via the identities of Section VII, a solution of the Euler system of equations (6–1).

Magnitude of Spin-Dependent Electromagnetic Field

Now we shall demonstrate that, for magnetogas-dynamical systems on a laboratory or astronomical scale, the effects of the spin-dependent field $f^{jk}{}_{(\pm)}$ are completely negligible. (Recall that $f^{jk}{}_{(\pm)}$ has its origin in the small contribution $\zeta\rho^j{}_{(\pm)}$ to the fluid momentum density that resulted from the presence of the spin angular momentum density. Thus $f^{jk}{}_{(\pm)}$ is really a spin-dependent mechanical effect, although it has been treated, for reasons of intuitive clarity, as a contribution to the electromagnetic field.)

In Appendix C it is shown that, for solutions of (8–1) that yield functions for ρ, u^j, μ^j, and ω^j that change significantly only over distances of the order L and in time intervals greater than L/c, we have

$$|f^{jk}{}_{(\pm)}| \sim \frac{q}{\alpha L^2} \tag{8–10}$$

where α is the fine-structure constant:

$$\alpha = \frac{q^2}{\hbar c} = \frac{1}{137.04} \tag{8–11}$$

Table I summarizes the comparison between $|f^{jk}{}_{(\pm)}|$ and the magnitudes $|F^{jk}|$ of the electromagnetic fields encountered in the sun and in a system of laboratory dimensions. Only crude estimates for the lower limits of $|F^{jk}|$ have been given, but these suffice to indicate that in macroscopic systems the effects of $f^{jk}{}_{(\pm)}$ are completely negligible. The third line of Table 1 has been included merely to demonstrate that, if one were to attempt to use the spinor formulation of magnetogas dynamics to construct models of nuclei or elementary particles, the effects of the spin-dependent field $f^{jk}{}_{(\pm)}$ would be not at all negligible.

TABLE 1.

	L(cm)	$\lvert f^{jk}{}_{(\pm)}\rvert$ (Gauss)	$\lvert F^{jk}\rvert$ (Gauss)
Sun	10^{11}	10^{-29}	>1
Laboratory	1	10^{-7}	>1
Nucleus	10^{-13}	10^{19}	10^{15}

Effect of Variable ϵ

The side condition (8–1d) is analogous to the 4-velocity normalization condition (6–1c) in the Euler system of equations in that both conditions introduce an algebraic nonlinearity into the problem, since they are quadratic in the unknown functions. We shall now demonstrate, however, that the spinor system of equations has the great advantage that, for problems on an astronomical or laboratory scale, the nonlinear side condition (8–1d) may be ignored.

In this regard, we already noted following (7–40) that dropping the constraint (8–1d) has no effect on the automatic normalization of $\mu^j{}_{(\pm)}$. Moreover, in Appendix C it is shown that, if we ignore this constraint, no change in the continuity equation (8–2) results, and the effect on (8–3) can be represented as a spurious mass contribution $(\Delta_\epsilon m)_{(\pm)}$ and a spurious 4-vector potential $(\Delta_\epsilon A^j)_{(\pm)}$. Under the same conditions used in estimating $|f^{jk}{}_{(\pm)}|$, we find

$$\left|(\Delta_\epsilon A^j)_{(\pm)}\right| \sim \left|a^j{}_{(\pm)}\right| \left(\frac{\lambda\!\!\!^{-}(\pm)}{L}\right) \tag{8–12}$$

where $\lambda\!\!\!^{-}_{(\pm)}$ is the Compton wavelength introduced in (7–47). Thus, for macroscopic systems, the effect of $(\Delta_\epsilon A^j)_{(\pm)}$ is even smaller than that of $a^j{}_{(\pm)}$, whereas, for systems of nuclear dimensions, this is obviously no longer the case.

In order to estimate the effect of the spurious mass $(\Delta_\epsilon m)_{(\pm)}$, we note that this may be regarded as arising from a spurious contribution to the specific enthalpy, which in turn may be regarded

as arising from an error $(\Delta_\epsilon T)_{(\pm)}$ in the fluid temperature. In Appendix C, it is shown that

$$|(\Delta_\epsilon T)_{(\pm)}| \sim \left(\frac{m_{(\pm)}c^2}{k}\right)\left(\frac{\lambda\!\!\!^{-}_{(\pm)}}{L}\right)^2 \qquad (8\text{–}13)$$

where k is the Boltzmann constant. In Table 2 $|\Delta_\epsilon T_{(-)}|$ (i.e., the error in the electron temperature) is compared with the range of temperatures encountered in the sun, laboratory, and in nuclear systems. (The case for protons leads to even smaller estimates.)

TABLE 2.

	L(cm)	$\lvert\Delta_\epsilon T_{(-)}\rvert$ (°K)	T(°K)
Sun	10^{11}	10^{-33}	10^3-10^7
Lab	1	10^{-11}	$0-10^3$
Nucleus	10^{-13}	10^{15}	$0-10^{10}$

Obviously, the effect of $\Delta_\epsilon T_{(\pm)}$ is completely negligible in the first two cases, and not at all negligible in the last case.

Finally, it is shown in Appendix C that

$$|\epsilon_{(+)}| \sim \frac{\lambda\!\!\!^{-}_{(+)}}{L}; \quad |\pi - \epsilon_{(-)}| \sim \frac{\lambda\!\!\!^{-}_{(-)}}{L} \qquad (8\text{–}14)$$

Thus, neglecting the side condition (8–1d) in the case of macroscopic systems will not produce a change in the sign of cos $\epsilon_{(\pm)}$, which we interpret as the sign of the electric charge of the particle. Another way of interpreting (8–14) is to say that, for macroscopic systems, the equations (8–1a) and (8–1b) come very close to satisfying the condition (8–1d) automatically, without anything being done to bring this about.

In summation, we conclude that, in the case of macroscopic magnetogas-dynamical systems, ignoring the side condition (8–1d) will introduce no significant error into the solution.

Stress-Energy Tensor

In Appendix C it is shown that the following equation results from the spinor equations (8–1):

$$\partial_k T^{jk}_{(\pm)} = \partial_k T^{kj}_{(\pm)} = [\rho\partial^j(\breve{m}c^2)]_{(\pm)} + F^{jk}(\sigma_Q \rho\mu_k)_{(\pm)} = k^j{}_{(\pm)} \qquad (8\text{–}15)$$

where

$$T^{jk}_{(\pm)} = \left[\rho\breve{m}c^2u^ju^k + \frac{\sigma\hbar c}{2}u^j\partial_l(\rho s^{kl}) - \frac{\sigma\hbar c}{2}\rho s^{jl}\partial^k u_l\right] \qquad (8\text{–}16)$$

and $k^j{}_{(\pm)}$ is the 4-force density acting on the fluid.

We see in (8–15) that it makes no difference whether we contract ∂_k with $T^{jk}{}_{(\pm)}$ or $T^{kj}{}_{(\pm)}$. This is a non-trivial result, inasmuch as the tensor $T^{jk}{}_{(\pm)}$ is not symmetric.

Equation (8–15) justifies our regarding $T^{jk}{}_{(\pm)}$ as the stress-energy tensor of the fluid. Comparing (8–16) with (6–11), we see that $t^{jk}{}_{(\pm)}$, the spin-dependent part of the stress-energy tensor, has the following form:

$$t^{jk}_{(\pm)} = \frac{\sigma\hbar c}{2}[u^j\partial_l(\rho s^{kl}) - \rho s^{jl}\partial^k u_l]_{(\pm)} \qquad (8\text{–}17)$$

Angular Momentum

In Appendix C it is shown that the following equation results from the system of spinor equations (8–1):

$$\partial_l M^{jkl}_{(\pm)} = \frac{1}{c}[x^j k^k_{(\pm)} - x^k k^j_{(\pm)}] \qquad (8\text{–}18)$$

where

$$M^{jkl}_{(\pm)} = -\frac{\sigma\hbar}{2}\epsilon^{jkln}(\rho\mu_n)_{(\pm)} + \frac{1}{c}[x^jT^{kl}_{(\pm)} - x^kT^{jl}_{(\pm)}] \qquad (8\text{–}19)$$

Comparing (8–19) with (6–27) and (6–30), we make the following identifications:

$$S^{jkl}_{(\pm)} = -\frac{\sigma\hbar}{2}\epsilon^{jkln}(\rho\mu_n)_{(\pm)} \qquad (8\text{–}20)$$

and

$$\vec{S}_{(\pm)} \equiv (S^{230}, S^{310}, S^{120})_{(\pm)} = \frac{\sigma\hbar}{2}(\rho\vec{\mu})_{(\pm)} = \left[(\rho u^0)\left(\frac{\sigma\hbar}{2}\frac{\vec{\mu}}{u^0}\right)\right]_{(\pm)} \qquad (8\text{–}21)$$

Thus $\frac{\sigma\hbar}{2}(\rho\vec{\mu})_{(\pm)}$ is the spin angular momentum density and, since $(\rho\mu^0)_{(\pm)}$ is the particle density in the observer's frame, $\left(\frac{\sigma\hbar}{2}\frac{\vec{\mu}}{u^0}\right)_{(\pm)}$ is the spin angular momentum of a single particle in the observer's frame.

In this regard, it is interesting to note that it follows directly from the Lorentz transformation that

$$\frac{\vec{\mu}}{u^0}=\frac{\overset{0}{\vec{\mu}}_{\parallel}}{}+\frac{\overset{0}{\vec{\mu}}_{\perp}}{u^0} \tag{8-22a}$$

where

$$\overset{0}{\vec{\mu}}_{\parallel}=\left(\frac{\overset{0}{\vec{\mu}}\cdot\vec{v}}{v^2}\right)\vec{v} \tag{8-22b}$$

is the component of $\overset{0}{\vec{\mu}}$ parallel to $\vec{v}$, and

$$\overset{0}{\vec{\mu}}_{\perp}=\frac{(v\times\overset{0}{\vec{\mu}})\times\vec{v}}{v^2} \tag{8-22c}$$

is the component of $\overset{0}{\vec{\mu}}$ perpendicular to $\vec{v}$. Thus

$$\lim_{\vec{v}\to c}\left(\frac{\vec{\mu}}{u^0}\right)\to\overset{0}{\vec{\mu}}_{\parallel} \tag{8-23}$$

which corresponds to the well-known property of particle spin to align itself parallel or antiparallel (depending on the sign of $\overset{0}{\vec{\mu}}\cdot\vec{v}$ in (8–22b)) to the particle velocity at high speeds.

Finally, it is shown in Appendix C that in the fluid rest-frame the following equation is valid:

$$\left[\frac{d\left(\frac{\sigma\hbar}{2}\overset{0}{\vec{\mu}}\right)}{d\tau}\right]_{(\pm)}=\left[\left(\frac{q\hbar\overset{0}{\vec{\mu}}}{2Mc}\right)\times(\overset{0}{\vec{B}}+\overset{0}{\vec{b}})\right]_{(\pm)} \tag{8-24}$$

This equation describes the precession in its own rest-frame of a particle having a spin angular momentum $\left(\frac{\sigma\hbar}{2}\overset{0}{\vec{\mu}}\right)_{(\pm)}$ and a magnetic moment $\left(\frac{q\hbar}{2Mc}\overset{0}{\vec{\mu}}\right)_{(\pm)}$ corresponding to a gyromagnetic ratio $\left(\frac{\sigma q}{Mc}\right)_{(\pm)}$ which in turn corresponds to a g-factor of 2 (referred, of course, to the total particle mass $M_{(\pm)}$ rather than the free particle mass $m_{(\pm)}$). The precession produced by $\overset{0}{\vec{b}}_{(\pm)}$ can be regarded as the result of a self-interaction of the electron or proton fluid with itself. In any case, Table 1 shows us that $|\overset{0}{\vec{b}}_{(\pm)}|\ll|\overset{0}{\vec{B}}|$ for macroscopic systems.

Dimensionless Form of Equations

Let us refer the particle masses to the electron mass m_e where

$$m_e=9.107\times10^{-28}gm \tag{8-25}$$

Thus, if $m_{(-)}$ and $m_{(+)}$ are the electron and proton masses respectively, we have

$$\overset{\prime}{m}_{(-)}=\frac{m_{(-)}}{m_e}=1 \tag{8-26a}$$

$$\overset{\prime}{m}_{(\pm)}=\frac{m_{(+)}}{m_e}=1836.1 \tag{8-26b}$$

where the dimensionless masses have been indicated by an overhead stroke. We shall refer all lengths to the Compton wavelength of the electron $\lambda\!\!\!^{-}_e$ where

$$\lambda\!\!\!^{-}_e=\frac{\hbar}{m_ec}=3.862\times10^{-11}\,\text{cm} \tag{8-27}$$

Thus we have the following relations between the dimensional and dimensionless (indicated by a stroke) quantities of principal interest:

$$t=(\lambda\!\!\!^{-}_e/c)\overset{\prime}{t}{}^{\circ}=1.2882\times10^{-21}\overset{\prime}{t}{}^{\circ}\ \text{sec} \tag{8-28a}$$

$$x^j=\lambda\!\!\!^{-}_e\overset{\prime}{x}{}^j=3.862\times10^{-11}\overset{\prime}{x}{}^j\ \text{cm} \tag{8-28b}$$

$$\partial_j=\lambda\!\!\!^{-}_e{}^{-1}\overset{\prime}{\partial}_j=2.590\times10^{10}\overset{\prime}{\partial}_j\ \text{cm}^{-1} \tag{8-28c}$$

$$\Box=\lambda\!\!\!^{-}_e{}^{-2}\overset{\prime}{\Box}=6.707\times10^{20}\overset{\prime}{\Box}\ \text{cm}^{-2} \tag{8-28d}$$

$$u^j{}_{(\pm)}=\overset{\prime}{u}{}^j{}_{(\pm)} \tag{8-28e}$$

$$\omega_{(\pm)}{}^j=\lambda\!\!\!^{-}_e{}^{-1}\omega_{(\pm)}{}^j=2.590\times10^{10}\overset{\prime}{\omega}_{(\pm)}{}^j\ \text{cm}^{-1} \tag{8-28f}$$

$$\rho_{(\pm)}=\lambda\!\!\!^{-}_e{}^{-3}\rho_{(\pm)}=1.7372\times10^{30}\overset{\prime}{\rho}_{(\pm)}cm^{-3} \tag{8-28g}$$

$$(\zeta^\alpha,\chi^\alpha)_{(\pm)}=\lambda\!\!\!^{-}_e{}^{-3/2}(\overset{\prime}{\zeta}{}^\alpha,\overset{\prime}{\chi}{}^\alpha)=4.168\times10^{15}(\overset{\prime}{\zeta}{}^\alpha,\overset{\prime}{\chi}{}^\alpha)\ \text{cm}^{-3/2} \tag{8-28h}$$

$$A^j=(q/\lambda\!\!\!^{-}_e)\overset{\prime}{A}{}^j=12.434\overset{\prime}{A}{}^j\ \text{statvolt} \tag{8-28i}$$

$$N_{(\pm)}=qN_{(\pm)}=4.802\times10^{-10}\overset{\prime}{N}_{(\pm)}\ \text{statvolt}-\text{cm} \tag{8-28j}$$

$$F^{jk}=(q/\lambda\!\!\!^{-}_e{}^2)\overset{\prime}{F}{}^{jk}=3.220\times10^{11}\overset{\prime}{F}{}^{jk}\ \text{statvolt/cm} \tag{8-28k}$$

$$g=(\alpha c^2)\overset{\prime}{g}=6.55\times10^{18}\overset{\prime}{g}\ \text{erg/gm} \tag{8-28l}$$

$$h_{(\pm)}=(\alpha c^2)(\overset{\prime}{H}\overset{\prime}{h})_{(\pm)}=6.558\times10^{18}(\overset{\prime}{H}\overset{\prime}{h})_{(\pm)}\ \text{erg/gm} \tag{8-28m}$$

Two dimensionless coupling constants will be needed: the fine-structure constant α,

$$\alpha=\frac{q^2}{\hbar c}=7.297\times10^{-3}=\frac{1}{137.04} \tag{8-29}$$

and the dimensionless gravitational constant $\overset{\prime}{\Gamma}$,

$$\overset{\prime}{\Gamma}=\Gamma\left(\frac{m_e}{q}\right)^2=2.398\times10^{-43} \tag{8-30}$$

The dimensionless spinor equations (8–1) have the form

$$i\partial'_{\bar{\alpha}\beta}\zeta'^{\beta}_{(\pm)}=\frac{m'_{(\pm)}}{\sqrt{2}}\chi'^{(\pm)}_{\alpha}+\alpha\{m'_{(\pm)}[g'+(H'h')_{(\pm)}]\chi'_{\bar{\alpha}}-[A'_{\bar{\alpha}\beta}+\partial'_{\alpha\bar{\beta}}N'_{(\pm)}]\zeta'^{\beta}_{(\pm)}\} \quad (8\text{–}31a)$$

$$i\partial'_{\bar{\alpha}\beta}\chi'^{\beta}_{(\pm)}=\frac{m'_{(\pm)}}{\sqrt{2}}\zeta'^{(\pm)}_{\bar{\alpha}}+\alpha\{m'_{(\pm)}[g'+(H'h')_{(\pm)}]\zeta'_{\bar{\alpha}}+[A'_{\bar{\alpha}\beta}+\partial'_{\bar{\alpha}\beta}N'_{(\pm)}]\chi'^{\beta}_{(\pm)}\} \quad (8\text{–}31b)$$

where $N'_{(-)}$ and $N'_{(+)}$ are dimensionless real scalar functions of the space-time coordinates that determine the gauges of the 4-vector potential that one chooses to use in the solution of the spinor equations for the electron and proton gases. There is no need that the same gauge be used in the two cases. These scalar functions, which did not appear in (8–1), have been inserted in (8–31) simply to make the arbitrariness of the gauge more explicit.

The algebraically nonlinear condition (8–1d) has not been included in (8–31) because we saw that ignoring it introduced no significant error into the solutions of macroscopic problems.

The field equations (6–8) in dimensionless form are as follows:

$$\left.\begin{aligned}&\rho'_{(\pm)}\partial'_{\beta}h'_{(\pm)}=[\gamma_{(\pm)}-1]h'_{(\pm)}\partial'_{\beta}\rho'_{(\pm)} \quad (8\text{–}32a)\\ \text{or}\\ &h'_{(\pm)}=[(\rho'/\rho'_{0})^{(\gamma-1)}]_{(\pm)} \quad (8\text{–}32b)\end{aligned}\right\}$$

$$\Box'A'_{\bar{\alpha}\beta}-\partial'_{\bar{\alpha}\beta}(\partial'^{\bar{\nu}\lambda}A'_{\bar{\lambda}\nu})=4\pi[(\rho'\mu'_{\bar{\alpha}\beta})_{(+)}-(\rho'\mu'_{\bar{\alpha}\beta})_{(-)}] \quad (8\text{–}32c)$$

$$\Box'g'=-4\pi\Gamma'[(\rho'm')_{(+)}+(\rho'm')_{(-)}] \quad (8\text{–}32d)$$

where from (7–28) and (7–35)

$$\rho'_{(\pm)}=\sqrt{2}\,|\zeta'_{\alpha}\chi'^{\alpha}|_{(\pm)}-\sqrt{2}\,|\zeta'^{1}\chi'^{2}-\zeta'^{2}\chi'^{1}|_{(\pm)} \quad (8\text{–}32e)$$

and from (7–20)

$$(\rho'u'_{\bar{\alpha}\beta})_{(\pm)}=(\zeta'_{\bar{\alpha}}\zeta'_{\beta}+\chi'_{\bar{\alpha}}\chi'_{\beta})_{(\pm)} \quad (8\text{–}32f)$$

or, using (7–28)

$$(\rho'u'_{\bar{1}1})_{(\pm)}=(\zeta'^{\bar{2}}\zeta'^{2}+\chi'^{\bar{2}}\chi'^{2})_{(\pm)}$$

$$(\rho'u'_{\bar{2}2})_{(\pm)}=(\zeta'^{\bar{1}}\zeta'^{1}+\chi'^{\bar{1}}\chi'^{1})_{(\pm)}$$

$$(\rho'u'_{\bar{1}2})_{(\pm)}=-(\zeta'^{\bar{2}}\zeta'^{1}+\chi'^{\bar{2}}\chi'^{1})_{(\pm)}$$

$$(\rho'u'_{\bar{2}1})_{(\pm)}=-(\zeta'^{\bar{1}}\zeta'^{2}+\chi'^{\bar{1}}\chi'^{2})_{(\pm)}$$

where the vertical bars in (8–32e) indicate the modulus of the invariant $(\zeta'_{\alpha}\chi'^{\alpha})_{(\pm)}$ which, if (8–1d) is not satisfied, will be complex (although the imaginary part will be extremely small for macroscopic problems).

Note that we have written the electromagnetic field equation (8–32c) in terms of the irreducible form $A_{\bar{\alpha}\beta}$ of the 4-potential instead of the usual form A^{j} because it is $A_{\bar{\alpha}\beta}$ that appears in the spinor equations (8–31).

In (8–32a) and (8–32b) both the differential and integrated forms of the "thermal field equation" have been given. For problems involving harmonic expansions, the differential form (8–32a) would probably be more convenient, but for the purposes of the present discussion we shall refer to the integrated form (8–32b).

It will be noted from (8–32) that the source terms of all the field equations are algebraically nonlinear expressions of the spinor components; but, given the functional dependence of the spinor components on the space-time coordinates, it is a simple matter to determine the source terms and then solve the field equations. (Working with (8–32b), one would use the binomial theorem to generate a series involving the ratio of the higher harmonics in the harmonic expansion for ρ to the lowest harmonic, and then terminate the series after enough terms to provide sufficient accuracy.) The fields found by this procedure could then be substituted into the spinor equations (8–31) in order to calculate spinor functions more accurate than those used to calculate the fields. The solution of the equations (8–31) for given g', h', and $A'_{\bar{\alpha}\beta}$ is no problem since the equations are linear. This procedure is the basis for a straight-forward iteration solution of the complete magnetogasdynamical problem. The equations (8–31) have been cast into a form in which all the interaction terms are contained in the square braces preceded by the coupling constant $\alpha=\frac{1}{137}$. The smallness of this constant encourages the hope that the convergence of the solution would be rapid.

It has been noted that the gauge function $N'_{(\pm)}$ is completely arbitrary, and its presence in the spinor equations is a great asset since it can be chosen partially to cancel out unwanted higher harmonics in g' and $h'_{(\pm)}$ which necessarily arise because the source terms of the field equations are algebraically nonlinear functions of the spinor components. To a lesser degree the constants $H'_{(\pm)}$ and $H'_{(-)}$ may also be adjusted to minimize

the effects of higher harmonics, but we must recall that the choice of these two constants is restricted by the constraint (6–9) which in dimensionless form reads

$$\overset{\prime}{m}_{(-)}\overset{\prime}{H}_{(-)} \approx \overset{\prime}{m}_{(+)}\overset{\prime}{H}_{(+)} \qquad (8\text{–}33)$$

How close this relation must come to being an exact equality depends on the magnitude of the difference between $\rho_0{}^{(-)}$ and $\rho_0{}^{(+)}$, and how great a difference between the temperatures of the electron and proton gases one is willing to regard as physically admissible.

It has already been noted that there is no need that $\overset{\prime}{N}_{(+)}$ and $\overset{\prime}{N}_{(-)}$ be equal. Moreover, we are free to choose different $\overset{\prime}{N}_{(\pm)}$ and $\overset{\prime}{H}_{(\pm)}$ at each different stage of the iteration. It may even be possible in certain time-independent problems to choose $\overset{\prime}{N}_{(\pm)}$ and $\overset{\prime}{H}_{(\pm)}$ in such a way as to allow a separation of the angular and radial dependence of the equations. In such a case an iteration procedure would be unnecessary since the system of partial differential equations would reduce to a nonlinear system of ordinary differential equations which could be solved by numerical means.

In order to make the significance of $\overset{\prime}{N}_{(\pm)}$ clearer, it has been shown in Appendix C that introducing a gauge transformation characterized by the real scalar function $\overset{\prime}{N}_{(\pm)}$ is equivalent to multiplying $\overset{\prime}{\zeta}{}^{\beta}{}_{(\pm)}$ by $e^{-i\alpha\overset{\prime}{n}(\pm)}$ and $\overset{\prime}{\chi}{}^{\beta}{}_{(\pm)}$ by $e^{i\alpha\overset{\prime}{n}(\pm)}$.

APPENDIX A: ENERGY INJECTION AND VISCOSITY

Energy Injection

In Section II we saw that the possibility existed of taking energy injection into account by choosing an appropriate functional form for $Q^{j}{}_{(\pm)}$. Let us postulate the following form for $Q^{j}{}_{(\pm)}$:

$$Q^{j}{}_{(\pm)} = (\Lambda c\mu^{j})_{(\pm)} \qquad (A\text{–}1)$$

where $\Lambda_{(\pm)}$ is a scalar function of the fluid coordinates whose physical significance is discussed below. Substituting (A–1) into (2–22), we find that Euler's equation in the fluid rest-frame has the following form:

$$\left[\rho\frac{\partial(\breve{m}c^{2})}{\partial\tau}\right]_{(\pm)} = \left[\rho m\frac{\partial g}{\partial\tau}+\frac{\partial p}{\partial\tau}+\rho(\Lambda mc^{2})\right]_{(\pm)} \qquad (A\text{–}2a)$$

$$\left\{\rho\left[\frac{\partial(\breve{m}\breve{v})}{\partial\tau}\right]_{v=0}\right\}_{(\pm)} = -[\rho m\overset{\circ}{\nabla}g+\overset{\circ}{\nabla}p]_{(\pm)} \pm q\rho_{(\pm)}\overset{\circ}{E}$$

Thus the choice (A–1) produces no new 3-force in the fluid rest-frame, but it does produce a new term $\rho(\Lambda mc^{2})$ in (A–2a). This corresponds to an energy injection into the fluid in which Λ represents the fraction of the particle rest-energy that is injected per particle per unit time. Obviously Λ has the units of inverse time.

In general, $(\Lambda mc^{2})_{(+)} \neq (\Lambda mc^{2})_{(-)}$. The reason for this is that the nuclear reactions give the injected energy to the protons rather than to the electrons, and it is only through collisions that the electrons receive their share of the energy. If, however, we assume that energy equipartition establishes itself instantaneously (i.e., in a time very short compared with the time for the fluid to move a significant distance), then

$$(\Lambda m)_{(+)} = (\Lambda m)_{(-)} \qquad \text{(instantaneous equipartition)} \qquad (A\text{–}3)$$

Although energy injection introduces no new 3-force in the fluid rest-frame, we note from (2–22b) and (A–1) that in the observer's reference frame a 3-force $(\rho\mu^{0})\,(\Lambda m\vec{v})$ appears, where $\Lambda m\vec{v}$ is just the momentum per particle that is injected along with the energy. (If the particle energy, hence its mass, were increased without the supplementary force $\Lambda m\vec{v}$, then, by Newton's Second Law, the particle would necessarily slow down.)

Obviously, (A–1) applies to the case of energy loss (through radiation), as well as to energy injection. It is only necessary to make Λ negative instead of positive. For negative Λ, the force $\Lambda m\vec{v}$ represents a drag on the particle. This is the radiation drag that occurs when a charged particle loses energy by radiation.

As was emphasized in Section II, the use of (A–1) instead of the adiabatic condition (2–30) makes no difference in the form of Euler's equation written in the form (2–24). It does, however, change the "thermal field equation." From (2–15) and (A–1) we see that, instead of (2–31), we have

$$[\rho\partial^{j}h-(\gamma-1)h\partial^{j}\rho-\gamma\Lambda c(\rho\mu^{j};)]_{(\pm)}=0 \qquad (A\text{–}4)$$

Viscosity

For the sake of illustration, a rough and simple way will be given to take into account the viscous interaction between the two charged fluids. Let

$$Q^{j}{}_{(\pm)} = \frac{F}{(\rho m)_{(\pm)}}[(\rho u^{j})_{(\mp)}-(\rho u^{j})_{(\pm)}] \qquad (A\text{–}5)$$

where F is a suitably chosen invariant function of the fluid variables which has the dimensions of a force.

Now we note that for the proton gas, for example, the term $(\rho mcQ^0)_{(+)}$ on the right side of (2–22a), which represents the rate of energy injection per unit volume, has the following form:

$$(\rho mcQ^0)_{(+)} = cF[(\rho\mu^0)_{(-)} - (\rho\mu^0)_{(+)}] \quad \text{(A–6)}$$

The quantity in the brackets is the total change density which, because of the electrostatic screening effect, must be everywhere very close to zero. Thus, the energy injection is also very close to zero. The energy injection for the electron gas is just the negative of (A–6). Thus the energy gained by one field is lost by the other, and the total energy generated is zero.

We note that the force term $(\rho m\vec{Q})_{(+)}$ on the right side of (2–22b), which represents the viscous force on the proton gas, has the form

$$(\rho m\vec{Q})_{(+)} = \frac{F}{c}\left[(\rho u^0\vec{v})_{(-)} - (\rho u^0\vec{v})_{(+)}\right] \quad \text{(A–7)}$$

The second term in the brackets represents a dragging force that acts to slow the proton gas down. The first term is a force which tends to accelerate the proton gas in the direction in which the electron gas is moving. These are just the effects we would expect viscosity to produce. The viscous force acting on the electron gas is just the negative of the viscous force acting on the proton gas. If, for any reason, we wished to free ourselves of this constraint, we could do so very easily by modifying (A–5) so that $Q^j{}_{(+)}$ and $Q^j{}_{(-)}$ involved different invariant functions $F_{(+)}$ and $F_{(-)}$. In this case, the total energy injected into both fields at each point in space by means of the viscous forces is not in general zero.

From (2–15), we see that when $Q^j{}_{(\pm)}$ is given by (A–5) the "thermal field equation" has the following form:

$$\left[\rho\partial^j h - (\gamma-1)h\partial^j\rho + \frac{\gamma F}{m}(\rho u^j)\right]_{(\pm)} = F\gamma_{(\pm)}\left[\frac{(\rho u^j)}{m}\right]_{(\mp)} \quad \text{(A–8)}$$

The approximation based on (A–5) does not take into account the self-interaction of either fluid with itself that results because of viscosity. To do this we would have to introduce derivatives of the velocities into (A–5). In particular, we would introduce a term involving a suitable covariant generalization of the expression $(\vec{\nabla}\cdot\vec{\nabla})\vec{v}_{(\pm)}$.

APPENDIX B: EXPLICIT EXPRESSIONS FOR THE PARTICLE SPINORS

We saw in Section VII that the particle tetrapod has seven degrees of freedom, one of which, the particle density ρ, drops out if we work with a tetrapod normalized to unity. The remaining six degrees of freedom are to be identified with the three components of the particle velocity, and the three Euler angles needed to specify the orientation of the particle tripod in the rest-frame of the particle.

Rather than use the three Cartesian components of the particle velocity, we shall use $\beta = v/c$ and the two spherical angles $\hat{\theta}$ and $\hat{\varphi}$ that specify the direction of the particle velocity in the observer's reference frame. (The caret over $\hat{\theta}$ and $\hat{\varphi}$ merely indicates that these angles refer to the velocity, and distinguishes them from the angles θ, φ which will be used to specify the orientation of the particle tripod.) Thus we write the particle 4-velocity as follows:

$$\begin{aligned}
&\mu^0 = (1-\beta^2)^{-\frac{1}{2}};\ \beta = v/c \\
&\mu^1 = \mu^0\beta \sin\hat{\theta}\cos\hat{\varphi} \\
&\mu^2 = \mu^0\beta \sin\hat{\theta}\sin\hat{\varphi} \\
&\mu^3 = \mu^0\beta \cos\hat{\theta}
\end{aligned} \quad \text{(B–1)}$$

(There will be no need in this appendix for (+) and (−) subscripts since it is understood that everything applies equally well to either of the two charged fluids.)

In order to specify the angular orientation of the particle tripod, we imagine that the observer accelerates himself and his coordinate system in the direction of the particle velocity until his velocity is the same as that of the particle, i.e., until he is in the particle rest-frame. This is accomplished without rotating his coordinate system. The orientation of the tripod $\vec{k}$, $\vec{\lambda}$, and $\vec{\mu}$ is then easily specified in terms of the Euler angles φ, θ, and Ψ that would carry the observer's

own x, y, and z axes over into the positions occupied by the $\vec{\hat{k}}$, $\vec{\hat{\lambda}}$, and $\vec{\hat{\mu}}$ vectors respectively. Thus, we first rotate the observer's tripod of coordinates axes an angle $\tilde{\varphi}$ about his z axis, then an angle $\tilde{\theta}$ about his y *axis*, and finally an angle $\tilde{\Psi}$ about the direction in which the observer's z axis finds itself after the first two rotations have been carried out. The observer's tripod, like the tripod $(\vec{\hat{k}}, \vec{\hat{\lambda}}, \vec{\hat{\mu}})$ is assumed to constitute a right-handed system, and the positive directions for the rotations are given by the right-hand screw rule. Note that $\tilde{\theta}$ specifies the rotation about the y *axis*, rather than the x axis as is frequently the case. The reason for this choice is that it makes the angular dependence of $\vec{\hat{\mu}}$ similar to that of (μ^1, μ^2, μ^3) in (B–1). Thus we have

$$\begin{aligned}\hat{\mu}^1 &= \sin\tilde{\theta}\cos\tilde{\varphi}\\ \hat{\mu}^2 &= \sin\tilde{\theta}\sin\tilde{\varphi}\\ \hat{\mu}^3 &= \cos\tilde{\theta}\end{aligned} \tag{B–2a}$$

$$\begin{aligned}\hat{k}^1 &= \cos\tilde{\theta}\cos\tilde{\varphi}\cos\tilde{\Psi} - \sin\tilde{\varphi}\sin\tilde{\Psi}\\ \hat{k}^2 &= \cos\tilde{\theta}\sin\tilde{\varphi}\cos\tilde{\Psi} + \cos\tilde{\varphi}\sin\tilde{\Psi}\\ \hat{k}^3 &= -\sin\tilde{\theta}\cos\tilde{\Psi}\end{aligned} \tag{B–2b}$$

$$\begin{aligned}\hat{\lambda}^1 &= -(\cos\tilde{\theta}\cos\tilde{\varphi}\sin\tilde{\Psi} + \sin\tilde{\varphi}\cos\tilde{\Psi})\\ \hat{\lambda}^2 &= -(\cos\tilde{\theta}\sin\tilde{\varphi}\sin\tilde{\Psi} - \cos\tilde{\varphi}\cos\tilde{\Psi})\\ \hat{\lambda}^3 &= \sin\tilde{\theta}\sin\tilde{\Psi}\end{aligned} \tag{B–2c}$$

The expressions (B–2) are valid in the particle rest-frame. It is now a straight-forward matter to transform these three vectors to the observer's original frame of reference. Let $\vec{v}_1$ be the velocity unit 3-vector, i.e.

$$\vec{v}_1 = \vec{v}/v = (\sin\hat{\theta}\cos\hat{\varphi},\ \sin\hat{\theta}\sin\hat{\varphi},\ \cos\hat{\theta}) \tag{B–3}$$

Then from the Lorentz transformation we have

$$\mu^0 = \mu^0\beta(\vec{\hat{\mu}}\cdot\vec{v}_1) \tag{B–4a}$$

$$\vec{\mu} = (\mu^1, \mu^2, \mu^3) = \vec{\hat{\mu}} + (u^0 - 1)(\vec{\hat{\mu}}\cdot\vec{v}_1)\vec{v}_1 \tag{B–4b}$$

where

$$\vec{\hat{\mu}}\cdot\vec{v}_1 = \sin\hat{\theta}\sin\tilde{\theta}\cos(\hat{\varphi}-\tilde{\varphi}) + \cos\hat{\theta}\cos\tilde{\theta} \tag{B–4c}$$

$$k^0 = \mu^0\beta(\vec{\hat{k}}\cdot\vec{v}_1) \tag{B–5a}$$

$$\vec{k} = (k^1, k^2, k^3) = \vec{\hat{k}} + (u^0 - 1)(\vec{\hat{k}}\cdot\vec{v}_1)\vec{v}_1 \tag{B–5b}$$

where

$$\vec{\hat{k}}\cdot\vec{v}_1 = \sin\hat{\theta}\sin(\hat{\varphi}-\tilde{\varphi})\sin\tilde{\Psi} + \sin\hat{\theta}\cos\tilde{\theta}\cos(\hat{\varphi}-\tilde{\varphi})\cos\tilde{\Psi} - \cos\hat{\theta}\sin\tilde{\theta}\cos\tilde{\Psi} \tag{B–5c}$$

$$\lambda^0 = u^0\beta(\vec{\hat{\lambda}}\cdot\vec{v}_1) \tag{B·6a}$$

$$\vec{\lambda} = (\lambda^1, \lambda^2, \lambda^3) = \vec{\hat{\lambda}} + (u^0 - 1)(\vec{\hat{\lambda}}\cdot\vec{v}_1)\vec{v}_1 \tag{B–6b}$$

where

$$\vec{\hat{\lambda}}\cdot\vec{v}_1 = \sin\hat{\theta}\sin(\hat{\varphi}-\tilde{\varphi})\cos\tilde{\Psi} - \sin\hat{\theta}\cos(\hat{\varphi}-\tilde{\varphi})\cos\tilde{\theta}\sin\tilde{\Psi} + \cos\hat{\theta}\sin\tilde{\theta}\sin\tilde{\Psi} \tag{B–6c}$$

By means of (B–1) – (B–6), all sixteen components of the tetrapod (normalized to unity) have been specified as functions of β, $\hat{\theta}$, $\hat{\varphi}$, $\tilde{\theta}$, $\tilde{\varphi}$, and $\tilde{\Psi}$. We must now find expressions for the components of ζ^α and χ^α in terms of these variables (plus ρ and ϵ) such that the relations (7–27) are satisfied. It can be verified by direct calculation that the following are the desired expressions:

$$\zeta^\alpha = 2^{-1/4}\rho^{1/2}e^{1/2(\epsilon-\tilde{\Psi})}\hat{\zeta}^\alpha \tag{B–7a}$$

$$\chi^\alpha = 2^{-1/4}\rho^{1/2}e^{1/2(\epsilon+\tilde{\Psi})}\hat{\chi}^\alpha \tag{B–7b}$$

where

$$\hat{\zeta}^1 = [\cosh v/2 + \sinh v/2\cos\hat{\theta}]\cos\tilde{\theta}/2e^{-i\tilde{\varphi}/2} + \sinh v/2\sin\hat{\theta}\sin\tilde{\theta}/2e^{-i(\hat{\varphi}-\tilde{\varphi}/2)} \tag{B–8a}$$

$$\hat{\zeta}^2 = [\cosh v/2 - \sinh v/2\cos\hat{\theta}]\sin\tilde{\theta}/2e^{i\tilde{\varphi}/2} + \sinh v/2\sin\hat{\theta}\cos\tilde{\theta}/2e^{i(\hat{\varphi}-\tilde{\varphi}/2)} \tag{B–8b}$$

$$\hat{\chi}^1 = -[\cosh v/2 + \sinh v/2\cos\hat{\theta}]\sin\tilde{\theta}/2e^{-i\tilde{\varphi}/2} + \sinh v/2\sin\hat{\theta}\cos\tilde{\theta}/2e^{-i(\hat{\varphi}-\tilde{\varphi}/2)} \tag{B–8c}$$

$$\hat{\chi}^2 = [\cosh v/2 - \sinh v/2\cos\hat{\theta}]\cos\tilde{\theta}/2e^{i\tilde{\varphi}/2} - \sinh v/2\sin\hat{\theta}\sin\tilde{\theta}/2e^{i(\hat{\varphi}-\tilde{\varphi}/2)} \tag{B–8d}$$

where

$$v = \tanh^{-1}\beta \tag{B–8e}$$

and

$$\begin{aligned}\cosh v/2 &= \sqrt{\tfrac{1}{2}(u^0+1)}\\ \sinh v/2 &= \sqrt{\tfrac{1}{2}(u^0-1)}\end{aligned} \tag{B–8f}$$

Let us now find expressions for the variables ρ, ϵ, β, $\hat{\theta}$, $\hat{\varphi}$, $\tilde{\theta}$, $\tilde{\varphi}$, and $\tilde{\Psi}$ in terms of the spinors ζ^α

and χ^α. From (7–35) we have

$$\rho=[2(\zeta_\alpha\chi^\alpha)(\zeta_{\dot\beta}\chi^{\dot\beta})]^{\frac{1}{2}} \tag{B–9}$$

and

$$e^{i\epsilon}=\left[\frac{\zeta_\alpha\chi^\alpha}{\zeta_{\dot\beta}\chi^{\dot\beta}}\right]^{1/2} \tag{B–10}$$

In order to find expressions for the other variables, it is convenient to introduce the functions A and B defined as follows:

$$A=\frac{\zeta^1}{\sqrt{\zeta_\alpha\chi^\alpha}}+\frac{\chi^{\bar 2}}{\sqrt{\zeta_{\dot\beta}\chi^{\dot\beta}}}$$
$$=\sqrt{2(u^0+1)}\cos\tilde\theta/2e^{-i/2(\tilde\Psi+\tilde\varphi)} \tag{B–11a}$$

$$B=\frac{\zeta^2}{\sqrt{\zeta_\alpha\chi^\alpha}}-\frac{\chi^1}{\sqrt{\zeta_{\dot\beta}\chi^{\dot\beta}}}$$
$$=\sqrt{2(u^0+1)}\sin\tilde\theta/2e^{-i/2(\tilde\Psi-\tilde\varphi)} \tag{B–11b}$$

From (B–11) it follows that

$$\cos\tilde\theta=\frac{A\bar A-B\bar B}{A\bar A+B\bar B} \tag{B–12}$$

$$e^{i\tilde\varphi}=\left[\frac{\bar AB}{A\bar B}\right]^{1/2} \tag{B–13}$$

$$e^{i\tilde\Psi}=\left[\frac{\bar A\bar B}{AB}\right]^{1/2} \tag{B–14}$$

In order to find β, $\hat\theta$, and $\hat\varphi$, it is most convenient to use the following relations, which result from (7–26), (7–25), and (7–22):

$$\rho u^0=\frac{1}{\sqrt{2}}[\zeta^1\zeta^{\bar 1}+\zeta^2\zeta^{\bar 2}+\chi^1\chi^{\bar 1}+\chi^2\chi^{\bar 2}] \tag{B–15a}$$

$$\rho\mu^1=\rho\mu^0\beta\sin\hat\theta\cos\hat\varphi=\sqrt{2}R[\zeta^1\zeta^{\bar 2}+\chi^1\chi^{\bar 2}] \tag{B–15b}$$

$$\rho\mu^2=\rho\mu^0\beta\sin\hat\theta\sin\hat\varphi=-\sqrt{2}I[\zeta^1\zeta^{\bar 2}+\chi^1\chi^{\bar 2}] \tag{B–15c}$$

$$\rho u^3=\rho u^0\beta\cos\hat\theta=\frac{1}{\sqrt{2}}[\zeta^1\zeta^{\bar 1}-\zeta^2\zeta^{\bar 2}+\chi^1\chi^{\bar 1}-\chi^2\chi^{\bar 2}] \tag{B–15d}$$

Having found μ^0 from (B–15a) and (B–9), we use the following relation to find:

$$\beta=\frac{1}{u^0}[(u^0)^2-1]^{1/2} \tag{B–17}$$

From (B–15b) – (B–15d) we have

$$\tan\hat\theta=\frac{1}{u^3}[(u^1)^2+(u^2)^2]^{1/2} \tag{B–18}$$

$$\tan\hat\varphi=u^2/u^1 \tag{B–19}$$

In the solution of a magnetogas-dynamical problem of the self-excited dynamo type, we would solve the spinor equations (8–1) or (8–31) and arrive at expressions for ζ^α and χ^α as functions of time t and the spherical coordinates r, θ, and φ. We would then use the above expressions to find ρ, β, $\hat\theta$, $\hat\varphi$, $\tilde\theta$, $\tilde\varphi$, and $\tilde\Psi$ as functions of the coordinates (t, r, θ, φ).

APPENDIX C: DIFFERENTIAL SPINOR RELATIONS

Observable Quantities

Using the spinors ζ^α and x^α, and the gradient operator $\partial_{\alpha\dot\beta}$ (or ∂_j) as the basic ingredients, it is possible to construct many differential expressions. Before any physical meaning can be given to these expressions, however, it is necessary to translate them into expressions involving the observable quantities ρ, ϵ, u^j, μ^j, ω^j, and s^{jk} which are defined as follows:

$$\rho e^{i\epsilon}\equiv\sqrt{2}(\zeta_\alpha\chi^\alpha) \tag{C–1}$$

$$\rho\mu^j\equiv\sigma^j_{\alpha\dot\beta}(\zeta^\beta\zeta^{\bar\alpha}+\chi^\beta\chi^{\bar\alpha} \tag{C–2}$$

$$\rho\mu^j\equiv\sigma^j_{\alpha\dot\beta}(\zeta^\beta\zeta^{\bar\alpha}-\chi^\beta\chi^{\bar\alpha}) \tag{C–3}$$

$$\omega^j\equiv\tfrac{1}{2}\lambda_l\partial^j k^l \tag{C–4a}$$

where

$$\rho k^j\equiv\sigma^j_{\alpha\dot\beta}(\zeta^\beta\chi^{\bar\alpha}+\chi^\beta\zeta^{\bar\alpha}) \tag{C–4b}$$

$$\rho\lambda^j\equiv-i\sigma^j_{\alpha\dot\beta}(\zeta^\beta\chi^{\bar\alpha}-\chi^\beta\zeta^{\bar\alpha}) \tag{C–4c}$$

Using (C–4b) and (C–4c) in (C–4a), ω^j can also be written as follows:

$$\omega^j=I\left[\left(\frac{\chi^\beta}{\sqrt{\zeta_\alpha\chi^\alpha}}\right)\partial^j\left(\frac{\zeta_\beta}{\sqrt{\zeta_\alpha\chi^\alpha}}\right)\right] \tag{C–5a}$$

or

$$\omega^j=\tfrac{1}{2}I[(\zeta_\alpha\chi^\alpha)^{-1}(\chi^\beta\partial^j\zeta_\beta-\zeta_\beta\partial^j\chi^\beta)] \tag{C–5b}$$

The dual tensors s^{jk} and $\hat s^{jk}$ are defined as follows:

$$s^{jk}\equiv-\epsilon^{jkln}\mu_l\mu_n=-\tfrac{1}{2}\epsilon^{jkln}s_{ln} \tag{C–6}$$

$$\hat s^{jk}\equiv\tfrac{1}{2}\epsilon^{jkln}s_{ln}=u^j\mu^k-u^k\mu^j \tag{C–7}$$

The following orthogonality properties result from (C–6):

$$s^{jk}u_k=u_j s^{jk}=0 \tag{C–8a}$$

$$s^{jk}\mu_k=\mu_j s^{jk}=0 \tag{C–8b}$$

It can be shown that s^{jk} and $\hat{s}^{jk}$ are related to the spinors ζ^α and χ^α as follows:

$$\hat{s}^{jk}=R[(\zeta_\nu\chi^\nu)^{-1}g^{kl}\sigma_l^{\beta\dot{\lambda}}\sigma^j_{\dot{\lambda}\alpha}(\zeta^\alpha\chi_\beta+\chi^\alpha\zeta_\beta)] \quad \text{(C-9)}$$

$$s^{jk}=-I[(\zeta_\nu\chi^\nu)^{-1}g^{kl}\sigma_l^{\beta\dot{\lambda}}\sigma^j_{\dot{\lambda}\alpha}(\zeta^\alpha\chi_\beta+\chi^\alpha\zeta_\beta)] \quad \text{(C-10)}$$

Thus we see that the symmetric spinor expression $(\zeta^\alpha\chi_\beta+\chi^\alpha\zeta_\beta)$ is to be associated with the dual tensors $\hat{s}^{jk}$ and s^{jk}. The antisymmetric spinor expression $(\zeta^\alpha\chi_\beta-\chi^\alpha\zeta_\beta)$ corresponds to the Kronecker delta function $\zeta_j{}^k$ as shown by the following identity:

$$\zeta_j{}^k=-(\zeta_\nu\chi^\nu)^{-1}\sigma_j^{\beta\dot{\lambda}}\sigma^k_{\dot{\lambda}\alpha}(\zeta^\alpha\chi_\beta-\chi^\alpha\zeta_\beta) \quad \text{(C-11)}$$

In this appendix we shall have no need to label quantities with the (+) and (−) subscripts. When the sign of the particle charge enters an equation it will be indicated by σ, where $\sigma=\pm1$.

Gradients of Spinors

Using the definitions (C-1) to (C-5) it can be verified that the following expressions for the gradients of ζ^β and χ^β are valid identities:

$$\partial_j\zeta^\beta=\zeta^\beta[\tfrac{1}{2}(\partial_j\ln\rho+\mu_i\partial_ju^i)+i(\omega_j+\tfrac{1}{2}\partial_j\epsilon)]$$
$$-\frac{e^{i\epsilon}}{\sqrt{2}}\chi_{\bar{\alpha}}\partial_j(u^{\beta\bar{\alpha}}+\mu^{\beta\bar{\alpha}}) \quad \text{(C-12a)}$$

$$\partial_j\chi^\beta=\chi^\beta[\tfrac{1}{2}(\partial_j\ln\rho-\mu_i\partial_ju^i)-i(\omega_j-\tfrac{1}{2}\partial_j\epsilon)]$$
$$+\frac{e^{i\epsilon}}{\sqrt{2}}\zeta_{\bar{\alpha}}\partial_j(u^{\beta\bar{\alpha}}-\mu^{\beta\bar{\alpha}}) \quad \text{(C-12b)}$$

These identities can be written in a more symmetric form, as follows:

$$\partial_k\zeta^\beta=-\sqrt{2}e^{i\epsilon}\sigma_j^{\beta\dot{\lambda}}\chi_{\dot{\lambda}}[(2\rho)^{-1}\partial_k(\rho\mu^j)+i(u^j\omega_k$$
$$+\tfrac{1}{2}\mu^j\partial_k\epsilon-\tfrac{1}{2}s^{jl}\partial_ku_l)] \quad \text{(C-13a)}$$

$$\partial_k\chi^\beta=-\sqrt{2}e^{i\epsilon}\sigma_j^{\beta\dot{\lambda}}\zeta_{\dot{\lambda}}\Big[(2\rho)^{-1}\partial_k(\rho\mu^j)$$
$$+i(u^j\omega_k+\frac{1}{2}\mu^j\partial_k\epsilon-\frac{1}{2}s^{jl}\partial_ku_l)\Big] \quad \text{(C-13b)}$$

If we multiply these two identities by $\sigma_{\bar{\alpha}\beta}{}^k$, contracting the k and the β, we arrive at the following identities:

$$\partial_{\bar{\alpha}\beta}\zeta^\beta=\zeta^\beta\sigma^k_{\bar{\alpha}\beta}[\tfrac{1}{2}(\partial_k\ln\rho-\mu_j\partial_ku^j-\partial^j\hat{s}_{jk}+s_{kj}\partial^j\epsilon)$$
$$+i(\omega_k+\tfrac{1}{2}\partial^js_{jk}+\tfrac{1}{2}\hat{s}_{kj}\partial^j\epsilon)] \quad \text{(C-14a)}$$

$$\partial_{\bar{\alpha}\beta}\chi^\beta=\chi^\beta\sigma^k_{\bar{\alpha}\beta}[\tfrac{1}{2}(\partial_k\ln\rho+\mu_j\partial_ku^j+\partial^j\hat{s}_{jk}-s_{kj}\partial^j\epsilon)$$
$$-i(\omega_k+\tfrac{1}{2}\partial^js_{jk}+\tfrac{1}{2}\hat{s}_{kj}\partial^j\epsilon)] \quad \text{(C-14b)}$$

Alternative expressions for $\partial_{\bar{\alpha}\beta}\zeta^\beta$ and $\partial_{\bar{\alpha}\beta}\chi^\beta$ could be found by contracting (C-12) instead of (C-13).

Using (C-12) – (C-14), it is possible to derive the following identities:

Scalar Identities

$$\zeta^{\bar{\alpha}}\partial_{\bar{\alpha}\beta}\zeta^\beta-\chi^{\bar{\alpha}}\partial_{\bar{\alpha}\beta}\chi^\beta=\tfrac{1}{2}\partial_j(\rho\mu^j)$$
$$+iu_j[\rho\omega^j+\tfrac{1}{2}\partial_k(\rho s^{kj})+\tfrac{1}{2}\rho\hat{s}^{jk}\partial_k\epsilon] \quad \text{(C-15)}$$

$$\zeta^{\bar{\alpha}}\partial_{\bar{\alpha}\beta}\zeta^\beta+\chi^{\bar{\alpha}}\partial_{\bar{\alpha}\beta}\chi^\beta=\tfrac{1}{2}\partial_j(\rho u^j)$$
$$+i\mu_j[\rho\omega^j-\tfrac{1}{2}\partial_k(\rho s^{kj})+\tfrac{1}{2}\rho\hat{s}^{jk}\partial_k\epsilon] \quad \text{(C-16)}$$

Vector Identities

$$g^{jl}\sigma_l^{\nu\bar{\alpha}}(\chi_\nu\partial_{\bar{\alpha}\beta}\zeta^\beta-\zeta_\nu\partial_{\bar{\alpha}\beta}\chi^\beta)=$$
$$=-\frac{e^{i\epsilon}}{\sqrt{2}}\Big\{s^{jk}\Big[\rho\omega_k+\frac{1}{2}\partial^l(\rho s_{lk})\Big]$$
$$+\frac{1}{2}u^j\partial_k(\rho u^k)-\frac{1}{2}\mu^j\partial_k(\rho\mu^k)\Big\} \quad \text{(C-17)}$$
$$-\frac{ie^{i\epsilon}}{2\sqrt{2}}\Big\{\rho\partial^j\epsilon+2\hat{s}^{jk}\Big[\rho\omega_k+\frac{1}{2}\partial^l(\rho s_{lk})\Big]$$
$$+\rho s^{jk}[u^l\partial_l\mu_k-\mu^l(\partial_lu_k-\partial_ku_l)]\Big\}$$

$$g^{jl}\sigma_l^{\nu\bar{\alpha}}(\chi_\nu\partial_{\bar{\alpha}\beta}\zeta^\beta+\zeta_\nu\partial_{\bar{\alpha}\beta}\chi^\beta)=$$
$$=\frac{e^{i\epsilon}}{2\sqrt{2}}\{\rho u^k\partial_k\mu^j+\rho\omega_k[(\partial^ju^k-\partial^ku^j)$$
$$-\epsilon^{jkln}u_l\partial_n\epsilon]+\mu^j\partial_k(\rho u^k)-u^j\partial_k(\rho\mu^k)\} \quad \text{(C-18)}$$
$$-\frac{ie^{i\epsilon}}{\sqrt{2}}\Big\{\rho\omega^j+\frac{1}{2}\partial_k(\rho s^{kj})+\frac{1}{2}\rho\hat{s}^{jk}\partial_k\epsilon\Big\}$$

Tensor Identities

$$g^{jl}\sigma_l^{\beta\nu}\sigma_{\nu\alpha}{}^k(\zeta^\alpha\partial_{\lambda\beta}\zeta^\lambda-\chi^\alpha\partial_{\bar{\lambda}\beta}\chi^{\bar{\lambda}})=$$
$$=\tfrac{1}{2}g^{jk}\{\tfrac{1}{2}(\partial_i(\rho\mu^l)-iu_n$$
$$[\rho\omega^n+\tfrac{1}{2}\partial_l(\rho s^{ln})+\tfrac{1}{2}\rho\hat{s}^{nl}\partial_l\epsilon]\}$$
$$+\tfrac{1}{2}\{\tfrac{1}{2}[\partial^j(\rho\mu^k)-\partial^k(\rho\omega^j)]-\epsilon^{jkln}\mathfrak{F}_{ln}\}$$

$$-\frac{i}{4}\left\{\begin{array}{l} s^{jk}\partial_l(\rho u^l)+2\left[\rho\omega^j+\frac{1}{2}\partial_l(\rho s^{lj})+\frac{1}{2}\rho\hat{s}^{jl}\partial_l\epsilon\right]u^k \\ \qquad -2\left[\rho\omega^k+\frac{1}{2}\partial_l(\rho s^{lk})+\frac{1}{2}\rho\hat{s}^{kl}\partial_l\epsilon\right]u^j \\ +\rho u^l\partial_l s^{jk}-\rho s^j{}_l[(\partial^l u^k-\partial^k u^l)-\epsilon^{lkpq}u_p\partial_q\epsilon] \\ \qquad +\rho s^k{}_l[(\partial^l u^j-\partial^j u^l)-\epsilon^{ljpq}u_p\partial_q\epsilon] \end{array}\right\} \tag{C-19}$$

$$\begin{aligned} &g^{jl}\sigma_l^\beta{}^r\sigma^k_{r\alpha}(\zeta^\alpha\partial_{\lambda\beta}\zeta^\lambda+\chi^\alpha\partial_{\lambda\beta}\chi^\lambda)= \\ &\quad=\tfrac{1}{2}g^{jk}\{\tfrac{1}{2}\partial_l(\rho u^l)-i\mu_n, \\ &\qquad\qquad [\rho\omega^n+\tfrac{1}{2}\partial_l(\rho s^{ln})+\tfrac{1}{2}\rho\hat{s}^{nl}\partial_l\epsilon]\} \\ &\quad+\tfrac{1}{2}\{\tfrac{1}{2}[\partial^j(\rho u^k)-\partial^k(\rho u^j)]-\epsilon^{jkln}Q_{ln}\} \end{aligned}$$

$$-\frac{i}{4}\left\{\begin{array}{l} s^{jk}\partial_l(\rho\mu^l)-2\left[\rho\omega^j-\frac{1}{2}\partial_l(\rho s^{lj})+\frac{1}{2}\rho\hat{s}^{jl}\partial_l\epsilon\right]\mu^k \\ \qquad -2\left[\rho\omega^k+\frac{1}{2}\partial_l(\rho s^{lk})+\frac{1}{2}\rho\hat{s}^{kl}\partial_l\epsilon\right]\mu^j \\ +\rho\mu^l\partial_l s^{jk}-\rho s^j{}_l[(\partial^l u^k-\partial^k\mu^l)-\epsilon^{lkpq}\mu_p\partial_q\epsilon] \\ \qquad +\rho s^k{}_l[(\partial^l\mu^j-\partial^j\mu^l)-\epsilon^{ljpq}\mu_p\partial_q\epsilon] \end{array}\right\} \tag{C-20}$$

where

$$g_{jl}\sigma_{\bar{\alpha}\beta}{}^l(\zeta^{\bar{\alpha}}\partial_k\zeta^\beta-\chi^{\bar{\alpha}}\partial_k\chi^\beta)=\tfrac{1}{2}\partial_k(\rho\mu_j)+iS_{jk} \tag{C-21}$$

$$g_{jl}\sigma_{\bar{\alpha}\beta}{}^l(\zeta^{\bar{\alpha}}\partial_k\zeta^\beta+\chi^{\bar{\alpha}}\partial_k\chi^\beta)=\tfrac{1}{2}\partial_k(\rho u_j)+i\mathfrak{F}_{jk} \tag{C-22}$$

where

$$S_{jk}=\rho[u_j\omega_k+\tfrac{1}{2}\mu_j\partial_k\epsilon-\tfrac{1}{2}s_{jl}\partial_k u^l] \tag{C-23}$$

$$\mathfrak{F}_{jk}=\rho[\mu_j\omega_k+\tfrac{1}{2}u_j\partial_k\epsilon-\tfrac{1}{2}s_{jl}\partial_k\mu^l] \tag{C-24}$$

Spinor Equations

The relations (C-15) – (C-24) are just identities based on the definitions (C-1) – (C-10). By introducing spinor equations of motion, and substituting these into the above identities, we can find the fluid equations of motion in terms of the observable quantities defined in (C-1) – (C-10). The spinor equations of motion are postulated to have the following form:

$$i\hbar\partial_{\bar{\alpha}\beta}\zeta^\beta=\frac{\tilde{m}c}{\sqrt{2}}\chi_{\bar{\alpha}}-\frac{q}{c}A_{\bar{\alpha}\beta}\zeta^\beta \tag{C-25a}$$

$$i\hbar\partial_{\bar{\alpha}\beta}\chi^\beta=\frac{\tilde{m}c}{\sqrt{2}}\zeta_{\bar{\alpha}}+\frac{q}{c}A_{\bar{\alpha}\beta}\chi^\beta \tag{C-25b}$$

where

$$\tilde{m}=m(1+g/c^2+h/c^2) \tag{C-25c}$$

We shall at times impose the following constraint on the solutions of (C-25):

$$I(\zeta_\beta\chi^\beta)=0 \tag{C-26a}$$

which is equivalent to the constraint

$$\cos\epsilon=\sigma=\pm 1 \tag{C-26b}$$

or

$$\begin{aligned} &\epsilon=0 \text{ for } \sigma=+1 \\ &\epsilon=\pi \text{ for } \sigma=-1 \end{aligned} \tag{C-26c}$$

where ϵ is the phase angle common to ζ^β and χ^β and σ is the sign of the particle charge. The symbol σ will always represent either $+1$ or -1, but in much of what follows we shall not impose conditions (C-26), with the result that in such cases $\cos\epsilon\neq\sigma$. When condition (C-26) is imposed, however, we note that the product $\sigma\cos\epsilon$, which occurs in some of the following expressions, equals $+1$.

Fluid Equations of Motion

We shall first derive the fluid equations of motion without imposing the constraint (C-26). In this way it will be possible to estimate the error introduced by neglecting this constraint.

Substituting (C-25) into (C-15) and (C-16), we have from the real parts of these identities the

following relations:

$$\partial_j(\rho\mu^j) = \frac{2\rho}{\bar{\lambda}} \sin \epsilon \qquad \text{(C-27a)}$$

where

$$\bar{\lambda} = \frac{\hbar}{\tilde{m}c} \qquad \text{(C-27b)}$$

and

$$\partial_j(\rho u^j) = 0 \qquad \text{(C-28)}$$

These equations hold for each of the two charged fluids individually. (C-28) is just the statement of charge conservation, or conservation of the number of particles, for each of the two fluids taken individually.

Equation (C-27) allows us to estimate the magnitude of ϵ for the case that we solve (C-25) without imposing the constraint (C-26). We note that, if we limit ourselves to solutions in which ρ and μ^j are smoothly varying functions whose values change significantly only over distances comparable with L and in time intervals greater than L/c, where L is a length that specifies the dimensions of the system, then from (C-27) we have

$$|\sin \epsilon| = \left|\frac{\bar{\lambda}}{2\rho}\partial_j(\rho\mu^j)\right| \sim \frac{\bar{\lambda}}{L} \approx \frac{\lambda}{L} \qquad \text{(C-29)}$$

where in the last step we have replaced $\bar{\lambda}$ by λ (defined in (7–47) in terms of the free, rather than the bound, particle mass) because the gravitational and thermal energy of a particle is small compared with its rest energy. From (C-29) we see that $|\sin \epsilon|$ is very small for macroscopic systems. Thus, for such systems, we have

$$\begin{aligned} |\epsilon| &\sim \frac{\lambda}{L} \text{ for } \sigma = +1 \\ |\pi - \epsilon| &\sim \frac{\lambda}{L} \text{ for } \sigma = -1 \end{aligned} \qquad \text{(C-30)}$$

where the first case applies to positively charged particles, and the second case to negatively charged particles.

If we impose the condition (C-26), we have, instead of (C-27)

$$\partial_j(\rho\mu^j) = 0 \quad \text{for } \cos\epsilon = \sigma \qquad \text{(C-31)}$$

Substituting (C-25) into (C-18), we arrive at two real vector equations, one of which is the following:

$$\sigma\hbar\rho\omega^j = \rho(\sigma \cos \epsilon)\tilde{m}cu^j - \frac{\sigma\hbar}{2}\partial_k(\rho s^{kj}) - \\ - \frac{\sigma\hbar}{2}\rho s^{jk}\partial_k\epsilon + \frac{\rho(\sigma q)}{c}A^j \qquad \text{(C-32)}$$

In order to gain an intuitive feeling for this equation, let us examine first the second term on the right side. Using (C-6), we can derive the following identity:

$$-\frac{\sigma\hbar}{2}\partial_k(\rho s^{kj}) = \rho\tilde{m}cu^j + \sigma\hbar\rho\pi^j \qquad \text{(C-33a)}$$

where

$$\tilde{m} = -\frac{\sigma\hbar}{2c\rho}u_j\,\partial_k(\rho s^{kj}) \qquad \text{(C-33b)}$$

and

$$\pi^j = (2\rho)^{-1}\epsilon^{jklm}u_k\partial^l(\rho\mu_m) - \tfrac{1}{2}s^{jk}u^l\partial_i u_k \qquad \text{(C-33c)}$$

We note that, because of (C-8a) and the antisymmetry of ϵ^{jklm}

$$\pi^j u^j = 0 \qquad \text{(C-34)}$$

Let us evaluate $\sigma\hbar\rho\pi^j$ in the particle rest-frame:

$$\begin{aligned} \sigma\hbar\rho\vec{\pi} &= [\sigma\hbar\rho(\pi^1,\pi^2,\pi^3)]v_{-0} \\ &= \left[\vec{\nabla}\times\left(\frac{\sigma\hbar}{2}\rho\vec{\mu}\right)\right]_{v_{-0}} - \frac{\sigma\hbar}{2c^2}\dot{\rho}\vec{\mu}\times\left[\frac{d\vec{v}}{d\tau}\right]_{v_{-0}} \qquad \text{(C-35)} \\ &= \left[\vec{\nabla}\times\left(\frac{\sigma\hbar}{2}\rho\vec{\mu}\right)\right]_{v_{-0}} + \left[\rho\frac{d}{d\tau}\left(\frac{\vec{v}}{c^2}\times\frac{\sigma\hbar\vec{\mu}}{2}\right)\right]_{v_{-0}} \end{aligned}$$

If we interpret $\frac{\sigma\hbar}{2}\rho\vec{\mu}$ as the particle spin angular momentum density, then the first term on the right side of (C-35) is just the contribution to the linear momentum density arising from the spin angular momentum density. This linear momentum density is completely analogous to the equivalent current density in a magnetized body that is given by the curl of the magnetization.

In order to understand the second term on the right side of (C-35), we first note that a body whose 3-velocity is $\vec{v}$ and whose mass and angular

momentum in its rest-frame are respectively m and $\frac{\sigma\hbar}{2}\vec{\mu}$ experiences a displacement $\vec{d}$ of its center-of-mass given by the well-known relation(*)

$$\vec{d}=\frac{\vec{v}\times\left(\frac{\sigma\hbar}{2}\vec{\mu}\right)}{\breve{m}c^2} \qquad \text{(C-36)}$$

Thus (C-35) may be written

$$\sigma\hbar\rho\overset{0}{\vec{\pi}}=\left[\vec{\nabla}\times\left(\frac{\sigma\hbar}{2}\rho\vec{\mu}\right)\right]_{v=0}+\left[\rho\frac{d(\breve{m}\vec{d})}{d\tau}\right]_{v=0} \qquad \text{(C-37)}$$

The second term on the right side of (C-37) is the momentum density that results from the change with time of the mass moment of a particle.

Since $\tilde{m}$, which is defined in (C-33b), is an invariant, its value in the particle rest-frame equals its value in all frames.

Thus

$$\rho\tilde{m}=-\frac{\sigma\hbar}{2c}[\partial_k s^{k0}]_{v=0}$$
$$=-\left[\vec{\nabla}\cdot\left\{(\rho u^0)\frac{\vec{v}\times\left(\frac{\sigma\hbar}{2}\vec{\mu}\right)}{c^2}\right\}\right]_{v=0} \qquad \text{(C-38)}$$

where we have made use of (5-2b). Using (C-36) in (C-38), we have

$$\rho\tilde{m}=-[\vec{\nabla}\cdot(\rho u^0\breve{m}\vec{d})]_{v=0} \qquad \text{(C-39)}$$

Thus ρm is just the contribution to the mass density that results from the center-of-mass displacement given by (C-36).

Thus, when we impose the constraint (C-26), the vector equation (C-32) can be written in the particle rest-frame as follows:

$$\sigma\hbar\rho\dot{\omega}^0=\rho\breve{m}c-c[\vec{\nabla}\cdot(\rho u^0\breve{m}\vec{d})]_{v=0} \text{ for } \cos\epsilon=\sigma \qquad \text{(C-40a)}$$

$$\sigma\hbar\rho\dot{\vec{\omega}}=[\sigma\hbar\rho(\omega^1,\omega^2,\omega^3)]_{v=0}$$
$$=-\left[\vec{\nabla}\times\left(\frac{\sigma\hbar}{2}\rho\vec{\mu}\right)\right]_{v=0}+\left[\rho\frac{d(\breve{m}\vec{d})}{d\tau}\right]_{v=0}$$
$$+\frac{\rho(\sigma q)}{c}\vec{A} \qquad \text{(C-40b)}$$
$$\text{for } \cos\epsilon=\sigma$$

This shows us that $\sigma\hbar\rho\omega^j$ is just the rigorously correct expression for the 4-vector canonical momentum density including all the spin effects. Since the spin-dependent contribution to the right side of (C-40a) is very small compared with $\rho\breve{m}c$, the right side of (C-40a) is always positive. Because of the presence of the factor σ on the left, we have the result that the sign of $\dot{\omega}^0$ depends on the sign of the particle charge. This is exactly what we concluded from (7-14), which resulted from identifying the direction of rotation of $\vec{k}$ and $\vec{\lambda}$ about $\vec{\mu}$ with the sign of the particle charge. Thus we see that identifying $\cos\epsilon$ with σ, the sign of the particle charge, as we did in (C-26b), has as a consequence the fact that, for solutions of the spinor equations (C-25), the direction of rotation of $\vec{k}$ and $\vec{\lambda}$ about $\vec{\mu}$ (all derived from the spinors by means of (7-27)) is dependent on the sign of the particle charge. This proves the consistency of the two ways of identifying the sign of particle charge—either as $\cos\epsilon$, or as the direction of rotation of $\vec{k}$ about $\vec{\mu}$.

We can derive the equation of motion (6-6a) by substituting (C-32) into (7-44). Doing this, we have

$$-\partial^j\Phi=Mcu^j+\frac{\sigma q}{c}(A^j+a^j) \text{ for } \cos\epsilon=\sigma \qquad \text{(C-41a)}$$

where

$$M=\breve{m}+\tilde{m} \qquad \text{(C-41b)}$$

is to be regarded as the total mass per particle and

$$a^j=\frac{\hbar c}{q}(\pi^j-r^j)=\frac{q}{\alpha}(\pi^j-r^j) \qquad \text{(C-41c)}$$

where

$$\alpha=\frac{q^2}{\hbar c}=\frac{1}{137.04} \qquad \text{(C-41d)}$$

is the fine-structure constant and π^j and r^j are defined in (C-33c) and (7-42) respectively. a^j is to be regarded as an effective electromagnetic potential to be associated with the magnetic moment of the particle. It is to be noted that, whereas A^j is the same in the dynamical equations for each of the two charged fluids, a^j in (C-41a) represents the two different potentials $a^j_{(+)}$ and $a^j_{(-)}$.

We have already seen in Section III that (C-41) suffices to yield a complete dynamical description of each charged fluid for the case of given thermal, gravitational, and electromagnetic fields.

*See, for example, ref. 10, p. 172, eq. 48. (The difference in sign between this equation and (C-36) results merely from a difference in sign in the definition of velocity.)

Equation (C-39) gives what might be called a kinetic explanation of the mass increment $\tilde{m}$, based as it is on the center-of-mass displacement produced by the motion of the particle. We shall now derive an electromagnetic explanation. First, we arrive at an expression for $(\partial^j u^k - \partial^k u^j)$ by taking the curl of (C-41a):

$$(\partial^j u^k - \partial^k u^j) = u^j \partial^k \ln M - u^k \partial^j \ln M - \frac{\sigma q}{Mc^2}(F^{jk} + f^{jk}) \quad \text{(C-42a)}$$

where

$$f^{jk} = \partial^j a^k - \partial^k a^j \quad \text{(C-42b)}$$

Now we note that (C-33b) can be rewritten as follows:

$$\tilde{m} = -\frac{\sigma\hbar}{2c\rho} u_k \partial_j (\rho s^{jk}) = \frac{\sigma\hbar}{2c} s^{jk} \partial_j u_k = \frac{\sigma\hbar}{4c} s^{jk} (\partial_j u_k - \partial_k u_j) \quad \text{(C-43)}$$

where we have made use of (C-8a) and the antisymmetry of s^{jk}. Substituting (C-42) into (C-43), we have

$$\tilde{m} = \frac{q\hbar}{4Mc^3} s^{jk}(F_{jk} + f_{jk}) = \frac{q\hbar}{4Mc^3} u_j [\epsilon^{jkln} u_k (F_{ln} + f_{ln})] \quad \text{(C-44)}$$

where, in the second step, we have used (C-6). Evaluating the invariant $\tilde{m}c^2$ in the particle rest-frame, we have

$$\tilde{m}c^2 = -\left[\frac{q}{Mc}\left(\frac{\hbar}{2}\vec{\mu}\right)\cdot(\vec{B} + \vec{b})\right] \quad \text{(C-45)}$$

where we have used (2-20) and (5-6). Thus $\tilde{m}$ is the mass corresponding to the interaction energy of a magnetic dipole $\frac{q\hbar}{2Mc}\vec{\mu}$ in a magnetic field $(\vec{B} + \vec{b})$. We note that the magnitude of the gyromagnetic ratio is $\frac{q}{Mc}$, which is the same value we obtain from the Dirac Theory, except that in our case the particle mass M includes the thermal, gravitational, and dipole-interaction energy contributions to the mass, as well as the rest mass.

Magnitude of Spin-Dependent Electromagnetic Field

Now let us estimate the magnitudes of a^j and f^{jk}. If we regard the magnitudes of u^j, μ^j, and s^{jk} as being of order unity, and consider only solutions for which these quantities, as well as $\ln\rho$, change significantly only over a distance of order L and in times intervals greater than L/c, then from (C-33c) we have

$$|\pi^j| \sim \frac{1}{L} \quad \text{(C-46)}$$

Thus from (7-43), (C-46), and (C-41c), we have

$$|a^j| \sim \frac{q}{\alpha L} \quad \text{(C-47)}$$

and from (C-42b), it follows that

$$|f^{jk}| \sim \frac{q}{\alpha L^2} \quad \text{(C-48)}$$

Gauge Transformations

Now let us study the effect of a gauge transformation on equation (C-41a). Let $\tilde{A}_j$ and A^j differ only by the gauge transformation generated by the scalar function η, i.e.

$$A^j = \tilde{A}^j + \partial^j \eta \quad \text{(C-49)}$$

Substituting this into (C-41a), we have

$$-\partial^j\left(\Phi + \frac{\sigma q}{c}\eta\right) = Mcu^j + \frac{\sigma q}{c}(\tilde{A}^j + \partial^j \eta) \quad \text{(C-50)}$$

Thus we see that a gauge transformation is equivalent to adding a scalar function to the de Broglie phase function Φ (or Hamilton's Characteristic Function).

If $\tilde{\zeta}^\alpha$ and $\tilde{\chi}^\alpha$ are the solutions to the spinor equations (C-25) in which A^j is used to describe the electromagnetic field, whereas ζ^α and χ^α are the solutions resulting when the field is described by A^j, then we find from (C-50), (7-8), and (7-33), or by direct substitution of (C-49) into (C-25), that

$$\tilde{\zeta}^\beta = e^{-i\left(\frac{e}{\hbar c}\eta\right)}\zeta^\beta = e^{-i\alpha\eta'}\zeta^\beta \quad \text{(C-51a)}$$

$$\tilde{\chi}^\beta = e^{+i\left(\frac{e}{\hbar c}\eta\right)}\chi^\beta = e^{+i\alpha\eta'}\chi^\beta \quad \text{(C-51b)}$$

where

$$\eta' = \frac{\eta}{\chi} \quad \text{(C-51c)}$$

is the dimensionless form of η, and α is the fine-structure constant introduced in (C-41d). Thus

we see that a gauge transformation is equivalent to a phase change of the spinors.

From (C–50) it is evident that it is always possible to choose η so that Φ has the form

$$\Phi = -mc^2 t \tag{C–52}$$

Using (7–8), (7–33), and (C–52), we see that, for such a choice of gauge, ζ^β and χ^β may be written as follows:

$$\zeta^\beta = e^{i\left(\frac{\sigma mc^2}{\hbar}t\right)}\left[\left(\frac{\rho e^{i\epsilon}}{\sqrt{2}}\right)^{1/2}\hat{\zeta}^\beta\right] \tag{C–53a}$$

$$\chi^\beta = e^{-i\left(\frac{\sigma mc^2}{\hbar}t\right)}\left[\left(\frac{\rho e^{i\epsilon}}{\sqrt{2}}\right)^{1/2}\hat{\chi}^\beta\right] \tag{C–53b}$$

The significance of this way of writing the spinors is that it shows that they can always be written in a form such that the fast time dependence is completely contained in a phase factor whose time dependence is given by the de Broglie frequency but which has no spatial dependence. For a magnetogas-dynamical system in which all the observable quantities are time-independent, the square brackets in (C–53) are completely time independent. In such a case ζ^β and χ^β are irreducible representations of the symmetry operation consisting of a displacement of the origin of the observer's time axis. Thus it would seem that the choice of gauge that corresponds to (C–52), and hence to (C–53), has a fundamental significance that other choices, such as the Lorentz Gauge, do not enjoy.

Error Caused by Variable ϵ

The relations (C–41) assumes that the constraint (C–26) is satisfied. In order to estimate the effect of neglecting this constraint, we substitute (C–32) for arbitrary ϵ into (7–44) and obtain

$$-\tilde{v}^j\Phi = [(\sigma\cos\epsilon)\check{m} - \frac{\sigma\hbar}{2c}\mu^k\partial_k\epsilon + \tilde{m}]cu^j + \frac{\sigma q}{c}\left(A^j + a^j + \frac{\hbar}{2q}\mu^j\frac{d\epsilon}{d\tau}\right) \tag{C–54}$$

Thus the effect of not holding ϵ constant is to introduce an error $\Delta_\epsilon m$ into the mass and an error $\Delta_\epsilon A^j$ into the 4-potential, where

$$\Delta_\epsilon m = -\check{m}(1-\sigma\cos\epsilon) \sim \frac{\sigma\hbar}{2c}\mu^k\partial_k\epsilon \tag{C–55}$$

$$\Delta_\epsilon A^j = \frac{\hbar}{2q}\mu^j\frac{d\epsilon}{d\tau} = \frac{\hbar c}{2q}\mu^j u^k\partial_k\epsilon \tag{C–56}$$

Using (C–30), we have

$$|1-\sigma\cos\epsilon| \sim (\lambda\!\!\!^{-}/L)^2 \tag{C–57}$$

$$\left|\frac{\sigma\hbar}{2c}\mu^k\partial_k\epsilon\right| \sim \frac{\hbar}{2c}\left|\frac{\epsilon}{L}\right| \sim \frac{\hbar}{2c}\frac{\lambda\!\!\!^{-}}{L^2} = \frac{m}{2}\left(\frac{\lambda\!\!\!^{-}}{L}\right)^2 \tag{C–58}$$

$$|\Delta_\epsilon 1^j| \sim \frac{\hbar c}{2q}\left|\frac{\epsilon}{L}\right| \sim \frac{\hbar c}{2q}\frac{\lambda\!\!\!^{-}}{L^2} = \left(\frac{q}{2\alpha L}\right)\left(\frac{\lambda\!\!\!^{-}}{L}\right) \tag{C–59}$$

For the purposes of an estimate, we may replace $\check{m}$ in (C–55) with m. Thus from (C–55), (C–57), and (C–58), we have

$$|\Delta_\epsilon m| \sim m(\lambda\!\!\!^{-}/L)^2 \tag{C–60}$$

Using (C–47), we can write (C–59) as follows:

$$|\Delta_\epsilon A^j| \sim |a^j|(\lambda\!\!\!^{-}/L) \tag{C–61}$$

which shows immediately that, for all macroscopic dynamical systems, $\Delta_\epsilon A^j$ is *a fortiori* negligible if a^j is negligible.

In order to gain an intuitive feeling for the significance of (C–60), let us regard $\Delta_\epsilon m$ as being caused by an error $\Delta_\epsilon h$ in the specific enthalpy. Since the effective mass associated with h is $m(h/c^2)$, we have

$$|\Delta_\epsilon h| \sim c^2(\lambda\!\!\!^{-}/L)^2 \tag{C–62}$$

Using (2–2b) and (2–9), $\Delta_\epsilon h$ can in turn be expressed as an equivalent error $\Delta_\epsilon T$ in the temperature:

$$|\Delta_\epsilon T| \sim \frac{m}{k}|\Delta\epsilon h| \sim \frac{mc^2}{k}(\lambda\!\!\!^{-}/L)^2 \sim \frac{10^{-14}\ \text{cm}^2\ ^\circ\text{K}}{L^2}\ \text{for protons} \sim \frac{10^{-11}\ \text{cm}^2\ ^\circ\text{K}}{L^2}\ \text{for electrons} \tag{C–63}$$

which shows immediately that, for systems on a macroscopic scale, $\Delta_\epsilon T$ (and hence $\Delta_\epsilon m$) is completely negligible.

Precession of Particle Spin

Substituting the spinor equations of motion (C–25) into the complex identity (C–18) yields

two real vector equations. One of these is (C–32). The other is

$$u^j\partial_j\mu^k=\mu_j[(\partial^j u^k-\partial^k u^j)-\epsilon^{jkln}u_l\partial_n\epsilon] \quad \text{(C–64)}$$

where we have made use of (C–27) and (C–28).

As a preliminary to explaining the physical significance of (C–64), we first introduce the 4-vector Ω^j defined as follows:

$$\Omega^j\equiv\frac{c}{2}\epsilon^{jkln}u_k\partial_l u_n \quad \text{(C–65)}$$

The physical significance of Ω^j becomes clear when we consider its value in the fluid rest-frame:

$$\dot{\Omega}^0=0;\ \dot{\vec{\Omega}}=(\Omega^1,\ \Omega^2,\ \Omega^3)_{v=0}=\tfrac{1}{2}(\vec{\nabla}\times\vec{v})_{v=0} \quad \text{(C–66)}$$

Thus Ω^j is just the four-dimensional generalization of the local angular velocity associated with the fluid vorticity.

The following identity follows from the definition of Ω^j:

$$(\partial^j u^k-\partial^k u^j)=\frac{2}{c}\epsilon^{jkln}u_l\Omega_n+(u^j u^l\partial_l u^k-u^k u^l\partial_l u^j) \quad \text{(C–67)}$$

Thus

$$\mu_j(\partial^j u^k-\partial^k u^j)=\frac{2}{c}\mu_j(\epsilon^{jkln}u_l\Omega_n)-\frac{1}{c}u^k\mu_j\frac{du^j}{d\tau} \quad \text{(C–68)}$$

and (C–64) becomes

$$\frac{d\mu^k}{d\tau}=2\mu_j\epsilon^{jkln}u_l(\Omega_n-\frac{c}{2}\partial_n\epsilon)-u^k\mu_j\frac{du^j}{d\tau} \quad \text{(C–69)}$$

In the fluid rest-frame we have

$$\frac{d\dot{\mu}^0}{d\tau}=\frac{1}{c}\left(\vec{\mu}\cdot\frac{d\vec{v}}{d\tau}\right)_{v=0} \quad \text{(C–70a)}$$

$$\frac{d\dot{\vec{\mu}}}{d\tau}=2\left[\left(\vec{\Omega}-\frac{c}{2}\vec{\nabla}\epsilon\right)\times\vec{\mu}\right]_{v=0} \quad \text{(C–70b)}$$

Equation (C–70a) is just an identity. This is most easily seen by noting that the last term on the right side of (C–69) can be transformed as follows:

$$-u^k\mu_j\frac{du^j}{d\tau}=+u^k v_j\frac{d\mu^j}{d\tau} \quad \text{(C–71)}$$

Making this transformation in (C–69), (C–70a) becomes the identity

$$\frac{d\dot{\mu}_0}{d\tau}=\left(u^0 u_j\frac{d\mu^j}{d\tau}\right)_{v=0}=\left(\frac{d\mu}{d\tau}\right)_{v=0} \quad \text{(C–72)}$$

As a preliminary to interpreting (C–70b), we substitute (C–42) into (C–65) and obtain

$$\Omega^j=-\frac{\sigma q}{4Mc}\epsilon^{jkln}u_k(F_{ln}+f_{ln}) \quad \text{(C–73)}$$

In the fluid rest-frame this becomes

$$\dot{\Omega}^0=0;\quad \dot{\vec{\Omega}}=-\frac{\sigma q}{2Mc}(\dot{\vec{B}}+\dot{\vec{b}}) \quad \text{(C–74)}$$

which is just the Larmor Condition we met in (2–44). Thus (C–73) is the relativistic statement of the Larmor Condition.

If we substitute (C–74) into (C–70b), we obtain

$$\frac{d\left(\frac{\sigma\hbar}{2}\dot{\vec{\mu}}\right)}{d\tau}=\left(\frac{q\hbar}{2Mc}\dot{\vec{\mu}}\right)\times(\dot{\vec{B}}+\dot{\vec{b}})+\frac{\sigma\hbar c}{2}\dot{\vec{\mu}}\times\dot{\vec{\nabla}}\epsilon \quad \text{(C–75)}$$

Neglecting for the moment the second term on the right, which vanishes when we impose the constraint (C–26), we see that this equation describes the precession in its own rest-frame of a particle having spin angular momentum $\frac{\sigma\hbar}{2}\dot{\vec{\mu}}$ and a magnetic dipole moment $\frac{q\hbar}{2Mc}\dot{\vec{\mu}}$ in a magnetic field $(\dot{\vec{B}}+\dot{\vec{b}})$. These values correspond to the gyromagnetic ratio $\frac{\sigma q}{Mc}$.

The second term on the right corresponds to an additional precession whose angular velocity is $-c\nabla\epsilon$. With the same basic assumptions used in making previous estimates, we find

$$\frac{\left|\frac{\sigma\hbar c}{2}\dot{\vec{\mu}}\times\nabla\epsilon\right|}{\left|\frac{q\hbar}{2Mc}\dot{\vec{\mu}}\times(\dot{\vec{B}}+\dot{\vec{b}})\right|}\sim\frac{\hbar c}{q|\dot{\vec{B}}+\dot{\vec{b}}|L^2} \quad \text{(C–76)}$$

In the case of a system of laboratory dimensions, we can take $L\sim 1$ cm and $|\dot{\vec{B}}|\sim 1$ gauss. We have already seen that for such a case $|\dot{\vec{b}}|\ll|\dot{\vec{B}}|$, and so $\dot{\vec{b}}$ can be neglected. Thus we find that the ratio (C–76) of the precession velocities is of order 10^{-7}. For larger L or $\dot{\vec{B}}$, the ratio would be even smaller. Thus, for macroscopic systems, the spurious pre-

cession resulting from not holding ϵ constant (i.e. not imposing the constraint (C–26)) is completely negligible compared with the real precession given by the first term on the right side of (C–75).

Finally we note that, substituting the spinor equations (C–25) into (C–19), we obtain from the imaginary antisymmetric part of this equation

$$u^l\partial_l s^{jk} = s^j{}_l[(\partial^l u^k - \partial^k u^l) - {}^{lkpq}u_p\partial_q\epsilon] - s^k{}_l[(\partial^l u^j - \partial^j u^l) - \epsilon^{ljpq}u_p\partial_q\epsilon] \quad \text{(C–77)}$$

where we have made use of (C–28) and (C–32). (C–77) is equivalent to (C–64), except that the spin has been represented by the tensor s^{jk} instead of the vector μ^j. The 3-vector equation obtained by writing the space-like components of (C–77) in the particle rest-frame is just (C–70b), which has already been discussed.

Stress-Energy Tensor

Substituting the spinor equations of motion (C–25) into (C–21), the imaginary part of the resulting equation yields

$$I[\partial_{\bar\alpha\beta}(\zeta^{\bar\alpha}\partial_k\zeta^\beta - \chi^{\bar\alpha}\partial_k\chi^\beta)] = \partial^j\mathfrak{F}_{jk} = \frac{\rho c}{\hbar}\cos\epsilon\partial_k\check m + \frac{\rho q}{\hbar c}u_l\partial_k A_l \quad \text{(C–78)}$$

where $\mathfrak{F}_{jk}$ is defined in (C–23). As a preliminary to explaining this relation, let us define a 4-vector p^j as follows:

$$p^j = \sigma\hbar\omega^j - \frac{\sigma q}{c}A^j \quad \text{(C–79)}$$

Since $\sigma\hbar\rho\omega^j$ has been interpreted as the total (or canonical) particle momentum, including spin effects and the contribution of the external electromagnetic field, p^j is just the inertial part of the particle momentum, including spin effects. From (C–32) we have

$$p^j = (\sigma\cos\epsilon)\check m c u^j - \frac{\sigma\hbar}{2\rho}\partial_k(\rho s^{kj}) - \frac{\sigma\hbar}{2}\hat s^{jk}\partial_k\epsilon \quad \text{(C–80)}$$

Using (C–33), this can also be written

$$p^j = [(\sigma\cos\epsilon)\check m + \tilde m]cu^j + \sigma\hbar\Pi^j - \frac{\sigma\hbar}{2}\hat s^{jk}\partial_k\epsilon \quad \text{(C–81)}$$

Now let us define the tensor T_{jk} as follows:

$$T_{jk} \equiv \sigma\hbar c\mathfrak{F}_{jk} - \sigma q\rho u_j A_k = c\rho\left[u_j p_k + \frac{\sigma\hbar}{2}\mu_j\partial_k\epsilon - \frac{\sigma\hbar}{2}s_{jl}\partial_k u^l\right] \quad \text{(C–82)}$$

From (C–82), (C–21), and (C–23) we have

$$T^{jk} = \sigma\hbar c I[\sigma^j_{\bar\alpha\beta}(\zeta^{\bar\beta}\partial^k\zeta^\beta - \chi^{\bar\alpha}\partial^k\chi^\beta)] - \sigma q[\sigma^j_{\bar\alpha\beta}(\zeta^{\bar\alpha}\zeta^\beta + \chi^{\bar\alpha}\chi^\beta)A^k \quad \text{(C–83)}$$

which expresses T^{jk} directly in terms of the spinors ζ^α and χ^α.

Substituting (C–82) into (C–78) and using (C–28), we have

$$\partial^j T_{jk} = \rho(\sigma\cos\epsilon)\partial_k(\check m c^2) + \sigma q\rho(\partial_k A_l - \partial_l A_k)u^l \quad \text{(C–84)}$$

For the case in which condition (C–26) is satisfied, (C–84) becomes

$$\partial^j T_{jk} = \rho\partial_k(\check m c^2) + \sigma q\rho\mathfrak{F}_{kl}u^l = k_k \qquad \text{for } \cos\epsilon = \sigma \quad \text{(C–85)}$$

where k_k is the force density defined in (6–16).

We note that (C–85) is identical with (6–15) except that the contraction on the left side of (C–85) involves the first index, instead of the second as in (6–15). We shall now show that $\partial^j T_{jk} = \partial^j T_{kj}$ (which is not obvious, since T_{jk} is not symmetric).

Substituting the spinor equations of motion into the identity (C–19), we have from the real antisymmetric part of the resulting equation the following relation:

$$\tfrac{1}{2}[\partial^j(\rho\mu^k) - \partial^k(\rho\mu^j)] - \epsilon^{jkln}\mathfrak{F}_{ln} = -\frac{q\rho}{\hbar c}\epsilon^{jkln}u_l A_n \quad \text{(C–86)}$$

Contracting this with ϵ_{pqjk} and using (C–82), we arrive at the following:

$$\frac{1}{c}(T_{jk} - T_{kj}) = -\frac{\sigma\hbar}{2}\epsilon_{jkln}\partial^l(\rho\mu^n) \quad \text{(C–87)}$$

Because the divergence of the right side vanishes, we have the desired result:

$$\partial^j T_{jk} = \partial^j T_{kj} \quad \text{(C–88)}$$

Thus (C–85) is identical with (6–15), and we are justified in interpreting T_{jk} as the stress-energy tensor for the fluid.

Substituting (C–80) into (C–82), we have for the case $\cos\epsilon = \sigma$

$$T^{jk} = \rho\check m c^2 u^j u^k - \frac{\sigma\hbar c}{2}u^j\partial_l(\rho s^{lk}) - \frac{\sigma\hbar c}{2}\rho s^{jl}\partial_k u_l \qquad \text{for } \cos\epsilon = \sigma \quad \text{(C–89)}$$

Comparing with (6–11), we have

$$t^{jk} = -\frac{\sigma\hbar c}{2}[u^j\partial_l(\rho s^{lk}) + \rho s^{jl}\partial_k u_l] \quad \text{for } \cos\epsilon = \sigma \qquad \text{(C–90)}$$

where t^{jk} is the spin-dependent part of T^{jk}.

As discussed in Section V, the fluid energy density is given by T^{00}; the fluid energy flux density $U^j{}_{fl}$ (designated by $U^j{}_{(\pm)}$ in Section V) is given by cT^{0j}; and the fluid momentum density $G^j{}_{fl}$ (designated by $G^j{}_{(\pm)}$ in Section V) is given by $\frac{1}{c}T^{j0}$. It can be shown that in the fluid rest-frame these quantities assume the following form:

$$\dot{T}^{00} = \rho(\check{m}+\tilde{m})c^2 \qquad \text{for } \cos\epsilon = \sigma \qquad \text{(C–91)}$$

$$\vec{\dot{U}}_{fl} = c^2\rho\left[\frac{d(\check{m}\vec{d})}{d\tau}\right]_{v=0} + c^2\left[\vec{\nabla}\times\rho\left(\frac{\sigma\hbar}{2}\vec{\mu}\right)\right]_{v=0} \quad \text{for } \cos\epsilon = \sigma \qquad \text{(C–92)}$$

$$\vec{\dot{G}}_{fl} = \rho\left[\frac{d(\check{m}\vec{d})}{d\tau}\right]_{v=0} \quad \text{for } \cos\epsilon = \sigma \qquad \text{(C–93)}$$

where $\vec{d}$ is defined in (C–36). These expressions make the role of particle spin intuitively evident. The first term on the right side of (C–92) is the energy flux arising from the change in displacement of the center-of-mass of an accelerating particle having spin. $\vec{\dot{G}}_{fl}$ is just the corresponding momentum density. The second term on the right side of (C–92) is the energy flux associated with the linear momentum density arising from the spin angular momentum. If this term (divided by c^2) were to appear in $\vec{\dot{G}}_{fl}$ as well, it would, when we came to calculate the angular momentum density $\vec{r}\times\vec{G}_{fl}$ associated with T^{jk}, give rise to an angular momentum contribution that had its origin in the particle spin. The fact that this term does not appear in $\vec{\dot{G}}_{fl}$ is consistent with the fact that we treat the spin angular momentum density $\vec{S}$ as a separate contribution that is not included in $\vec{r}\times\vec{G}_{fl}$.

Angular Momentum

From (C–85) and (C–88), we obtain the following:

$$(T^{jk} - T^{kj}) = -\partial_l(x^jT^{kl} - x^kT^{jl}) + (x^jk^k - x^kk^j) \qquad \text{(C–94)}$$

Substituting this into (C–87), we have

$$\partial_l M^{jkl} = \frac{1}{c}(x^jk^k - x^kk^j) \qquad \text{(C–95a)}$$

where

$$M^{jkl} = S^{jkl} + \frac{1}{c}(x^jT^{kl} - x^kT^{jl}) \qquad \text{(C–95b)}$$

and

$$S^{jkl} = -\sigma\frac{\hbar}{2}\epsilon^{jkln}(\rho\mu_n) \qquad \text{(C–95c)}$$

As shown in Section V, (C–95a) and (C–95b) constitute the differential form of the statement of conservation of angular momentum, whose integral form is

$$\frac{d}{dt}\int_{v3}(\vec{S} + \vec{r}\times\vec{G}_{fl})dV_3 = \int_{v3}(\vec{r}\times\vec{k})dV_3 \qquad \text{(C–96a)}$$

where from (C–95c) we have

$$\vec{S} \equiv (S^{230}, S^{310}, S^{120}) = \frac{\sigma\hbar}{2}\rho\vec{\mu} = (\rho u^0)\left(\frac{\sigma\hbar}{2}\frac{\vec{\mu}}{u^0}\right) \qquad \text{(C–96b)}$$

The integrand on the left in (C–96a) is the total angular momentum density, and the integrand on the right is the torque density. Since $\vec{S}$ is the spin angular momentum density, and (ρu^0) is the particle density in the observer's reference frame, we see from (C–96b) that $\frac{\sigma\hbar}{2}\frac{\vec{\mu}}{u^0}$ is to be interpreted as the spin angular momentum of a single particle as seen in the observer's frame.

RESULTS FROM THE IMP-I RETARDING POTENTIAL ANALYZER*

G. P. SERBU

Presented are some preliminary experimental results obtained with a planar geometry geometry retarding potential analyzer which was flown on the IMP-I Satellite. The plasma energy spectrum for both ions and electrons was measured in the range from 0 to 100 electron volts. Charged particle density measurements have been obtained continuously from 1000 km to 30 earth radii.

The results show a sharp decrease of about an order of magnitude in charged particle density at about $4.5R_E$, similar to the decrease deduced from whistler observations. The electrons exhibited thermal energies for geocentric distances less than 4.5 R_E. The average electron energy then increased gradually to values above 100 electron volts at about 8 R_E. The observed satellite potential was less than 1 volt positive.

INTRODUCTION

Measurement of the ionized plasma enveloping the earth have been reported on by numerous investigators to date. The region to 30 earth radii has been extensively traversed by a number of satellites, beyond this distance measurements have been made from the Soviet Lunik probes and the American Mariner series.

Primarily the energy spectrum of positively charged particles, presumably protons, has been investigated, and only a few measurements on the electron spectrum below 10 keV are available to date.

Presented are some preliminary experimental results obtained with a retarding potential experiment designed to measure the number density and the energy of ions and electrons in the energy range below 100 eV at distances to 30 earth radii.

2. INSTRUMENTATION

The retarding potential analyzer gives information on the arrival direction and energy distribution of both ions and electrons up to 100 eV. The detector is a charged particle trap of planar geometry which is programmed with appropriate voltages such that the number of charged particles of either polarity can be measured separately as a function of a given energy interval.

The charged particle trap is a circular cup 7 cm in diameter mounted such that the aperture is flush with the satellite skin, and so that it looked out at right angles to the spin axis of the satellite.

The outside aperture is a hole of 5 cm^2 in area over which is stretched a fine wire mesh of 95 percent transmission to light. Surrounding the aperture is a tungsten surface of 35 cm^2 area which is electrically connected to the aperture grid. Spaced parallel to the aperture and 4 mm behind it is the retarding grid. The collector is a disk of tungsten which is, parallel to, and 4 mm behind the retarding grid. The geometry and size of the aperture and the relative spacings provide a view angle for the trap of 5 steradians. Figure 1 shows the total viewing direction of the trap as it was spin-modulated at the satellite spin rate of 22 revolutions per minute. Nearly all directions are viewed during one revolution, with the sun vector lying within 20° of the normal to the trap once each revolution.

The collector current is measured by a logarithmic amplifier whose analog output is presented directly to telemetry. The electrometer sensitivity is from 10^{-11} to 10^{-6} amperes of either polarity. An internal current calibrator is used to check the electronics in flight.

FIGURE 2.—Schematic diagram of sensor and the various programmed voltages.

Figure 2 shows a schematic diagram of the sensor and also the sequence of voltages programmed to the various trap elements in order to define the four modes of operation: low (30 eV) and high (100 eV) ion spectrum and the low (30 eV) and high (100 eV) electron spectrum. A mechanical programmer which operates in synchronism with the telemetry system, is used to switch the voltages to the trap. As an example, the low energy (30 eV) ion spectrum is done as follows: the aperture grid and guard electrode are maintained at −30 volts with respect to the satellite skin, thus all electrons with energy less than 30 eV are excluded from the trap and all positive ions are accelerated through the aperture. The retarding grid voltage is changed in fifteen equal steps between zero volts and plus 28 volts. A current measurement is made and telemetered at each retarding potential step. Only those ions with energies in excess of the retarding potential will pass through the retarding grid and impinge on the collector. In this manner a current voltage characteristic is obtained for ions with energy below 30 eV.

During the ion measurement photoemission current from the collector appear as a positive current with an expected magnitude of about 10^{-8} amperes. As the collector views the sun the photoemission current amplitude will vary as the cosine of the angle between the sun vector and the trap normal and it will be repetitive with the spin cycle, thus the photocurrent can be corrected for in the data. A highly accurate solar aspect sensor is used to find the precise time that the sun vector lies in the plane normal to the trap.

The electron mode of operation is such that the positive 20-volt potential on the collector suppresses all photoelectron emission from the collector. However, photoelectrons can be emitted from the grids and will appear as a negative current, the expected value being 5.10^{-10} amperes. Grid photoemission currents can also be easily corrected for in the electron data.

The 30 eV and 100 eV ion spectra are obtained first and then the trap voltages are reversed and the 30 eV and 100 eV electron spectra are obtained. The entire ion and electron sequence is repeated once every 10 minutes, each individual 15 step spectrum analysis is done within 5.4 seconds.

3. RESULTS

Figure 3 shows a 30 eV electron spectrum which was obtained at 2.2 earth radii (R_e) geocentric distance. The data points are the measured current values, plotted on a logarithmic scale as a function of the known retarding potential voltage. The resultant semilogarithmic plot is a current-voltage characteristic which yields information on the mean energy and the density of electrons. The observed two orders of magnitude decrease in collector current with two volts negative retardation suggests a maxwellian distribution of electron velocities. A second component or high-energy "tail" to the distribution is noted beyond 2 volts.

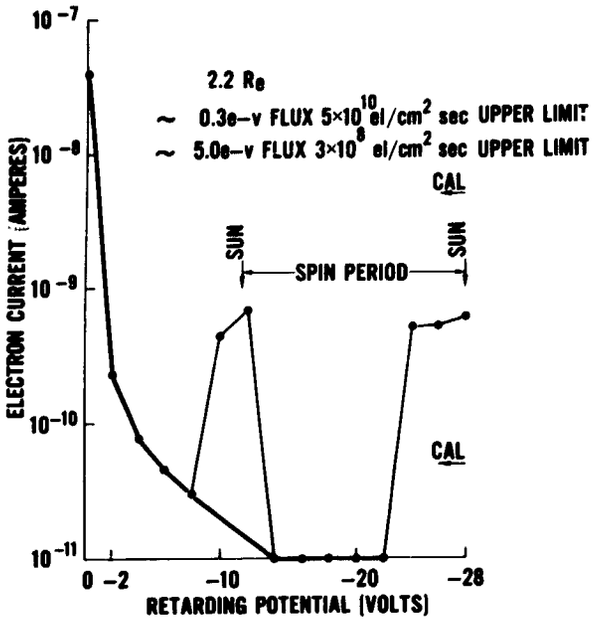

FIGURE 3.—The 30 eV electron spectrum for 2.2 R_e geocentric.

The primary slope yields a value of 0.3 eV or an equivalent electron temperature of 3500°K. From the governing equation:

$$I_- = \tfrac{1}{4} N_e \bar{V}_- eA\, e^{-ve/kT_e} \qquad (1)$$

where I_- is the meaured current, N_e the electron density, $\bar{V}_-$ most probable velocity, A area, v retarding potential, e electronic charge, k Boltzmann constant and T_e the electron temperature. We compute the electron density if A, the effective area is known. Low energy electrons which normally would not impinge on the aperture are deflected into the aperture along the accelerating +30 volt electric field lines; thus an uncertainty in the effective collection area exists. Using the geometric aperture area we compute a flux of 5×10^{10} electrons/cm² sec, this flux could be a factor of 10 too large due to the collection area uncertainty. Using equation (1) a flux of 5.10^{10} el/cm² sec with a mean energy of 0.3 eV at 2.2 R_e; if maxwellian in distribution, represents an electron density of 3.5×10^{3} el/cm³. The high energy component of 5.0 eV has an upper flux value of 3.10^{8} el/cm² sec. It has been suggested by Hanson (1) that at 7000 km, approximately this altitude, a 10^{8} el/cm² sec flux of 5 eV photoelectrons exists. These photoelectrons are formed at altitudes above 300 km and diffuse along magnetic field lines; Mariani (2) extended the work of Hanson and describes the role that these photoelectrons may play in the explanation of the "equatorial" or "geomagnetic" anomaly. Since these electrons are constrained to follow field lines the flux will drop off with the cube of the distance; thus beyond 3 R_e this flux should be below the minimum sensitivity of this experiment.

In Figure 3 the current to the trap decreases below the minimum sensitivity at retarding potentials greater than −12 volts, thus fewer than 1×10^{7} electrons/cm² sec exist with energy in excess of 12 eV. The two photoemission peaks correlate well with the indicated sun position. The magnitude of the photoemission current is consistent with the value of 5×10^{-10} amperes computed on the basis of solar illumination of the 95 percent transparent grid.

Satellites, in general, are charged negative* owing to the high velocity of electrons compared with either the velocity of the satellite or the thermal velocity of ambient ions. However, at very high altitudes, and in interplanetary space, where the electron concentrations are small, a satellite might tend to have a net positive charge due to the photoelectric effect (Ja L Al'Pert et al, 5).

A direct measurement of the net charge, or the resultant potential difference between satellite and plasma as a consequence of the accumulated charge, can be based on observed current-voltage characteristics, Loeb (6); such as the one in Figure 3. Since a positive potential will accelerate ambient electrons to the satellite the measured electron current will not be retarded until an opposing voltage of equal magnitude to that of the satellite potential is reached. At that potential the characteristic will change slope and a further increase in negative voltage will retard the electron current. It is evident from the data of Figure 3 that a break in the curve could exist for potentials more negative than +2 volts; therefore, the satellite potential is not more than 1 volt positive, more probably it is only a few tenths of a volt negative. There is not evidence throughout the magnetosphere that the satellite potential is ever positive.

The 30 eV electron spectrum obtained at 4.6 R_e geocentric is shown in Figure 4. The slope of

*Jastrow and Pearse (3), Beard and Johnson (4)

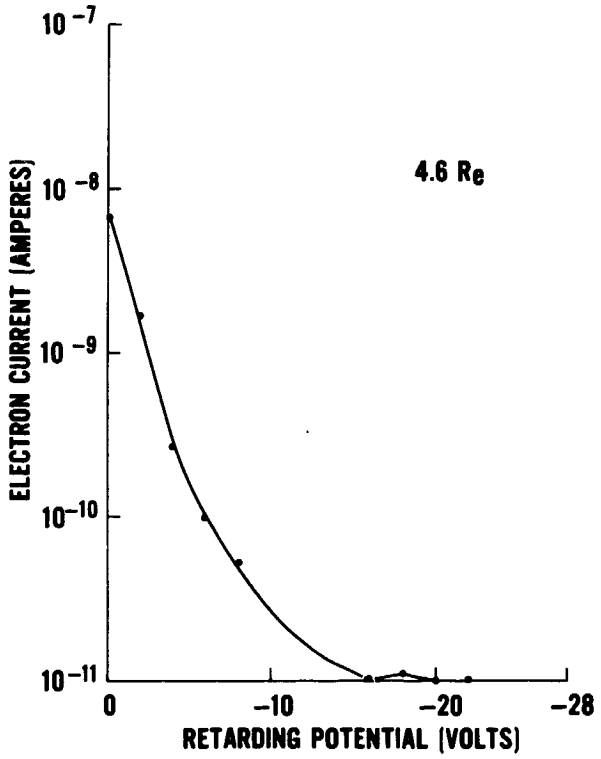

FIGURE 4.—The 30 eV electron spectrum for 4.6 R_e geocentric.

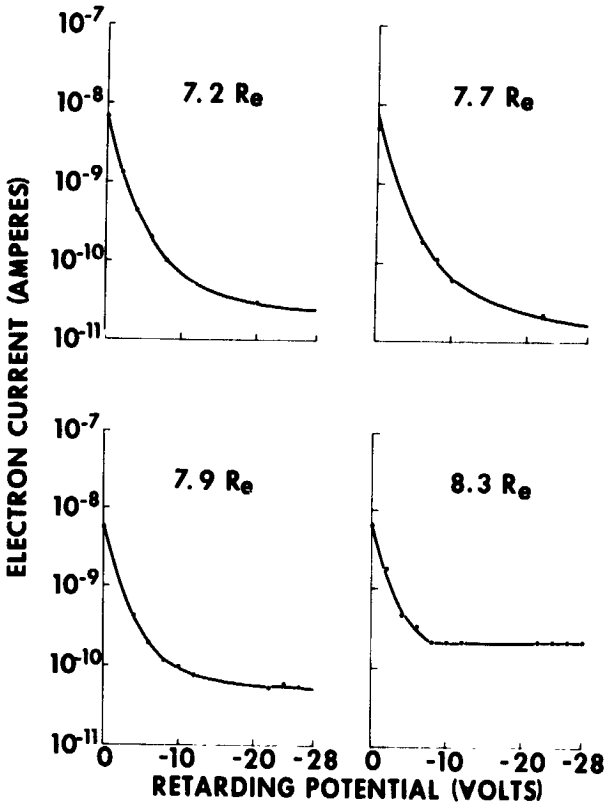

FIGURE 5.—A successive series of 30 eV electron spectra depicting the transit into a region characterized by a residual current in the trap, due to an omnidirectional flux of electrons.

this characteristic yields an electron energy value of 1.4 eV, or an equivalent gas temperature of 16,400°K. A maximum flux of 9×10^9 electrons/cm² sec is computed from the data, assuming the effective area to be equal to the geometric area. Converting to energy, Figure 4 data yields, 2.2×10^{-2}ergs/cm²sec, thus when we compare this to the value of 1 to 10ergs/cm²sec for particles with $E\geq200$ eV obtained by the Explorer XII Cadmium Sulphide Total Energy Detector (CSDTE) Freeman et al (7), it is apparent that a large number of low energy electrons, $E\leq1.4$ eV, exist in the second radiation belt, however, their energy content represents only a small fraction of the total particle energy Gringauz et al (8) infers from the Soviet charge particle traps that in this region an electron flux of 10^9 electrons/cm²sec with energies below 200 eV is present.

Figure 5 shows a consecutive series of 30 eV electron spectra obtained between 7.2 and 8.3 R_e. It is apparent from all spectra that a residual negative current component is measured even at the maximum retardation voltage of 28 volts. Similar data, obtained at 9.2 R_e, is shown in more detail in Figure 6. The residual current amplitude is not roll modulated, thus at 8.2 R_e, on the sunlit side of earth, the satellite crossed into a region of omnidirectional electrons with energy in excess of 100 eV at a flux value of 1.5×10^8 electrons/cm²scc. Gringauz et al (9, 10, 11) observed, with Lunik 1 and also with Lunik 2 and Mars 1, a flux of ($1-2\times10^8$el/cm²sec) at these distances with an energy larger than 200 eV, this region has been labeled by him as "the outermost belt of charged particles."

Figure 7 shows the 100 eV ion and electron spectra obtained at 9.0 and 9.1 R_e. The omnidirectional current residual in both traps at 100 volt retardation indicates that both ions and electrons are present in the outermost belt of charged particles with energies in excess of 100 eV. The data of Figure 7 may also be used to illustrate that the net current flow to the satellite is essentially zero. At zero retardation, the current flow to the collector should be representative of any given area on the surface of the satellite, thus in order to maintain a constant satellite to plasma

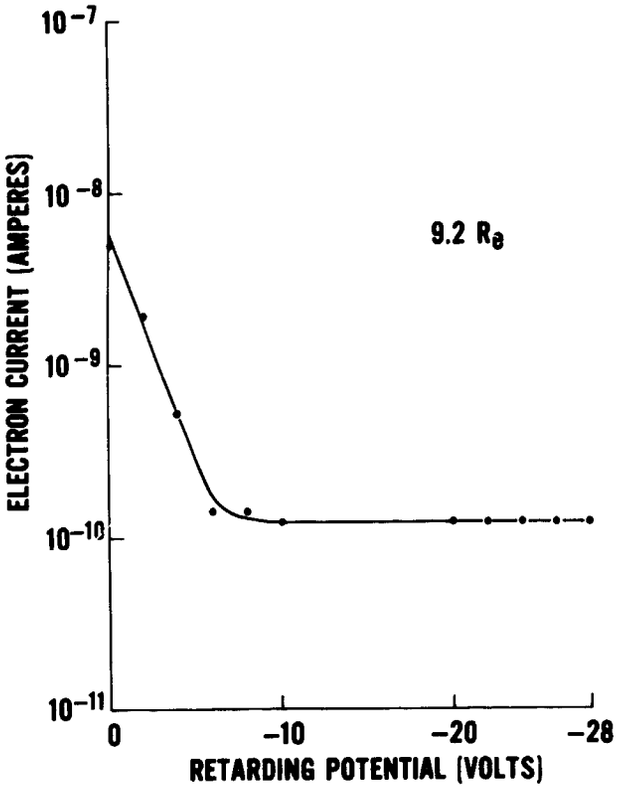

FIGURE 6.—The 30 eV electron spectrum for 9.2 R_e geocentric.

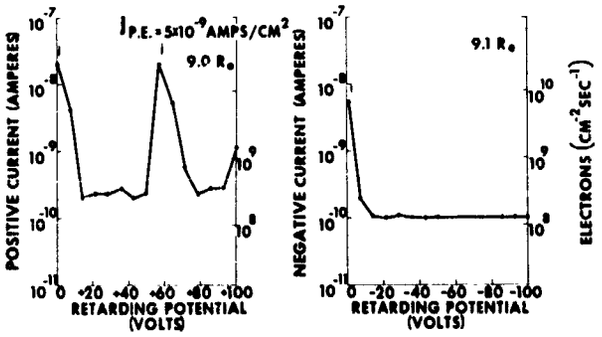

FIGURE 7.—The 100 eV ion and electron spectra obtained at 9.0 R_e and 9.1 R_e geocentric.

potential it must be shown that the net current flow to the satellite is zero. The photoemission current constitutes a positive current flow, i.e. electrons flowing outward from the satellite, which acts over the illuminated cross sectional area of the satellite. The negative current is, on the other hand, effective over the entire area of the satellite velocity, and so electrons diffuse inward from all directions. In order to have a net zero current flow the ratio of the photocurrent to electron current must be equal to 4 which is the inverse ratio of the areas to which these current flows are effective. From Figure 7 the current ratios at zero volt retardation are seen to be 4; thus the trap currents at zero retardation are inferred to be representative of the overall current flow to the satellite and we deduce that the equilibrium satellite potential in sunlight is stabilized near zero volts.

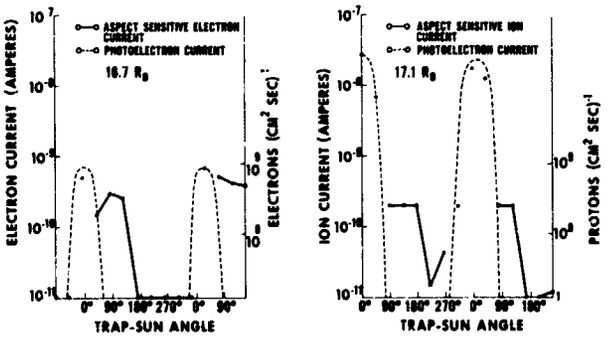

FIGURE 8.—The ion and electron currents plotted as a function of trap-sun angle orientation. These responses typify the data obtained at distances beyond 16.2 R_e geocentric on the first IMP–1 orbit.

The data in Figure 8 is representative of the trap currents at distances beyond 16.2 R_e geocentric. Positive and negative currents have been plotted as a function of orientation relative to the sun. This presentation was chosen since attempts at plotting the currents as a function of retarding voltages were fruitless. After subtracting out data points which are due to photoemission, the dashed curve, a residual net current in both traps, is evident at 90 degree clockwise rotation from the sun, in the anti-solar direction the currents to the trap drop below 1×10^{-11} amperes. Since the retarding potentials do not affect the trap currents it is evident that the negative current measurement represents a net negative charge entering the trap with energies in excess of 100 eV, and that the positive current measurement represents a sum of net positive charge plus secondary electron emission. Assuming a secondary electron emission efficiency of 100 percent these observations are consistent with the computation that what is seen beyond 16.2 R_e, i.e. in the solar wind region is a net flux of both ions and electrons of the order of 10^8 particles/cm²sec with energies in excess of 100 eV.

4. CONCLUSIONS

An overall summary of these observations may be made with the use of Figure 9, which is a plot of the electron flux as a function of geocentric distance. The three plotted curves were computed from the negative current in the trap found in the 0 to −5 volt retardation interval, the −5 to −10 volt and the −100 volt interval.

The flux of electrons with energies $0 \leq E \leq 5$ eV shows a steep decrease with distance between 3 and 5 R_e. This type of electron drop-off is in agreement with whistler observations, Carpenter (12) refers to the decrease as the "equatorial knee" and points out that the equatorial knee moves further out; i.e. beyond 3 R_e, during magnetically quiet periods. Out to about 3 R_e we note that the flux in the energy interval $5 \leq E \leq 10$ eV is decreasing with distance. This energy interval contains the previously mentioned Hanson photoelectrons, evident in Figure 2. Furthermore the drop off in flux evident in Figure 9 lends credulity to our belief that in this region we observe a flux of trapped photoelectrons produced at altitudes above 300 km.

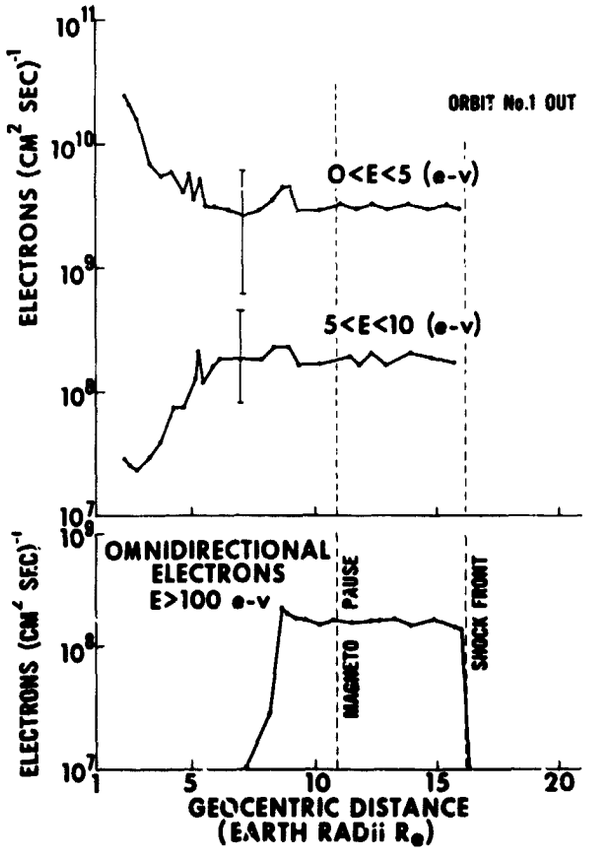

FIGURE 9.—Plot of the electron flux as a function of geocentric distance. Three electron energy intervals are shown.

Beyond 3 R_e an increase in the flux of electrons with energy $5 \leq E \leq 10$ eV is noted, at 7 R_e this flux is comparable to the flux of lower energy electrons. The error bars in the figure reflect the previously discussed uncertainty in the "effective collection area." Thus the overall picture is one of an initial sharp decrease in thermal electron concentration accompanied by an increase in the average energy of electrons, such that, at some 7 R_e geocentric there are nearly as many electrons with energy greater than 5 eV as there are those with energy below 5 eV. At 8.2 R_e geocentric, on the sunlit side of earth, with a payload-earth-sun angle of 25 degrees, a flux of 2×10^6 electrons/cm² sec omnidirectional electrons with energy greater than 100 eV is observed. There is no significant variation in this flux rate across the magnetosphere; the magnetosphere boundary was determined through the IMP-I magnetometer data of Ness (12). Beyond 16.2 R_e the flux of these omnidirectional particles drops off sharply. Whereas, crossing of the magnetosphere boundary is not evident from the trap data, the crossing of the shock front is. On the earth side of the shock front the trap currents are governed by the retarding potential voltages. Outside the shock front the trap currents are governed by the trap-sun angle orientation.

The recent controversy Gringauz (13), Van Allen (14), concerning the observations of particles in the outermost belt of charged particles and whether or not these particles are trapped is not resolved on the basis of these IMP observations; since it is possible to explain the observed constant flux across the magnetosphere boundary either on the basis of some unknown mechanism for solar wind penetration as suggested by Gringauz or on the basis that the total trapped flux inside the boundary just equals the flux outside the boundary, a possibility not excluded by the measurements of Explorer XII and IV. Frank et al (15).

5. ACKNOWLEDGMENTS

Messrs. W. J. Archer and J. Luce were responsible for the instrumentation associated with this

experiment. Also acknowledged are the helpful discussions with Mr. R. E. Bourdeau.

EFFECT OF COMPRESSIBILITY, ROTATION AND MAGNETIC FIELD ON THE DRAG ON A SPHERE OSCILLATING IN A CONDUCTING, VISCOUS MEDIUM*

M. P. SINGH†

I. INTRODUCTION

The role of rotation and magnetic fields in cosmical fluid dynamics is well known. Recently, some attention has been given by several authors (1–7) on the interaction of Coriolis forces and Lorentz forces on flow phenomena.

It is generally accepted (1, 2) that hydromagnetic flow in the earth's liquid core is somehow responsible for the main geomagnetic field, and therefore a theory of the dynamics of core motions is required in order to understand a plausible theory of the earth's magnetic field. It has been suggested that the near coincidence between the geographic and geomagnetic poles is the result of the strong influence of Coriolis forces, due to the earth's rotation, on motions in the core.

So much of meteorology depends ultimately upon the dynamics of a revolving fluid. The large-scale and moderate motions of the atmosphere are greatly affected by the rotation of the earth. Kelvin is said to have pointed out (8) that rotation confers on a fluid certain properties resembling those of an elastic solid, and a rotating fluid can transmit waves. In the case of an infinite liquid, rotating as a rigid body about an axis, the amount of energy possessed by the liquid is infinite and it is of great interest to know how small disturbances propagate in such a liquid.

To understand some of these phenomena, it will be interesting to study the flow of a rotating fluid around elementary bodies. We consider here small oscillations of a sphere in a compressible, viscous, electrically conducting and rotating medium in the presence of a uniform magnetic field. In addition to the above mentioned interests, this problem may have some applications in connection with the transmission of sound by fog (see 9, p. 659).

The classical problem of the oscillation of a sphere in a viscous fluid was first considered by Stokes (9, p. 643). The drag force experienced by the sphere is (in dimensionless form)‡

$$X_0 = -6\pi u_s\left(\frac{1}{R_e}+\frac{1}{\sqrt{2R_e}}\right)-2\pi\frac{du_s}{dt}\left(\frac{1}{3}+\frac{3}{\sqrt{2R_e}}\right). \quad (1)$$

It is the purpose of the present investigation to determine the effects of the magnetic field, compressibility, coriolis forces and their mutual interaction on the drag and other physical variables. Because of the motion of the fluid in the magnetic field, an associated electrical field is produced which, according to Ohm's law sets up electrical currents in the fluid if the latter is a conductor. The interaction of these currents with the magnetic field then produces a body force which must be included in the Navier-Stokes equations for the motion of the fluid. The effect of this body force is to inhibit the motion of the fluid across the lines of force. The viscous effect gives rise to viscous dissipative waves, the magnetic effect is responsible for Alfvén waves while the compressibility and rotation produce sound and the so-called Taylor waves respectively. Their mutual interaction will make the situation even more complicated. In the next section, we make several assumptions to make the problem mathematically more amenable.

†Dr. Singh is a National Academy of Sciences—National Research Council Postdoctoral Resident Research Associate.

‡The dimensionless quantities and parameters in (1) are explained in section II.

II. FUNDAMENTAL EQUATIONS AND FORMULATION OF THE PROBLEM

Let the sphere oscillate along the axis of the rotating fluid which is taken to be the x-axis. The origin is at the mean position of the center of the sphere. Let the uniform magnetic field be $H^0\underline{i}$. The equations of motion of a compressible, viscous, unbounded fluid rotating with a constant angular velocity $\Omega\underline{i}$, referred to a rotating frame of reference are (in m.k.s. units)

$$\rho\frac{d\underline{v}}{dt}+2\rho\underline{\Omega}\times\underline{v}+\rho\underline{\Omega}\times(\underline{\Omega}\times\underline{r}) = -\nabla p+\mu \text{ curl } \underline{H}\times\underline{H}+\rho\nu\nabla^2\underline{v}+\frac{\rho\nu}{3}\nabla \text{ div } \underline{v}, \quad (2)$$

where ρ is the density, $\underline{v}$ the velocity of the fluid, $\underline{H}$ is total magnetic field, p is the pressure, r is the radial coordinate: $r^2=y^2+z^2$, ν the kinematic viscosity (assumed constant) and μ the magnetic permeability (assumed constant).

The equation of continuity is

$$\text{div } (\rho\underline{v})+\frac{\partial\rho}{\partial t}=0. \quad (3)$$

The physical equation (the conduction of heat is neglected) is

$$\frac{1}{p}\frac{dp}{dt}=\frac{\gamma}{\rho}\frac{d\rho}{dt},$$

(where γ denotes the ratio of two specific heats) which can be written as (9, p. 654)

$$p=p^0+\rho^0 c^2 s, \quad (4)$$

where c is the velocity of sound in the absence of viscosity, p^0, ρ^0 represent pressure and density in the undisturbed state and s denotes the condensation

$$\rho=\rho^0(1+s). \quad (5)$$

Maxwell's equations with the usual notation for electromagnetic quantities are

$$\text{(i) curl } \underline{H}=\underline{J}, \qquad \text{(ii) div } \underline{H}=0,$$
$$\text{(iii) curl } \underline{E}=-\mu\frac{\partial\underline{H}}{\partial t}, \qquad \text{(iv) div } \underline{E}=0, \quad (6)$$
$$\text{(v) } \underline{J}=\sigma[\underline{E}+\mu\underline{v}\times\underline{H}],$$

where the electrical conductivity σ is treated as constant.

From (i), (iii) and (v) we obtain

$$\frac{\partial\underline{H}}{\partial t}-\text{curl } (\underline{v}\times\underline{H})=\frac{1}{\mu\sigma}\nabla^2\underline{H}. \quad (7)$$

As in the classical problem, the convective terms in (2) will henceforth be neglected. This is justified if

$$R_s=a|v_s|/\nu\ll 1, \quad (8)$$

where v_s is the velocity of the sphere and a is its radius.

Further linearization of (2) and (3) is possible by means of (5) which yields

$$\rho^0\frac{\partial\underline{v}}{\partial t}+2\rho^0\underline{\Omega}\times\underline{v}+\underline{\Omega}\times(\underline{\Omega}\times\underline{r}) = -\nabla p+\mu \text{ curl } \underline{H}\times\underline{H}+\rho^0\nu\nabla^2\underline{v}+\frac{\rho^0\nu}{3}\nabla \text{ div } \underline{v} \quad (9)$$

and

$$\text{div } \underline{v}+\frac{\partial s}{\partial t}=0. \quad (10)$$

These equations will be now reduced to a dimensionless form by referring the length to a, the radius of the sphere, the velocity to $a\lambda$ ($\lambda/2\pi$ is the frequency of the oscillation), the time to $1/\lambda$, the magnetic field to H^0, the electric field to $\mu a\lambda H^0$, the current density $\underline{J}$ to H^0/a and the pressure to $\rho^0 a^2\lambda^2$. The equations (6), (7) then become

$$\text{(i) curl } \underline{H}=\underline{J}, \qquad \text{(ii) div } \underline{H}=0,$$
$$\text{(iii) curl } \underline{E}=\frac{\partial\underline{H}}{\partial t}, \qquad \text{(iv) div } \underline{E}=0, \quad (11)$$
$$\text{(v) curl } \underline{H}=R_m[\underline{E}+\underline{v}\times\underline{H}]$$

and

$$\nabla^2\underline{H}=R_m\left[\frac{\partial\underline{H}}{\partial t}-\text{curl } (\underline{v}\times\underline{H})\right] \quad (12)$$

where

$$R_m \text{ (Magnetic Reynolds number)}=a^2\lambda\mu\sigma. \quad (13)$$

In addition, we introduce the following parameters:

$$R_e \text{ (Reynolds number)}^*=a^2\lambda/\nu \quad (14a)$$

*It should be noted that we have used $a\lambda$ as velocity in the definition of the Reynolds number. There still is another important dimensionless parameter α/a, where α is the amplitude of the oscillatory motion of the sphere. It is assumed that this quantity is small compared to unity.

The velocity of sphere is $v_s\,\underline{i}=\alpha\,\lambda\,e^{\Omega t}\,\underline{i}$, or in dimensionless form, $u_s\,\underline{i}=\alpha/a\,e^{it}\,\underline{i}$.

The Reynolds number for the flow might also have been defined as

$$R_s=a\alpha\lambda/\nu\ (=R_e\,\alpha/a).$$

It is necessary that

$$R_s\ll 1,$$

whereas the requirement for R_e is less severe.

$$\beta\ (\text{magnetic pressure number})=\frac{\mu H^{02}}{\rho^0 a^2\lambda^2}, \tag{14b}$$

the ratio of the magnetic pressure to dynamic pressure, and

$$\delta=2\Omega/\lambda, \tag{14c}$$

the inverse of the so-called Rossby number $R_o=\lambda/(2\Omega)=1/\delta$. In terms of these parameters, equations (9) and (10) reduce to

$$\frac{\partial \underline{v}}{\partial t}+\delta\underline{i}\times\underline{v}=\beta\ \text{curl}\ \underline{H}\times\underline{H}+\frac{1}{R_e}\nabla^2\underline{v}-\left(c^2+\frac{i}{3R_e}\right)\nabla s$$

and

$$\text{div}\ \underline{v}=-\frac{\partial s}{\partial t} \tag{16}$$

where velocity of sound c is now in non-dimensional form referred to $a\lambda$, and if we assume that

$$R_o\gg 1, \tag{17}$$

so as to neglect second and higher powers of δ, the centrifugal force in (9) being of 0 (δ^2) is dropped* in (15).

The boundary conditions on $\underline{v}$ are $\underline{v}=u_s\,\underline{i}$ on the surface of the sphere and is zero at infinity. If the conductivity σ' of the sphere† is comparable to the conductivity σ of the fluid, we require that $\underline{H}$ should be continuous across the surface of the sphere, while at infinity, $\underline{H}=\underline{i}$.‡

We next make two important assumptions:

(1) The magnetic Reynolds number R_m is a small parameter. We can then find a perturbation solution for small R_m. This is a valid assumption in most practical problems and this technique has been adopted in several discussions (see for example, Ludford [10] and Tamada [11]).

(2) The magnetic pressure is comparable to dynamic pressure, i.e. we assume $\beta=0(1)$.

We assume an expansion in powers of R_m:

$$\begin{aligned}\underline{v}&=\underline{v}_o+R_m\underline{v}_1+\cdots\\ \underline{H}&=\underline{H}_o+R_m\underline{H}_1+\cdots\\ \underline{E}&=\underline{E}_o+R_m\underline{E}_1+\cdots\\ s&=s_o+R_m s_1+\cdots\end{aligned} \tag{18}$$

and obtain a set of equations from (11), (12), (15) and (16) with appropriate boundary conditions. It should be noted that some of the complications which arise from boundary conditions in magneto-gas-dynamics are conveniently absent in this problem.

III. SOLUTION OF THE RESULTING EQUATIONS

Zeroth Order Equations

(i) curl $\underline{H}_o=0$, div $\underline{H}_o=0$, that is the magnetic field to this order is independent of the fluid velocity. The same equations hold inside the sphere and the boundary conditions are that $\underline{H}_o=\underline{i}$ at infinity and it is continuous across the surface of the sphere. The solution is, therefore,

$$\underline{H}_o\equiv\underline{i}. \tag{19}$$

(ii) The electric field $\underline{E}_o$ satisfies curl $\underline{E}_o=0$, div $\underline{E}_o=0$, both in the fluid and the sphere. The continuity of the tangential electric field on the surface of the sphere and vanishing of $\underline{E}_o$ at infinity implies

$$\underline{E}_o\equiv 0. \tag{20}$$

(iii) The zeroth order flow fields and pressure fields are unaffected by the magnetic field and are given by§

$$(\nabla^2+h^2)\underline{v}_0=-i\left(\frac{k^2-h^2}{k^2}\right)\nabla s_0-\delta R_e\underline{v}_0\times\underline{i} \tag{21}$$

*Notice that for large values of radial distance, our neglecting centrifugal force may not be justified even though δ^2 is negligible. In the Incompressible case, it presents no difficulty since it can be absorbed with pressure term. However, in Compressible case, this cannot be done. But since we are primarily interested in the effects of Coriolis forces on the motion, following the standard procedure in such cases (see for example Hide and Roberts 1960 [2] and Talwar 1964 [5]), centrifugal force may be ignored.

†The discussion will be valid even if the sphere is an insulator. We assume that the permeabilities of the sphere and the fluid are equal.

‡These conditions imply that the tangential components of electric field will be continuous across the sphere and that $\underline{E}=0$ at infinity.

§The boundary condition $\underline{v}=u_s\,\underline{i}=\frac{\alpha}{a}e^{it}\,\underline{i}$ on the surface of the sphere and the linearity of the system of differential equations imply that the only time dependence of the physical variables is a factor e^{it}.

and

$$\text{div } \underline{v}_0 = -i\, s_0 \tag{22}$$

where

$$k^2 = \frac{3R_e}{4i + 3R_e c^2} \tag{23}$$

$$h^2 = -i\, R_e. \tag{24}$$

As in the non-rotating case, we have here axial symmetry in that the physical variables are independent of the azimuthal coordinate φ.* However, the azimuthal components of velocity and magnetic field will be non-zero here in contrast to the non-rotating case in which v_φ and H_φ were zero.

From (21) and (22) it follows that $v_{cx} = 0(1)$, $v_{or} = 0(1)$ and $v_{o\varphi} = 0(\delta)$ and hence

$$(\nabla^2 + k^2) s_o = 0(\delta^2). \tag{25}$$

It follows that the coupled equations (21) can be simplified in this case. In fact, in view of (17) and (25), v_{cx} and v_{or} satisfy identically the same system of equations and boundary conditions as in the non-rotating case. The solution is therefore (9, p. 656)

$$\text{(i) } s_0 = A \times f_1\,(kR) \tag{26}$$

$$\text{(ii)} \underline{v}_{-0} = \frac{i}{k^2} \nabla s_0 + \underline{v}^c_{-0}$$

where the first term in (ii) is a particular integral of (21) and (22) and the last term

$$\underline{v}^c_{-0} = B\left[2 f_0(hR) \nabla x - h^2 R^5 f_2(hR) \nabla \frac{x}{R^3}\right], \tag{27}$$

is the complementary function. (R, Θ, φ)** are the spherical polar coordinates. The function $f_n\,(\zeta)$, defined as

$$f_n(\zeta) = \left(-\frac{1}{\zeta}\frac{d}{d\zeta}\right)^n \frac{e^{-\zeta}}{\zeta}, \tag{28}$$

represents spherical waves with rapidly diminishing amplitude—the one with argument $\zeta = hR$ denotes boundary layer effects (viscous) while the one with argument $\zeta = kR$ essentially represents compressibility effects (sound waves). The constants A and B are given by

$$A = \frac{-ik^2 h f_1'(h) u_s}{2k f_1(h) f_1'(k) + h f_1'(h)[k f_1'(k) + f_1(k)]},$$
$$B = \frac{k f_1'(k) u_s}{3[2k f_1(h) f_1'(k) + h f_1'(h)\{k f_1'(k) + f_1(k)\}]}. \tag{29}$$

Now v_{0_φ} can be determined in a straight-forward manner from (21). In fact, exactly similar arguments can be applied while determining $\underline{H}_1$ and $\underline{v}_1$ to show that only azimuthal components H_{1_φ} and $v_1{}^\varphi$ are affected by rotation. In view of this decoupling of the system of equations, the rotational effects, which only generate azimuthal components of velocity and magnetic field, are discussed in Appendix and henceforth, we would only consider non-rotating case.

First Order Equations

(i) The first order magnetic field $\underline{H}_1$ satisfies

$$\nabla^2 \underline{H}_1 = -i s_0 \underline{i} - \frac{\partial \underline{v}_0}{\partial x},$$
$$\text{div } \underline{H}_1 = 0,$$

whose solution is

$$\underline{H}_1 = \underline{H}^c_1 + \frac{i}{k^2} s_0 \underline{i} + \frac{i}{k^4} \nabla \frac{\partial s_0}{\partial x} + \frac{1}{h^2} \frac{\partial \underline{v}_0{}^c}{\partial x} \tag{30}$$

where the first term is the complementary function

$$\underline{H}^c_1 = C \nabla \frac{P_2(\cos\theta)}{R^3} \tag{30a}$$

and the remaining terms represent a particular integral.

On the other hand, inside the sphere, curl $\underline{H}_1 = 0$, div $\underline{H}_1 = 0$, which shows that the sphere acts like an insulator up to this order. It follows that

$$\underline{H}_1 = D \nabla [R^2 P_2(\cos\theta)] \tag{31}$$

inside the sphere. The constants C and D in (30a) and (31) are determined by the requirement that $\underline{H}_1$ is continuous across the surface of the sphere.

(ii) Finally, the first order flow fields and pressure fields are given by

$$\left.\begin{aligned} (\nabla^2 + h^2) \underline{v}_1 &= \beta R_e \left[\nabla H_{1x} - \frac{\partial \underline{H}_1}{\partial x}\right] - i\left(\frac{k^2 - h^2}{k^2}\right) \nabla s_1, \\ \text{div } \underline{v}_1 &= -i s_1 \end{aligned}\right\} \tag{32}$$

*(r, φ, x) are the cylindrical coordinates.

**$x = R \cos\theta$, $r = R \sin\theta$.

from which it follows that

$$(\nabla^2+k^2)s_1=\beta k^2\left[\frac{i}{k^2}\frac{\partial^2 s_0}{\partial x^2}+is_0+\frac{\partial v_{0x}^c}{\partial x}\right]^* \quad (33)$$

We have therefore

$$s_1=s_1^c+\frac{i\beta}{2}\times\frac{\partial s_0}{\partial x}-\frac{Ai\beta}{2}\times f_0(kR)+\frac{\beta k^2}{k^2-h^2}\frac{\partial v_{0x}^c}{\partial x} \quad (34)$$

where the first term

$$s_1^c=E_1R\cdot P_1(\cos\theta)\,f_1(kR)+E_2R^3\cdot P_3(\cos\theta)f_3(kR) \quad (35)$$

is the complementary function of (33) and the remaining terms are a particular integral; and

$$v_1=v_1^c-\frac{\beta}{2k^2}\left\{\nabla\left(x\frac{\partial s_0}{\partial x}\right)-\frac{2}{h^2-k^2}\nabla\frac{\partial^2 s_0}{\partial x^2}\right\}-\frac{\beta}{k^2}\nabla s_0+$$
$$+\frac{\beta h^2}{k^2(h^2-k^2)}\frac{\partial s_0}{\partial x}\underline{i}+\frac{\beta A}{2k^2}\nabla[xf_0(kR)]+\frac{i}{k^2}\nabla s_1^c- \quad (36)$$
$$-\frac{i\beta}{2}\times\frac{\partial v_0^c}{\partial x}-\frac{i\beta}{2}\frac{k^2+h^2}{k^2-h^2}v_{0x}^c\underline{i}.$$

Here the first term

$$v_1^c=F_1\left[2f_0(hR)\nabla x-h^2R^5f_2(hR)\nabla\frac{x}{R^3}\right]$$
$$+F_2\left[4f_2(hR)\nabla\{R^3P_3(\cos\theta)\}\right. \quad (37)$$
$$\left.-3h^2R^9f_4(hR)\nabla\frac{P_3(\cos\theta)}{R^4}\right]$$

is the complementary function of (32) and the remaining terms are a particular integral. The constants E_1, E_2, F_1 and F_2 are determined by the requirement that $\underline{v}_1=0$ at $R=1$.

The following points are worth noting in our solution:

(a) The terms (like $f_n(hR)$) containing the coefficients B, F_1 and F_2 represent the compressibility effects on viscous waves.

(b) The terms (like $f_n(kR)$) containing the coefficients A, E_1 and E_2 represent viscous effects on sound waves.

(c) The terms corresponding to the coefficients C and D represent the potential part of the magnetic field.

*v_{0x}^c is the x-component of the complementary function v_0^c given by (27).

At this point, we would discuss in some more detail the case when the fluid is incompressible.

IV. INCOMPRESSIBLE CASE

The solution in this case can be obtained from the above in the limit as $c\to\infty$ (i.e., $k\to 0$), $s\to 0$ and $c^2s\to p$. (38)

It is clear that we will still have terms (a) and (c) and the corresponding coefficients will be in the limit:

$$B\to\frac{u_s}{2f_0(h)},\quad F_1\to-\frac{\beta Bi}{10}\left[5+h^2\frac{f_1(h)}{f_0(h)}\right],$$
$$F_2\to-\frac{\beta Bih^2}{35}[4+f_1(h)/f_2(h)] \quad (39)$$
$$C\to\frac{h^2B}{5}[f_2(h)-2f_3(h)]\text{ and }D\to-\frac{u_s}{10}.$$

Evidently waves (sound) represented by (b) will no longer be present and the corresponding terms from (b) can be obtained by the limiting process (38):

$$p_0=c^2s_0\to A_1\frac{P_1(\cos\theta)}{R^2}$$

$$p_1=c^2s_1\to\left[\frac{D_1}{R^2}+\beta\left\{\frac{6}{5}BRf_1(hR)-\frac{2}{5}\frac{A_1i}{R^2}\right\}\right]P_1(\cos\theta)$$
$$+\left[\frac{D_2}{R^4}-\beta\left\{\frac{6}{5}Bh^2R^3f_3(hR)\right.\right.$$
$$\left.\left.+\frac{3}{5}\frac{A_1i}{R^2}-\frac{3C}{R^4}\right\}\right]P_3(\cos\theta)$$

$$\underline{v}_0:\ \frac{i}{k^2}\nabla s_0\to A_1i\nabla\frac{P_1(\cos\theta)}{R^2}$$

$$\underline{v}_1:\ -\frac{\beta}{2k^2}\left\{\nabla\left(x\frac{\partial s_0}{\partial x}\right)-\frac{2}{h^2-k^2}\nabla\frac{\partial^2 s_0}{\partial x^2}+2\nabla s_0\right.$$
$$\left.-\frac{2h^2}{h^2-k^2}\frac{\partial s_0}{\partial x}i-A\nabla(xf_0(kR))\right\},$$
$$+\frac{i}{k^2}\nabla s_1^c\to i\nabla\left[D_1\frac{P_1(\cos\theta)}{R^2}+D_2\frac{P_3(\cos\theta)}{R^4}\right],$$
$$+3i\beta C\nabla\frac{P_3(\cos\theta)}{R^4}+\frac{\beta}{h^2}\nabla\frac{\partial^2 p_0}{\partial x^2}$$
$$-\frac{\beta}{10}\frac{\partial}{\partial x}\left[\frac{1}{R^3}\nabla\left(R^5\frac{\partial p_0}{\partial x}\right)-R^2\nabla\frac{\partial p_0}{\partial x}\right]$$

$$\underline{H}_1:\ \frac{i}{k^2}s_0i+\frac{i}{k^4}\nabla\frac{\partial s_0}{\partial x}\to\frac{A_1i}{5}\left[\frac{1}{R^3}\nabla(R^2P_2(\cos\theta))-\right.$$
$$\left.-R^2\nabla\frac{P_2(\cos\theta)}{R^3}\right] \quad (40)$$

where

$$A_1 = -ih^2 B f_2(h),$$

$$D_1 = -\frac{\beta B h^2}{10 f_0(h)}[3f_1^2(h) - f_0(h) f_2(h)],$$

$$D_2 = -\frac{3}{5}\beta B\left[f_0(h) - 5f_1(h) + h^2 \cdot \frac{f_1(h) f_3(h)}{f_2(h)}\right].$$

Next, we can write down the total drag experienced by the sphere*

$$X = -\pi u_s\left[6\left\{\frac{1}{R_e} + \frac{1}{\sqrt{2R_e}}\right\} + \frac{\beta R_m}{5}\left(2 + \frac{3}{\sqrt{2R_e}}\right)\right] - \pi\frac{du_s}{dt}\left[2\left\{\frac{1}{3} + \frac{3}{\sqrt{2R_e}}\right\} - \frac{3\beta R_m}{5\sqrt{2R_e}}\right]. \quad (41)$$

The terms in the curly brackets represent the non-magnetic effect, while the last term in each square bracket represents a hydromagnetic effect. The first square bracket gives a frictional force varying as the velocity: the first term is the Stokes drag for the classical problem in which the sphere undergoes motion of translation; the second term is the oscillatory effect in non-magnetic case; the third term is hydromagnetic, non-viscous, oscillatory effect and the last term is hydromagnetic viscous effect due to oscillation. The magnetic field tends to increase the resistance.

The second square bracket gives the correction to the inertia of the sphere. This amounts to the fraction

$$\frac{1}{2} + \frac{9}{2\sqrt{2R_e}}\left(1 - \frac{\beta R_m}{10}\right)$$

of the mass of fluid displaced, instead of ½ as in the frictionless, non-magnetic case. The effect of the magnetic field is to decrease the apparent mass of the fluid.

Although the derivations strictly do not hold for this case, we may consider the value $R_e \to \infty$ while at the same time keeping $R_e \ll 1$. We then find

$$X = -2\pi\left[\frac{1}{3}\frac{du_s}{dt} + \frac{1}{5}\beta R_m u_s\right],$$

a result which can be checked in a straightforward manner from the corresponding hydromagnetic inviscid problem. The non-magnetic part provides the inertia effect and the magnetic part contributes to the frictional part of the drag.

When the period $\frac{2\pi}{\lambda}$ is made infinitely long, the drag reduces to the Stokes drag in the classical problem in which the sphere moves uniformly in a straight line. This is understandable because as $\lambda \to 0$, the uniform magnetic field H^0 should also approach zero in view of

$$\beta = \frac{\mu H^{0^2}}{\rho^0 a^2 \lambda^2} = 0(1)$$

and so the magnetic effect is absent in this limit.

V. DISCUSSION

First we will discuss the conditions under which our analysis can be expected to give a close approximation to the true flow.

We have neglected the displacement current in comparison with the conduction current, which is justified if

$$\frac{a^2\lambda^2}{L^2} \ll 1, \quad (42)$$

which follows from the order of magnitudes of the various terms in the Maxwell equation (6, *i*) where L is the velocity of light. This is satisfied by all hydromagnetic flow problems in the laboratory. An associated condition, that the excess charge may be neglected, is also satisfied if (42) holds.

As in the classical problem, the convective terms have been neglected. This is justified if† $\alpha \ll a$ (43)

(where α is the amplitude of the oscillation and a is the radius of the sphere), provided

$$R_e = \frac{a^2\lambda}{\nu} = 0(1), \quad (44)$$

which follows from (15), remembering that $s \to 0$, $c^2 s \to p$ in the Incompressible case. For common

*There will be no contribution of the Maxwell stress to the order we are interested in, as there are no currents on the surface of the sphere:

$$\underline{J} = R_m[\underline{E}_0 + \underline{v}_0 \times \underline{H}_0]_{s=1} = 0.$$

†This condition justifies the omission of convective terms both in zeroth order and first order approximations as can be seen by the orders of magnitudes of various terms involved in the momentum equation.

liquids in hydromagnetic experiments, $\nu = 0(10^{-6})$ in m.k.s. units and hence we must make

$$a^2\lambda = 0(10^{-6}). \tag{44a}$$

Next, in the zeroth order approximation of the momentum equation, we neglected the Lorentz force $\underline{J}\times\underline{B} = \beta$ curl $\underline{H}\times\underline{H}$. This is justified if

$$\beta = \frac{\mu H^{0^2}}{\rho^0 a^2 \lambda^2} = 0(1) \tag{45}$$

and

$$R_m = a^2\lambda\mu\sigma \ll 1. \tag{46}$$

In the case of liquid Sodium and Mercury, for example, $\mu\sigma = 0(1)$ and so (46) follows in view of (44a). Condition (45) implies that magnetic pressure is at most comparable to dynamic pressure, which holds for weak field, say 50 gauss or less. In short, our analysis in valid for the oscillations of small globules in the presence of weak magnetic fields.

The following table gives some typical values of these parameters for Mercury, Liquid Sodium and Saturated Salt Water at 25°C when

$$a = .05 \text{ cm}, \quad B^0 = 25 \text{ gauss}, \quad \lambda = 25.$$

	Liquid Sodium	Saturated Salt Water At 25° C	Mercury
R_e	3	6	60
β	25	25	2
R_m	11×10^{-5}	2×10^{-10}	85×10^{-5}

Finally, to study the nature and properties of the solution, it will be convenient to introduce the stream functions Ψ and Φ (where

$$v_z = -\frac{1}{r}\frac{\partial\Psi}{\partial r}, \quad v_r = \frac{1}{r}\frac{\partial\Psi}{\partial x}, \quad H_z = -\frac{1}{r}\frac{\partial\Phi}{\partial r}, \quad H_r = \frac{1}{r}\frac{\partial\Phi}{\partial x}.$$

For the sake of brevity, we write the results here in a shorter form:

$$\Psi = e^{it}\sin^2\theta\left[\frac{a_1(R_e)}{R} + a_2(R_e, R)e^{-(1+i)\sqrt{Re/2}(R-1)}\right]^* + e^{it}\sin^2\theta\left[\frac{a_3(R_e)}{R} + \frac{a_4(R_e)}{R^3} + a_5(R_e, R)e^{-(1+i)\sqrt{Re/2}(R-1)}\right]$$
$$+ e^{it}\sin^2\theta\cos^2\theta\left[\frac{a_6(R_e)}{R} + \frac{a_7(R_e)}{R_3} + a_8(R_e, R)e^{-(1+i)\sqrt{Re/2}(R-1)}\right] \tag{47}$$

(where the terms under the bar represent the non-magnetic part);

$$\Phi = e^{it}\cos\theta\sin^2\theta\left[b_1(R_e) + \frac{b_2(R_e)}{R^2} + b_3(R_e, R)e^{-(1+i)\sqrt{Re/2}(R-1)}\right] \tag{48}$$

As $R_e \to \infty$, $a_1 \to -\frac{1}{2}\frac{\alpha}{a}$, $a_3 \to -\frac{3}{20}i\beta R_m\frac{\alpha}{a}$, $a_4 \to \frac{3}{20}i\beta R_m\frac{\alpha}{a}$, $a_6 \to \frac{3}{4}i\beta R_m\frac{\alpha}{a}$, $a_7 \to -\frac{3}{4}i\beta R_m\frac{\alpha}{a}$, $b_1 \to \frac{1}{4}R_m\frac{\alpha}{a}$

and

$$b_2 \to -\frac{3}{20}R_m\frac{\alpha}{a}. \tag{49}$$

If Φ_s is the corresponding function for the magnetic lines of force inside the sphere,

$$\Phi_s = \frac{1}{10}\frac{\alpha}{a}R_m R^3\cos\theta\sin^2\theta\, e^{it}, \tag{50}$$

which is current-free and hence up to this approximation, the sphere acts like an insulator.

From (47) and (48) it follows that there are three types of terms in the solution:

(1) *Wave-like* (corresponding to the appearance of a boundary layer), effective in a small distance from the surface of the sphere and behaving like $\exp[-(1+i)\sqrt{R_e/2}(R-1)]$. The nature of boundary layer solution is essential the same in hydromagnetics as in a non-magnetic case. The term $\exp[-(1+i)\sqrt{R_e/2}(R-1)]$ represents a

*The wave-like term $\exp[-(1+i)\sqrt{R_e/2}(R-1)]$ comes from the functions $f_n(hR)$ defined by (28).

wave of vibrations propagated from the boundary of the sphere with the velocity $\sqrt{2/R_e}$, but with rapidly diminishing amplitude, the falling off within a wave length being in the ratio $e^{-2\pi}$, or 1/535. The linear magnitude $\sqrt{2/R_e}$, important in all problems of oscillations in incompressible viscous fluids, indicates the extent to which the effects of viscosity penetrate into the fluid. In the case of Mercury its value is .018 $P^{\frac{1}{2}}$ cms, where P is the period of oscillation in seconds. For liquid Sodium, the corresponding value is .079 $P^{\frac{1}{2}}$.

(2) *Irrotational*

$$\left(\frac{\sin^2\theta}{R}, \frac{\cos\theta \sin^2\theta}{R^2}\right), \text{ and}$$

(3) *Rotational*

$$\left(\frac{\sin^2\theta}{R^3}, \frac{\sin^2\theta \cos^2\theta}{R}, \frac{\sin^2\theta \cos^2\theta}{R^3}, \text{in}^2\theta \cos\theta\right).$$

In the non-magnetic case, the motion in the flow field is essentially irrotational at large distances, and it is an interesting result that the magnetic field generates vorticity.

In the case of a magnetic field, the term $\frac{\cos\theta \sin^2\theta}{R^2}$ is current free, while the term $\cos\theta\sin^2\theta$ is responsible for currents at large distances.

From (49) it follows that for large distances, the disturbance in the present problem differs only in amplitude and phase from the one generated by the oscillation of a sphere in a frictionless fluid in the presence of a magnetic field.

The diagrams 1, 2 and 3 illustrate the effects of various parameters on the flow fields. Figure 1 shows how the drag on the sphere varies as it

oscillates. It also shows the influence of conductivity and viscosity on the drag. Figure 2 shows the effect of Reynolds number R_e on magnetic lines of force. The viscosity tends to contract the lines of force. On the other hand, Figure 3 shows the stretching effect of the magnetic field on the stream lines (compare Figure 3 (*a*) and (*b*); (*c*) and (*d*)). Viscosity also tends to produce similar effects on the flow (compare Figure 3 (*a*) and (*c*); (*b*) and (*d*)).

APPENDIX

As pointed out earlier, the only effect of rotation in this problem is that azimuthal components of $\underline{v}$ and $\underline{H}$ are affected in that they are non-zero here in contrast to the non-rotating case in which v_φ and H_φ are zero.

To determine $v_{0\varphi}$, we use (21) which gives

$$\left[\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial r^2}+\frac{1}{r}\frac{\partial}{\partial r}-\frac{1}{r^2}+h^2\right]v_{0\varphi}=\delta R_e v_{0r} \tag{A1}$$

and the boundary conditions are

$$v_{0\varphi}=0 \text{ at } R=1 \text{ and at infinity.} \tag{A2}$$

The solution is (using (26))

$$v_{0\varphi}=B_1\times rf_2(hR)+\frac{\delta R_e}{h^2-k^2}\frac{i}{k^2}\frac{\partial s_0}{\partial_r}-\frac{3i\delta}{2}Bh^2\times rf_1(hR) \tag{A3}$$

where the first term is the complementary function and the remaining terms are a particular

integral. The constant B_1 can be chosen in such a way that the boundary condition $v_{0\varphi}=0$ at $R=1$ is satisfied.

Next, $H_{1\varphi}$ can be determined by

$$\left[\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial r^2}+\frac{1}{r}\frac{\partial}{\partial r}-\frac{1}{r^2}\right]H_{1\varphi}=-\frac{\partial v_{0\varphi}}{\partial x}, \tag{A4}$$

while inside the sphere

$$\left[\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial r^2}+\frac{1}{r}\frac{\partial}{\partial r}-\frac{1}{r^2}\right]H_{1\varphi}=0 \tag{A5}$$

and we require the continuity of $H_{1\varphi}$ across the surface of the sphere.

The solution is

$$H_{1\varphi}=B_2\frac{P_1^1(\cos\theta)}{R^2}+B_3\frac{P_3^1(\cos\theta)}{R^4}+\frac{\delta R_e i}{k^4(h^2-k^2)}\cdot\frac{\partial^2 s_0}{\partial\times\partial r}$$
$$-\frac{3i\delta B}{2}\left[\frac{2}{h^2}\frac{\partial^2}{\partial x^2}+x\frac{\partial}{\partial x}+1\right]rf_1(hR)+$$
$$+\frac{B_1}{h^2}\frac{\partial}{\partial x}[xrf_2(hR)], \tag{A6}$$

and inside the sphere

$$H_{1\varphi}=C_1R\cdot P_1^1(\cos\theta)+C_2R^3\cdot P_3^1(\cos\theta). \tag{A7}$$

The first two terms in (A6) are the complementary function and the remaining terms are a particular integral. The constants B_2, B_3, C_1 and C_2 are determined by the requirement that $H_{1\varphi}$ is continuous at $R=1$.

Finally, $v_{1\varphi}$ is determined by

$$\left[\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial r^2}+\frac{1}{r}\frac{\partial}{\partial r}-\frac{1}{r^2}+h^2\right]v_{1\varphi}=\beta R_e v_{0\varphi}+\delta R_e v_{1r} \tag{A8}$$

and the boundary conditions $v_{1\varphi}=0$ at $R=1$ and at infinity. (A9)

The solution is

$$v_{1\varphi}=G_1R^2\cdot P_2^1(\cos\theta)f_2(hR)+G_2R^4\cdot P_4^1(\cos\theta)f_4(hR)+$$
$$+\delta R_e\left[-\frac{\beta}{2k^2}\left\{\frac{4h^2-2k^2}{(h^2-k^2)^2}\frac{\partial s_0}{\partial r}+\frac{x}{h^2-k^2}\frac{\partial^2 s_0}{\partial x\partial r}-\right.\right.$$
$$-\frac{4}{(h^2-k^2)^2}\frac{\partial^3 s_0}{\partial r\partial x^2}-\frac{A}{h^2-k^2}\left(\times\frac{\partial f_0(kR)}{\partial r}-\right.$$
$$\left.\left.-\frac{2}{h^2-k^2}\frac{\partial^2 f_0(kR)}{\partial r\partial x}\right)\right\}-\frac{3}{8}B\beta i\times r\left\{f_1(hR)-\right.$$
$$\left.-f_0(hR)+h^2x^2f_2(hR)\right\}+\frac{i}{k^2(h^2-k^2)}\frac{\partial s_1^c}{\partial r}-$$
$$-\frac{3}{2h^2}(h^2F_1-4F_2)xrf_1(hR)+$$
$$+\frac{15}{4}F_2xrf_3(hR)(-4x^2+3r^2)\Big]-\frac{B_1\beta_i}{2}xrf_1(hR) \tag{A10}$$

where the first two terms are the complementary function and the remaining are a particular integral. The constants G_1 and G_2 are determined by the requirement that $v_{1\varphi}=0$ at $R=1$.

It is clear from the above solution that there will be no contribution of Maxwell and Viscous stresses (produced due to rotation) on the drag—a result in agreement with our previous conclusions (see Singh, 1964 [12]).

Since the wave-like terms $f_n(\zeta)$ are damped heavily, it follows that in non-rotating compressible case, the flow will be essentially current free and irrotational at large distances. Our solution above shows that the effect of rotation will be to produce vorticity and current which again agrees with our conclusions in (12).

Concluding, it should be noted that the nature of wave propagation remains essentially similar in both rotating and non-rotating cases.

ON OSCILLATING SPHERE IN A ROTATING VISCOUS FLUID*

M. P. SINGH†

The moderate and large-scale motions of the atmosphere are greatly influenced by the vorticity of the earth's rotation. In the case of an infinite liquid, rotating as a rigid body about an axis, the amount of energy possessed by the liquid is infinite and it is of great interest to know how small disturbances propagate in such a liquid. To understand some of these phenomena, it will be interesting to study the flow of a rotating fluid around elementary bodies.

Here we consider small oscillations of a sphere in an incompressible, viscous fluid rotating with a constant angular velocity. For flow in the absence of rotation, the problem was first considered by Stokes [Lamb, 1932] on the assumption that the Reynolds number $R_s = a|V_s|/\gamma$ was negligibly small (so as to discard convective terms), where V_s is the velocity of the sphere, a is the radius of the sphere and γ the kinematic viscosity. It is the purpose of the present investigation to determine the effect of the coriolis forces on the flow pattern.

Let the sphere oscillate along the axis of the rotating fluid which is taken to be the x-axis. The origin is at the mean position of the center of the sphere. The equations of motion of an incompressible, viscous, unbounded liquid rotating about x-axis with a constant angular velocity $\Omega\underline{i}$ referred to a rotating frame of reference are

$$\frac{\partial \underline{v}}{\partial t} + \underline{v}\cdot\nabla\underline{v} + 2\underline{\Omega}\times\underline{v} + \underline{\Omega}\times(\underline{\Omega}\times\underline{r}) = -\frac{1}{\rho}\nabla p + \gamma\nabla^2\underline{v} \quad (1)$$

where ρ is the density, $\underline{v}$ the velocity of the fluid, p is the pressure and r is the radian coordinate:

$$r^2 = y^2 + z^2.$$

The equation of continuity is

$$\operatorname{div}\underline{v} = 0.$$

As in the classical problem, the convective terms in (1) will henceforth be neglected. This is justified if

$$R_s = a|V_s|/\gamma << 1.$$

The equations (1) and (2) will be reduced to a non-dimensional form by referring the length to a, the radius of the sphere, the velocity to $a\lambda$ ($\lambda/2\pi$ is the frequency of the oscillation), the time to $1/\lambda$ and the pressure to $\rho a^2\lambda^2$. Then we have

$$\frac{\partial \underline{v}}{\partial t} = -\nabla p + \delta\underline{v}\times\underline{i} + \frac{1}{R_e}\nabla^2\underline{v} \quad (4)$$

and

$$\operatorname{div}\underline{v} = 0 \quad (5)$$

where

$$R_e(\text{Reynolds number})\ddagger = a^2\lambda/\gamma \quad (6)$$

and

$\delta = 2\Omega/\gamma$, the inverse of the so-called Rossby number

$$R_0 = \frac{\lambda}{2\Omega} = \frac{1}{\delta} \quad (7)$$

and the centrifugal force $-\delta^2\nabla r^2/8$ has been absorbed in the pressure term.

†Dr. Singh is a National Academy of Sciences—National Research Council Postdoctoral Resident Research Associate.

‡It should be noted that we have used $a\lambda$ as velocity in the definition of the Reynolds number. There still is another important dimensionless parameter ϵ/a, where ϵ is the amplitude of the oscillatory motion of the sphere. It is assumed that this quantity is small compared to unity. The velocity of sphere is $V_s\underline{i} = \epsilon\lambda e^{\lambda t}\underline{i}$, or in dimensionless form: $U_s\underline{i} = \epsilon/a\, e^{it}\underline{i}$. The Reynolds number for the flow might have also been defined as $R_e = a\epsilon\lambda/\gamma$ ($= R_e\,\epsilon/a$). It is necessary that $R_e << 1$, whereas the requirement for R_e is less severe.

The boundary conditions on $\underline{v}$ are that $\underline{v}=U_s\underline{i}$ at the sphere $R=1$

(where $R^2=r^2+x^2$) and $\underline{v}=0$ at infinity. (8)

As in non-rotating case, we have here axi-symmetry in that the physical variables are independent of the azimuthal coordinate*Φ. However, the azimuthal component of velocity v_Φ is non-zero here in contrast to the non-rotating case in which v_Φ is zero.

We next make an important assumption in that the Rossby number R_0 is large so as to neglect second or higher powers of δ. (9)

From (4) and (5) it follows that $v_x=0(1)$, $v_r=0(1)$ and $v_\Phi=0(\delta)$, hence

$$\nabla^2 p=0(\delta^2). \tag{10}$$

It follows that the coupled equations (4) can be simplified in this case. In fact, in view of (9) and (10), v_x and v_r satisfy identically the same system of equations and boundary conditions as in non-rotating case. The solution is therefore [Lamb, 1932]

$$p=A\frac{P_1(\cos\theta)}{R^2} \tag{11}$$

and

$$\underline{v}=Ai\nabla\frac{P_1(\cos\theta)}{R^2}+2Bf_0(hR)\nabla(RP_1(\cos\theta))$$
$$-Bf_2(hR)h^2R^5\nabla\frac{P_1(\cos\theta)}{R^2} \tag{11}$$

where (R, θ, Φ) are the spherical polar coordinates† and

$$h^2=-iR_\epsilon. \tag{12}$$

The function $f_n(\xi)$, defined as

$$f_n(\xi)=\left(-\frac{1}{\xi}\frac{d}{d\xi}\right)^n\frac{e^{-i\xi}}{\xi} \tag{13}$$

essentially represents boundary layer effects, while the constants A and B are given by

$$A=-ih^2f_2(h)\,B,\quad B=U_s/2f_0(h). \tag{14}$$

Finally, v_Φ remains to be determined, which satisfies

$$\left[\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial r^2}+\frac{1}{r}\frac{\partial}{\partial r}-\frac{1}{r^2}+h^2\right]v_\Phi=\delta R_\epsilon v_r \tag{15}$$

and the boundary conditions

$$v_\Phi=0 \text{ at } R=1 \text{ and at infinity.} \tag{16}$$

The solution of (15) and (16) is

$$v_\Phi=-\frac{3}{2}\delta BR_\epsilon xrf_1(hR)+3\delta A\frac{xr}{R^5}+cxrf_2(hR) \tag{17}$$

where

$$c=3B\delta R_\epsilon\left[1+\frac{f_1(h)}{2f_2(h)}\right]. \tag{18}$$

To summarize, the following conclusions are noteworthy:

(i) The azimuthal component of velocity is non-zero in contrast to non-rotating case in which $v_\Phi=0$.

(ii) The rotating effect generates vorticity in that for large distances, the flow pattern is irrotational in non-rotating case. In rotating case, the azimuthal component of velocity is responsible for vorticity for large R.

(iii) The wave-like terms $f_n(hR)$ (corresponding to a boundary layer) appearing in the solution, effective in a small distance from the surface of the sphere and behaving like $\exp[-(1+i)\sqrt{R_\epsilon/2}(R-1)]$ are essentially similar in nature in rotating and non-rotating cases.

(iv) The drag on the sphere remains unchanged (due to rotation) to the order δ since v_x, v_r and p remain unchanged to that order.

In a forthcoming paper, the above discussion will be extended to a compressible fluid in the presence of a magnetic field.

VARIATIONS OF GEOMAGNETIC ACTIVITY WITH LUNAR PHASE*

HAROLD L. STOLOV† AND A. G. W. CAMERON

An analysis of 31 years of K_p data suggests a variation of geomagnetic disturbance with lunar phase. A general increase in geomagnetic activity of about 4 percent begins after full moon and lasts for seven days. A general decrease in geomagnetic activity of about 4 percent is found for the seven days preceding full moon. A study of randomized data indicates that the probability that these variations should have occurred by chance is less than 5 percent. The effect is found to be associated with the K_p data derived from periods of geomagnetic quiet conditions; it is not evident in the data from disturbed periods.

INTRODUCTION

Reports of lunar influence on a number of geophysical variables have appeared in the literature. *Bradley et al.* [1962] and *Adderley and Bowen* [1962] claim to find a lunar influence on rainfall. *Bigg* (1963*a*] presents evidence for a lunar modulation of freezing nucleus concentrations measured in the lower atmosphere. *Bowen* [1963] reports variations in the incoming meteor rate with lunar phase, and *Adderley* [1963] claims a lunar effect on the amount of atmospheric ozone. *Dorman and Shatashvili* [1961] present evidence for a lunar diurnal variation in the intensity of the neutron component of cosmic radiation dependent on lunar phase. Acceptable physical mechanisms for the various lunar modulation effects are not easy to find.

The search for a better understanding of these surprising lunar influences led *Bigg* [1963*b*, *c*] to re-examine the earlier work of *Sucksdorff* [1956] on influence of the moon on geomagnetic disturbances. Several confusing and contradictory claims have been made in previous lunar-geomagnetic activity studies:

1. That there is a distinct decrease of geomagnetic activity, averaging 12 percent during new moon, and a less marked decrease of 7 percent during full moon. Geomagnetic activity is 7 percent higher than average during first quarter [*Sucksdorff*, 1956].

2. That there is a minimum of geomagnetic disturbance at new moon, 20 percent lower than any other minimum on the curve, and a broad maximum of geomagnetic activity shortly after full moon [*Bigg*, 1963*b*].

3. That there is a decrease in the frequency of magnetic storms at new moon and a tendency for magnetic storms to occur preferentially near first and third quarters [*Bigg*, 1963*b*].

4. That the decrease in the frequency of magnetic storms at new moon applies only to the gradual-commencement type of storm. The sudden-commencement storms show an increased frequency at new moon [*Bigg*, 1963*c*].

Bartels [1963] shows that the conclusions stated in paragraph 3 are questionable, since randomizing the data yields variations of size comparable to those in the lunar data.

It is the purpose of this paper to determine, by further investigation, whether genuine influences of the moon on geomagnetic activity may be present. It is suggested herein that correlations with lunar phase do exist in the geomagnetic data for the last 31 years; they may prove valuable in seeking to understand the solar wind-magnetosphere interactions. After the present study was completed another study was published [*Bell and Defouw*, 1964] in which similar conclusions were reached. Since the present method of analysis is quite different from that of Bell and Defouw, it is thought to be of interest to present it also.

PROCEDURE

There are now available K_p indices for more than 31 years, consisting of more than 90,000 well-determined values of standard quality. They represent a detailed history (8 values per day) of the disturbance variations of the geomagnetic field over nearly three sunspot cycles. The scientific community is indebted to the late Professor J. Bartels and his collaborators for their dedicated efforts in the compilation of this series. The K_p index is a world-wide measure of geomagnetic activity expressed on a quasi-logarithmic scale and based on the measurements at a fixed group of 12 observatories in upper middle geomagnetic latitudes. The K_p index is traditionally taken to be a measure of the velocity of the solar corpuscular stream. The Mariner 2 measurements of *Snyder et al.* [1963] establish with a considerable degree of certainty that the classical view is well taken.

Our search for a lunar influence on K_p began with the establishment of a suitable reference level with which to compare the magnetic activity at individual times during the lunar cycle. The mean value of K_p for each lunar synodic period was taken; this is called $\bar{K}_p$. The difference between each K_p value during the lunar month and $\bar{K}_p$ was found. This difference, divided by $\bar{K}_p$ and multiplied by 100, is the percent departure of magnetic disturbance from the reference level.

$$\% \text{ departure} = 100(K_p - \bar{K}_p)/\bar{K}_p$$

Percent departure was found for all the lunar synodic periods contained in the 31 years of K_p data. Mean values of the percent departures (8 per day) that were taken during the course of the lunar cycle are shown in Figure 1. Figure 1 is the output of a plotter where each vertical marker represents one of the mean values of per cent departure. Figure 1 shows the following features: (*a*) A broad maximum of geomagnetic activity ($\approx$4 percent) begins a half day after full moon and lasts nearly seven days. (*b*) A broad minimum of geomagnetic activity ($\approx$4 percent) exists for about seven days preceding full moon. (*c*) There is nothing at new moon but random statistical fluctuations.

These results are generally unexpected, in view of the emphasis given to the new moon position by previous investigators, who have usually suggested some type of 'shadowing' mechanism at new moon.

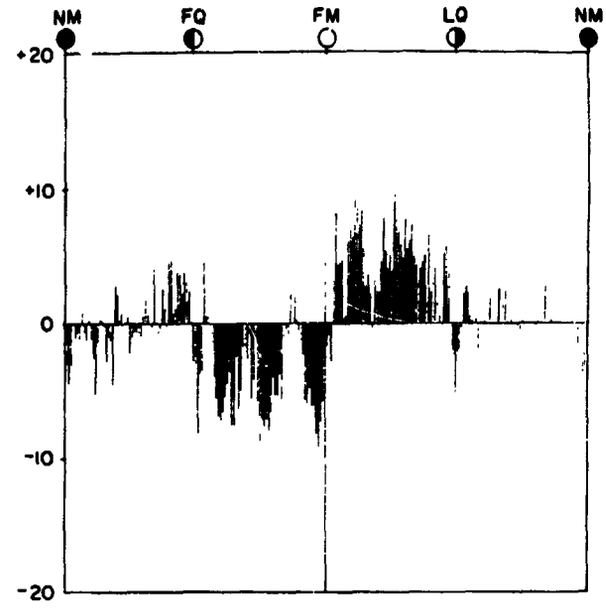

FIGURE 1.—Mean values of the percent departures of K_p as a function of lunar phase (31 years of K_p data).

Several additional studies were performed to examine the above conclusions.

1. To test the significance of the departures observed before and after full moon, and to determine if they might have originated in random fluctuations, a series of artificial lunar periods of 25, 26, 27, 28, 29, 30, 31, and 32 days were run through the same computer program using all the 31 years of K_p data in each case. In all these random data there were five cases when essentially clean departures of about 4 percent existed for periods of about three days, and three cases when departures of about 3 percent existed for periods of about four days. The normal departure lasts only one day or less. As examples of the random data, Figures 2 and 3 are presented for the 27-day and 29-day runs, respectively. Figures 2 and 3 show more than one random negative departure comparable to the meaningless departure at new moon in Figure 1. Many more were found in the runs that have not been reproduced. There is nothing like the seven-day departures of Figure 1 in any of this set of random data.

2. It is not clear what statistical laws we should expect the frequency distribution of departures from the null axis to follow. Accordingly,

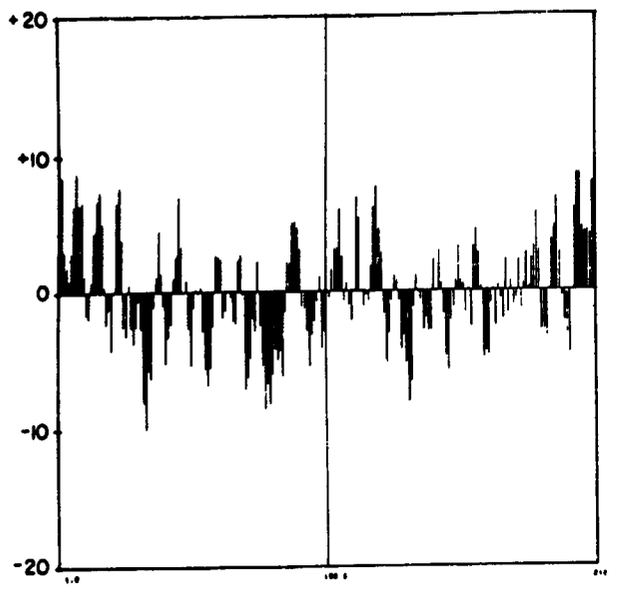

FIGURE 2.—Mean values of the percent departure of K_p for 27-day periods (31 years of K_p data).

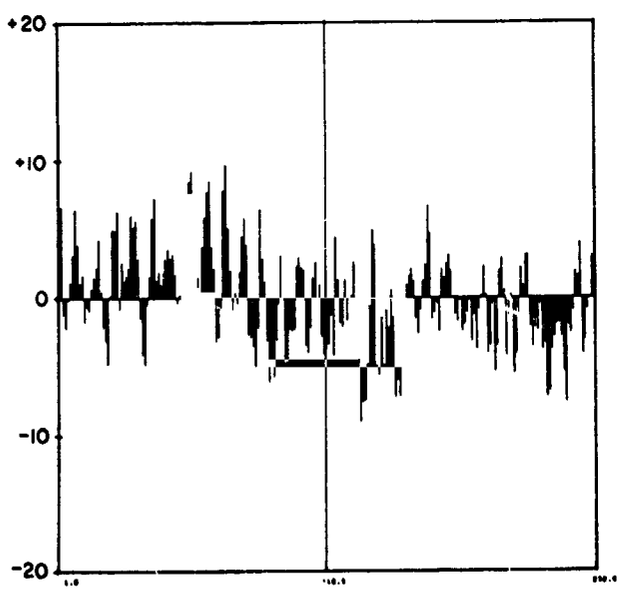

FIGURE 3.—Mean values of the percent departure of K_p for 29-day periods (31 years of K_p data.)

we have determined the distribution function empirically by a systematic randomization of the data used. This randomization was accomplished in the following manner. Each lunar month used here contains 241 three-hour intervals, 120 on each side of the three-hour interval during which full moon occurs. Each point of Figure 1 is an average performed separately for each three-hour interval in the superposition of lunar months. Therefore 120 fictitious superpositions of the lunar months were made by shifting the positions of the three-hour intervals of each lunar month, those pieces of data shifted off one end of the month being shifted in on the other end. In general, in the mth superposition the data of the nth lunar month were shifted $2mn$ positions. In this way 120 randomized diagrams equivalent to Figure 1 were obtained. Two studies were made of the properties of these diagrams.

Let us define an excursion length as the number of three-hour intervals adjacent to one another in which the departure from zero has the same sign (positive or negative). The number distribution of the excursion lengths was found by summing all those in the 120 randomized cases and dividing by 120; this distribution is shown by the histogram in Figure 4. Also potted in Figure 4 is the actual distribution of excursion lengths in Figure 1 (denoted by crosses). The probability that a single case will contain an excursion length equal to or

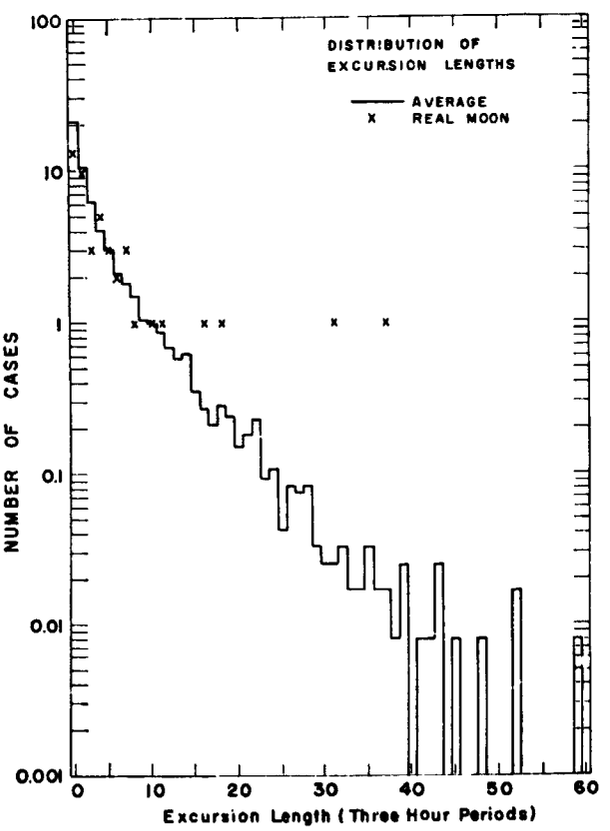

FIGURE 4.—Frequency distribution of excursion lengths calculated from the 120 averages of randomized lunar periods, compared to the distribution found for Figure 1.

greater than some value can be determined by summing the histogram upward from the point under consideration. Figure 1 contains two large excursion lengths. If the probabilities of their occurrence in the same case can be considered independent, then the probability of their occurring by chance turns our to be 0.035.

Let us define an excursion area as an excursion length multiplied by the average percent departure during the excursion. The distribution of excursion areas was calculated in the same way as described above for excursion lengths; the results are shown in Figure 5. Once again the crosses represent the data of Figure 1. If the two high points of the Figure 1 data have independent probabilities of occurrence, then the probability that a case like Figure 1 would arise by chance is 0.0074. Since it is possible that the presence of one large excursion area might slightly enhance the probability of occurrence of somewhat larger excursion areas associated with the excursions of the opposite sign, it is possible that the above value may slightly underestimate the true probability of occurrence of two large excursion areas in a single case.

In any event it seems safe to state that the probability of occurrence of Figure 1 by chance is less than 5 percent, the level of probability below which a distribution is usually considered to have statistical significance.

3. To examine further the effects observed before and after full moon, two separate runs of per cent departures were made, each for eight years of data only. The first was for the eight years of the quiet sun consisting of K_p indices from 1932; 1933, 1934, 1942 (last half only), 1943, 1944, 1953, 1954, and 1955 (first half only). The second was for the eight years of the disturbed sun consisting of K_p indices from 1937, 1938, 1939 (first half only), 1947, 1948, 1949, 1957, 1958, and 1959 (first half only). Figures 6 and 7 represent the results of this study. For the quiet sun (Figure 6), when fluctuations of K_p are expected to be small, the previously observed effects occur as found in Figure 1. For the disturbed sun (Figure 7), when random fluctuations of K_p are expected to be large, the effects about full moon exhibit a considerably more randomized pattern.

4. Instead of using the Zurich relative sunspot numbers to distinguish those periods of strong solar plasma flow from the quieter periods, the

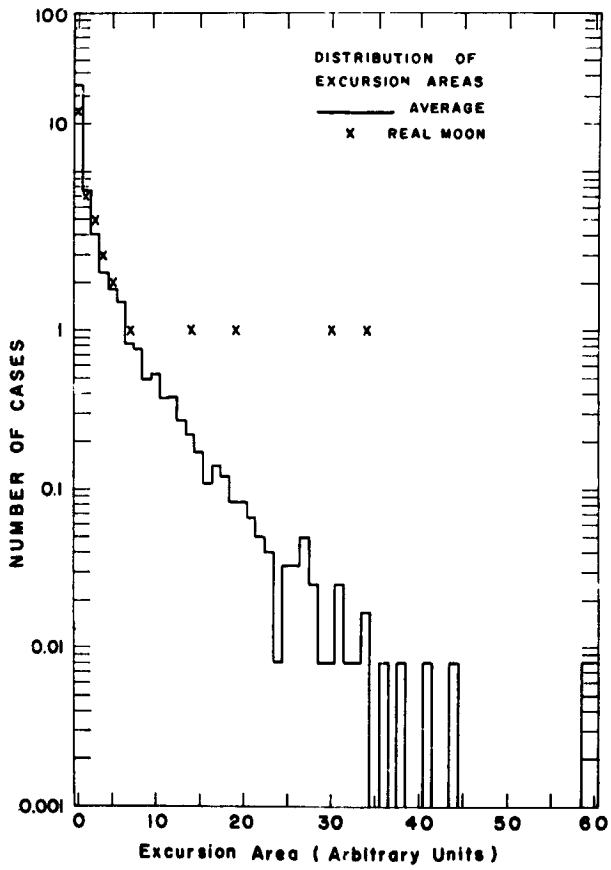

FIGURE 5.—Frequency distribution of excursion areas calculated from the 120 averages of randomized lunar periods, compared to the distribution found for Figure 1.

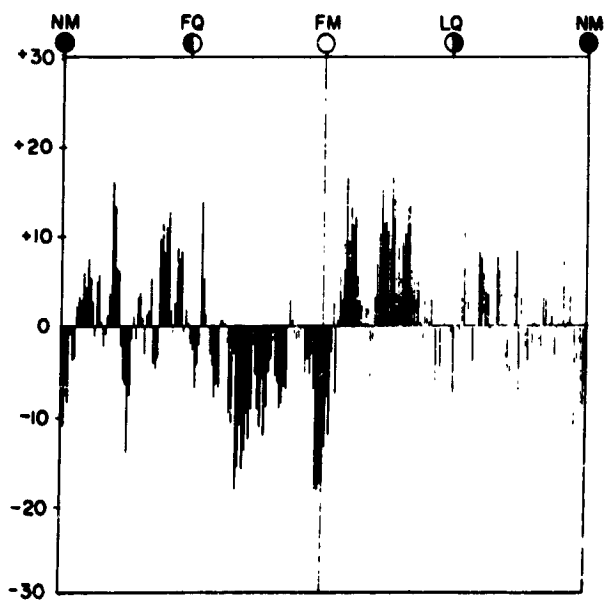

FIGURE 6.—Mean values of the percent departure of K_p as a function of lunar phase (8 quiet sun years only).

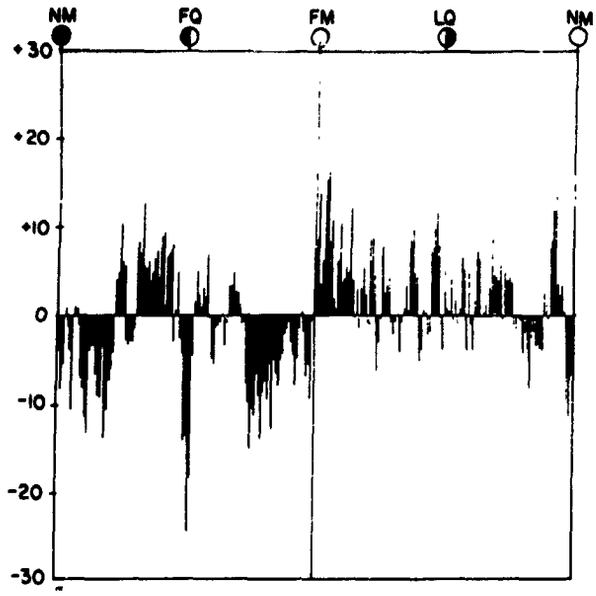

FIGURE 7.—Mean values of the percent departure of K_p as a function of lunar phase (8 disturbed sun years only).

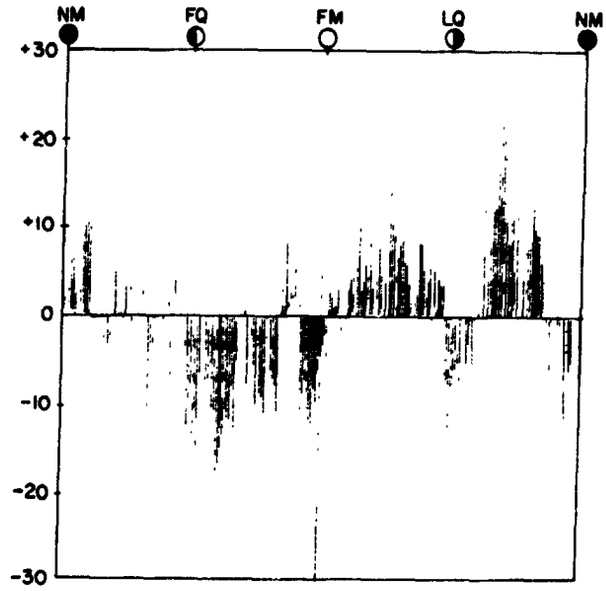

FIGURE 9.—Same as Figure 6 ($\bar{K}_p$ values of the next to the lowest quarter only).

$\bar{K}_p$ values themselves might be used. In this study the 382 lunar periods were divided into four groups on the basis of different levels of $\bar{K}_p$. All four groups were run through the same per cent departure analysis. The results for the lowest to the highest $\bar{K}_p$ groups are shown in Figures 8, 9, 10, and 11, respectively. In Figure 8 the random fluctuations of K_p are expected to be small, and the observed lunar effects of Figure 1 are seen to be

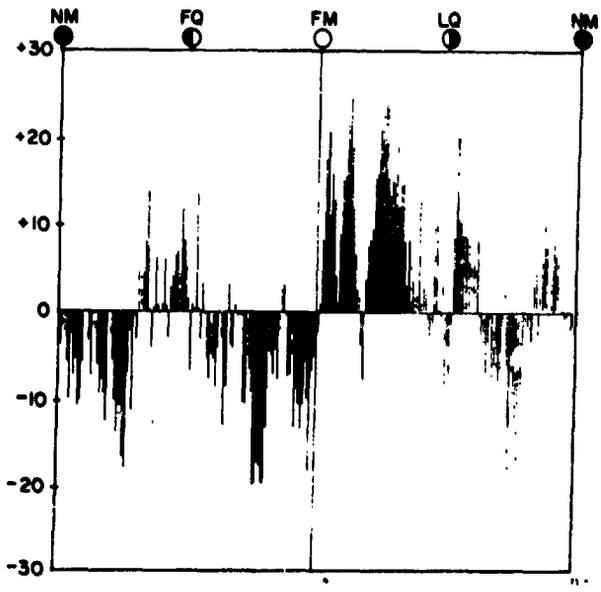

FIGURE 8.—Mean values of the percent departures of K_p as a function of lunar phase ($\bar{K}_p$ values of the lowest quarter only).

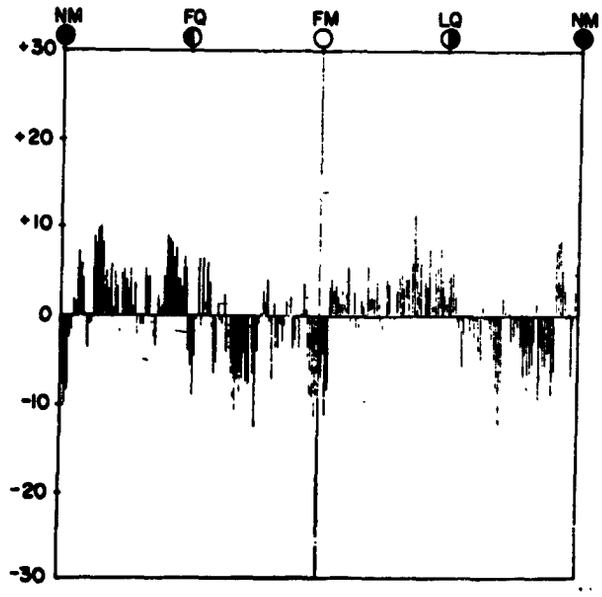

FIGURE 10.—Same as Figure 6 ($\bar{K}_p$ values of the next to the highest quarter only).

present. In Figure 11 the random fluctuations of K_p are expected to be large, and the effects at full moon are not evident. The figures for the two intermediate groups represent a gradation between Figures 8 and 11. The lunar periods assembled to form Figure 8 are not necessarily those of Figure 6, nor are those of Figure 11 the same as the lunar periods of Figure 7. In fact, they are not the same in more than half the cases. This

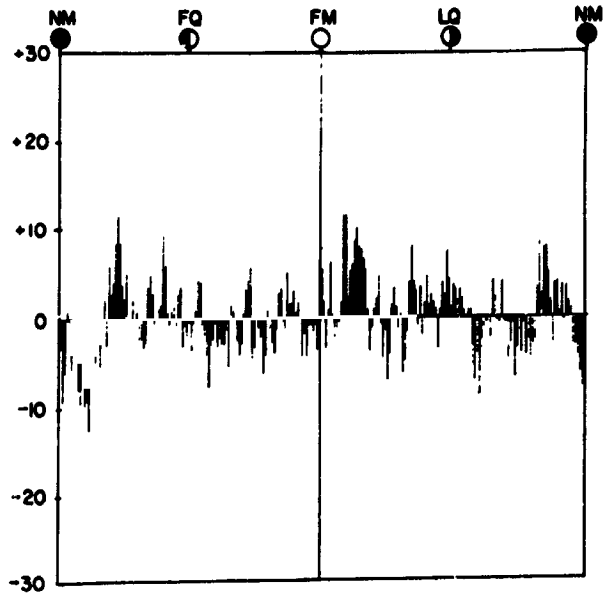

FIGURE 11.—Same as Figure 6 ($\bar{K}_p$ values of the highest quarter only).

is not surprising when we remember the occurrence of disturbed periods in low sunspot years or quiet periods in high sunspot years.

Bartels [1964] has previously reached the conclusion that there is no evidence for a lunar effect on geomagnetic activity during disturbed periods. His analysis was based upon the daily $\bar{K}_p$ sums of 30 or greater during 1932–1961 and on magnetic character figures C_i of 1.3 or higher for 1884–1961. Our analysis presented above is fully in agreement with his conclusion.

DISCUSSION

It has been shown that for the last 31 years geomagnetic activity has been on the average ≈4 per cent smaller for the period beginning after lunar first quarter and lasting until just after full moon and that it has been on the average ≈4 percent greater from just after full moon until last quarter.

Similar perturbations of the general level of the K_p index have been found in an analysis by *Michel et al.* [1964]. These authors note that magnetic perturbations persist for about three days, and hence they do not consider their longer effects near full moon as more than statistical fluctuations.

Another technique that can be applied to this problem is that of autocorrelation analysis, to determine whether there is any regularity to the K_p pattern associated with a lunar month of 29.5 days. It is well known that such effects are associated with the 27-day period of rotation of the sun. We appreciate very much receiving permission to report that Shapiro and Ward (private communication, 1964) have applied the technique of 'power spectrum' analysis to compute a single spectrum from 80 years of C_i data. In a general region of enhanced power centered on a frequency corresponding to the solar rotation period, this spectrum shows two peaks, the principal one near 27 days, and another peak, somewhat smaller, near 29.5 days. They have sufficient resolution in the spectrum between 27 and 29 days to determine that two distinct peaks are present. Shapiro and Ward consider the physical reality of the peak at 29.5 days to be uncertain at this time.

Any physical mechanism to account for the variations of geomagnetic activity about full moon must be sought in the interactions between the moon and the tail of the geomagnetic cavity formed by the magnetosphere embedded in the flow of solar wind.

ACKNOWLEDGMENT

It is a pleasure to acknowledge the able assistance of Mr. Bernard Goldstein, who programmed and carried out the numerical computations on the IBM 7094 computer and S-C 4020 plotter.

PROPAGATION OF HYDROMAGNETIC WAVES IN THE MAGNETOSPHERE*

MASAHISA SUGIURA

Characteristics of waves in a two-component cold plasma are reviewed. Using the Clemmow-Mullaly-Allis diagram, the topological types of the wave-normal surfaces are shown. A consistent system of labeling the modes, initially given by Allis, is explained. Reversal in the polarization in the electric field is examined, and all the modes in which the reversal occurs are specified. There is no polarization reversal in ULF to VLF waves in the magnetosphere. The lower hybrid resonance frequency in the magnetosphere is discussed.

The equations of motion for an electromagnetic ray are derived. Defining the action for the ray in analogy with that for a particle in classical mechanics, the principle of least action is proved. It is shown that if the dispersion relation is homogeneous in the wave vector and the frequency, the principle of least action implies the principle of least time, i.e., Fermat's principle. When the principle of least time holds, as is the case with Alfvén compressional waves, the trajectory of a ray can be determined from a variational equation, from which the problem can be formulated in Hamiltonian form. For the axially symmetric case, the generalized momentum conjugate to the azimuthal coordinate is a constant of motion. Using this relation, "allowed" and "forbidden" regions are defined, when a set of initial conditions for the ray is given. This method is applied to a model magnetosphere with a dipole magnetic field. It is shown that the accessibility of hydromagnetic rays originating from the boundary of the magnetosphere to the earth is greatly limited. For a distorted magnetosphere the canonical equations for a hydromagnetic ray are integrated by a numerical method. Typical trajectories in the equatorial plane are shown, and the effects of the deformation of the dipole field on the ray trajectories are discussed.

1. INTRODUCTION

Hydromagnetic waves can be derived by a low-frequency approximation in a general scheme of treating plasma waves. For a complete understanding of the characteristics of hydromagnetic waves it is desirable to review plasma waves in general for the entire range of frequency and for all possible values of plasma parameters.

Clemmow and Mullaly (1954) presented a comprehensive study of the dependence of the phase refractive index n, derived by the Appleton-Hartree approximation, on the angle θ which the direction of phase propagation makes with that of the magnetic field. These authors developed a systematic method of investigating the topological genera of the $(n\theta)$ surface. Allis (1959), and Allis, Buchsbaum, and Bers (1963) modified the scheme by using the wave-normal surface which is obtained by inverting the (n,θ) surface about the origin. Stix (1962) has given an excellent summary of the wave-normal surface topology for waves in a cold plasma. In Sections 2.1 to 2.9 we will follow Stix's representation.

Stix (1962) called a diagram showing topological genera of the wave-normal surfaces for various regions in plasma parameter space the "Clemmow-Mullaly-Allis diagram," or, in short, the "CMA diagram." The CMA diagram for an idealized two-component cold plasma is presented in Section 2.4, and the characteristics of modes for different regions in plasma parameter space are reviewed. The labeling of modes by the sense of polarization, i.e., "right-handed" or "left-handed," for the propagation parallel to the magnetic field, or by "ordinary" or "extraordinary" mode according as the refractive index for the

*Published as *Goddard Space Flight Center Document X-612-64-240*; and presented at the Symposium on Ultra Low Frequency Electromagnetic Fields (from 30 c/s to 0.001 c/s), Boulder, Colorado, August 17–20, 1964.

propagation perpendicular to the magnetic field is independent or dependent on the magnetic field is explained using the CMA diagram.

In Section 2.6 the wave-normal surface topology in those regions in the CMA diagram that are relevant to ULF and VLF waves in the magnetosphere is studied.

Reversal of the polarization in the electric field that may occur for v not equal to 0 is examined in detail (Section 2.7), and the lower hybrid resonance frequency in the magnetosphere is presented (Section 2.8.)

In Sections 3.1 to 3.3 geometrical electromagnetics, or ray theory, is formulated, and in Sections 3.4 to 3.8 the theory is applied to the propagation of hydromagnetic waves in the magnetosphere.

Analogy between the Hamiltonian form of classical mechanics and geometrical electromagnetics is demonstrated (Sections 3.2, 3.3, 3.4), and validity of Fermat's principle in geometrical electromagnetics is examined (Section 3.3). The action is defined for a ray, and the principle of least action is established. It is then shown that if the dispersion relation is homogeneous in $\vec{k}$ and ω, the principle of least action implies the principle of least time, i.e., Fermat's principle. This is the same result as that obtained by Weinberg (1962) by the eikonal theory.

By formulating the ray theory in Hamiltonian form it is shown (Section 3.5) that when the magnetic field and the plasma are axially symmetric, and when the wave-normal surface is spherical, the generalized momentum conjugate to the azimuthal coordinate is a constant of motion. Applying this result to the propagation of hydromagnetic waves in a dipole model magnetosphere (Section 3.5), we will define, for a set of initial conditions of a ray, "forbidden" and "allowed" regions for the ray in the same manner at Störmer (1953) did for a charged particle moving in a dipole magnetic field. It will be shown that because of the Alfvén velocity maximum at an altitude of several thousand kilometers above ground the accessibility of hydromagnetic rays generated in the outer regions of the magnetosphere to the immediate vicinity of the earth is very limited.

When the magnetic field is not axially symmetric, the canonical equations must be integrated. In Section 3.8 we will present examples of hydromagnetic ray trajectories computed by numerical method for a model magnetosphere that takes into account the distortion of the dipole field by solar wind. Trajectories in the equatorial plane alonge are presented in Section 3.8; more detailed discussions will be given in a separate paper.

2. PROPAGATION OF HYDROMAGNETIC WAVES

2.1 The Dispersion Relation

The dispersion relation for waves in a cold plasma in a uniform magnetic field has been given by Åström (1950), Sitenko and Stepanov (1957) and Allis (1959). Here we only outline the derivation of the dispersion relation; for the details, see, e.g., Stix (1962)

We assume that in the unperturbed stat the magnetic field $\vec{B}_0$ and the plasma are static and uniform, and we take $\vec{B}_0$ and the quantities characterizing the plasma to be zero-order quantities. The perturbation $\vec{B}$ in the magnetic field, the electric field $\vec{E}$, the current and the particle velocities are considered to be first-order variables, and the relevant equations are all linearized by ignoring second- and higher-order terms. The first-order variables are assumed to change as $\exp i\,(\vec{k}\cdot\vec{r}-\omega t)$.

Considering the displacement current to be the sum of that in vacuum and the plasma current, and by Fourier analysis the electric displacement $\vec{D}$ can be expressed in the form

$$\vec{D}=\vec{K}\cdot\vec{E}$$

thus defining the dielectric tensor $\vec{K}$.

The expression for $\vec{D}$ and Maxwell's equations yield the following dispersion relation in terms of the refractive index n:

$$An^4-Bn^2+C=0 \qquad (1)$$

where

$$
\begin{aligned}
A &= S\sin^2\theta + P\cos^2\theta \\
B &= RL\sin^2\theta + PS(1+\cos^2\theta) \\
C &= PRL \\
S &= \tfrac{1}{2}(R+L) \\
R &= 1-\sum_k(\Pi_k^2/\omega^2)/(1+\epsilon_k\Omega_k/\omega) \\
L &= 1-\sum_k(\Pi_k^2/\omega^2)/(1-\epsilon_k\Omega_k/\omega) \\
P &= 1-\sum_k\Pi_k^2/\omega^2 \\
\Pi_k^2 &= 4\pi n_k q_k^2/m_k \\
\Omega_k &= |q_k|B_0/(m_k c) \\
\epsilon_k &= q_k/|q_k|
\end{aligned}
\tag{2}
$$

Here the subscript k refers to the particle of type k whose mass and charge are m_k and q_k, respectively, and c is the velocity of light; π_k and Ω_k are the plasma frequency and the cyclotron frequency for the k-th constituent; ϵ_k merely specifies the sign of the charge.

2.2 The Wave-Normal Surface

When all the plasma parameters and the frequency ω are specified, n is a function of θ, the angle between the static magnetic field $\vec{B}_0$ and the wave vector $\vec{k}$. Denoting the unit vector in the direction of $\vec{k}$ by $\vec{k}$, $\vec{k}/n$ gives the phase velocity, measured in units of c, in the direction of phase propagation.

We define the wave-normal surface by revolving about the direction of the magnetic field $\vec{B}_0$ the locus of the tip of the vector $\vec{k}/n$ when θ is changed from 0 to π; since the magnetic field and the plasma are assumed to be uniform, at each point in space the wave-normal surface is axially symmetric about the direction of the magnetic field. Thus the topological nature of the wave-normal surface is determined by the dependence of n on θ.

From the dependence of the coefficients A and B in (1) on θ as indicated in (2) it is obvious that the wave-normal surface is symmetric with respect to the plane through the origin and normal to the magnetic field; namely, $n(\theta)=n(\pi-\theta)$.

The solutions of (1) are

$$n^2=(B\pm F)/(2A) \tag{3}$$

where

$$F^2=(RL-PS)^2\sin^4\theta+P^2(R-L)^2\cos^2\theta$$

There are two branches in n^2, and for real values of θ, n is either pure real or pure imaginary.

The solutions for n^2 for propagation at $\theta=0$ (parallel to the magnetic field) and $\theta=\frac{1}{2}\pi$ (perpendicular to the magnetic field) reduce to the following simple expressions.

For $\theta=0$,

$$n^2=R \tag{4}$$

$$n^2=L \tag{5}$$

and for $\theta=\frac{1}{2}\pi$,

$$n^2=RL/S \tag{6}$$

$$n^2=P \tag{7}$$

It can be shown that for $\theta=0$, the polarization of the electric field for the branch with $n^2=R$ is circular and right-handed and that for the branch $n^2=L$ also circular but left-handed.

For $\theta=\frac{1}{2}\pi$, the phase velocity for the branch with n^2 given by (6) depends on the magnetic field, whereas that for the branch represented by (7) is independent of the magnetic field.

These characteristics at $\theta=0$ and $\theta=\frac{1}{2}\pi$ will be used later for labeling the modes.

To study the shape of the wave-normal surface it is important to know where n^2 becomes 0 or infinity. For instance, if n^2 crosses 0 from positive to negative, then n becomes imaginary and hence the wave becomes evanescent.

Equation (1) shows that $n^2=0$ is a solution only if $C=0$, namely, if

$$P=0, \text{ or } R=0, \text{ or } L=0. \tag{8}$$

Then the phase velocity is infinite.

The other case, $n^2=\infty$ occurs when $A=0$; from (2) we see that this happens when θ satisfies the relation

$$\tan^2\theta=-P/S \tag{9}$$

Thus, if P and S are of opposite sign, then at θ satisfying (9) and also at $\pi-\theta$, n^2 is infinite and the phase velocity is zero. When this happens, n^2 is zero at no other real θ. At $\theta=0$, n^2 is ∞

when $S=\pm\infty$, and at $\theta=\frac{1}{2}\pi$, n^2 is ∞ when $S=0$.

A circumstance in which $n^2=0$ is called a cutoff and that in which $n^2=\infty$ a resonance (Allis, 1959). Allis calls the resonances at $\theta=0$ and $\theta=\frac{1}{2}\pi$ the principal resonances.

From (4) and (5) we see that at $\theta=0$, $n^2=\pm\infty$, or $L=\pm\infty$. The definitions in (2) show that the case $R=\pm\infty$ corresponds to electron cyclotron resonance and the case $L=\pm\infty$ to ion cyclotron resonance. Indeed, the polarization of the electric field in each case can be shown to be in the same direction as that of gyration of the respective particle.

The resonance at $\theta=\frac{1}{2}\pi$, corresponding to $S=0$, is called the hybrid resonance; there are two branches in the solution to $S=0$, and according to the frequency, the two resonances are called the upper and the lower hybrid resonances. The lower hybrid resonance will be discussed in Section 2.8.

In the limit $\theta\to 0$ and $P\to 0$, a resonance may or may not result, depending upon the path of approach to this double limit (Stix, 1962).

The topological characteristics of the wave-normal surfaces can be classified into three categories. If n^2 is positive for all real values of θ, the wave-normal surface is topologically equivalent to a sphere.

As we have seen, if P and S are of opposite sign, there is a resonance at θ_{res} satisfying (9). In this case, if n^2 is positive for $0\leqslant\theta\leqslant\theta_{res}$, and for $\pi-\theta_{res}\leqslant\theta\leqslant\pi$ and negative for $\theta_{res}<\theta<\pi-\theta_{res}$, the wave-normal surface is equivalent to a dumbbell-shaped lemniscoid. If the sign of n^2 in these regions is reversed, the wave-normal surface is equivalent to a wheel-shaped lemniscoid.

2.3 Plasma Parameter Space

To determine the wave-normal surfaces for the two branches of n^2 certain parameters of the plasma must be specified. Equations (1) and (2) indicate that the wave-normal surfaces are uniquely determined when the ratios π_k/ω and Ω_k/ω (and ϵ_k) are specified for all k. Thus, if we imagine $2k$-dimensional space with $2k$ mutually orthogonal axes representing π_k/ω and Ω_k/ω, the wave-normal surfaces for the two branches of n^2 can be assigned to every point in this plasma parameter space. However, if we specify fixed parameters, such as ratios of number densities of different types of particles, and mass ratios, the minimum number of coordinate axes required is reduced.

To be specific in our representation we now limit ourselves to a neutral cold plasma consisting of electrons and hydrogen ions. We denote the plasma frequencies and the cyclotron frequencies for electrons and ions by affixing subscript e or i to π and Ω.

The quantities R, L, and P defined in (2) are then reduced to much simpler expressions:

$$R=1-\alpha/[(1+\Omega_i/\omega)(1-\Omega_e/\omega)] \tag{10}$$

$$L=1-\alpha/[(1-\Omega_i/\omega)(1+\Omega_e/\omega)] \tag{11}$$

$$P=1-\alpha \tag{12}$$

where

$$\alpha=(\pi_e^2+\pi_i^2)/\omega^2 \tag{13}$$

Since $\Omega_e/\Omega_i=m_i/m_e\equiv\mu$, is a fixed parameter, we see that two-dimensional parameter space, i.e., a plane, suffices for our purpose. Following Allis (1959) and Stix (1962) we take Ω_e^2/ω^2 as ordinate and α as abscissa; we are only concerned with the quadrant bounded by the positive axes.

2.4 The Clemmow-Mullaly-Allis Diagram

We now divide this plasma parameter plane into bounded areas by curves representing the principal resonances and cutoffs. To make the bounding curves reasonably separated from each other it is helpful to take the ion-to-electron mass ratio μ to be smaller than its actual value. Following Allis and Stix, we take μ to be 4 for our illustrative purpose.

By examining the wave-normal surfaces in the manner described in the preceding Section it can be shown that the topological type of each of the wave-normal surfaces for the two branches remains the same throughout each of the bounded areas.

The CMA diagram constructed in this way is shown in Figure 1. In each of the bounded areas the topological types of the wave-normal surfaces for the two branches are indicated. Wherever only one wave-normal surface is drawn, the mode corresponding to the other branch is evanescent, and in the area to the right of the curve $L=0$ and

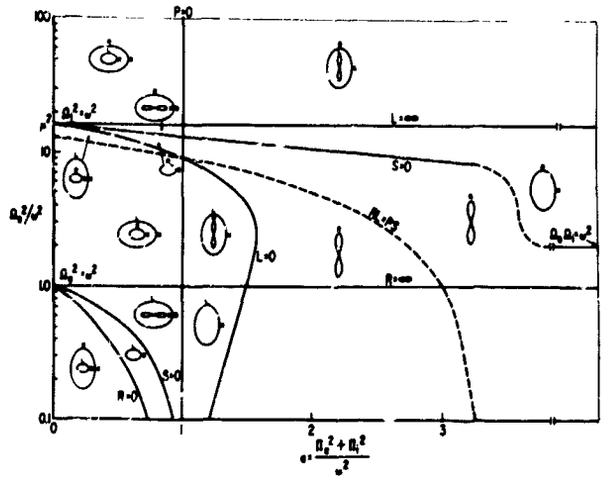

FIGURE 1.—The CMA diagram for a two-component cold plasma, showing the topological characteristics of the wavenormal surfaces.

below the horizontal line $R=\infty$ both branches are evanescent.

The curve for $RL-PS=0$ is drawn in with broken lines. This curve represents neither cutoff nor resonance, but it proves to be useful in labeling the modes.

As we have seen in Section 2.2 the polarization in the electric field is either right-handed or left-handed at $\theta=0$. The wave-normal surfaces in Figure 1 are labeled R or L on top of each sketch according as the polarization at $\theta=0$ is right-handed or left-handed, respectively.

For the propagation across the magnetic field, i.e., $\theta=\frac{1}{2}\pi$, we found that n^2 for one of the two branches depends on the magnetic field and that n^2 for the other branch is independent of the magnetic field. Allis (1959) termed the mode with n^2 dependent on the magnetic field "extraordinary" mode and the mode with n^2 independent on the magnetic field "ordinary" mode. We follow Allis' nomenclature, and wherever the propagation in this direction ($\theta=\frac{1}{2}\pi$) is possible, the symbol 0 or X is attached to the right of each sketch of the wave-normal surface, according as the mode is "ordinary" or "extraordinary."

This system of labeling the modes seems to be most systematic and is recommended for the general use to eliminate confusion that has existed in the past.

As we shall see in Section 2.9, for frequencies much less than the ion cyclotron frequency the wave-normal surface for the mode labeled with R and X in Figure 1 becomes a sphere, that is, n^2 is independent of θ. For this reason Åström (1950) called this mode "ordinary" and the other "extraordinary," and Åström's nomenclature has been used widely in the literature dealing with hydromagnetic waves. However, this labeling is not consistent with Allis' system. Since the spherical wave-normal surface in question is merely an approximation valid only for frequencies well below the ion cyclotron frequency, Allis' system seems to be preferable.

As is evident in Figure 1, a right-handed (or left-handed) mode at $\theta=0$ may be either an ordinary or extraordinary mode at $\theta=\frac{1}{2}\pi$, and hence labeling the modes with only one label R or L, or 0 or X is not adequate.

It is also noted that the polarization in the electric field may reverse its direction in some regions in the plasma parameter plane (Stix, 1962). This problem will be discussed in detail in Section 2.7.

The two modes can be distinguished by still another labeling method. The two modes are labeled "fast" or "slow" by comparing the size of the wave-normal surfaces. There can be no crossing of the wave-normal surfaces for the two branches so that the labeling with "fast" or "slow" mode can be made unambiguously. Wherever only one branch is nonevanescent, it is reasonable to assume that the wave-normal surfaces change continuously in the plasma parameter plane and to label that mode consistently with the naming of the corresponding mode in the neighboring bounded areas where a comparison of two modes is possible.

2.5 A Model Magnetosphere

In Section 2.6 a CMA diagram for ULF and VLF waves in the magnetosphere will be presented. The model magnetosphere to be used for the CMA diagram and also for all the discussions of hydromagnetic waves in the later Sections is described in this Section.

We approximate the earth's magnetic field by a dipole except in Section 3.8 where the distortion of the dipole field due to solar wind is taken into account.

The electron density distribution in the magnetosphere adopted here is based on the recent determination by Liemohn and Scarf (1964) using

nose whistlers. Among the electron density distributions which these authors considered to give self-consistent results, we adopt the simplest distribution, namely, the model in which the electron density is inversely proportional to the distance from the earth's center. Their results apply to the region of the magnetosphere approximately from 3 to 5 earth-radii. We assume that this inverse cube law for the electron density holds in regions below and above these altitudes. To be precise, we assume that the electron density varies as $N_0(a/r)^3$ on the equatorial plane from 15,000 km geocentric distance to the boundary of the magnetosphere which is taken to be at $10a$; here a is the radius of the earth and N_0 is taken to be 1.41×10^4 electrons/cm^3 (Liemohn and Scarf, 1964).

For altitudes below the bottom limit of the above distribution (15,000 km geocentric distance) we base our model on that given by Dessler, Francis, and Parker (1960), but to ensure continuity of the electron density we apply smoothing. In so doing the region below 15,000 km was divided into two regions and in each region the electron density was expressed in a power series. At the boundary between the two regions and at 15,000 km geocentric distance, the electron density and its first derivative with respect to radial distance are made continuous. The density was expressed analytically for the convenience for the numerical calculations required later in the ray treatment.

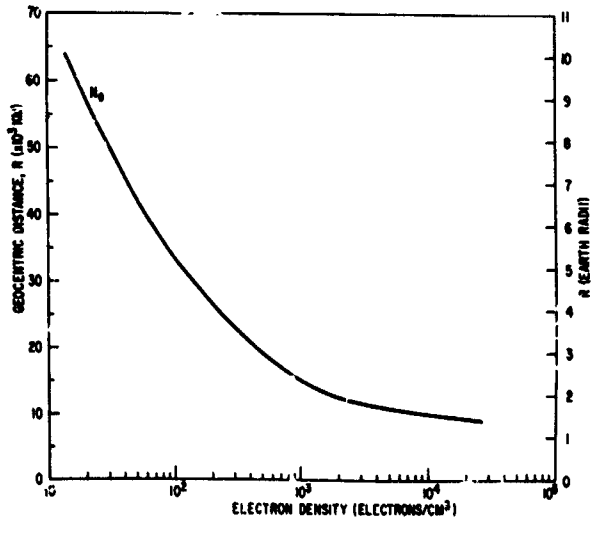

FIGURE 2.—The electron density distribution in the model magnetosphere used in this paper.

Figure 2 shows the electron density distribution constructed in the manner described above and used throughout this paper. The distribution given in Figure 2 refers to that in the equatorial plane, but we assume that the electron density is a function of radial distance alone.

Figure 3 shows the electron plasma frequency and the electron cyclotron frequency as functions of geocentric distance. The former is assumed to be spherically symmetric, but the latter, of course, varies with latitude.

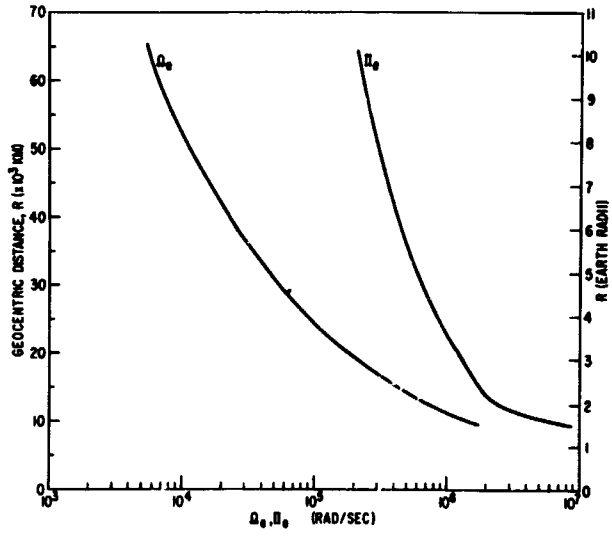

FIGURE 3.—The electron cyclotron frequency and the electron plasma frequency as functions of distance from the earth's center.

2.6 The CMA Diagram for ULF and VLF Waves In the Atmosphere

Having obtained in Section 2.3 the whole view of the CMA diagram for an idealized plasma in which the ion-to-electron mass ratio is taken to be 4, we now ask what regions in the plasma parameter plane are relevant to propagation of ULF and VLF waves in the magnetosphere. We will now take the actual value for the hydrogen-ion-to-electron mass ratio μ.

In Section 2.3 we took α and Ω_e^2/ω^2 as coordinates, but the conditions that are of interest to us now make it more convenient to use π_e/ω as abscissa and Ω_e/ω as ordinate.

A CMA diagram for ULF and VLF with these coordinate axes is shown in Figure 4. The diagram can be used in two ways. If the frequency ω is specified, the change in the plasma parameters

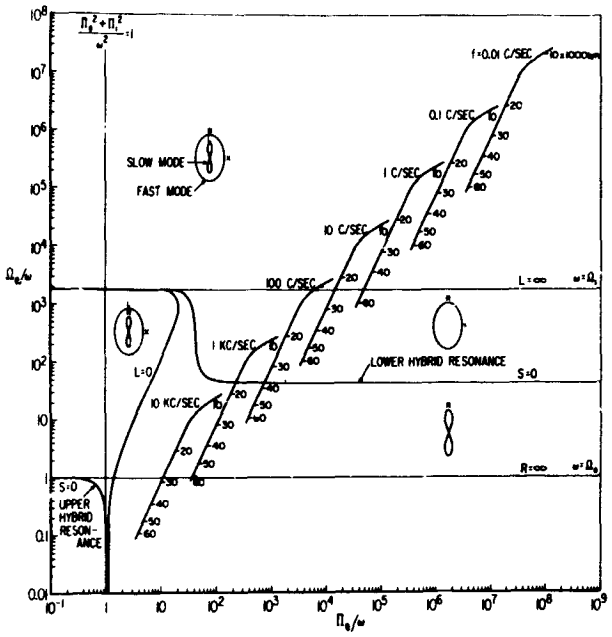

FIGURE 4.—The CMA diagram for ULF and VLF waves in the model magnetosphere.

with distance from the earth's center (for instance, on the equatorial plane) can be represented by a curve along which the radial distance is marked.

Alternatively, if a position in the magnetosphere is specified, a continuous change in the wave frequency at that position can be represented by a continuous curve in the CMA diagram.

For the sake of convenience we take the former representation. In Figure 4, curves are drawn for frequencies from 0.01 c/sec to 10 kc/sec. Since the plasma parameter variations with radial distance are the same for all frequencies, curves for different frequencies can be obtained from one of them by merely displacing it parallel to a fixed straight line.

Since the magnetic field varies with latitude, the curves drawn in Figure 4 for the equatorial plane will be changed at higher latitudes, but the changes are only slight because of the logarithmic scale in the diagram, and the general features which are discussed below will not be altered appreciably.

First, we observe that for waves with frequencies below about 1 c/sec, two modes are possible. One has a wave-normal surface topologically equivalent to a sphere; its electric field has right-handed circular polarization at $\theta=0$, and the mode is "extraordinary" at $\theta=\frac{1}{2}\pi$; this mode is the "fast" mode. The other mode, which is the "slow" mode, has a wave-normal surface topologically equivalent to a dumbbell-shaped lemniscoid, and its electric field has left-handed circular polarization at $\theta=0$. In the hydromagnetic approximation the former mode corresponds to Alfvén compressional wave and the latter to Alfvén shear wave. It is the latter mode that Alfvén (1942) originally derived by treating plasma as a conducting fluid.

In the frequency range approximately from 1 c/sec to 100 c/sec, ion cyclotron resonance takes place at some altitude, and above this altitude only the fast mode can propagate. (We are concerned here only with altitudes above several hundred kilometers above ground level.)

For each frequency in the range from several tens cycles/sec to several kilocycles/sec, the lower hybrid resonance (at $\theta=\frac{1}{2}\pi$, and $S=0$) is encountered at a certain altitude, and above that altitude the wave-normal surface is transformed to a dumbbell-shaped lemniscoid; propagation across the magnetic field becomes impossible. The mode prevailing at frequencies above the lower hybrid resonance frequency is the "whistler" mode.

As we go to still higher frequencies we reach electron cyclotron resonance, and the whistler mode is destroyed. If we cross the cutoff $L=0$ from right to left in Figure 4, we have one or two modes, according as the frequency is above or below the electron cyclotron resonance. In the latter case the slow mode represents the whistler mode.

2.7 Polarization Reversal

In this Section we examine polarization at θ not equal to zero. In Section 2.4 we already mentioned the possibility of reversal of polarization.

Stix (1962) showed that for one of the branches the polarization of the electric field changes direction of rotation at θ satisfying the relation

$$\sin^2\theta = P/S \qquad (14)$$

Clearly, for this reversal of polarization to take place at real θ, P and S must be of the same sign and $|P/S| \leqslant 1$. Even these conditions are both satisfied, the reversal may occur in an evanescent branch. Thus it is worthwhile examining the problem in detail.

From the condition that P and S are of the same sign we can eliminate about one half of the

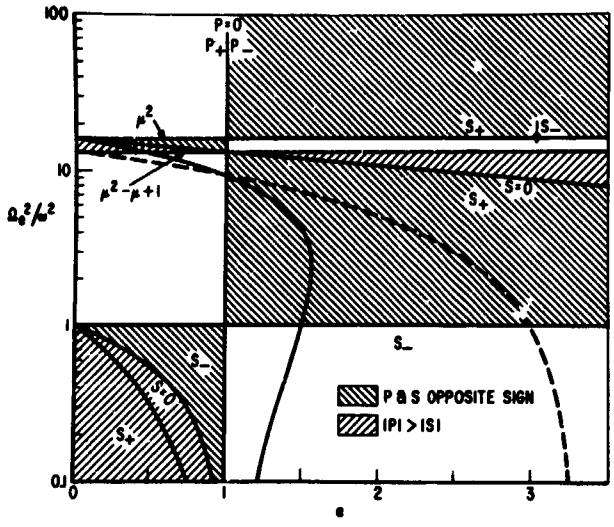

FIGURE 5.—Areas in the plasma parameter plane in which the polarization reversal can occur at θ satisfying (14).

bounded areas in the CMA diagram. By the second condition, namely, that $|P/S| \leqslant 1$, parts of the remaining areas are further eliminated. In Figure 5, areas where polarization reversal cannot occur are shaded; signs of P and S are indicated by a small symbol + or −. The coordinates in Figure 5 are the same as in Figure 1, and the ion-to-electron mass ratio μ is again taken to be 4; this is just for schematical representation, and our discussion in this Section applies to the case in which μ is taken to be the actual ion-to-electron mass ratio. The horizontal line at $\Omega_e^2/\omega^2 = \mu^2$ corresponds to $\Omega_i^2 = \omega^2$, i.e., ion cyclotron resonance. Another horizontal line at $\Omega_e^2/\omega^2 = \mu^2 - \mu + 1$ plays an important role in the following discussions. This comes about from the fact that $P - S$ has the factor $\Omega_e^2/\omega^2 - (\mu^2 - \mu + 1)$ in the numerator. For $\mu > 1$, $\mu^2 - \mu + 1$ is less than μ^2 and is greater than 1. It can be shown that $\mu^2 - \mu + 1$ is the ordinate (Ω_e^2/ω^2) for the intersection of $P = 0$ and $S = 0$, and that the curve $RL - PS = 0$ intersects the Ω_e^2/ω^2 axis at $\mu^2 - \mu + 1$.

From Figure 5 it is already clear that the reversal can never occur in magnetosphere in waves with frequencies below the ion cyclotron frequency.

Next we examine in which branch the polarization reversal takes place, if it does at all, without limiting ourselves to the conditions of our immediate interest.

By examining the polarization of the electric field it can be shown that if the polarization reversal occurs, then it does so in the branch that comes from the positive sign in (3) when $RL + PS - 2S^2$ is negative, and in the branch from the negative sign in (3) when this quantity is positive.

It is, therefore, instructive to locate the solution to the equation

$$RL + PS - 2S^2 = 0 \tag{15}$$

The left-hand side of (15) can be written as follows:

$$\begin{aligned} RL + PS - 2S^2 = {} & \alpha x^2 (\mu^2 - x^2)^{-2} (1 - x^2)^{-2} [x^6 \\ & - \{2\mu^2 - (1+\alpha)\mu + 2\} x^4 + \{\mu^4 - (1+\alpha)\mu^3 + 3\mu^2 \\ & - (1+\alpha)\mu + 1\} x^2 - \mu^2 \{(1-2\alpha)\mu^2 - (1 \\ & - 3\alpha)\mu + 1 - 2\alpha\}] \end{aligned} \tag{16}$$

where $x = \Omega_e/\omega$

The expression on the right-hand side of (16) can also be written as

$$\begin{aligned} & -\alpha x^2 (\mu^2 - x^2)^{-2} (1 - x^2)^{-2} [(x^2 - \mu^2) \{x^2 - (\mu^2 - \mu \\ & + 1)\} (x^2 - 1) + \alpha\mu \{(x^2 - \mu^2)(x^2 - 1) + 2\mu(\mu - 1)^2\}] \end{aligned}$$

Though the latter expression is convenient to determine α when x^2 is given, we will use (16) to obtain the solution to (15). From (16) we see that $x^2 = 0$ is a solution of (15), which, however, is of no interest to us.

We now examine the solution of the equation that is obtained by equating the content of the square brackets in (16) to zero. Since the equation so obtained is cubic in x^2, we can determine the number of real roots by examining the discriminant. This method is helpful in locating the solutions.

For $\alpha \gg \mu$ and x^2 not very much greater in order of magnitude than μ, x^2 becomes independent of α, and we have two positive roots:

$$x^2 = \mu^2(1 - 2/\mu) \quad \text{or} \quad 2\mu$$

thus, giving two positive roots for x

$$x = \mu(1 - 2/\mu)^{\frac{1}{2}} \quad \text{or} \quad (2\mu)^{\frac{1}{2}}$$

Numerically, these are approximately 1835.50 and 60.64, respectively.

There are three positive real roots (x^2 satisfying (15)) for positive α less than 0.175. Between

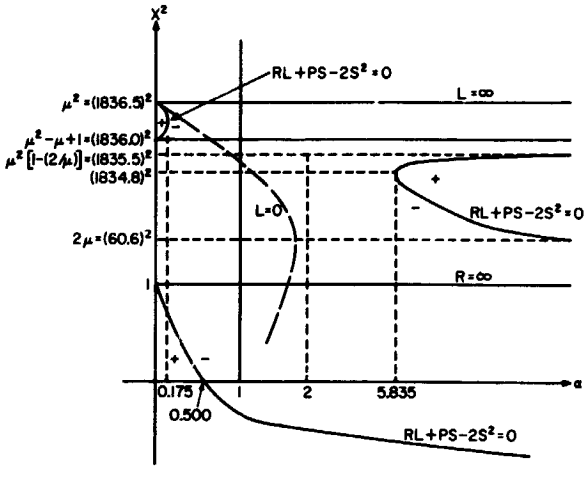

FIGURE 6.—Illustrating the solutions to $RL+PS-2S^2=0$.

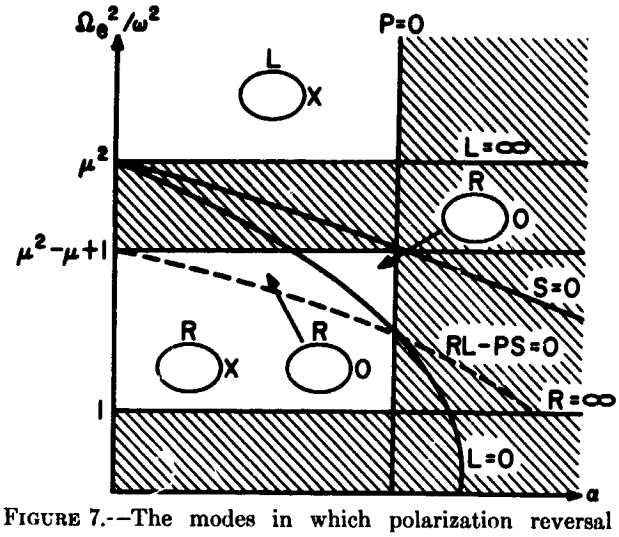

FIGURE 7.—The modes in which polarization reversal occurs at θ satisfying (14).

0.175 and 5.835 there is only one negative real root. For α greater than 5.835 there are two positive real roots and one negative real root. (The numbers quoted are accurate to ± 0.005.)

The curves representing (15) are schematically shown in Figure 6; the sign for $RL+PS-2S^2$ is also indicated for areas separated by the curves.

We now combine the results in Figures 5 and 6. In so doing we observe that the intersection of $R=\infty$ and $L=0$ is at $\alpha=2(1-1/\mu)<2$. We see that all the unshaded areas in Figure 5 where the polarization reversal can occur are in the regions where $RL+PS-2S^2$ is negative. Thus the reversal occurs in the branch resulting from the plus sign in (3).

We reach the conclusion that there is no polarization reversal in the nonevanescent modes to the right of the vertical line $\alpha=1$, and that for α less than 1 the polarization reversal occurs in the L–X mode for $\omega^2<\Omega_i^2$ and in the R–O or R–X mode for $\Omega_i^2(1-1/\mu+1/\mu^2)<\omega^2<\Omega_e^2$.

The mode in which the polarization reversal occurs are indicated in Figure 7, which summarizes the discussions given in this Section.

We conclude that for ULF and VLF waves ni the magnetosphere the polarization reversal at θ satisfying (14) does not occur.

2.8. The Lower Hybrid Resonance

We see from (6) that for propagation across the magnetic field, i.e., for $\theta=\frac{1}{2}\pi$, there is resonance at $S=0$. As is indicated in Figures 1 and 4, there are two such resonances, and the one at lower frequency is called the lower hybrid resonance and the other at higher frequency the upper hybrid resonance.

Approximate expressions for the two hybrid resonance frequencies can be obtained by ignoring terms of order μ^{-1} compared with unity in the dispersion relation for $\theta=\frac{1}{2}\pi$. Stix (1962) gives for the lower hybrid resonance frequency ω_{LH}

$$1/\omega_{LH}^2=1/(\Omega_i^2+\Pi_i^2)+1/\Omega_i\Omega_e \qquad (17)$$

and for the upper hybrid resonance frequency ω_{UH}

$$\omega_{UH}^2=\Omega_e^2+\Pi_e^2 \qquad (18)$$

In the frequency range we are concerned here and for the plasma parameters appropriate to the magnetosphere the lower hybrid resonance frequency can be approximated to a good accuracy by the geometric mean of the ion and electron cyclotron frequencies:

$$\omega_{LH}=(\Omega_i\Omega_e)^{\frac{1}{2}} \qquad (19)$$

A clear physical picture for this resonance was given by Auer, Hurwitz, Jr., and Miller (1958).

The lower hybrid resonance frequency in the magnetosphere at different distances from the earth's center is given in Table 1.

2.9. The Hydromagnetic Approximation

When the wave frequency ω is well below the ion cyclotron frequency Ω_i, the quantities R and

TABLE 1.—*The lower hybrid resonance frequency f_{LH} at various distances from the center of the earth.*

L in (10) and (11) are simplified and both R and L can be approximated by $1+\gamma$, where $\gamma=4\pi\rho c^2/B_0^2$; here $\rho=n_im_i+n_em_e$, i.e., the plasma density. With these approximations for R and L the dielectric tensor defined in Section 2.1 becomes diagonal. The component K_1 of the dielectric tensor perpendicular to the magnetic field than takes the well-known form (Spitzer, 1956)

$$K_1=1+\gamma$$

If α is large, as is the case with ULF waves in the magnetosphere, P in (12) can be approximated by $-\alpha$. With these approximations for R, L, and P the dispersion relation is simplified and readily factored, giving the following two modes. One of these modes gives

$$n^2=1+\gamma \tag{20}$$

and the other

$$n^2\cos^2\theta=1+\gamma \tag{21}$$

In the first mode n^2 is independent of θ. For this reason Åström (1950) called this mode "ordinary" mode, and the second "extraordinary" mode. However, a closer examination shows that the first mode corresponds to the branch labeled R–X in Figure 4 and the second to that labeled L. Hence the exact expression for n^2 for the first mode depends on the magnetic field for $\theta=\frac{1}{2}\pi$. The problem of labeling the modes has already been discussed in Section 2.4.

By studying the ion velocity the mode corresponding to (20) can be shown to represent *compressional* wave, and the other mode (21) *shear* wave.

From a comparison of phase velocity for these two modes one finds that the compressional mode is the fast mode and that the shear mode is the slow mode.

From the continuity of the wave-normal surface we see that the Alfvén compressional mode (or the fast hydromagnetic mode) and the whistler mode belong to the same family. The Alfvén shear mode (or the slow hydromagnetic mode) disappears at the ion cyclotron frequency.

When $\gamma\gg1$ the phase velocities for the compressional and shear modes recede to V_A and V_A cos θ, respectively, where $V_A=B_0/>\sqrt{4\pi\rho}$, which is usually called the Alfvén velocity. The condition that $\gamma\gg1$ is equivalent to the condition that $V_A/c\ll1$.

These approximations for the phase velocities can be readily obtained by a fluid-dynamical treatment of plasma with infinite conductivity and by neglecting displacement current.

3. RAY THEORY

3.1. Introduction

So far we have reviewed the wave modes in a cold plasma by studying the wave-normal surfaces. The basis for the study was the dispersion relation. We now investigate propagation of hydromagnetic waves from a somewhat different angle by constructing a ray theory. As the plane wave theory described in the preceding Sections has limitations in its application, the ray theory developed in the following Sections is valid only under certain conditions. However, just as the general discussions of wave modes are useful in understanding the propagation of waves, the theoretical study of the behavior or rays may be helpful in understanding some of the electromagnetic phenomena occurring in the magnetosphere.

Although the theoretical discussions in Sections 3.2 and 3.3 are of general nature, the theory is applied in Sections 3.4 to 3.8 to propagation of hydromagnetic waves in the magnetosphere.

3.2. The Equations of Motion of a Ray

The basis of the theory is that the ray propagates with the group velocity. Hines (1951) and

Auer, Hurwitz, Jr., and Miller (1958) have shown that the constructive interference maximum of a wave packet moves with the group velocity. We also assume that the mode in which the waves constituting the wave packet propagate is the same throughout its motion in the anisotropic medium. Coupling between different modes is assumed not to take place.

Denoting the position of a ray by $\vec{r}$ and the group velocity by $\vec{v}_g$, we write the equation of motion for the ray as follows.

$$\dot{\vec{r}}=\vec{v}_g \tag{22}$$

where the dot signifies differentiation with time t. The group velocity $\vec{v}_g$ is given by

$$\vec{v}_g=\partial\omega/\partial\vec{k} \tag{23}$$

The wave frequency ω and the wave vector $\vec{k}$ are related by the dispersion relation which we write

$$D(\vec{k},\ \omega,\ \vec{r},\ t)=0 \tag{24}$$

We introduce a parameter τ along the path of the ray. Then, using (23) and (24), the equation of motion (22) can be written in the following form.

$$\frac{d\vec{r}/d\tau}{dt/d\tau}=-\frac{\partial D/\partial\vec{k}}{\partial D/\partial\omega} \tag{25}$$

From our assumption D is constant along the trajectory, and hence we have

$$\delta D=\left(\frac{\partial D}{\partial\vec{k}}\cdot\frac{d\vec{k}}{d\tau}+\frac{\partial D}{\partial\omega}\frac{d\omega}{d\tau}+\frac{\partial D}{\partial\vec{r}}\cdot\frac{d\vec{r}}{d\tau}+\frac{\partial D}{\partial t}\frac{dt}{d\tau}\right)=0 \tag{26}$$

For (26) to hold for any τ the content in the parentheses must be zero. We group the four terms in the paretheses in (26) as follows:

$$\left(\frac{\partial D}{\partial\vec{k}}\cdot\frac{d\vec{k}}{d\tau}+\frac{\partial D}{\partial\vec{r}}\cdot\frac{d\vec{r}}{d\tau}\right)+\left(\frac{\partial D}{\partial\omega}\frac{d\omega}{d\tau}+\frac{\partial D}{\partial t}\frac{dt}{d\tau}\right)=0 \tag{27}$$

If each of the two factors in (27) is zero, the required condition (26) is satisfied. Equations (25) and (27) are satisfied by the following set of equations:

$$d\vec{r}/d\tau=\partial D/\partial\vec{k} \tag{28}$$

$$d\vec{k}/d\tau=\partial D/\partial\vec{r} \tag{29}$$

$$dt/d\tau=\partial D/\partial\omega \tag{30}$$

$$d\omega/d\tau=\partial D/\partial t \tag{31}$$

If D is independent of time, the last equation (31) states that ω is conserved along the ray trajectory. Third equation (30) gives the relation between time t and parameter τ.

The above set of equations clearly indicates an analogy between the ray theory and classical mechanics. The wave vector $\vec{k}$ and the frequency ω of a ray play the roles of the momentum and the energy of a particle, respectively. However, this analogy does not enable us to formulate the ray theory in Hamiltonian form. This is because the motion of a ray corresponds to that of a particle of zero mass, and hence it is expected that the Lagrangian for the ray is identically zero. In the end of the following Section we will show that the Lagrangian indeed vanishes.

However, when Fermat's principle is valid the problem can be formulated in Hamiltonian form. Hence we now examine under what conditions Fermat's principle is consistent with our formulation.

3.3. Fermat's Principle

Weinberg (1962) showed that when the *eikonal* is stationary, the principle of least time, i.e., Fermat's principle, holds if the dispersion relation is homogeneous in $\vec{k}$ and ω In this Section we drive the same condition by pursuing the formulation in the preceding Section.

In classical mechanics the principle of least action holds when the Hamiltonian is conserved. We limit ourselves to the case when the frequency ω is conserved along the path, that is, D is conserved along the path.

We first define the action A for the ray by the integral

$$A=\int_{t_1}^{t_2}\vec{k}\cdot\dot{\vec{r}}dt \tag{32}$$

where the dot means, as before, differentiation with t.

Next, we calculate the variation ΔA, where the Δ-variation differs from the δ-variation appearing in virtual displacement; in the latter, time is kept unchanged, whereas in the former the process involves a change dt (see, e.g., Goldstein, 1951). For any function f of $\vec{r}$ and t, the Δ-variation of f is

$$\Delta f=d\tau\left(\frac{\partial f}{d\tau}+\dot{f}\frac{dt}{d\tau}\right)=\delta f+\dot{f}\Delta t \tag{33}$$

In particular,

$$\Delta\vec{r}=\delta\vec{r}+\dot{\vec{r}}\Delta t \tag{34}$$

Applying the Δ-variation to (32) we have

$$\Delta A=\int_{t_1}^{t_2}\delta(\vec{k}\cdot\dot{\vec{r}})dt+\vec{k}\cdot\dot{\vec{r}}\Delta t\Big|_{t_1}^{t_2} \tag{35}$$

The first integral can be calculated in the following way:

$$\int_{t_1}^{t_2}\delta(\vec{k}\cdot\dot{\vec{r}})dt=\int_{t_1}^{t_2}\delta\vec{k}\cdot\dot{\vec{r}}dt+\int_{t_1}^{t_2}\vec{k}\cdot\delta\dot{\vec{r}}dt=\int_{t_1}^{t_2}\delta\vec{k}\cdot\dot{\vec{r}}dt$$

$$-\int_{t_1}^{t_2}\dot{\vec{k}}\cdot\delta\vec{r}dt+k\cdot\delta\vec{r}\Big|_{t_1}^{t_2}=\int_{t_1}^{t_2}(\delta\vec{k}\cdot\dot{\vec{r}}-\dot{\vec{k}}\cdot\delta\vec{r})dt-\vec{k}\cdot\dot{\vec{r}}\Delta t\Big|_{t_1}^{t_2}$$

Here we used the fact that the order of the δ- and *dot*-operation can be interchanged, and partial integration was performed on the second integral on the right-hand side of the first line. To obtain the last result we used (34) and the condition that $\Delta\vec{r}=0$ at the end points.

Thus (35) reduces to

$$\Delta A=\int_{t_1}^{t_2}(\delta\vec{k}\cdot\dot{\vec{r}}-\dot{\vec{k}}\cdot\delta\vec{r})dt$$

Using (22), (23), (38), (29), and (30), the integrand can be transformed as follows:

$$\delta\vec{k}\cdot\dot{\vec{r}}-\dot{\vec{k}}\cdot\delta\vec{r}=-(\partial D/\partial\omega)^{-1}\left(\delta\vec{k}\cdot\frac{\partial D}{\partial\vec{k}}+\delta\vec{r}\cdot\frac{\partial D}{\partial\vec{r}}\right)$$

$$=-(\partial D/\partial\omega)^{-1}\delta D=0$$

Thus we have proved that

$$\Delta A=0$$

Namely, in our system the principle of least action holds if the action is defined by (32). Having proved this principle we go back to the expression for ΔA given in (35). If

$$\vec{k}\cdot\dot{\vec{r}}=\text{constant}\neq 0 \tag{36}$$

then (35) reduces to

$$\Delta(t_2-t_1)=0$$

which implies the principle of least time, or Fermat's principle. The condition (36) can be rewritten as follows:

$$-(\vec{k}\cdot\partial D/\partial\vec{k})/(\partial D/\partial\omega)=\text{constant} \tag{37}$$

A sufficient condition for (37) to hold is that D is homogeneous in $\vec{k}$ and ω, because if D is homogeneous in $\vec{k}$ and ω, i.e., if

$$D(\alpha\vec{k},\ \alpha\omega)=\alpha^n D(\vec{k},\ \omega)$$

Euler's homogeneity equation becomes

$$\vec{k}\cdot\frac{\partial D}{\partial\vec{k}}+\omega\frac{\partial D}{\partial\omega}=nD=0 \tag{38}$$

Thus the constant in (37) takes the value of ω.

The homogeneity equation (38) can be transformed into the form

$$\vec{v}_g\cdot\frac{\vec{k}}{\omega}=1$$

which implies the equality of the group and phase velocities.

It is pointed out here that the action (32) is the same as the eikonal S in Weinberg's formulation, and that the principle of least action derived here is equivalent to the principle of stationary S in Weinberg's eikonal theory.

For the Alfvén compressional mode the dispersion relation is homogeneous in $\vec{k}$ and ω, and hence Fermat's principle holds. As a matter of fact, for this mode the group velocity is equal to the phase velocity. However, for the shear mode the dispersion relation is not homogeneous in the components of $\vec{k}$, and thus Fermat's principle does not hold. As has been noted by Weinberg (1962), the application of Fermat's principle by Francis, Green and Dessler (1959) is justified.

In concluding this Section a remark is made on the Lagrangian. In classical mechanics the Lagrangian L is related to the Hamiltonian by

$$L=\vec{p}\cdot\dot{\vec{r}}-H$$

where $\vec{p}$ is the momentum.

If we define the Lagrangian for the ray by

$$L=\vec{k}\cdot\dot{\vec{r}}-\omega$$

then from (36) our Lagrangian is identically zero, confirming our expectation expressed in Section 3.2. Thus the ray theory cannot be constructed in Hamiltonian form using the Lagrangian defined above.

3.4 A Ray Theory for Modes with Isotropic Phase Velocity

In this and the following Sections we discuss the case in which the phase velocity is isotropic. We specifically study propagation of a hydromagnetic ray. For the Alfvén compressional mode the group velocity is the same as the phase velocity. Hence we simply refer to these velocities by the single term the Alfvén velocity.

Fermat's principle states that the motion of a ray from a point P_1 to another point P_2 is such that the variation of the line intergral $\int_{P_1}^{P_2} ds/V$ for fixed P_1 and P_2 is zero, i.e.,

$$\delta \int_{P_1}^{P_2} ds/V(r,\theta,\phi) = 0 \qquad (39)$$

where $V(r.\theta.\phi)$ is the Alfvén velocity. We use a spherical coordinate system (r,θ,ϕ) in this and following Sections; when we refer to the magnetosphere the origin of the spherical coordinate system is taken to coincide with the earth's center. In the preceding Sections θ was the angle which $\vec{k}$ makes with the magnetic field, but in the rest of the paper θ is the polar angle.

We write (39) in the form

$$\delta \int_{t_1}^{t_2} \frac{(\dot{r}^2 + r^2\dot{\theta}^2 + r^2\dot{\phi}^2 \sin^2\theta)^{\frac{1}{2}}}{V(r,\theta,\phi)} dt = 0 \qquad (40)$$

where t_1 and t_2 are the times when the ray is at P_1 and P_2, and where the dot means differentiation with respect to time t.

Equation (40) is formally the same as the equation expressing Hamilton's principle for a system whose Lagrangian is equal to the integrand in (40). Thus we take the integrand of (40) as the Lagrangian of our system, and define the generalized momenta conjugate to r, θ, ϕ by

$$p_k = \partial L/\partial \dot{q}_k \qquad (k = 1, 2, 3)$$

where it is understood that the subscript k refers to r, θ, ϕ components and that q_k $(k = 1, 2, 3)$ represents r, θ, ϕ, respectively.

The Hamiltonian H of the system is

$$H = \sum_k p_k \dot{q}_k - L$$

$$= V(r, \theta, \phi)^2[p_r^2 + p_\theta^2/r^2 + p_\phi^2/(r^2\sin^2\theta)] - 1$$

Then the canonical equations can readily be formed. Stegelmann and von Kenschitzki (1964) proceeded to integrate the cononical equations numerically.

3.5. Axially Symmetric Case: *Allowed and Forbidden Regions for a Ray*

It is obvious that if the Alfvén velocity is independent of ϕ, the Hamiltonian does not contain ϕ explicity; thus, ϕ is a *cyclic* coordinate. It follows that the conjugate momentum p_ϕ is a constant of motion. From the definition of p_ϕ we immediately obtain the equation

$$(r^2\dot{\phi}\sin^2\theta)/V(r,\theta)^2 = \text{constant} \qquad (41)$$

This equation, of course, is the canonical equation for ϕ with p_ϕ constant.

Since $\phi = V d\phi/ds$, where s is path length along the trajectory, (41) can be written as follows:

$$(R^2/V) d\phi/ds = \alpha \qquad (42)$$

where

$$R = r \sin\theta \qquad (43)$$

and where α is a constant.

We define an angle χ by the equation

$$R\, d\phi/ds = \sin\chi \qquad (44)$$

so that χ is the angle between the tangent to the ray in the direction of its motion and the meridian plane. As can be seen in (44) the sign of χ is taken such that χ is positive when ϕ increases as the ray advances. Figure 8 illustrates the angle χ.

Using χ, (42) reduces to

$$(R/V) \sin\chi = \alpha \qquad (45)$$

For rays belonging to α, (45) gives the angle χ as a function of r and θ.

Since $-1 \leqslant \sin\chi \leqslant 1$, we have the relation

$$= 1 \leqslant \alpha V/R \leqslant 1 \qquad (46)$$

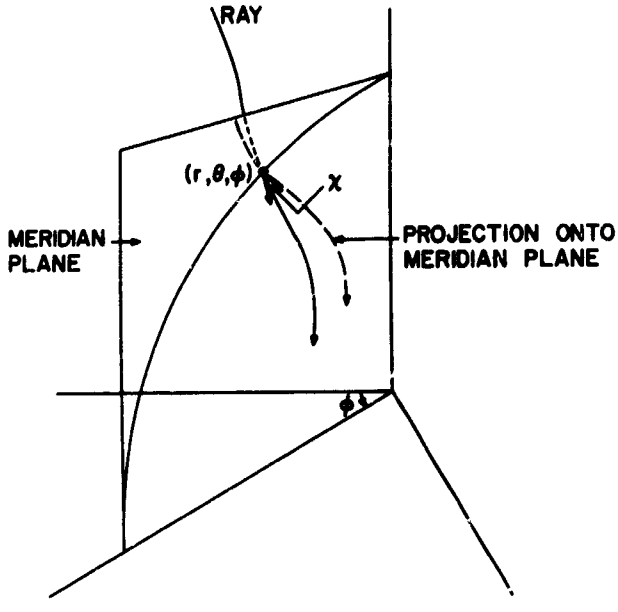

FIGURE 8.—Illustrating the angle χ.

Thus, given the value of α, (46) defines the "allowed" region for the rays belonging to α. Areas outside the allowed region are forbidden to these rays.

The constant α can be taken as the initial condition specified by r_0, θ_0, and χ_0:

$$\alpha = (R_0/V_0) \sin \chi_0 \qquad (47)$$

where R_0 and V_0 are the values of R and V at r_0, θ_0.

It should be noted that the angle χ_0 does not specify the initial direction of a ray completely, except in the equatorial plane. To specify the initial direction of a ray completely one more angle is needed (Section 3.8); however, we only need χ_0 for the time being.

When the initial conditions r_0, θ_0, and χ_0 are given, the *allowed* and *forbidden regions* can be mapped out using (46) without integrating the equations of motion.

The problem is formally identical with that in Störmer's work on the motion of a charged particle in a dipole magnetic field (Störmer, 1955). In Störmer's problem also the Hamiltonian does not contain ϕ explicitly.

The meaning of (44) becomes more explicit if we limit ourselves to rays confined in the equatorial plane. The Alfvén velocity V is now a function of r alone, and χ is the angle which the tangent to the ray trajectory makes with the radial direction. Let χ be measured positively from the inward radial direction toward the direction of increasing ϕ (which is taken to be eastward) and let χ vary from $=\pi$ to π; thus rays with $-\frac{1}{2}\pi < \chi < \frac{1}{2}\pi$ are inbound and those with $|\chi| > \frac{1}{2}\pi$ are outbound, and when $\chi = \pm\frac{1}{2}\pi$, a ray is tangent to the circle of radius r.

The angle χ at r is related to its initial value χ_0 at the point source at r_0 by

$$\sin \chi = (r_0/r)(V/V_0) \sin \chi_0$$

If $V(r)$ is a maximum at $r = r_m$ and is a monotonically decreasing function of r with increasing r, then for $r_0 > r > r_m$, the inequality $|\chi| > |\chi_0|$ always holds. This simply implies the obvious result that the ray is bent away from the region of high Alfvén velocity.

The Alfvén velocity is a maximum at several thousand kilometers altitude and decreases both above and below this level (Dessler, 1958). The Alfvén velocity increases again near the F_2 peak. but we are not concerned here with the propagation of hydromagnetic waves in the ionosphere. We only consider the ray trajectories above 600 km altitude.

It is of interest to find the critical initial angle $\chi_{0,c}$ at which an inbound ray from a point source at a great distance is reflected away from the earth at the region ($r = r_m$) of the Alfvén velocity maximum. This critical initial angle can be determined by

$$|\sin \chi_{0,c}| = (r_m/r_0) \quad (V_0/V_m)$$

where V_m is the value of V at r_m.

For a rough estimate, taking $r_0 = 60{,}000$ km, $r_m = 10{,}000$ km, and $V_0 = 400$ km/sec, $V_m = 2{,}000$ km/sec, we obtain $|\sin \chi_{0,c}| = 1/30$, and hence $|\chi_{0,c}|$ is about 1.9°. There are uncertainties in the distribution of Alfvén velocity in the magnetosphere, but $\chi_{0,c}$ is not likely to be changed greatly as more accurate information on the Alfvén velocity distribution becomes available.

3.6. A Further Remark on Ray Tracing in the Equatorial Plane

In Section 3.5, time t used for the variable in the variation equation. However, any one of

the three coordinates can be used as the variable in place of t.

If we choose ϕ as the variable, and if we confine ourselves to the equatorial plane, the integrand L in the variation equation reduces to

$$L(r, r') = (r'^2 + r^2)^{\frac{1}{2}} / V(r)$$

where the prime represents differentiation with respect to ϕ.

Considering this function as the Lagrangian, Lagrange's equation of motion is

$$\frac{d}{d\phi}\left(\frac{\partial L}{\partial r'}\right) - \frac{\partial L}{\partial r} = 0$$

This is the equation used by Francis, Green and Dessler (1959).

Denoting the momentum conjugate to r by p, the Hamiltonian for the system is given by

$$H = pr' - L$$

where

$$p = \partial L / \partial r'$$

It is understood that H is expressed as a function of r and p. Then the Hamiltonian does not contain Φ explicitly. Thus the Hamiltonian is a constant of motion. We immediately arrive at the equation:

$$r' \frac{\partial L}{\partial r'} - L = \text{constant}$$

This is the equation which Francis, Green and Dessler (1959) derived mathematically and used for their calculation of the transit time for the ray, and which Dessler, Francis, and Parker (1960) used for their two dimensional ray tracing.

3.7. Hydromagnetic Rays in the Magnetosphere: Axially Symmetric Case

Using the method described in Section 3.5, we will now investigate the accessibility of hydromagnetic rays originating from the magnetospheric boundary to the vicinity of the earth. We use the same model magnetosphere as the one presented in Section 2.5; for the magnetic field we approximate the geomagnetic field by a centered dipole.

As was shown in Section 3.5, when the position $(r_0\theta_0)$ of the point source and the initial value of χ of the ray are specified, we can determine the allowed and forbidden regions by (46) and (47).

We place the point source at the distance of 10 earth-radii from the earth's center, i.e., $r_0 = 10a$, where a is the earth's radius. and we determine allowed and forbidden regions for $\theta_0 = 30°$, 60°, and 90°; the last value of θ_0 places the source on the equatorial plane.

Typical diagrams showing the allowed and forbidden regions are presented in Figure 9. In the Figure, forbidden regions are indicated by patches and the open areas represent allowed regions. The patched circle in the center represents the earth and the poisition of the point source can be at any of the four arrows on the great circle whose radius is ten times that of the earth. All the diagrams are symmetric with respect to the equator, and the three dimensional allowed (or forbidden) region can be obtained by rotating each diagram about the vertical axis through the center, namely, the dipole axis.

For very small values of χ_0 (well below 1°, say), that is, when the initial direction of the ray deviates from the meridian plane only by a small angle, the ray can reach the earth's vicinity except directly above the poles. As χ_0 increases the two

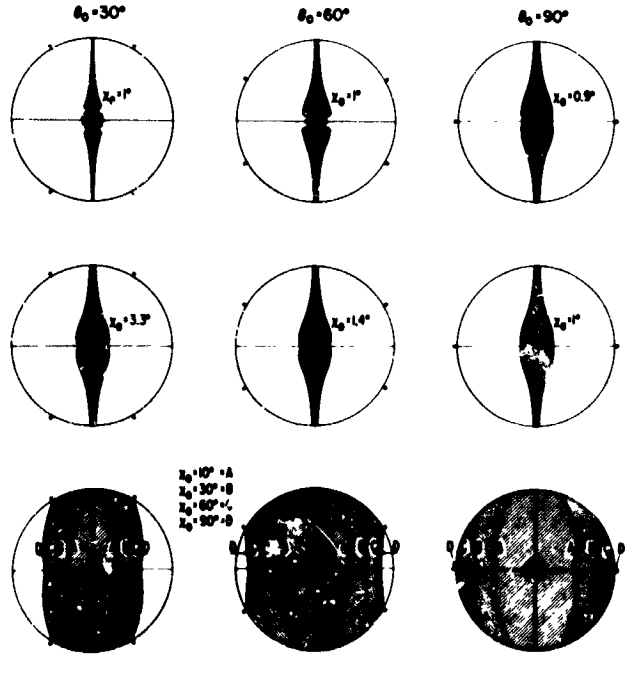

FIGURE 9.—Allowed and forbidden regions for a hydromagnetic ray in the magnetosphere with a dipole field.

forbidden regions around the axis, one in each hemisphere, become larger and extend to lower latitudes near the altitude of the Alfvén velocity maximum. When χ_0 reaches some critical value, the tips of the northern and southern forbidden regions touch each other on the equatorial plane. There is an allowed region between the ionosphere and the altitude at which the joining of the two forbidden regions takes place on the equatorial plane, but this inner allowed region is not accessible to the ray coming from outside.

When χ_0 exceeds the critical value, the earth is completely immersed in a forbidden region and the outer allowed region is more and more pushed outward, and finally, as χ_0 tends to 90° its inner surface approaches some limiting surface which intersects the large sphere (of radius r_0) at $\theta=\theta_0$ and $\theta=\pi-\theta_0$. When θ_0 is 90°, the allowed region for $\chi_0=90°$ degenerates to a circle of radius r_0 on the equatorial plane.

The critical value of χ_0 becomes smaller as θ_0 increases; for $\theta_0=30°$, 60°, and 90°, the critical χ_0 is 3.3°, 1.4°, and 0.9°, respectively. In Figure 9 the diagrams for these critical circumstances are included.

For $\chi_0=10°$, 30°, 60°, and 90° the forbidden regions are indicated in one diagram for each θ_0.

We conclude that the earth and its immediate vicinity are remarkably well protected from the hydromagnetic rays generated in the outer regions of the magnetosphere. This feature has been shown by Stegelmann and von Kenschitzki (1964) with their results from numerical ray tracing.

3.8. Hydromagnetic Rays in the Distorted Magnetosphere: Axially Asymmetric Case

The magnetosphere is contained in a cavity in the streaming solar plasma (Cahill and Amazeen, 1963; Ness et al., 1964). A number of workers have attempted to theoretically determine the shape of the boundary of the magnetosphere (for reference, see a review paper by Beard, 1964).

In this Section we only briefly discuss the effect of the distortion of the magnetosphere on the propagation of hydromagnetic waves.

In the absence of symmetry we have to write down the equations of motion and solve them by some numerical method.

For the sake of convenience we multiply the Hamiltonian given in Section 3.4 by the factor $\frac{1}{2}$. With this Hamiltonian the canonical equations are

$$\dot{r}=V^2p_r$$

$$\dot{\theta}=V^2p_\theta/r^2$$

$$\dot{\phi}=V^2p_\phi/(r^2\sin^2\theta)$$

$$\dot{p}_r=-(1/V)\partial V/\partial r+(V^2/r^3)(p_\theta^2+p_\phi^2/\sin^2\theta$$

$$\dot{p}_\theta=-(1/V)\partial V/\partial\theta+(V^2/r^2)p_\phi^2\cos\theta/\sin^3\theta$$

$$\dot{p}_\phi=-(1/\mathrm{V})\partial V/\partial\phi \qquad (48)$$

These equations are not completely independent. The Hamiltonian of the system is identically zero, and we have

$$p_r^2+p_\theta^2/r^2+p_\phi^2/(r^2\sin^2\theta)=1/V^2 \qquad (49)$$

Using (49) one of the variables can be eliminated from the set of equations (48). But it is found convenient to use (49) as a check in the numerical ray tracing calculation.

We define the direction of the tangent to the ray trajectory at a point P by two angles χ and η. The angle χ is the same as that defined in the preceding Section, and η is the angle which the tangent to the projection of the trajectory onto the meridian plane makes with the radial direction, namely,

$$\sin\chi=(d\phi/ds)\,r\sin\theta$$

$$\cos\eta=-(dr/ds)\sec\chi$$

We denote the initial values of χ and η at (r_0, θ_0, ϕ_0) by χ_0 and η_0, respectively.

The initial values of the momenta can be written in terms of r_0, θ_0, ϕ_0, χ_0, η_0, and $V(r_0, \theta_0, \phi_0)$.

For the deformed geomagnetic field we take the model proposed by Mead (1964). For the dipole field we take $g_1^0=-0.31$ gauss, and for the additional field due to the deformation we take

$$g_1^0=-0.2515/r_b^3 \text{ gauss}$$

$$g_2^1=0.1215/r_b^4 \text{ gauss}$$

where g's are well-known Gauss coefficients in the spherical harmonic expansion of the magnetic field, and where r_b is the distance, measured in earth-radii, from the earth's center to the boundary of the magnetosphere at the subsolar point. Here r_b is taken to be 10 earth-radii.

A computer program has been developed to integrate the equations of motion (48) with r_0, θ_0, ϕ_0, χ_0, and η_0 as the initial conditions. For integration the Runge-Kutta method was used.

In this paper, trajectories on the equatorial plane alone are discussed.

Figure 10 shows typical examples of the trajectories in the equatorial plane. The position of the point source is place at 10 earth-radii regardless of the longitude. This assumption is made because the location of the magnetospheric boundary is not well known on the dark side of the magnetosphere, and because with a fixed r_0 we can compare trajectories starting from sources at different longitudes more directly. Here longitude, ϕ, is measured eastward from the midnight meridian; in Figure 10 the midnight meridian is towards the left and the longitude increases counterclockwise.

In the lower half of Figure 10, trajectories starting at $\phi_0=0°$, 45°, 135°, and 180°, all with $\chi_0=0$ (i.e., rays directed initially towards the origin) are shown. In the upper half, trajectories with their initial position at $\phi_0=90°$ with $\chi_0=0$, 1°, 3°, 4°, 5°, 6°, and 7° are drawn.

The effect of the distortion of the magnetosphere on the ray trajectories can be described by saying that hydromagnetic rays tend to be "blown" towards the direction away from the sun. This is because the magnetic field is more compressed on the sunlit side of the magnetosphere that on its dark side, thus increasing the Alfvén velocity in the region facing the sun.

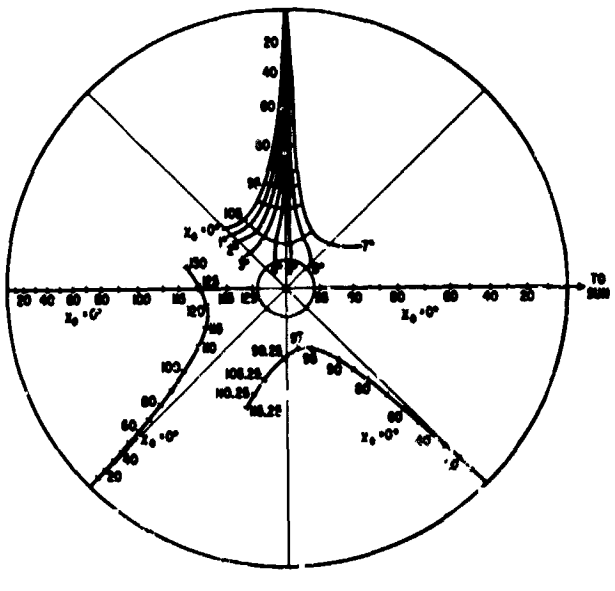

FIGURE 10.—Illustrating ray trajectories in the equatorial plane in the distorted magnetosphere.

However, the results presented in this Section should be interpreted with caution. Although the distortion of the geomagnetic field is taken into account, possible charges in the plasma density distribution associated with the distortion are not considered here. Appreciable asymmetry may be introduced in the plasma density, but no observational data are available as yet that indicate such an effect.

The magnetic field configuration on the dark side of the magnetosphere has also not as yet been established. Since the trajectories are sensitive to large scale magnetic field patterns, the actual trajectories in the magnetosphere may be different from those shown in this paper. Our purpose is to demonstrate qualitative characteristics of ray trajectories in the magnetosphere. However, for the model used in this Section the calculations are made as accurately as possible within the practical limitations.

It is observed in Figure 10 that if the point source is not in the meridian containing the sun (i.e., $\phi_0=0°$ or 180°), the ray directed initially towards the origin does not reach the earth. For the ray to reach the earth it must start with χ_0 slightly greater than 0. If χ_0 becomes too large, the ray is bent back at the region of Alfvén velocity maximum. This circumstance is shown for $\phi_0=90°$ in the upper half of Figure 10. At this ϕ_0, rays with $\chi_0=3.0°$ and less are "blown" towards the back of the magnetosphere. At χ_0 between 3.0° and 3.2° the ray begins to penetrate into the immediate vicinity of the earth, and this condition prevails till χ_0 reaches a value a little less than 6.5°. Beyond this latter angle the ray is again reflected away from the earth at the region of Alfvén velocity maximum.

In Figure 10 the time in seconds is indicated along the trajectories. It is of interest to compare the transit time from r_0 to some altitude near the earth for the trajectory in the midnight meridian with the corresponding transit time for the trajectory in the noon meridian. In Figure 10 the altitude of the point marked 95 seconds in the noon meridian and that of the point marked 129 seconds in the midnight meridian are within 4[illegible]

km from each other. The mean of the two altitudes is 1,363 km above the earth's surface. Thus the difference in the transit time from 10 earth-radii to this altitude is about 34 seconds.

However, as has already been mentioned, caution should be exercised in applying this result to any actual events that occur in the magnetosphere.

In concluding the discussions of the ray theory the following remarks are made. The hydromagnetic approximation is based on the condition that $\omega \ll \Omega_i$. Thus for the most part of the magnetosphere this approximation is good below 10 c/sec (Figure 4). There is another limitation to the ray theory, namely, that the wavelength be short compared with the dimension under consideration. We put this condition in the form $\omega \gg V/L$, where L is the typical scale length. If we take L to be the smallest value of the radius of curvature for the ray trajectories, then the minimum frequency may be set at about 1 c/sec. Thus, roughly speaking, the ray theory is applicable to propagation of hydromagnetic waves of frequencies about 1 to 10 c/sec.

A more extensive study of the ray trajectories in the magnetosphere and their physical implications will be reported later. For instance, the efficiency of energy transfer from solar winds to the ionosphere via hydromagnetic waves is considerably reduced by the limited accessibility of the hydromagnetic waves to the immediate vicinity of the earth.

A theoretical study of geometrical hydromagnetics based on a classical hydromagnetic fluid has been made by Bazer and Hurley (1963); their paper includes comprehensive reference to the literature on the subject.

4. CONCLUSIONS

We reviewed the possible modes of waves in a two-component cold plasma using the Clemmow-Mullaly-Allis diagram. A systematic method of labeling the modes was explained.

The modes relevant to propagation of ULF and VLF waves in the regions of plasma parameter space representing the conditions in the magnetosphere were reviewed. For frequencies below the ion cyclotron frequency there are two modes: the *fast mode* with right-handed circular polarization for propagation along the magnetic field and with phase velocity dependent on the magnetic field for propagation across it, and the *slow mode* with left-handed circular polarization for propagation along the magnetic field. Waves in the latter mode do not propagate across the magnetic field. Above the ion cyclotron frequency, only the fast mode represents propagating wave, and above the lower hybrid resonance frequency this mode becomes the whistler mode.

Reversal of polarization (in the electric field) depending upon the direction of phase propagation with reference to the direction of the magnetic field was discussed. We concluded that there is no such reversal in polarization in ULF and VLF waves in the magnetosphere.

The hydromagnetic approximation was examined and its relation to the more exact treatment was indicated.

In this paper we only discussed propagation of waves in a collisionless plasma. When the thermal motions of electrons and ions are included, the waves found in a cold plasma are modified. The modifications are often only slight, but in a hot plasma new modes are introduced which have no counterpart in a cold plasma. There are two such modes in a relatively low frequency range. They are ion acoustic waves and electrostatic ion cyclotron waves. These waves were not discussed in this paper; the reader is referred to discussions on these waves made, for instance, by Spitzer (1956), Bernstein (1958) and Stix (1962).

In the latter half of this paper, we changed the line of approach, and formulated a ray theory. The equations of motion of a ray were derived from a simple postulate that a ray moves with the group velocity. The action of the ray was defined in analogy with classical mechanics, and the principle of least action was proved. It was shown that the principle of least action takes the form of the principle of least time when the dispersion relation is homogeneous in the wave vector $\vec{k}$ and the frequency ω.

For the case in which the wave-normal surface is spherical, a ray theory was formulated in Hamiltonian form. In the axially symmetric case the generalized momentum conjugate to the azimuthal coordinate becomes a constant of motion. Using this relation, allowed and forbidden regions were defined for a hydromagnetic ray in the magnetosphere with the magnetic field approximated by that of a dipole. It was shown that a ray

originating from the magnetospheric boundary can reach the ionosphere only if the deviation of the initial direction of the ray from the meridian plane is small.

When the distortion of the geomagnetic field due to solar wind is taken into account, the ray trajectories in the magnetosphere are appreciably altered from those in a dipole field.

In spite of the limitations in its application the hydromagnetic ray theory for the magnetosphere should provide a guide towards a more complete understanding of propagation of hydromagnetic waves in the magnetosphere.

ACKNOWLEDGMENTS

I wish to thank Mr. W. F. Cahill for his valuable suggestions on the numerical calculations in this paper. I am indebted to Mr. W. H. Mish, Mrs. S. J. Hendricks, and Mrs. P. J. Connor for their helpful assistance in preparing the computer programs and performing the calculation.

HYDROMAGNETIC STABILITY OF THE MAGNETOSPHERE BOUNDARY*

31963

S. P. TALWAR†

1. INTRODUCTION

It is now generally established that a continual expansion of the solar corona leads to a solar wind which blows radially into space (Parker, 1963). The solar plasma interacts with the geomagnetic field confining it in a region called the magnetosphere. The magnetosphere is asymmetrical in form, and has the shape of a tear drop, having a "tail" pointing away from the sun. An important question about which there has been some controversy in literature is regarding the stability of the interface between the solar wind and the geomagnetic field. Dungey (1955) and Parker (1958) concluded on theoretical grounds that the interface is unstable. Dessler (1961) on the other hand, contends, on the basis of transient geomagnetic activity data obtained at the earth's surface from magnetometers, that the interface is stable. If the latter inference be correct, theories of aurora, magnetic storms, Van Allen radiation which make use of the concept of turbulent solar injection need to be re-examined.

The purpose of the present paper is to investigate the hydromagnetic stability of a model of the interface between the solar wind and the magnetosphere. The solar wind on impinging upon the magnetosphere boundary, slips past it, leading to a situation where Kelvin-Helmholtz instability should play an important role. We regard both the solar beam and the magnetosphere medium to be uniform, infinitely extended plasmas of zero dissipation and having a planar interface. Further, we assume that the solar wind and the magnetosphere medium carry homogenous constant magnetic fields which may be unequal, leading to a current sheet at the interface.

We shall regard the solar wind and the magnetosphere medium as continuum fluids. This assumption should be reasonable as the proton Larr or radius in interplanetary magnetic field can be shown to be small compared with typical dimension characterising the magnetosphere (Axford, 1962).

2. EQUATIONS OF THE PROBLEM

Consider a system of cartesian axes with the z-direction vertical. Suppose that a plane surface of discontinuity of tangential velocity (vortex sheet) and of magnetic field (current sheet) exist at the common, interface ($z=0$) between two semi-infinitely extended homogenous non-dissipative plasmas. Let the uniform velocities and the uniform magnetic fields (both in the horizontal λ- phase) be $\underline{U}_1$, $\underline{U}_2$ and $\underline{H}_1$, $\underline{H}_2$ respectively for $z<0$ and $z>0$ regions. Let ρ_1 and ρ_2 denote the uniform densities of the lower and the upper plasma characterised by sound speeds C_1 and C_2 respectively.

The steady state of the configuration requires

$$\nabla p = 0 \tag{1}$$

for either medium. Here p denotes the plasma pressure. Further the equilibrium of the interface is governed by

$$p_1+\frac{H_1^2}{8\pi}=p_2+\frac{H_2^2}{8\pi} \tag{2}$$

To investigate the stability of the initial steady state, let us consider the effect of a small velocity field disturbance u with components u, v, w in the x-, y-, z- directions.

*Published as *Goddard Space Flight Center Document X-640-64-38*, February; 1964 also published in *Journal of Geophysical Research*, 69 (13):-2707-2713, July 1, 1964.

†Goddard Space Flight Center, on leave from Department of Physics and Astrophysics, Delhi University, India. This work was done while the author held a Senior Resident Research Associateship of National Academy of Sciences.

We write,

$$\begin{aligned}
\underline{v} &= [U_{0x}, U_{0y}, o] + \underline{u}(x,y,z,t) \\
\rho &= \rho_0 + \delta\rho(x,y,z,t) \\
p &= p_0 + \delta p(x,y,z,t) \qquad (3) \\
\underline{H} &= [H_{0x}, H_{0y}, o] + \underline{h}(x,y,z,t)
\end{aligned}$$

where $\delta\rho$, δp, and $\underline{h}$ denote perturbations in density, pressure and magnetic field respectively and the suffix "O" refers to equilibrium values. The perturbations are assumed to be of first order of smallness so that powers higher than the first and their mutual products are neglected.

Assuming the components of the perturbations to vary with x, y, z, t, as (some functions of z). exp. $[ik_x z + ik_y y + nt]$ we may write the linearised hydromagnetic equations as,

$$\zeta_0(n+i\underline{k}\cdot\underline{U}_0)u = -ik_x\delta p - \frac{H_{0y}}{4\pi}(ik_x h_y - ik_y h_x) \qquad (4)$$

$$\zeta_0(n+i\underline{k}\cdot\underline{U}_0)v = -ik_y\delta p + \frac{H_{0x}}{4\pi}(ik_x h_y - ik_y h_x) \qquad (5)$$

$$\zeta_0(n+i\underline{k}\cdot\underline{U}_0)w = -D\delta p - \frac{H_{0x}}{4\pi}(Dh_x - ik_x h_z) + \frac{H_{0y}}{4\pi}(ik_y h_z - Dh_y) \qquad (6)$$

$$(n+i\underline{k}\cdot\underline{U}o)\delta\rho + -\rho_0\nabla\cdot\underline{u} \qquad (7)$$

$$Sp = c^2\delta\rho \qquad (8)$$

$$(n+i\underline{k}\cdot\underline{U}o)h_x = i\underline{k}\cdot\underline{H}_0 u - H_{0x}\nabla\cdot\underline{u} \qquad (9)$$

$$(n+i\underline{k}\cdot\underline{U}o)h_y = i\underline{k}\cdot\underline{H}_0 u - H_{0y}\nabla\cdot\underline{u} \qquad (10)$$

$$(n+i\underline{k}\cdot\underline{U}o)h_z + i\underline{k}\cdot\underline{H}_0 w \qquad (11)$$

and

$$ik_x h_x + ik_y h_y + Dh_z = o \qquad (12)$$

where D stands for d/d_z

Let us now eliminate some of the variables and derive an equation: for, say, the vertical component w of velocity perturbation vector. Multiply equations (4) and (5) by ik_x and ik_y respectively and add to obtain,

$$\zeta_0(n+i\underline{k}\cdot\underline{U}_0)(\nabla\cdot\underline{u} - Dw) - \frac{ik_y H_{0z}}{4\pi}(ik_x h_y - ik_y h_x) + \frac{ik_x H_{0y}}{4\pi}(ik_x h_y - ik_y h_z) = k^2\delta p \qquad (13)$$

where

$$k^2 = k_x^2 + k_y^2 \qquad (14)$$

Eliminate δp from equations (6) and (13) to get,

$$\begin{aligned}
&-\zeta_0(n+i\underline{k}\cdot\underline{U}_0)(D^2-k^2)w + \zeta_0(n+i\underline{k}\cdot\underline{U}_0)D\nabla\cdot\underline{u} \\
&+\frac{H_{0y}}{4\pi}[ik_x\{ik_x Dh_y - ik_y Dh_x\} + k^2\{Dh_{xy} - ik_y h_z\}] \\
&-\frac{H_{0x}}{4\pi}[ik_y\{ik_x Dh_y - ik_y Dh_x\} \\
&\qquad -k^2\{Dh_x - ik_x h_z] = 0 \qquad (15)
\end{aligned}$$

The magnetic field terms in equations (15) reduce to, on using the equations (9) $-$(12),

$$-\frac{(\underline{H}_0\cdot\underline{k})^2}{4\pi(n+i\underline{k}\cdot\underline{U}_0)}(D^2-k^2)w \qquad (16)$$

The perturbations equation (15) is written as,

$$\left[1+\frac{(\underline{k}\cdot\underline{V}_0)^2}{(n+i\underline{k}\cdot\underline{U}_0)^2}\right](D^2-k^2)w - D\nabla\cdot\underline{u} = 0 \qquad (17)$$

where $\underline{V}_0$ denotes the Alfvén velocity vector $\underline{H}_0/\Delta\pi\rho_0)^{\frac{1}{2}}$. The expression for $\nabla\cdot\underline{u}$ is now obtained from the equations (7), (8), (9), (10), and (13) as,

$$\begin{aligned}
&\nabla\cdot\underline{u}[c^2k^2 + (n+i\underline{k}\cdot\underline{U}_0)^2 + (\underline{k}\times\underline{V}_0)^2] \\
&\quad = (n+i\underline{k}\cdot\underline{U}_0)^2 Dw - \underline{k}\cdot\underline{V}_0(\underline{V}_0\times\underline{k})\zeta \qquad (18)
\end{aligned}$$

where ζ is written for $(ik_x v - ik_y u)$.

Let us now evaluate ζ by eliminating δp from equations (4) and (5). We get

$$\zeta[(n+i\underline{k}\cdot\underline{U}_0)^2 + (\underline{k}\cdot\underline{V}_0)^2] = -\nabla\cdot\underline{u}\ \underline{k}\cdot\underline{V}_0(\underline{k}\times\underline{V}_0) \qquad (19)$$

combining (18) and (19), we obtain

$$\begin{aligned}
&\nabla\cdot\underline{u}[\{(n+i\underline{k}\cdot\underline{U}_0)^2 + c^2k^2\}\{(n+i\underline{k}\cdot\underline{U}_0)^2 + (\underline{k}\cdot\underline{V}_0)^2\} \\
&\quad + (n+i\underline{k}\cdot\underline{U}_0)^2(\underline{k}\times\underline{V}_0)^2] \\
&\quad = (n+i\underline{k}\cdot\underline{U}_0)^2\{(n+i\underline{k}\cdot\underline{U}_0)^2 + (\underline{k}\cdot\underline{V}_0)^2\}Dw \qquad (20)
\end{aligned}$$

Substituting equation (20) in equation (17 we obtain

$$\begin{aligned}
&D^2w[\{(n+i\underline{k}\cdot\underline{U}_0)^2 + (\underline{k}\cdot\underline{V}_0)^2\}\{(n+i\underline{k}\cdot\underline{U}_0)^2 + c^2k^2\} \\
&\quad + (n+i\underline{k}\cdot\underline{U}_0)^2(\underline{k}\times\underline{V}_0)^2 - (n+i\underline{k}\cdot\underline{U}_0)^4] \\
&\quad = k^2w[\{(n+i\underline{k}\cdot\underline{U}_0)^2 + (\underline{k}\cdot\underline{V}_0)^2\}\{(n+i\underline{k}\cdot\underline{U}_0)^2 \\
&\quad + c^2k^2\} + (n+i\underline{k}\cdot\underline{U}_0)^2(\underline{k}\times\underline{V}_0)^2] \qquad (21)
\end{aligned}$$

as the equation determining w.

3. BOUNDARY CONDITIONS AND DISPERSION RELATION

For a configuration of two superposed uniform plasmas slipping past each other at the horizontal interface $z=0$, the respective solutions vanishing $at z=\pm\infty$, of equation (21) are written as,

$$w_1=A_1 e^{m_1 z} \quad (z<0)$$

and (22)

$$w_2=A_2 e^{-m_2 z} \quad (z>0)$$

where

$$m_j^2=k^2\frac{[n_j^2+(\underline{k}\cdot\underline{V}_j)^2][n_j^2+k^2c_j^2]+n_j^2(\underline{k}\times\underline{V}_j)^2}{[\{n_j^2+(\underline{k}\cdot\underline{V}_j)^2\}\{n_j^2+k^2c_j^2\}+n_j^2(\underline{k}\times\underline{V}_j)^2-n_j^4]} \quad (j=1,2) \tag{23}$$

Here n_j is written for $n+i\underline{k}\cdot\underline{U}_j$ for brevity.

At the common interface we have to satisfy the following boundary conditions,

(i) the normal component of velocity is continuous. This leads to

$$w_1-U_{1x}\frac{\partial\xi}{\partial x}-U_{1y}\frac{\partial\xi}{\partial y}=w_2-U_{2x}\frac{\partial\xi}{\partial x}-U_{2y}\frac{\partial\xi}{\partial y}=\frac{\partial\xi}{\partial\zeta} \tag{24}$$

where ζ denotes the small displacement of the interface. Using equation (22) we get

$$A_2=A_1\frac{n_2}{n_1} \tag{25}$$

(ii) The normal component of magnetic field is continuous.

One can easily verify that this condition is automatically satisfied as a consequence of (i).

(iii) The normal stress should be continuous across the interface. This means that

$$\delta p_1-\delta p_2+\frac{1}{4\pi}[\underline{H}_1\cdot(\underline{h})_1-\underline{H}_2\cdot(\underline{h})_2]=0 \tag{26}$$

Making use of equations (11), (12), (13), (20), and (25), and simplifying, the above equation (26) gives,

$$\zeta_2 m_2[n_2^2+(\underline{k}\cdot\underline{V}_2)]\frac{[\{n_2^2+(\underline{k}\cdot\underline{V}_2)^2\}(n_2^2+k^2c_2^2)+n_2^2(\underline{k}\times\underline{V}_2)^2-n_2^4]}{[\{n_2^2+(\underline{k}\cdot\underline{V}_2)^2\}(n_2^2+k^2c_2^2)+n_2^2(\underline{k}\times\underline{V}_2)^2]}$$

$$+\rho_1 m_1[n_1^2+(\underline{k}\cdot\underline{V}_1)^2]\frac{[\{n_1^2+(\underline{k}\cdot\underline{V}_1)^2\}(n_1^2+k^2c_1^2)+n_1^2(\underline{k}\times\underline{V}_1)^2-n_1^4]}{[\{n^2_1+(\underline{k}\cdot\underline{V}_1)^2\}(n_1^2+k^2c_1^2)+n_1^2(\underline{k}\times\underline{V}_1)^2]}=0 \tag{27}$$

Substituting the expressions for m_1, m_2 as given by equation (23), we finally obtain the dispersion relation in the following form,

$$\zeta_2[n_2^2+(\underline{k}\cdot\underline{V}_2)^2]\frac{[\{n_2^2+(\underline{k}\cdot\underline{V}_2)_2^2\}(n^2+k^2c_2^2)+n_2^2(\underline{k}\times\underline{V}_2)^2-n_2^4]^{1/2}}{[\{n_2^2+(\underline{k}\cdot\underline{V}_2)^2\}(n_2^2+k^2c_2^2)+n_2^2(\underline{k}\times\underline{V}_2)^2]^{1/2}}$$

$$+\rho_1[n_1^2+(\underline{k}\cdot\underline{V}_1)^2]\frac{[\{n_1^2+(\underline{k}\cdot\underline{V}_1)^2\}(n_1^2+k^2c_1^2)+n_1^2(\underline{k}\times\underline{V}_1)^2-n_1^4]^{1/2}}{[\{n_1^2+(\underline{k}\cdot\underline{V}_1)^2\}(n_1^2+k^2c^2)+n_1^2(\underline{k}\times\underline{V}_1)^2]^{1/2}}=0 \tag{28}$$

The equation (28) is the characteristic equation for n, the parameter determining the stability of the configuration. The above equation is rather unwieldly for discussion in the general case. We shall therefore discuss some special cases, assuming $\underline{H}_1$, $\underline{H}_2$, $\underline{U}_1$, $\underline{U}_2$ to be parallel vectors. This assumption should not be too bad to make as the solar wind drags the solar magnetic field with it during radial expansion.

4. DISCUSSION OF RESULTS

(A) Propagation Transverse to the Direction of Streaming ($k_x=0$, $k_y=k$)

If the streaming plasmas carry the same magnetic field (i.e., $H_1=H_2$) and are characterised by the same γ (ratio of the two specific heats) the equilibrium of the interface (equation (2)) gives

$$\zeta_1 C_1^2+\zeta_2 C_2^2 \tag{29}$$

Also

$$\zeta_1 V_1^2+\zeta_2 V_2^2 \tag{30}$$

The dispersion equation, when the wave vector is non-vanishing in direction transverse to streaming alone, reduces to

$$\zeta_2^2\left[1-\frac{U_p^2}{c^2+V^2}\right]=\zeta_1^2\left[1-\frac{U_p^2}{c_2^2+V_2^2}\right] \tag{31}$$

where U_p is the phase velocity of disturbance, given by $\frac{i\omega}{k}$.

The configuration of two slipping plasmas is, therefore stable, as can be easily verified, for perturbations characterised by $k_x=O$, $k_y=k$. The perturbation, having a non-vanishing wave number k_x along the direction of streaming may, however, bring about instability. Let us therefore investigate the question of the stability of the configuration for the other extreme case namely $k_x=k$, $k_y=O$.

(B) Propagation Parallel to the Direction of Streaming ($k_x=k$, $k_y=0$)

In this particular case, the general dispersion equation (28) reduces to,

$$\zeta_2\left[\frac{V_2^2-(U_2-U_p)^2}{c_2^2-(U_2-U_p)^2}\right]^{1/2}[c_2^2V_2^2-(U_2-U_p)^2(c_2^2+V_2^2)]^{1/2}=-\zeta_1\left[\frac{V_1^2-(U_1-U_p)^2}{c_1^2-(U_1-U_p)^2}\right]^{1/2}[c_1^2V_1^2-(U_1-U_p)^2(c_1^2+V^2)]^{1/2} \tag{32}$$

where c_1, c_2 and V_1, V_2 are related by equations (29) and (30) respectively. If both c_1 and c_2 tend to fininity, the above equation gives the dispersion formula for Kelvin-Helmholtz instability for incompressible fluids in hydromagnetics. This is the same as obtained and discussed in earlier papers (Talwar 1961, 1962).

To simplify the discussion still further let us take $U=-U_2=+U_1$. The equation (32) is then written as,

$$U_p^6(1-\delta)-2UU_p^5(1+\delta)-U_p^4(1-\delta)[U^2+(1+\delta)c_2^2]+4UU_p^3[U^2(1+\delta)+c_2^2(1+\delta^2)]$$
$$+U_p^2(1-\delta)\left[-U^4-6U^2c_2^2(1+\delta)+\frac{2c_2^4V_2^2}{c_2^2+V_2^2}\delta\right]+U_p\left[-2U^5(1+\delta)+4U^3c_2^2(1+\delta^2)-\frac{4Uc_2^4V_2^2}{(c_2^2+V_2^2)}\delta(1+\delta)\right]$$
$$+(1-\delta)\left[U^6-c_2^2U^4(1+\delta)+\frac{2U^2\delta c_2^4V_2^2}{c_2^2+V_2^2}\right]=0 \tag{33}$$

Here $\delta=\zeta_2/\zeta_1$ and we have made use of equations (29) and (30). The equation (33) is a sixth degree equation in phase velocity and to insure that the configuration of two slipping plasmas is stable also for perturbations along the direction of streaming, we require that all the roots of the above equation should be real. In a particularly simple case where we take $\delta=1$ so that different layers of the same plasma fluid permeated with a uniform horizontal magnetic field have a relative tangential velocity, the equation (33) gives,

$$U_p^4-2U_p^2(C^2+U^2)+\left[U^4-2U^2C^2+\frac{2C^4V^2}{C^2+V^2}\right]=0 \tag{34}$$

where now $C_1=C_2=C$ and $V_1=V_2=V$.

Equation (33) gives the following condition for the stability of the configuration

$$U>C\left[1+\left(\frac{C^2-V^2}{C^2+V^2}\right)^{1/2}\right]^{1/2} \tag{35}$$

Here U denotes the relative speed between two layers of the plasma characterised by the sound speed C and hydromagnetic speed V. In the absence of magnetic field we get the condition for stability as $U>\sqrt{2}C$. We thus conclude that whereas a tangential discontinuity in a liquid is unstable for all non-zero speeds in the absence of magnetic field, it is no longer so unless the relative speed is smaller than a certain critical value in a compressible fluid. In the presence of magnetic fields the stability of the vortex sheet in compressible plasmas is improved (as also is the case with

infinitely conducting liquids) in that the critical relative speed below which the configuration is unstable is decreased as a consequence of the magnetic field. Alternatively, we could conclude that any relative speed between two layers of plasma can be stabilized by a strong enough magnetic field given by,

$$V_*^2 = \frac{U^2C^2(2C^2 - U^2)}{(U^2 - C^2)^2 + C^4} \qquad (36)$$

Figures 1 and 2 respectively show the dependence of critical tangential velocity U^* in units of C as a function of V^2/C^2 and that of critical Alfvén speed against Mach number U/C.

The above results, it is felt, should have a useful application in regard to determining whether the interface of the magnetosphere with the solar wind is stable or not. Observations (Gringauz et. al. (1960); Bridge et. al. (1961)) show that the solar wind has a speed $\sim 250-400$ km/sec. and density $\sim$ 10 protons per c.c. under quiet solar conditions. When the sun is active these values may mount to $\sim 10^3$ km/sec. with densities $\sim$ 300 per c.c. The speed of the incoming solar wind is therefore supersonic as it hits the magnetosphere. As the solar wind streams along the magnetosphere boundary, the speed of solar plasma relative to the medium within the magnetosphere boundary is likely to diminish in value. This may be on account of internal motions within the magnetosphere (Gold, 1959). The internal convective motions (roughly along the magnetosphere boundary) may arise as a result of viscous-like interaction between the magnetosphere and the solar wind (Axford and Hines, 1961). If this relative speed is continuously diminished as the solar wind sweeps round from the day side to the night side of the magnetosphere, it may very well happen that the relative speed at some place on the interface becomes less than the critical value given by equation (35) and the part of the interface thereafter becomes unstable. This situation leading to the instability of the magnetosphere—solar wind interface is likely to arise towards the tail of the magnetosphere and under quiet solar conditions when the speed of the incoming solar wind is less anyway. A verification of the above ideas is possible if it can be ascertained that the characteristic effects of instability, e.g., turbulence, high level geomagnetic fluctuations, irregularities of ionisation density are observed during comparatively quiet solar conditions and more so towards the night side.

CERENKOV SCINTILLATION COUNTER MEASUREMENTS OF THE INTENSITY AND MODULATION OF LOW RIGIDITY COSMIC RAYS AND FEATURES OF THE GEOMAGNETIC CUTOFF RIGIDITY*

W. R. WEBBER† AND F. B. McDONALD

The primary cosmic radiation has been measured with a Cerenkov scintillation counter at various times in the solar cycle at locations having nominal cutoff rigidities of 0.8, 1.6, and 2.7 bv. Results are used here to delineate spectral features of low rigidity protons and α particles and to examine the rigidity and charge dependence of the eleven-year solar molulation. Details of particle transmission near the geomagnetic cutoff are also examined. The measurements indicate: (1) The observed nonsharp cutoff appears to be primarily due to expected transmission effects in a dipole-like field and to instrumental effects, and the actual cutoff is quasi-sharp in the Störmer sense. This is true even though the observed cutoff may be reduced to half that to be expected from the internal field, presumably because of external current systems flowing in the magnetosphere and its boundary. (2) The rigidity dependence of the eleven-year modulation of protons and that of α particles are closely similar above $\sim$1.2 bv. None of the presently proposed models for this modulation agree with our results. The implications of this lack of agreement are discussed, and it is concluded that certain general features of particle motion in the interplanetary medium not considered in present models may be of importance. One such general feature may be diffusive deceleration in the radially expanding interplanetary medium, which is shown to have the same effect as a static heliocentric electric field. (3) The differential spectrum of galactic cosmic rays near sunspot minimum at about 1-bv rigidity is either flat or falling slightly toward lower rigidities. The measurements in the rigidity range below 1 bv are compared with recent observations in this range.

INTRODUCTION

A detailed knowledge and comparison of the galactic cosmic ray proton and α-particle spectra at low rigidities (<2 bv) at various times in the solar cycle is essential in any attempt to select one of the various solar mechanisms proposed in recent years to account for the modulation of the primary radiation. In addition, a study of these spectra at sunspot minimum, when solar modulation effects are small, should provide information about the origin of cosmic rays and their propagation to the earth.

A number of difficulties arise in obtaining and interpreting such spectra. These are:

1. Secondary proton albedo effects, both upward-moving (splash) and downward-moving (reentrant), may contribute a significant background of low energy protons that do not reflect the true primary spectrum.

2. Low rigidity protons are directly produced in the atmosphere above the detector.

3. Solar cosmic rays, both protons and α particles of low rigidities frequently present near the earth, are superimposed on the galactic cosmic ray spectrum.

4. Where the geomagnetic cutoff is greater than instrumental cutoff effects, it may seriously modify the shape of the measured spectrum, not only because of the uncertainty of what geomagnetic cutoff to apply to a particular location, but also because the transmission of particles through the earth's field is not experimentally observed to have a sharp cutoff.

Early (1955–1959) in the solar cycle now being completed, *McDonald* [1956] and *McDonald and*

*Published in *Journal of Geophysical Research*, 69(15):3097–3114, August 1, 1964.

†University of Minnesota, Minneapolis.

Weber [1959] extensively surveyed the spectra and galactic cosmic ray spectral changes at low rigidities. The details of this survey are important for comparison with more recent measurements of the proton and α-particle spectra, and particularly with measurements made near the preceding sunspot minimum in 1954 and the one approaching in 1965.

The McDonald and Webber measurements of interest here were made during 1955–1956 at Minneapolis, where the problems connected with the geomagnetic cutoff and its effects on measured spectra are severe. In fact, these spectral measurements were used originally to define the geomagnetic cutoff existing at Minneapolis in an era when such measurements were of great value in understanding the influence of the non-dipole terms in the earth's field on the cutoff [*McDonald and Webber*, 1959].

At that time it was not clear whether the spectra of protons and α particles measured were the spectra actually existing outside the earth's magnetic field, although it was obvious that features of the low rigidity end of the primary proton spectrum were being measured. We noted that the measured spectra were not consistent with the observations of *Neher* [1957] and of *Winckler and Anderson* [1957] who, from their intensity-altitude data and studies of the latitude effect at balloon altitudes above 51°N, found evidence of a larger flux of low energy particles at that time in the solar cycle (see also *Webber* [1962]). It was also not clear how the cutoff influenced the character of the solar modulation as deduced from several flights at the same latitude, although the cutoff was assumed to operate the same way on all flights. Thus a simple ratio of differential intensities at different times should be a measure of the true solar modulation effect.

With this background information, several observers have recently reported measurements of the low rigidity ends of the primary proton and α-particle spectra. These measurements, made since the last of the McDonald and Webber flights in 1959, and showing features of the spectra during the period of decreasing solar activity, have attracted attention particularly to the problems associated with measuring and interpreting the low rigidity end of the proton spectrum. They have, in fact, provided a picture that is inconsistent with the earlier McDonald and Webber results if these latter measurements are interpreted as the ture primary proton spectra outside the earth's field.

Vogt [1962] and *Meyer and Vogt* [1963] recently reported intensities of low rigidity protons during 1960 and 1961 which considerably exceed those measured earlier by McDonald and Webber. The measurement by McDonald and Webber was made close to solar minimum at a time when the intensity of high rigidity (>1.5 bv) protons was actually greater. Such a modulation would appear to be inconsistent with the accepted pictures for the modulation of primary cosmic rays in a solar environment. Vogt and Meyer have interpreted this excess as possibly due to a steady solar particle emission at low rigidities or as due to protons ejected by large flares and stored for long periods in inter-planetary space. Other measurements made during this later period with emulsions and counters [*Fichtel et al.*, 1964, *Bryant et al.*, 1962] suggests a proton spectrum somewhere between that of Vogt and Meyer and the earlier McDonald and Webber results.

To aid in the understanding of solar modulation effects and to focus attention on the problems associated with the measurement and interpretation of the low rigidity proton spectrum, we report here the results of a balloon flight that carried a Cerenkov scintillation counter detector above International Falls in September 1956. Preliminary results of this flight have been reported elsewhere [*Webber*, 1962]; more detailed results are presented here, and their implications are discussed. The fact that this flight was made when the primary cosmic ray intensity had decreased only slightly from its sunspot minimum value and where the geomagnetic cutoff is appreciably lower than at Minneapolis are of great importance in interpreting these data. In fact, the data are used to determine the transmission features of the earth's field at rigidities near the cutoff value at quiet times near Minneapolis, as well as to determine more appropriate values for the low rigidity part of the primary spectra of protons and α particles near sunspot minimum. In particular, it will be argued that interpreting the spectrums measured by McDonald and Webber at Minneapolis as the spectra of galactic particles existing outside the earth's field (or, what is

equivalent, comparable to measurements at higher geomagnetic latitudes) is not correct.

EXPERIMENTAL RESULTS AND COMPARISON WITH OTHER MEASUREMENTS

The instrumentation used at International Falls is identical to that used in all other flights of this series, including those at Minneapolis, and has been described in detail [*McDonald*, 1956; *McDonald and Webber*, 1959]. Briefly, it consisted of a three-element telescope containing a NaI crystal scintillation counter, a lucite Cerenkov detector, and a Geiger counter tray (Figure 1). The NaI crystal and the Geiger counter tray are the defining elements of the telescope. For each particle which traverses these elements, the outputs from the Cerenkov counter and the NaI crystal are recorded. A notation is also made when a telescope event is accompanied by the triggering of more than one counter in the tray or of one of the systems of guard counters. The data, which are recorded on a continuously moving film with a superimposed time base, consist of a pulse height from the NaI crystal and the Cerenkov detector for each event. The energy calibration is obtained by measuring the most probable energy loss for α particles and protons at minimum ionization, $(E_a)_{min}$ or $(E_p)_{min}$, in both detectors. The selected intervals of ionization or Cerenkov loss are thus defined in terms of $(E_a)_{min}$ or $(E_p)_{min}$ and are matched to the corresponding kinetic energy and corrected for energy loss by ionization to the top of the atmosphere.

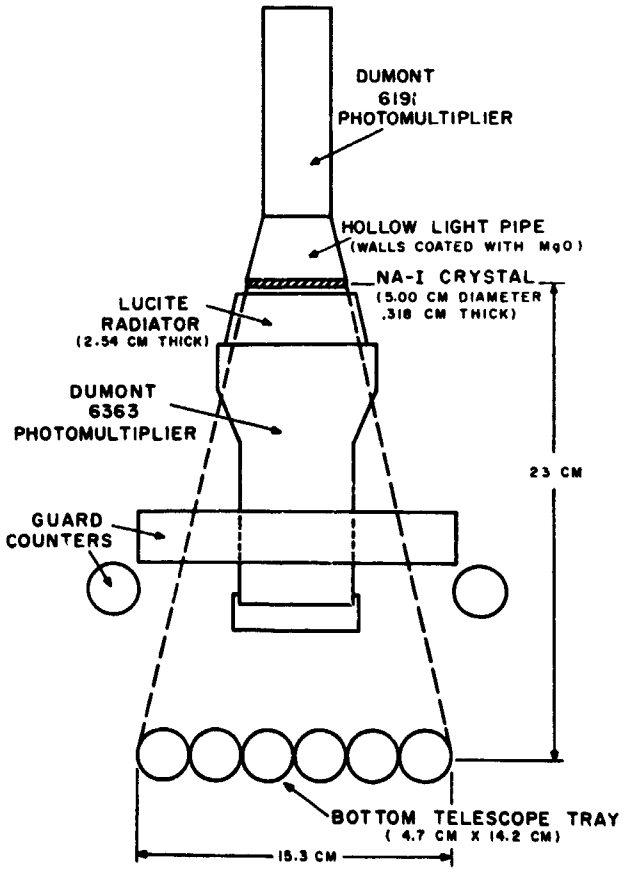

FIGURE 1.—The basic Cerenkov scintillation counter telescope.

The corrections necessary to deduce a true intensity of primary particles at the top of the atmosphere have been discussed in detail by *McDonald and Webber* [1959]. Making these corrections, particularly those for secondary protons produced in the atmosphere and for splash and re-entrant albedo, is greatly facilitated by examining the pulse height distributions in five-minute intervals as the balloons rise to altitude. The intensities of protons and α particles in each energy interval can thus be obtained as a function of altitude. The relatively large geometric factor of the telescope used (7.2 g/cm^2) and high altitude attained (5–6 g/cm^2) greatly enhances this method of analysis.

The same two instruments, unchanged in any way, were used for all flights in the series. A standard set of corrections was applied to all flights, this set of corrections having evolved over the series of flights at a variety of latitudes. This standardization makes possible direct comparison of measured results, in particular, changes in intensity, with a high degree of accuracy, although absolute intensities could be subject to systematic errors.

The flight to be discussed here was launched on September 7, 1956, at International Falls, Minnesota. The average floating altitude of the equipment was 6.5 g/cm^2 (the telescope itself had an additional 8.8 g/cm^2 of material) at a geomagnetic latitude of $59.5 \pm 0.2°$, with a corresponding Störmer cutoff rigidity of 0.8 ± 0.1 bv, according to the most accurate estimates based on the earth's internal field [*Quenby and Wenk*, 1962]. Pertinent details about this flight and others that we will use in our comparison are shown in Table 1.

Preliminary examination of the data from the flight of September 7, 1956, while it was at

altitude revealed two unusual decreases of approximately 20 per cent in the counting rate. The rate after the second decrease remained at the lower value, within experimental errors, for the rest of the flight. The indications were that two of the six Geiger counters in the tray had ceased to function, thereby reducing the effective area of telescope. Because of this possible uncertainty in the geometric factor, the data from this flight were not reported in the earlier analysis [*McDonald and Webber*, 1959].

A careful analysis of events that occurred during this flight revealed the following situation. The equipment performed normally while the balloon was rising to its peak altitude. Shortly after it reached peak altitude, the counting rate suddenly changed by 15 to 20 per cent within about 15 minutes. This rate remained constant for a few hours, then the counting rate dropped another 15 to 20 percent within 15 minutes. The rate remained at this lower level (65 to 70 percent of the initial rate) until the end of the flight. These rate changes were consistent with the fact that 2 of the 6 Geiger counters in the telescope tray had ceased to operate. Such a failure would be expected to affect only the geometric factor of the telescope, not the pulse height distribution. Examination of pulse height distributions before and after the changes in counting rate revealed no change in the distribution of pulse sizes. Upon recovery of the instruments, it was found that two Geiger counters were inoperative. Thus the data are believed to represent a true measure of the spectrum of incident particles. A more accurate geometric factor for the telescope was deduced independently by comparing the counting rates of the relativistic protons and α particles with those obtained under normal conditions when

TABLE 2.—*Proton and α-Particles Intensities Measured on September 7, 1956*

Particle and Rigidity Range, bv	Integral Intensity, particles/m² ster sec	Differential Intensity, particles/m² ster sec Mv

the sea level neutron monitor rates were at approximately the same level as for the September 1956 flight. This further confirmed the fact that the telescope geometric factor during the flight was 65–70 percent of the original value.

The differential intensities of primary protons in the rigidity range 0.54 to 1.20 bv and α particles in the range 1.20 to 4.5 bv deduced at the top of the atmosphere on September 7, 1956, are shown in Table 2 and in Figure 2. Also listed in Table 2 are certain integral intensity values for protons and α particles. The α-particle data in Figure 2 have been multiplied by 7.2 so that they can be directly compared with the proton values. These results are compared with results of two other flights in this general series; for this reason the data from the August 21, 1956, flight launched at Minneapolis are shown in Figure 2. The data from this flight have frequently been used as a measure of the intensity of low rigidity protons existing near the earth at sunspot minimum. These two flights are used to determine the features of the cutoff at Minneapolis.

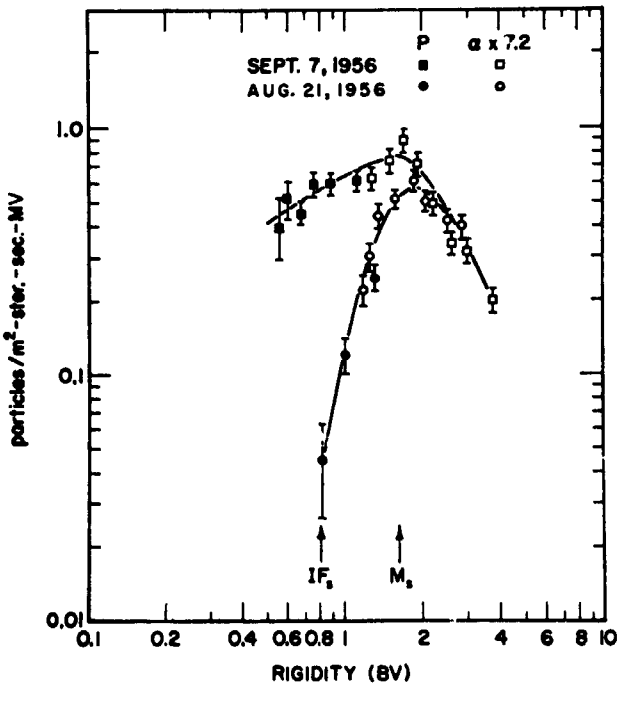

FIGURE 2.—Differential proton and α-particle intensities measured at International Falls on September 7, 1956, and at Minneapolis on August 21, 1956. Nominal Störmer cutoff rigidities at locations of flights are shown by arrows. Alpha-particle intensities are multiplied by 7.2.

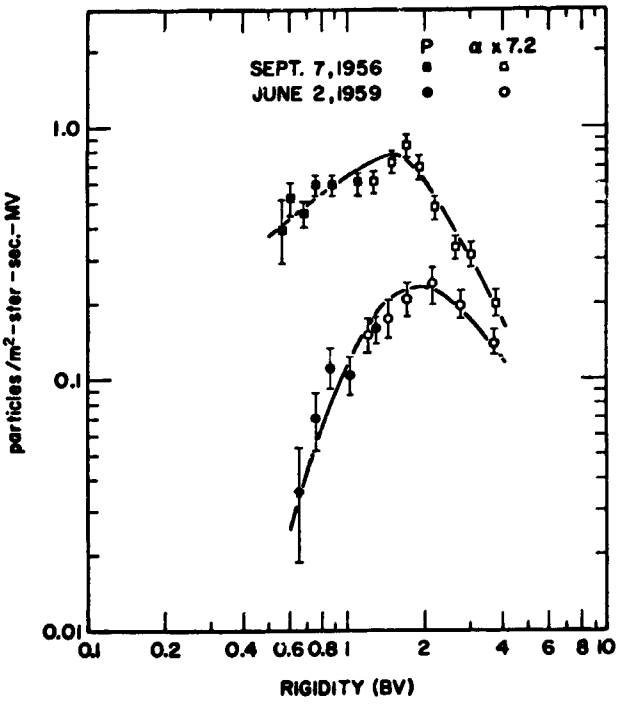

FIGURE 3.—Comparison of differential proton and α-particle intensities measured on two flights at International Falls: September 7, 1956, and June 2, 1959. Alpha-particle intensities are multiplied by 7.2.

In Figure 3 the data from a flight on June 2, 1959, also made at International Falls, are presented. The results of the International Falls flights in 1956 and 1959, when high latitude neutron monitors recorded a 10 percent decrease in counting rate, are compared, and features of the eleven-year modulation of primary cosmic rays near the earth are discussed.

FEATURES OF THE GEOMAGNETIC CUTOFF

During the two weeks between August 21 and September 7, 1956, the primary intensity, as measured by high latitude neutron monitors, changed by only 1.5 percent. Any major difference in the spectra of protons and α particles measured on these two dates might then reasonably be attributed to a difference in cutoff rigidity at the two locations. It is believed that these data were not affected by the very small solar proton event on August 31, 1956 [*McCracken*, 1959]. In particular, we might at this time expect to define certain features of the cutoff rigidity existing near Minneapolis. Examination of Figure 2 reveals a sharp divergence of the two spectra at

rigidities less than 2 bv, although the two spectra are identical above this rigidity within experimental errors. This divergence is noted for both protons and α particles and is grossly unlike any solar modulation process observed during this series of measurements. If the data are adjusted for the modulation that would be expected to accompany a 1.5 percent change in the counting rate of a high latitude neutron monitor, and if we take the ratio of the differential intensities measured near Minneapolis and near International Falls, the results shown in Figure 4 are obtained. If these results are to be interpreted as the effect of a geomagnetic cutoff, then, indeed, they do not fit the usual concept of a relatively sharp cutoff. However, before we discuss this in greater detail, a few preliminary remarks should be made.

Neither flight, at peak altitude, was exactly over Minneapolis or International Falls. The Minneapolis flight floated over southern Minnesota at an average cutoff rigidity of 1.6 ± 0.1 bv according to *Quenby and Wenk* [1962]. The International Falls flight floated over southern Ontario at an average cutoff of 0.8 ± 0.1 bv. Thus the cutoff difference is actually much greater than the difference between Minneapolis (1.35 bv) and International Falls (0.90 bv).

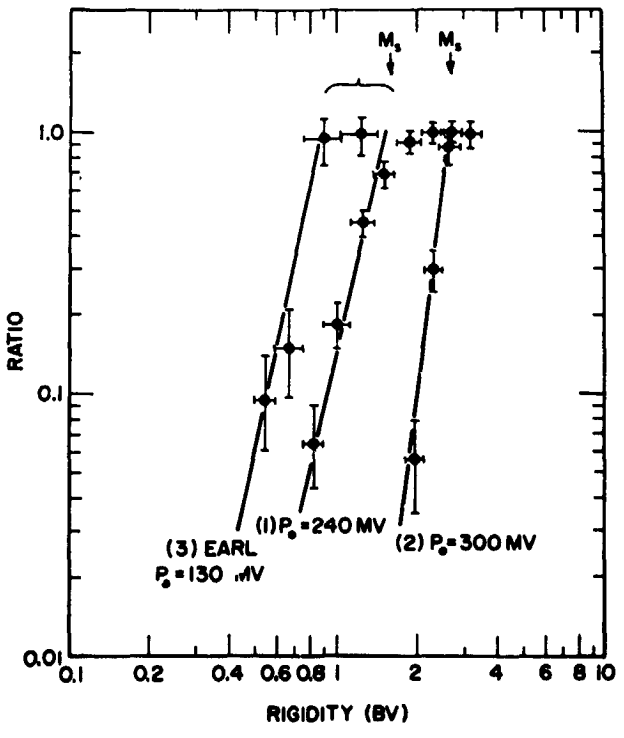

FIGURE 4.—Fraction of particles transmitted through the earth's field as a function of ridigity near the Störmer cutoff rigidity at various latitudes.

Observations at other periods in the sunspot cycle have revealed that the effective geomagnetic cutoffs associated with geomagnetic activity are frequently lower than those deduced only from the earth's internal field [*Winckler et al.*, 1961]. This may be true at geomagnetically quiet times as well [*Webber*, 1962; *Kellogg and Winckler*, 1961]. Such a lowered cutoff may be caused partly by a ring current of trapped protons having energies less than 1 Mev precessing in the earth's field. In view of the present understanding of these trapped protons, such a ring current may be a more or less persistent feature of the earth's magnetosphere during most, if not all, of the sunspot cycle. From a recent study covering the period 1959–1961, *Webber* [1963] has found that the average effective quiet time cutoff rigidity near Minneapolis is about 0.7 of that to be expected from the internal field only. If we associate this cutoff with the Störmer cutoff, it might be expected that a cutoff of about 1.1 bv would be appropriate for the Minneapolis flight and about 0.55 for the International Falls flight.

Turning to the interpretation of the data presented in Figure 4, we have represented the so-called transmission of the earth's field as a function of rigidity by the formula

$$T = \exp\left[-\frac{(P_c - P)}{P_0}\right]$$

where P_c is the rigidity, $T = 1$ (not to be confused with the Störmer cutoff), and P_0, the shape parameter of the cutoff, equals 260 ± 30 Mv in the present measurement. Such a representation is not claimed to have any physical meaning and is used merely to facilitate comparison of these results with those of *Earl* [1962] and *Freier* [1962], who have measured the transmission near the cutoff at Minneapolis during the incidence of solar protons in a magnetically active period.

On the basis of Störmer theory and Liouville's theorem, it is known that in a given direction at a given instant the transmission of particles through the earth's field drops sharply from 1 to zero at a value known as the Störmer cutoff rigidity. In any experiment, however, idealized conditions cannot be attained. Further, there are experimental errors inherent in the measurements of

rigidity, and, finally, there are transmission effects in the earth's field itself (penumbral effects), all of which tend to smear out what in reality may be a sharp Störmer cutoff. Keeping in mind the earlier discussion of the variability of the Störmer cutoff itself, we shall attempt to evaluate some of the effects that could smear the cutoff and see if they are compatible with the measurements shown in Figure 4. These effects include:

1. The penumbral effects in a dipole field. For values of the Störmer constant $\gamma < 0.93$, all orbits are allowed and relatively simple; for $\gamma > 1.00$, all orbits are forbidden. For $0.93 \leq \gamma \leq 1.00$, the orbits are very complex, and it is necessary to delineate the allowed and forbidden values of γ in this range which correspond to allowed and forbidden rigidities in a particular direction only. The width of this region of partial transmission corresponding to the above range of γ is 15 percent of the Störmer cutoff rigidity; e.g., in the vertical direction $P_s = 14.9 \cos^4\lambda/\gamma^2$. Although it is generally assumed that there is nearly perfect transmission in this penumbral region at latitudes greater than 50°, a careful study of the orbit calculations of *Störmer* [1955], *Schwartz* [1959], and *Kasper* [1959] reveals a systematic and clearly defined series of forbidden γ in the region of latitudes greater than 55°. These values of forbidden γ corresponds to perhaps 6 or 8 very narrow rigidity ranges in this penumbral region. These rigidity ranges become narrower, and some of them may vanish altogether, at higher latitudes. In a typical detector with a resolution of about ± 0.05 bv, these forbidden intervals (generally about 0.01 bv wide or less) will smear the cutoff rigidity slightly. This effect is shown in curve 1 of Figure 5 for a nominal Störmer cutoff of 1.1 bv and a detector resolution of ± 0.05 bv.

2. The experimental arrangement is such that the particles arrive at the detector over a finite range of angles. In our measurement the opening angle is $\pm 30°$ from the vertical, an angle that is also typical for the acceptance angle of emulsions and other counter devices. Such an angle introduces a spread of cutoffs that can be deduced from

$$P_s = \frac{59.2 \cos^4 \lambda}{[1+(1-\sin \epsilon \cos \phi \cos^3 \lambda)^{1/2}]^2}$$

where λ is the geomagnetic latitude, ϕ the azimuth measured from east, and ϵ the zenith angle. For a Störmer cutoff of 1.1 bv and an opening angle of $\pm 30°$ from the vertical, this effect introduces extremes of ± 65 Mv from the mean cutoff.

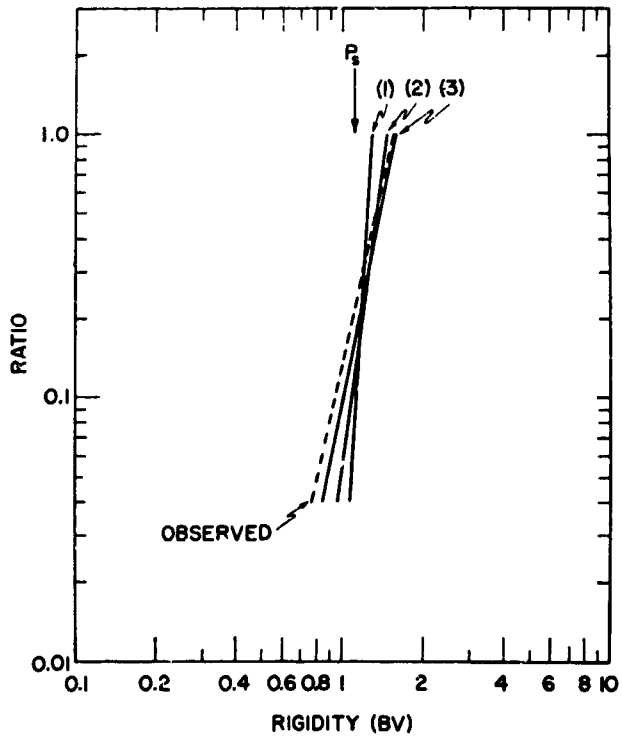

FIGURE 5.—Comparison of observed and predicted transmission of particles through the earth's field at rigidities near the Störmer cutoff rigidity.

3. In a balloon flight of a number of hours' duration, a drift of ± 25 miles from the mean geomagnetic cutoff is typical. Since the data are usually averaged over the whole flight, the drift may introduce a spread of ± 60 Mv at a cutoff of 1.1 bv. Curve 2 of Figure 5 shows the superposition of the aforementioned three effects, which are essentially geomagnetic.

In a very long observation period, a time-varying cutoff could seriously influence the measurements. Since the data were obtained during quiet periods, this effect is not considered.

There are also effects which are instrumental or which occur in the atmosphere above the detector. These include (1) Landau fluctuations in energy loss, both in the detector and in the atmosphere above the detector; (2) fragmentation of heavier nuclei into protons (or α particles) in the atmosphere above the detector (this effect [*Fowler et al.*, 1957] will principally contribute particles below the geomagnetic cutoff for protons

and α particles); and (3) experimental uncertainty in energy or rigidity measurements.

Finally, a small intensity of undentified deuterons or tritons or, in the case of α particles, unidentified He^3 nuclei would serve to diffuse the cutoff.

It is difficult to evaluate these effects analytically. In this study it is estimated that they would introduce a minimum uncertainty in rigidity of ± 10 percent. A superposition of all the effects discussed above is shown in curve 3 of Figure 5. Comparison of this curve with the dotted curve representing the experimental data suggests that we can interpret the vertical cutoff at Minneapolis on August 21, 1956, as a relatively sharp Störmer cutoff at 1.0 to 1.1 bv. These measurements do not exclude a diffuse cutoff over the interval 0.9 to 1.1 bv.

To extend our study of the measured transmission of particles near the cutoff rigidity, we shall examine data from another flight. This was made from Moberly, Missouri, and floated at an average cutoff rigidity of 2.7 ± 0.1 bv [*Quenby and Wenk*, 1962]. The data from this flight, which have been published by *McDonald* [1959] and *Webber* [1962], are consistent with an effective cutoff rigidity of 2.25 ± 0.1 bv. This cutoff was determined by measuring the point of a sudden break in the α-particle differential spectrum. A determination of the primary spectrum from an International Falls flight is available for a time, one year later, when the counting rate of high latitude sea level monitors was within 1 percent of the rate during the Missouri flight. Thus, if the ratio of differential intensities measured in Missouri and at International Falls is taken, the transmission curve shown in Figure 4 is obtained. The shape parameter of the cutoff in this case is given by $P_0 = 300$ Mv. Again, this is compatible with a quasi-sharp cutoff at 2.2 to 2.3 bv and a superposition of the instrumental effects discussed earlier.

Finally, these results (Figure 4) on the shape of the cutoff can be compared with those of *Earl* [1962] obtained near Minneapolis during the course of a solar cosmic ray event on September 4, 1960. Earl's measurements with a cloud chamber are consistent with a shape parameter $P_0 \sim 100$ Mv and a sharp Störmer cutoff at 0.55–0.60 bv. The cutoff was much below normal at Minneapolis at that time because of strong magnetic activity. In addition, because of the high intensity and steep spectrum of the solar particles, Earl could actually observe the change in cutoff during periods of less than one hour. The value of the shape parameter Earl obtained using solar cosmic rays is somewhat less than that obtained using galactic cosmic rays. However, this is to be expected for a number of reasons, one being, of course, that in the short time interval Earl used little balloon drift could occur. Earl's measurements also suggest that a better parameter for defining the experimental shape of the cutoff might be a relative shape parameter P_0/P_s, where P_s is the effective Störmer cutoff. For Earl's work this ratio is 0.18, and for our measurements 0.23 and 0.14 at 1.1 and 2.3 bv, respectively.

We have shown that our results can be explained by a sharp Störmer cutoff, and we believe that an intrinsic diffuse Störmer cutoff greater than ± 0.1 bv would manifest itself in our measurements. At Minneapolis this corresponds to an energy range for protons of 370 to 520, and we cannot rule out a diffuse cutoff over this interval.

Further, it appears that such a quasi-sharp cutoff exists, even though the cutoff may be reduced considerably below that appropriate to the internal field. The mechanisms responsible for the lowered cutoffs are thus limited to those that preserve motion in the earth's field in the Störmer sense. Specifically, such a cutoff would rule out an energy-dependent spatial diffusion through a disordered earth's outer field to positions where Störmer (or Alfvén) trajectories could be followed to the surface of the earth.

Before concluding this discussion of the features of the geomagnetic cutoff, it might be well to ask what, if any, are the effects of a cutoff on the measured spectrum of primary protons at International Falls presented in this paper. To obtain a useful answer to this problem, we recall that slightly south of Minneapolis, where the predicted Störmer cutoff is 1.6 bv, the measured transmission in the earth's field began to deviate from 1 about 1.5 ± 0.1 bv, and the data are consistent with a sharp Störmer cutoff of 1.0–1.1 bv. Most models for the change in cutoff due to external field systems suggest that the fractional change should not be a strong function of latitude between Minneapolis and International Falls. Thus, for

similar conditions, the effective Störmer cutoff during the International Falls flight might be expected to be approximately 0.5 bv and the effective transmission might begin to deviate from 1 at approximately 0.6–0.7 bv. If this happens, the experimental points below 0.7 bv may not represent the true primary spectrum near the earth. We shall consider the implications of this point in the next section.

THE ELEVEN-YEAR MODULATION OF THE GALACTIC COSMIC RAYS AND THE PRIMARY SPECTRUM AT LOW ENERGIES

Although it is possible that the spectrum measured at International Falls does not represent the true primary spectrum below 0.7 bv, we believe that it is possible to compare two flights at this location to obtain useful information on the modulation of the low rigidity primary radiation during the sunspot cycle. This information should be accurate at rigidities above 0.7 bv and below this rigidity as well, provided that the features of the cutoff have not changed between or during the two flights. The measurements we wish to compare were made on balloon flights at International Falls on September 7, 1956, and June 2, 1959, when the counting rates of high latitude neutron monitors decreased by about 10 percent because of the eleven-year variation in solar activity. The differential spectra measured on these two flights are shown in Figure 3. The difference in these two spectra is believed to represent the features of the eleven-year modulation acting during this period. For convenience when comparing these curves with various theoretical models, we have taken the ratio of the differential spectra measured on the two flights and present this information in Figure 6. This ratio, then, should represent the fractional modulation during this period of the galactic cosmic ray spectrum as a function of rigidity in the solar environment. At least two features of the modulation are of great importance: (1) the form of the fractional modulation as a function of rigidity, and (2) the relative fractional modulation of protons and α particles at the same rigidity. Taking the second feature first, we note that the rigidity region in which the proton and α-particle differential intensity measurements overlap is extremely small, from 1.15 to 1.30 bv. In this rigidity range,

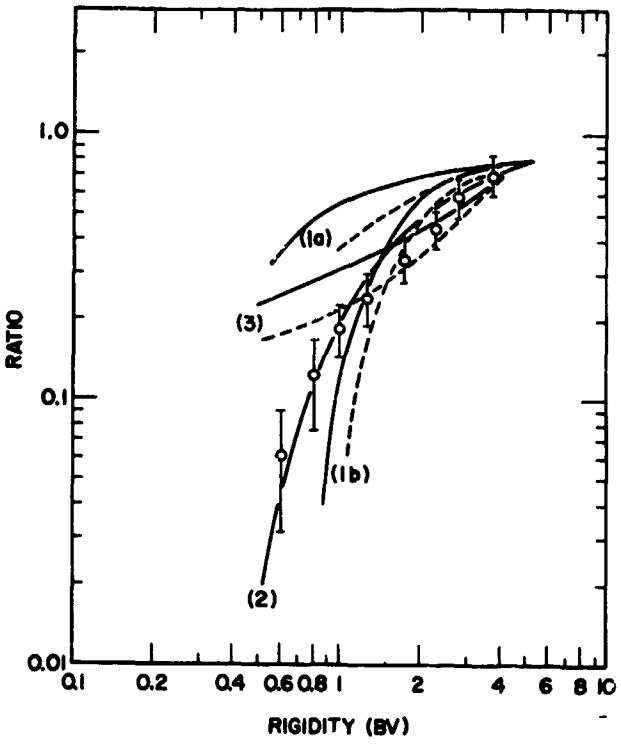

FIGURE 6.—The observed modulation of low rigidity primary cosmic rays during the solar cycle. Circles give the ratio of proton and α-particle intensities measured on June 2, 1959, to those measured on September 7, 1956, at International Falls. Curves 1a and 1b are two possible modulations according to PARKER [1962], curve 2 is the modulation expected according to ELLIOT [1960], and curve 3 is the modulation to be expected upon passage through an electric field of 400 Mv.

during a period when the differential intensity decreased to approximately 20 percent of its sunspot minimum value, there is no difference in the behavior of protons and α particle with an experimental error of approximately—15 percent on the individual measurements. Considering rigidities greater than 1.3 bv, we can make less definitive statements on the behavior of protons and α particles up to at least 4.5 bv by comparing their integral intensities measured above selected rigidities at various times in the sunspot cycle, in the series of flights with the Cerenkov scintillation counter. These data have been examined in detail by *Webber* [1962], who has concluded that the proton and α-particle variations in this rigidity range due to the eleven-year sunspot cycle are consistent within ± 15 percent.

To see how restrictive our data on the rigidity dependence of the fractional modulation and on the relative fractional modulation of protons and

α particle are in terms of a model for the long-term, or eleven-year, modulation of the galactic cosmic rays, let us investigate a few of the recent models that, at least to a first approximation, appear to predict a modulation similar to that observed. These include (1) the solar wind model of *Parker* [1962], (2) the general solar dipole field model of *Elliot* [1960], and (3) the heliocentric electric field deceleration model suggested first by *Nagashima* [1953] and more recently *Ehmert* [1960]. We shall compare the predictions of these models on the rigidity dependence of the eleven-year variation with our observations in some detail, beginning with Parker's solar wind model. The eleven-year variation we obtained corresponds to the quiet day intensity decrease discussed by Parker. For the fractional change in intensity as a function of rigidity, Parker obtains

$$\frac{\Delta j}{j_0}=\frac{4\Omega r \sin\theta}{W(1+4\gamma\Omega r^2 \sin\theta u_0/VaW)}$$

a modulation not unlike that behind the blast wave which Parker suggests causes the Forbush decrease. In the above expression, Ω is the solar angular velocity, r the distance to which the spiral field surrounding the sun is assumed to extend, θ the angle between the lines of force and a radius vector from the sun, γ a geometrical factor probably less than 1, V the average velocity of the solar wind, W the velocity of the cosmic ray particle, a an inner reference distance near the base of the corona, and u_0 a drift factor depending on the characteristics of the assumed general solar (dipole) field. In essence, the decreased intensity is a result of two effects: an outward sweeping of the cosmic ray particles by the solar wind, which dominates at low rigidities and produces a fractional modulation $\Delta j/j_0 \sim 1/W$, and a drift in a latitude across field lines from the polar regions into the equatorial plane (caused by gradients in the equatorial plane), which dominates at high rigidities and produces a fractional modulation

$$\frac{\Delta j}{j_0}\sim\left(\frac{Z}{A}\right)\frac{1}{K}$$

where a is taken to be about $2r$, $\sin\theta\sim 1$, $\Omega=2.7\times 10\alpha^{-6}$ rad/sec,

$$u_0=\frac{1\times 10^6}{Z}\,\frac{K(K+2)}{K+1}$$

and $V\sim 700$ km/sec near solar maximum. The other quantities are effectively unknowns and are determined by the modulation itself. We note that, as $\gamma\to 0$, $\Delta j/j_0\sim 1/W$ and sweeping alone dominates. The modulation is constant at high rigidities and is in disagreement with experiment. The greater the value of γ, the lower the rigidity at which the drift term begins to dominate in the modulation.

First let us try to fit the data near the upper end of our measurements at 5 bv. Then we require that $\Delta j/j_0=0.22$, which means $K/W>0.22$, and $r>40$ AU. Suppose we take $r=65$ AU; then $K/W=0.35$, and $\Delta j/j_0=0.35/[1+120(A/Z)v]$ at 5 bv. For $A/Z=1$, this give $v=5\times 10\alpha^{-3}$, and the rigidity at which the two effects are equal is approximately 7 bv. The form of the modulation, which is essentially velocity dependent, is shown as curve 1*a* in Figure 6. Notice the separation of protons and α particles above 1 bv and the small amount of modulation below 2 bv, both of which are not in agreement with our results.

On the other hand, let us fit the observations at, say, 1 bv. Then $\Delta j/j_0=0.82$, which gives $r\sim 130$ AU. If we also require that $\Delta j/j_0=0.22$ at 5 bv, then $v=1.5\times 10\alpha^{-2}$ and the rigidity at which the two effects are equal is about 2 bv. This is a somewhat better fit and is shown as curve 1*b* in Figure 6. It still, however, shows a separation of protons and α particles above 1 bv which is greater than the experimental evidence indicates. It also predicts $\Delta j/j_0>0.99$ at $P\sim 0.9$ bv, which is clearly outside the range of experimental uncertainty.

In effect our results on the eleven-year variation do not agree with the modulation expected with Parker's solar wind model. Since the presence of a solar wind in the interplanetary environment has been clearly established [*Neugebauer and Snyder*, 1962], it would appear that effects other than those considered by Parker in this admittedly simplified treatment are important to the decrease of cosmic ray intensity. Later we shall discuss what some of these effects might be.

Turning now to the general solar dipole field model of *Elliot* [1960], we see that the fractional modulation can be expressed in the form

$$\frac{\Delta j}{j_0}=\left\{1-\left[\frac{r_e^2 P}{45M_s}\right]^{\alpha(P)}\right\}$$

where

$$\alpha(P)=\left[\left\{1+4K'\left(\frac{P_0+P}{P}\right)^2\right\}^{1/2}-1\right]\Big/4$$

In this equation M_s is the dipole moment of the sun, P_0 is a quantity that is a measure of the strength of scattering centers and that gives a rigidity dependent scattering mean free path, and K_1 is a quantity that reflects the loss of particles into the solar surface. A study of the equation reveals the following effects of these three parameters: increasing or decreasing M_s (keeping α constant) increases or decreases the fractional modulation by a constant amount at each rigidity; increasing or decreasing M_s and decreasing or increasing α to obtain the same modulation at, say 5 bv will, respectively, slightly flatten or steepen $\Delta j/j_0$ versus P. Varying M_s, however, changes the rigidity dependence of the modulation very little.

The parameters K_1 and P_0 are not independent. If we keep the modulation constant at 5 bv and increase K_1 (corresponding to greater absorption by the sun) and decrease P_0, the $\Delta j/j_0$ versus P is flattened. If we decrease K_1 and increase P_0, the rigidity dependence of the fractional modulation is steepened. The best fit to the data, which also corresponds to the observed 5 percent decrease in high latitude neutron monitor counting rate, is shown as curve 2 in Figure 6; it is obtained with $M_s=1.8\times10^{35}$ gauss cm^3, $K=0.15$, and $P_0=2.4$ bv. This would correspond to a mean free path $\lambda_f\sim10^{11}$ cm (independent of rigidity) of the particles in the diffusing region near the solar equatorial plane.

Notice that this model gives excellent agreement with the observed rigidity dependence of the fractional modulation. It also predicts the same modulation for protons and α particles (in agreement with experiment), primarily because of the influence of the general solar dipole field and the application of Störmer theory to the arrival of particles near the earth. The agreement with rigidity dependence is a result of having three parameters available for adjustment. The physical reality of these parameters is not always clear. In particular, it appears that K_1 is not calculated in a consistent fashion. While we cannot reject Elliot's model on the basis of cosmic ray evidence alone (indeed, it gives remarkably good agreement), we feel it has not yet been demonstrated that such a model can predict the required cosmic ray decrease near the earth when reasonable ideas of diffusion are used in the evaluation of the constant K_1.

Finally, we compare our results with the heliocentric static electric field modulation. Here the intensity change comes about because of energy loss and the application of Liouville's theorem, which says that $D=J/P^2B$ is constant during the motion of the particles (D=density of particles in phase space, B=velocity). The form of the change in primary spectrum is given by

$$\frac{dj}{dE_e}(E-V)=\frac{dj}{dE_\infty}(E)\left\{\frac{(E-V)(E-V+2)}{E(E+2)}\right\}$$

where E and V are in bev, (dj/dE_e) $(E-V)$ is the differential intensity at the earth of particles with kinetic energy $(E-V)$, and (dj/dE_∞) (E) is the differential intensity of particles with energy E at large distances from the earth ($V=0$).

Setting $\Delta j/j_0=0.22$ at 5 bv gives the potential $V=400$ Mv and the fractional modulation shown in curve 3 of Figure 6. Note again the separation of protons and α particles and the modulation at low rigidities. The predicted proton—α-particle difference in fractional modulation reaches about 1.5 at low rigidities and is about 1.3 at rigidities between 5 and 1.5 bv where our proton and α-particle measurements overlap. Our results indicate that the modulation is the same in this region to within 10–15 percent. The flattening of the modulation at low rigidities (primarily determined by the shape of the unmodulated spectrum at slightly higher rigidities) is not in accordance with our measurements.

In summary, our results are not in agreement with the concept of a static heliocentric electric field, although experimental uncertainties do not permit us to regard this as a very powerful statement.

None of the three models discussed above for the long-term, or eleven-year depression of galactic cosmic ray intensity appears to agree satisfactorily with detailed measurements of the rigidity and charge dependence of the charges occurring during a particular interval of the recent cycle. The most fundamental difficulty seems to be that the

models predict a pronounced splitting of the proton and α-particle modulation, even above 1 bv, although this splitting is not observed above $\sim$1 bv. Also, the fact that the models cannot explain the observed rigidity dependence of the fractional modulation for protons alone suggests that perhaps some important feature of particle motion is not being considered in these models.

A number of other models have been proposed, and the problem seems mainly to be one of selecting which features of these models must be considered in understanding the eleven-year modulation. In this connection it is useful to use as a guide the recent direct measurements of the interplanetary field configuration and the recent detailed measurements relating to the propagation of the solar-flare-produced cosmic rays.

The direct measurements of the plasma [*Neugebauer and Snyder*, 1962] and magnetic field [*Coleman et al.*, 1962] on Mariner 1 are consistent with the concept that the interplanetary medium is moving outward, at relatively quiet times, with a velocity of about 400 km/sec. In addition, the Imp 1 data show the direction of the magnetic field to be primarily in the equatorial plane (N. F. Ness, private communication, 1964), and there is clear evidence from the Mariner 1 data of magnetic field and plasma variations of a character that would produce randomizing of the motions of cosmic ray particles. Such evidence points to a diffusion-like picture for at least part of the eleven-year modulation. The success with which the diffusion picture has been applied to the propagation features of solar cosmic rays [*Bryant et al.*, 1962; *Hofmann and Winckler*, 1963; *Webber*, 1963] also gives support to this idea.

Such a model has been invoked to explain the eleven-year variation by *Parker* [1958], who solved the steady state diffusion equation with convection,

$$\nabla\cdot(Vj) = \tfrac{1}{3}\nabla\cdot(\lambda\nabla(wj)$$

with some rather simple assumptions about the behavior of V, the outward velocity (convection) of the interplanetary medium, and λ, the effective mean free path between collisions (j is the density of particles, w their velocity). With the assumptions that no energy change occurs and that V is constant and radial, two solutions can be found: (1) If the features of the individual scattering centers are such that $lB \gg \rho B$ (l = scale of scattering centers, ρ = radius of curvature of a particle in field B), then

$$j,(r, E)/j(\infty, E) = \exp^{-const/W}$$

and (2) if the features of the individual scattering centers are such that $lB \ll \rho B$, then

$$j_2(r, E)/j(\infty, E) = \exp^{-const/WP^2}$$

where P is the particle rigidity. This simple form is obtained if we assume only one scale of inhomogeneities (i.e., l = constant), and the constants in the above equations are then determined by values chosen for l, B, V, and the dimensions of the disordered region around the sun [*Parker*, 1958]. Both solutions should be joined at some rigidity roughly equivalent to $PB \approx lB$; thus there will be a kink in the actual modulation owing to the simplifying assumptions about the scattering process [*Parker*, 1962].

Let us compare the experimental data with such a model. First we can use the best estimates of the average values B and V from space probe data; e.g., $B \sim 1\times10^{-4}$ G (in irregularities), and $V \sim 700$ km/sec (near solar maximum).

The value of B determines the point at which the two solutions are joined as $\mathbf{P}\sim1/35$. For the value of $l \sim 2\times10^{11}$ cm used by *Parker* [1958], $\mathbf{P}\sim6$ bv. The modulation at low rigidities is thus about $1/W$, and we have seen in discussing Parker's solar wind model that this is much too flat (curve 1*a*, Figure 5). We must thus attempt to deduce a more reasonable effective value of l. Evidence collected by *Webber* [1963] on the propagation of solar cosmic rays suggests that a possible break in the effective mean free path λ occurs at a rigidity of about 1.6 bv. Below this rigidity λ seems to be roughly a constant $\sim2\times10^{12}$ cm, whereas above this λ appears to vary with energy, although its energy dependence cannot be determined. If we take 1.6 bv as the point at which the scattering process changes character in Parker's simple description, then l becomes $\sim5\times10^{10}$ cm (recall that in Lilliot's model a value of $1\sim3\times10^{10}$ is necessary). The modulation will change from a form $\sim l/W$ to a form $\sim l/WP^2$ at this rigidity. It is in fact very similar to the modulation obtained with Parker's solar wind model, except that in this case it falls off more rapidly at high energies. Therefore, it is a rather poor fit to our

results at both ends. In fact, such a strong rigidity dependence at high energies is clearly incompatible with the long-term modulation observed by neutron monitors.

In spite of these difficulties, it seems that we should seriously consider the features of a diffusion-like model for the eleven-year modulation based on the solar cosmic ray observation. The theory as presently developed is in a most elementary form. The scattering process has been treated in a very simple way. In addition, the variation of λ with r and a distribution of scattering center sizes must be considered. The possible energy change in such a medium has not yet been considered in a workable form. We recognize that the modulation resulting from this diffusive deceleration in an expanding medium is much like that from a static electric field. It may be significant that the electric field modulation, with only a single adjustable parameter, can adequately fit the data over a very wide range and in fact predicts the dependence of the modulation observed at high energies (>10 bv).

The relation between a diffusive deceleration picture and a static electric field is even more intimate than is suggested by the similarity in the modulations. It can be reduced to the fundamental collision of a particle with a magnetic inhomogeneity which, in the case of the expanding medium, results in the inverse Fermi effect. The acceleration (or deceleration) in an individual scattering is caused in the last analysis by the induced electric field $\mathbf{E}=-(1/C)\ \mathbf{U}\times\mathbf{H}$, which is due to the velocity $\mathbf{U}$ of the scattering systems relative to the rest system in the solar system (e.g., the earth). This general feature of accelerating (or decelerating) mechanisms has been pointed out by *Parker* [1958]. *Laster et al.* [1962] have applied the diffusive deceleration picture to expanding magnetized clouds moving outward from the sun and suggest that these effects may dominate in the production of the Forbush decrease. We shall illustrate the basic idea by a specific example and note that the change in energy of the particle after reflection from a moving inhomogeneity is simply $\Delta\epsilon=Ze\int\mathbf{E}\cdot\mathbf{dS}$, where $\mathbf{dS}$ is measured along the path of the particle. Consider a particle moving toward a scattering center with velocity $\mathbf{V}$, the scattering center having a velocity $\mathbf{U}$, small compared with $\mathbf{V}$, and in the same direction as $\mathbf{V}$. If we assume the particle is spiraling around $\mathbf{H}$ and moving into a region of increasing field, $\mathbf{E}$ will oppose $\mathbf{V}$. Then $\Delta\epsilon=2Ze(\mathbf{E})r\sin\theta$, where $r=\epsilon V\gamma/ZeHc$, $\epsilon=mc^2$, $\theta=(\pi/2)-\psi$, and ψ is the pitch angle of a particle. Thus $\Delta\epsilon/\epsilon=-UV/c^2$, a decrease in total energy which is precisely equal to that obtained using the conservation of energy and momentum in an elastic collision with a moving wall. This change occurs only in the longitudinal component of the momentum; the transverse component first increases and then decreases to its initial value during the course of the collision.

The summation of many such collisions will have the equivalent effect of a net decelerating potential without the necessity of a very large uniform electric field near the sun. It is true that, at a particular location in the expanding region, particles will be found with a distribution of energy losses as opposed to the constant energy loss in the static field case; however, the effective modulation should be very similar and should be deduced by the approach of *Laster et al.* [1962].

We believe that, in trying to disentangle the effects of diffusion, energy loss, convection, drift, and other possible general characteristics of particle motion (all of which probably exist to some extent in the interplanetary region), it is important to obtain and study detailed information on the modulation of the galactic cosmic radiation, including measurements of the form of the modulation for different charge components not only at the earth but also at other locations in the solar system. Our results suggest that no single effect dominates over the extended rigidity range, although we feel that a general diffusion process, in which some form of diffusive deceleration occurs, may be an important factor producing the eleven-year modulation.

Finally, it is worth while to compare our results with those of other observers, particularly those for the period after 1959 when our measurements ceased. Comparing α particles first, we note that in the period 1955–1959 the low rigidity differential α-particle spectra over the range 1 to 3 bv measured by the Cerenkov scintillation counter technique and photographic emulsions are in essential agreement within the experimental errors, usually approximately 20 percent. Furthermore, the intensity of these low rigidity α particles is

uniquely related to the counting rates of high latitude neutron monitors during this period.

In Figure 7 we show the differential α-particle spectrum measured on July 7, 1961, by *Fichtel et al.* [1964] using emulsions. The lower dashed curve is the spectrum that would be predicted by the Cerenkov scintillation counter for July 7, 1961, on the basis of the observed neutron monitor intensities and the regression curve established during the 1955–1959 period. Thus it appears that the recovery of this component is proceeding in a manner compatible with the features established during the period 1955–1959.

Turning now to the protons, we note that no measurement comparable to ours is available on low rigidity protons (e.g. <2 bv) during the period 1955–1959. Recently a number of measurements have been made on low rigidity protons

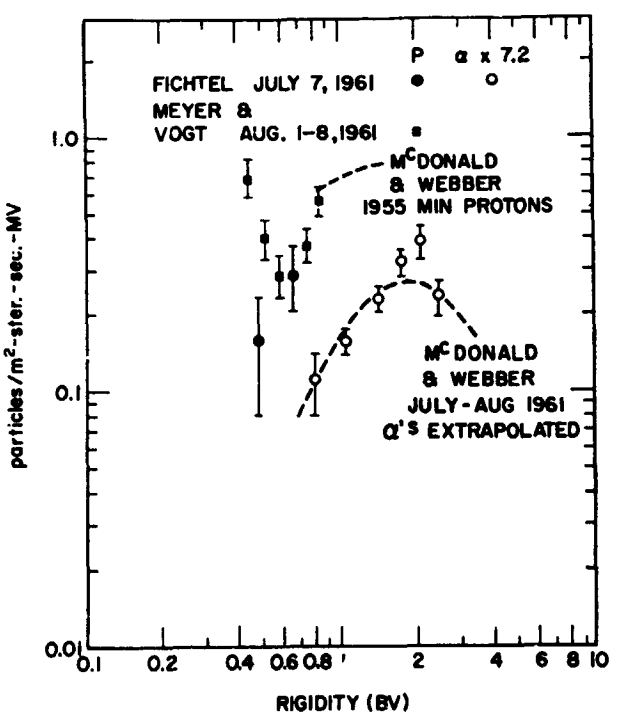

FIGURE 7.—Comparison of predicted proton and α-particle intensities according to regression curves of McDONALD and WEBBER [1962] (dashed lines) and those measured at comparable times during July and August 1961 by other observers. Note the apparent excess of low rigidity protons as measured by these observers and the good agreement for the α-particles (lower dashed curve). Upper dashed curve refers to proton intensity reported in this paper and measured at a time when the neutron monitor rate was near its sunspot minimum value and about 10 percent higher than at the time of the July-August proton measurements shown.

by both counter techniques and emulsions. Comparable measurements were made with these techniques during July–August 1961 [*Meyer and Vogt*, 1963; *Fichtel et al.*, 1964]. Their results, shown in Figure 7, can be directly compared with the α-particle spectrum also given in Figure 7 (see also Table 1). These results cover the range 0.4–0.8 bv and appear to be in general agreement, except that they appear to diverge at low rigidities. Since they are at rigidities less than 0.8 bv, the region of comparison with our result is not large, although some reasonable and interesting comparisons can be made. First, although the rigidity ranges for protons and α particles do not overlap in any one experiment, it appears that, for a reasonable extension of the proton spectrum measured below 0.8 bv in 1961, there is a definite excess of protons relative to the measurements of α particles above 1 bv reported here and to the emulsion measurements as well. Such an excess might be expected in a number of models for the long-term modulation, although the relative excess of protons as a function of rigidity is quite different from that which would be predicted by any of these models. Second, the intensity of protons measured by *Meyer and Vogt* [1963] or *Fichtel et al.* [1964] at 0.8 bv is comparable to our intensity at this rigidity measured at a time when the high latitude neutron monitor rate was 9 percent higher than in the July–August 1961 period. We do not believe the intensity we have measured at this rigidity is depressed because of geomagnetic cutoff effects. If this discrepancy is real, it may indicate the presence of an unusual modulation of galactic protons at low rigidities during the period of decreasing solar activity or the possibility that excess solar protons at low rigidities are contained in the interplanetary field for long periods [*Vogt*, 1962; *Meyer and Vogt*, 1963]. It will take further definitive measurements on the low rigidity proton and α-particle spectra to decide these problems.

VI. PLANETOLOGY

ON THE EARLY HISTORY OF THE EARTH*

WILLIAM L. DONN†, BERTRAM D. DONN AND WILBUR G. VALENTINE‡

According to current astrophysical models of the sun, solar luminosity has increased with time at a theoretical rate depending on the nature of the model and the "zero-age" of the sun. The determination of the earliest occurrence of running water on the earth's surface may establish a calibration point on the luminosity curve. Our investigation of the nature and age of the oldest rocks suggests that erosion by running water occurred at least 4 billion years ago. Calculation of the evolution of terrestrial surface temperatures based on the most favorable solar model and current estimates of the composition of the early atmosphere indicate that either some revision to the model is necessary or that the earth and sun must be older than 4.5 and 5 billion years, respectively.

The rate of weathering of bedrock and resulting erosion vary directly with temperature, atmospheric moisture content and organic acids from vegetation. Since these all increased with geologic time, it is suggested that bedrock erosion, which would have been slow initially, must also have increased with time. With the presumption of an interaction between sedimentary load and geologic activity, the duration of geosynclinal cycles also should have decreased with time.

The oldest rocks so far dated (about 3.5 billion years) are pegmatites, granites and granite gneiss complexes all of which represent terminal processes in respective geologic cycles, the beginnings of which are inferred at about 4 billion years ago.

The presence of a substantial sialic crust at this time is indicated by the compositions of both igneous rocks and metasediments.

The origin of the continents is examined in the light of these geologic data and inferences, and on the assumption of a pregeologic accumulation of the earth by accretion from cold, solid objects, probably in the form of whisker-like crystals. Theories of origin of continents by segregation from the mantle cannot be reconciled with the time scale provided by calculations from the thermal history of the earth and the currently accepted age of 4.5 billion years. An alternative hypothesis is discussed according to which the continents originated by impact of extra-terrestrial material with subsequent modification by geological processes and mantle admixture.

INTRODUCTION

As the dating of the oldest rocks in the earth's crust is pushed further back in time, the interpretation of early geologic processes begins to merge with the realm of astrophysical thought relating to the origin of the sun and earth and the rest of the solar system. One of the most significant developments in astrophysics, in recent years has been the clear demonstration that stars must be forming continuously. Involved in this scheme is the mechanism of star formation and evolution together with an estimate of stellar ages. In the borderland between astronomy and geology, geochemistry, geophysics and astrophysics provide information and insight in the investigation of the problem of the origin of the earth and solar system. And in the realm of geology, the dating of rocks of great antiquity provides the necessary data for the interpretation of processes in the primeval earth. These areas of investigation must ultimately yield a consistent pattern for they deal with connected and continuous stages in the development of the sun and earth.

Although any current attempt at a synthesis must be a hazardous one, we believe the attempt is now justified in view of the progress in these related areas. And although the analysis may be only partly successful, it may nevertheless indicate both consistencies and inconsistencies in models and theories, and also suggest where vital boundary conditions exist for fitting theories and observations. A suggestion of this nature was made by Schwarzchild (1958) when he asked whether the predicted increase in luminosity of

*Published in the *Geological Society of America Bulletin*, 76:287–306, March 1965.

†Lamont Geological Observatory and the City College of New York.
‡Brooklyn College.

the sun could have had observable geological effects. An important, but brief examination of this point was made by Ringwood (1960).

As part of this investigation we prefer to reverse the thinking of Schwarzchild and Ringwood by determining what bearings earliest observable geologic processes have on theoretical prediction of increasing solar luminosity. This in turn has further implications related to many facets of the primeval earth.

The analysis in this report is divided into three major parts. In the first, a summary of the current background relating to the origin of the sun and earth is given. In the second part, a summary of the data of the oldest rocks is presented with analyses which are the basis for the astronomical and geological conclusions in the third and final section.

ACKNOWLEDGMENTS

We are especially grateful to Professors J. L. Kulp and A. Poldevaart of Columbia University for making available unpublished data on some of the oldest rocks from east Africa and western United States and for the helpful discussion they provided. We also wish to thank Sir Harold Jeffreys and Dr. Kurt Lowe for their reading of, and related comments on the entire manuscript and Dr. Walter Bucher for his helpful discussion on certain of the arguments. The research at the Lamont Geological Observatory was supported by a research gift from the U. S. Steel Foundation.

ASTRONOMICAL BACKGROUND

Origin of Solar Type Stars

Astronomical evidence indicates that stars are forming continuously from clouds of dust and gas as elaborated by Burbidge and Burbidge (1958).

Under suitable conditions (Hoyle, 1960; Spitzer, 1963; Cameron, 1962) these clouds may convert kinetic energy either to radiant energy which is lost to space, or to energy of molecular dissociation and ionization resulting in contraction of the cloud. These processes would lead to increasing temperature and density with the cloud becoming luminous at some stage. Ultimately, the central temperature and density would reach a point where nuclear reactions occur releasing energy at a more rapid rate and finally causing contraction to cease. The initial nuclear energy phase is relatively long in the life history of a star so that most stars have observable features characteristic of this phase. In the Russell-Hertzsprung diagram, which shows stellar luminosities plotted against color or temperature, there is a marked concentration in a narrow region called "the main-sequence" (Struve, 1950; Arp, 1958; Schwarzchild, 1958). Stars in this phase of development, such as the sun, are therefore referred to as "main-sequence" stars. During their evolution they deviate progressively away from the main sequence, but the sun, which is at least 5 billion years old still lies within this group indicating it has undergone little evolutionary change.

In general, stars form as very localized multiple systems (van de Kamp, 1953) with binaries predominating. On a larger scale they seem to form primarily in groups with members numbering in the hundreds. Theories of star formation, reviewed by Burbidge and Burbidge (1959), are not detailed enough to account for these features except in a general way. Whatever the processes of star formation may be, it is believed that main-sequence stars like the sun are surrounded initially by clouds of gas and dust. Evidence to support this view arises from the interpretation (Herbig, 1962) of the T Tauri class of variable stars as being in process of formation. These stars cover a range of spectra which includes that of the sun.

It is not an unreasonable hypothesis that under some circumstances, particularly for single stars, a planetary system may develop out of the surrounding nebulosity. This is the reasoning behind the current theories of the origin of planetary systems (Hoyle, 1960; Cameron, 1962).

In order to interpret both chemical analyses of meteorites and of the earth's crust, and radioactive dating measurements, a knowledge of the primordial composition is required. A thorough discussion of abundances of the elements has been given by Suess and Urey (1956). However, their discussion did not take into account the now well established result that element distributions differ among star groups in the galaxy (Schwarzschild, 1958; Burbidge and Burbidge, 1958; Aller, 1958).

The theory of element formation in stars starts with a pure hydrogen galaxy from which the

individual stars form. Nuclear processes supply stellar energy and in the process convert hydrogen to heavier elements. At a late stage of development stars must eject a considerable fraction of their masses into interstellar space as in the case of supernovae. The resulting nebulosity leads to a second generation of stars enriched in heavier elements. The sun appears to belong to a still later cycle in which the concentration of heavier elements has been increased still further.

Age and Evolution of the Sun

The age of the sun places limits on the time scale for formation of the earth. Initial luminosity and subsequent evolutionary changes for the sun are primary factors determining the temperature of the cloud from which the earth formed and subsequently the earth's surface temperature.

The major initial evolutionary change in a star is its increasing luminosity. Calculations for the sun, first carried out by Schwarzschild (1958) and his associates showed that with an initial composition of 75–80 percent hydrogen, an increase of about 40 percent in luminosity would have occurred in about 5 billion years.

In general the age of the sun has been assumed to be about 5 billion years (Schwarzchild, 1958) on the basis that it is not much older or younger than the earth (4.55 b.y., Patterson, 1956).

Haselgrove and Hoyle (1959) have attempted to deduce the sun's age from the time it would take a homogeneous star of the sun's mass and initial composition to evolve to the present sun. Once the sun became a main-sequence star the conversion of hydrogen to helium in its central regions would destroy the homogeneity by producing a growing core depleted in hydrogen. Hoyle's calculations start with an initial sun composed of 75 percent hydrogen and having a hydrogen to helium mass ratio of 3, a value also adopted by Suess and Urey (1956). Although the rate of helium formation in the galaxy is an uncertain quantity, determinations of the hydrogen to helium mass ratio (Aller, 1958) for luminous hot stars formed within the past 10^8 years vary from 2 to 5. Because these stars are much younger than the sun, they should contain relatively less hydrogen and more helium.

The "zero-age" sun would have had about 0.7 of the present luminosity. With the adopted composition, 5.3 billion years would have been required to attain the present luminosity. The rate of stellar evolution is greater at lower hydrogen concentrations (Hoyle, 1959). Thus, Hoyle's age of 5.3 b.y. (billion years) would be increased somewhat if the initial hydrogen content of the sun were greater than 75 percent, the value for recently formed stars.

Figure 1 shows the luminosity variation of the sun according to Hoyle's calculations. These

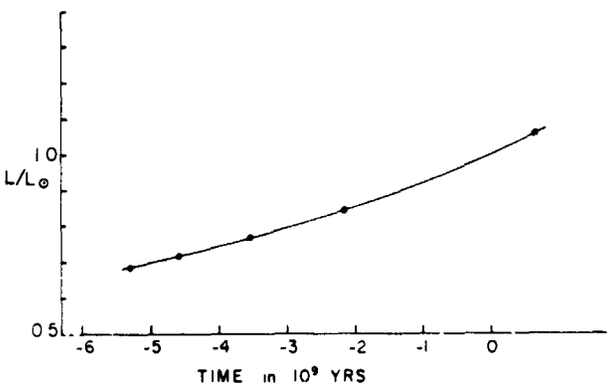

FIGURE 1.—The variation of solar luminosity with time in terms of the ratio of the past luminosity (L) to the present luminosity (L.) (Based on the calculations of Haselgrove and Hoyle, 1959).

results are in general agreement with those of Schwarzschild (1958) and Sears (1959). An increase in solar luminosity by about 30 percent since its formation must have occurred. The geological implications of this effect first called attention to by Schwarzschild (1958) and later Ringwood (1961) will be considered in a later section. Possible implications for solar evolution based on the earliest geological record will also be discussed later.

Origin of the Earth

In the last two decades or so, much effort has been devoted to the problem of the origin of the planets and meteorites. Although no comprehensive, generally accepted theory has appeared, some important conclusions regarding the conditions of formation seem to have become firmly established.

Conditions of accumulation.—Quite conclusive evidence for the formation of the earth and

meteorites from solids at low temperatures has been presented by Brown (1952) and Urey (1957 a, b).

Brown compared ratios of terrestrial to cosmic abundances of the noble gases, Ne, A, Kr, and Xe, with similar ratios for the more reactive gases, H_2O, CO_2, N_2 and O_2. For the latter group the ratios of terrestrial to cosmic abundances are much higher than for the inert noble gases. Because all of the above molecules have comparable molecular weights, gas phase fractionation in a gravitational field could not have played an important part in their accumulation. The reactive gases must therefore have been retained chemically in solids until the earth was large enough to hold them in gaseous form. A consequence of this reasoning is that the atmosphere and hydrosphere must be entirely of secondary origin.

Brown suggests that H_2O was probably in the form of hydrated minerals. This would have limited temperatures to values below which such hydrates are stable.

Urey (1957a) carried out a somewhat similar analysis for less volatile elements and confirmed the low temperature solid accumulation hypothesis. Zinc, cadmium, arsenic, and mercury are relatively volatile or form volatile compounds in a mixture having cosmic proportions of the elements. As no evidence for the depletion of these elements exists, they must have also been captured in the form of solid particles. Urey concludes that temperatures during the formation of the earth were less than a few hundred degrees centigrade. However, temperatures could not have been extremely low or the noble gases would have condensed out or have been adsorbed on the solid particles and their depletion would have been less than observed. Hence, the temperature of accumulation seems limited to a range that approximates present surface temperature ranges.

Mechanism of planet accumulation.—The major attempts to explain the formation of the four inner or terrestrial planets from solids are those by Urey (1957a, b, 1958) and the Soviet School (Schmidt, 1955, 1958; Levin, 1957, 1959). A discussion of the subsequent development of meteorites after accumulation has been given by Anders and his associates (Fish et. al., 1960; Anders and Goles, 1961). As the surface temperature, composition and structure of the growing planet depend upon the accumulation mechanism, this process has an important bearing upon the structure of the earth and the primitive crust.

The mechanism for causing more or less spherical, solid grains to aggregate into large masses has been obscure in all attempts to form large objects. A recent proposal (Donn and Sears, 1963) points out that in the solar nebula condensing particles should have included a large proportion of irregularly shaped grains in the form of plates, filaments and various combinations. These particles would have the properties associated with minute perfect crystals or whiskers, i.e., mechanical strength and elasticity several orders of magnitude greater than for bulk material of the same composition. The shape and strength of these grains provide a means for them to cohere upon collision. The resulting aggregate would be a low density porous object and an efficient collector of all particles striking it.

Composition of accreting material.—The composition of the particles from which the earth formed depended upon the temperature of the nebula and its history. In Urey's two-stage process the fragmented solids were of metallic or silicate composition. If temperatures were low enough, some of the volatile components of the gas would have condensed also. A difficulty with this scheme which Urey (1957a) has emphasized is the mechanism of accumulation of the primary and secondary objects into the planets.

In general one would expect solid grains condensing in the solar nebula to form whiskery particles as noted by Donn and Sears (1963). The condensation of nebular material into spherical particles would have required very special conditions such as proposed by Wood (1963) for the origin of chondrules.

The water in the earth may have resulted from the accretion of ice grains. This would require quite low temperatures in the region of the earth as proposed by Schmidt (1955) and Opik (1962). Brown (1952) and Latimer (1950) proposed that the water was included in hydrated minerals. Hydrated silicates with their complex crystal structure could form from a melt (Urey, 1957a), but this hardly seems possible from the vapor phase. The means of accumulation could have been as simpler hydrated molecules (MgOH, NH_4OH), as ice particles, or as adsorbed water on

silicate grains (Urey, 1952a).

A rather thorough discussion of chemical reactions in the solar nebula has been given by Urey (1952b). Latimer (1950) and Eucken (1944) have also considered this problem. At low temperatures, stable, non-volatile grains are SiO_2, Fe_2SiO_4, Mg_2SiO_4, FeS, and Fe_3O_4 as well as various metallic oxides. Among stable volatile constituents are H_2O, NH_3 and NH_4OH. Presumably the original grains had much the above composition.

Temperature of an accreting earth.—The temperature of the accreting earth was a dominant factor in determining the composition and structure of the earth and the rate of attaining its ultimate characteristics. A complete discussion becomes too involved to include here, but a survey of analyses of such temperatures is presented. The following factors contributed to the heating of the earth as it formed: (1) temperature of the solar nebula, (2) conversion of potential and kinetic energy of particles to heat, (3) release of chemical energy of metastable species stored at low temperatures, (4) work done in compressing material from initial low density, and (5) radioactive decay.

Because of the requirement of a low temperature accumulation the first factor was negligible. Initially process 2 was inefficient because of low impact velocity and small mass. As the earth became larger both factors in 2 became more effective and at some stage a high surface temperature may have developed. However as the terminal stage approached with the earth near full size the rate of growth must have declined, approaching zero as accumulation was completed. This feature has not been taken into account in any of the temperature determinations (ter Haar and Wergeland, 1947; Benfield, 1950, etc.) although it was pointed out by Levin (1957). The net effect was that thermal radiation combined with a slow rate of conversion of kinetic or potential energy to heat would have prevented high surface temperature in the final stages of formation. Local high temperatures probably occurred from occasional impacts at that stage because the accumulating grains would have aggregated into larger objects (Öpik, 1962; Donn and Sears, 1963) which would have generated high temperatures in the impact zone. Urey's lunar calculation (1952, p. 37) suggests that rapid cooling would occur in these locally heated zones.

In a low temperature nebula, chemical heating (process 3) may have been important for objects much smaller than the earth or during the initial stages of growth. When the earth was nearly full size chemical energy would be released immediately on impact and its effect included in the impact heating which would be small at this stage.

Process 4, the compressional heating, has been investigated by Lubimova (1958) and MacDonald (1959) whose results show that the temperature rise in the center would have been only a few hundred degrees. In fact, Lubimova concludes that the rise from the combined effects of impact, radioactive heating and compression would only have been 1200 degrees.

Most calculations of temperatures arising from radioactive decay, process 5, do not apply because in the present case we are concerned with an earth of essentially uniform composition. MacDonald (1959) found for such circumstances that melting temperatures for a metallic phase would be attained 0.5 to 2×10^9 years after aggregation. Differentiation of a core would then occur a long time after aggregation. MacDonald does not consider mantle-crust differentiation but it is apparent that it would take longer yet if it could occur at all.

In summary, present ideas concerning the origin and accumulation processes are far from definitive but certain conclusions can be drawn regarding the characteristics of the earth at the termination of the astronomical phase of its development—the accumulation of its complete mass. The earth's composition was basically that of a uniform mixture of relatively cold solid grains during accumulation. Such accumulation requires the subsequent heating and segregation of the interior for the development of the present structure. By the terminal stage the central region was probably well in the process of heating, although the outer portion must still have retained its primeval composition and structure. At the time of the earliest determinable geological processes the data of the oldest rocks shows that the crust was already well-differentiated. In the following sections we will try to connect the astronomical with the geological phases by a further interpretation of the oldest rocks.

THE OLDEST ROCKS

The other important evidences that must be considered in forming an opinion about early conditions on the earth are the characteristics of the oldest rocks that have been discovered. Regions in which the rocks of greatest known antiquity occur are southeastern Africa, the Kola Peninsula in the USSR, North America from central Canada to northwestern United States and Western Australia. (Although the oldest date known to us was reported by Charbert for a migmetite from French Guiana, the determination —3.93 b.y.—is considered too pulminary for inclusion in this discussion.)

Southeast Africa

The Sebakwian System represents one of the oldest groups of rocks found in the continent of Africa. The micas from a pegmatite cutting this system near Gwelo have been dated by the K–Ar method (Kulp and Poldervaart, personal communication) at 3.44 b.y. which must be regarded as a terminal date for the Sebakwian. We emphasize that this, and all K-Ar dates must be considered as minimal owing to the possibility of escape of argon. Although the conclusions that follow later are based on the experimental values, a revision to greater ages may be justified in the future.

According to the description given by MacGregor (1951), the Sebakwian rocks outcrop in a general northeast-southwest belt from near Mt. Darwin to Filabusi in eastern Southern Rhodesia. However, based on more recent observations, Poldervaart (Personal Communication) considers that only the rocks near Gwelo are authentic Sebakwian. The Gwelo rocks include high grade metamorphics such as granulites, whose original lithology is uncertain, feldspathic or arkosic quartzites and dirty sandstones with lenses of conglomerate.

Resting with high angular unconformity on the Sebakwian System is the Bulawayan System (MacGregor, 1941), which consists of volcanic greenstones with interbedded algal limestones at the base, followed by arkoses, graywackes and ferruginous cherty quartzite. At the Bikita Mine, a pegmatite intrusive into this sequence has been dated at 2.6 to 2.8 b.y. (Kulp and Poldervaart, Personal Communication). All of these rocks have been complexly folded and metamorphosed and "invaded" by granite batholiths.

Rocks of an antiquity equivalent to that of the Sebakwian occur to the south in Swaziland. As described by Hunter (1957), the basement complex designated the Swaziland System, is composed of complexly folded gneisses, granulites and migmatites. The lowest member of the system contains granodioritic gneisses with augen of feldspar and quartz, and granulites with intercalated quartz schists. The only clearly recognizable metasediments occur as lenses of quartzite. The paragneisses are predominantly light-colored, being composed essentially of quartz and feldspars. These rocks grade into darker varieties containing hornblende and pyroxene. The nature and composition of the presumed metasediments described here and in further detail by Hunter suggest strongly an origin from a sialic source.

The granites formed in the metamorphism of the Swaziland System have been dated tentatively at 3.44 b.y. by Allsopp, Roberts, Schreiner and Hunter (1962), who used the *Rb-Sr* method on the entire rock sample. This date which must also be regarded as a terminal date for the Swaziland cycle, is weak because it is based on a rock with a low radiogenic *Sr* content. But it is strengthened by the stratigraphic position below a younger granite with an average age of 3.07 b.y.

Dates from rocks in the Belgian Congo approaching this antiquity have been obtained. Ages of 3.31 to 3.43 b.y. have resulted from the method of modern lead in galena (Holmes and Cahen, 1957). These dates extend the region of oldest rocks northward from the exposures in Southern Rhodesia.

The greatest age so far obtained was determined from a charnokite granite collected by A Poldervaart to the southeast of Lake Victoria in northern Tanganyika from a hill representing the remnants of a thrust sheet (A. Poldervaart personal communications). A *K-Ar* age of 3.6 b.y. was determined at Lamont (Kulp and Engles, 1963). Although this age is consistent with that from other rocks of greatest antiquity in southeast Africa, it might be considered as tentative because of the low potassium content of about 2 percent whereas the more reliable *K-Ar* ages are usually based on a potassium content greater than 6 percent.

Kola Peninsula

The early Precambrian rocks in the Kola Peninsula are highly metamorphosed and complexly folded. Although the age relations are not entirely clarified, a fairly organized picture can be interpreted from recent Soviet publications from which the following descriptions are taken (Vinogradov and Tugarinow, 1961, Lazko, 1962; Pryatkina, 1960; Makiyevshii and Nikolayeva, 1962; Polkanov and Gerling, 1959; Kharatonov, Ozhinskii, Volodin and Polfyerov, 1961).

The oldest rocks are the Katarchean System consisting of a lower biotite gneiss complex (Kola Series) and an upper series composed of a variety of gneisses and amphibolites. This group is now recognized as being older than the lower Archean with which it was formerly included.

The lower Katarchean is a geosynclinal pile which extends eastward from the Kola Fjord (north-northeast of Murmansk). The major rock types are biotite, gneisses and garnetiferous gneisses. According to Maciyevskii and Nikolayeva (1962) the oldest biotite gneisses, which are restricted to the crests of anticlines, often contain dark-colored amphibolitic slates and magnetic quartzites. The younger garnetiferous gneisses contain more alumina and less iron oxide and magnesia.

A *K-Ar* age determinations of 3.44 to 3.48 b.y. by Polkanov and Gerling (1960) were made on biotites from a biotite gneiss of the Kola series in the Veronya River valley. Kouvo and Kulp (1961) have confirmed these dates. We again emphasize that the date refers to the metamorphism of the rocks, hence it is terminal for the lower Katarchean. The dates for the termination of the upper Katarchean, given by Polkanov and Gerling (1960) and Pryatkina (1960), fall between 2.6 and 2.8 b.y.

It is also worthy of emphasis that the presence of the quartzite lenses in the lower Katarchean or Kola Series must indicate the existence of a sialic parent rock from which the lower Katarchean sediments were derived. This will be discussed further in a later section.

The metamorphic rock sequence in the southern part of the Kola Peninsula is not as clearly defined as in the north. Lazko (1962) describes a Kola-like White Sea Series of biotite gneisses, biotite-garnet gneisses, and sillimanite gneisses, containing many amphibolites and pyroxenic slates. These may be correlative with some part of the Katarchean of the northern Kola region according to Maciyevskii and Nikolayeva (1962). In the Kandalash Bay shore region, a belt of granitized gneisses contains amphibolites which include carbonate lenses. A *K-Ar* date of 3.25 b.y. on a granite from the southern part of the Kola Peninsula is given by Polkanov and Gerling (1960). Although positive correlations have not yet been made, this date supports the view that the rocks of the southern part of the Kola Peninsula are at least equivalent to some part of the Katarchean of the northern portion of the Peninsula.

North America

One of the older parts of the Canadian shield is found along the Winnipeg River in southeastern Manitoba. The oldest rocks, which are known as the Rice Lake Series are divided into three phases. (Wright, 1932). The lowest, Mangotagan Phase, is composed of quartzite, graywacke, slate, chert and conglomerate in part recrystallized into granite schist and gneiss.

Numerous pebbles and boulders of granite are found in the Mangotagan conglomerate. The granitic source from which this material has been derived must have been exposed during the time of sedimentation of many of the Mangotagan sedimentary units although no outcrops of the original rock have so far been found. It must be noted that Davies (1956) offered some inconclusive reasons to question the conglomeratic nature of the Mangotagan conglomerate, suggesting the rounded and elongated granite fragments were intrusions into an original schist, but conglomeratic origin proposed by Wright (1932), Derry (1930) and Springer (1949) seems a stronger argument.

The Rice Lake series has been invaded by pegmatites that postdate the metamorphism of the series. *Rb-Sr* age determinations (reviewed by Gastil, 1960) on lepidolite from these pegmatites give an age of about 2.65 b.y. which must be considered a terminal date for the Rice Lake cycle.

The tightly folded Rice Lake formations thus appear to be a correlative of the Bulawayan series of Southern Rhodesia and of the upper Katarchean of the Kola Peninsula. The granite boulders in the lower Rice Lake conglomerate must have been

derived from either a still older orogenic belt or a primordial granite source. If the former, the rocks involved in the orogenic belt might well be correlative with the Sebakwian System, the Swaziland System and the Kola Series.

Rocks of very great antiquity seem to crop out in a belt extending from the southern part of the Canadian shield into the northern Rocky Mountains. To the south of the Rice Lake area, very ancient granite gneiss is exposed in localities along the Minnesota River Valley in southwestern Minnesota. Catanzaro (1963) obtained *U-Pb* isotopic ages that are recognized as discordant and low, of 2.64 to 3.28 b.y. from two zircon samples from the Morton granite gneiss, and one from the Montivideo granite gneiss. Assuming the discordance to be the result of lead loss from continuous diffusion, a minimum age of zircon crystallization of 3.3 b.y. is interpreted. Assuming episodic lead loss during distinct metamorphic stages, the minimum age is 3.55 b.y. These oberrvations again lead to the inference that a substantial sialic crust was present during one of the earliest recognizable stages of geologic history.

Another study of the *U-Pb* system in zircons from ancient rocks was made by Catanzaro and Kulp (1964) for the Beartooth Mountains of Montana. The major rock units in the area of Quad Creek, where many of the samples were taken, occur in a tightly folded syncline. This group consists of Precambrian granite gneiss, migmatite, metasedimentary rocks (primarily paraamphibolites and quartzites derived from arenites, lutites, and possible calcilutites) and metamorphosed mafic dikes and stocks (Eckelmann and Poldervaart, 1957). The ages of 2.6 to 3.1 b.y. are based upon $Pb^{207}-Pb^{206}$ in zircons and are recognized as discordant and low. Assuming episodic lead loss during known metamorphic stages, a minimum age of 3.12 b.y. is obtained. On the basis of continuous diffusion of lead, a minimum age of 3.5 b.y. is interpreted.

It must again be noted that these ancient Beartooth metasediments contain zircon grains of much greater antiquity than the matrix. Although zircon occurs in most igneous rocks, it preponderates in granites which seems the likely source of the sedimentary zircon. This, together with the presence of metamorphosed quartz sandstones, the source of which has not yet been discovered, indicate the early erosion of a sialic parent rock.

The Beartooth metasediments in the Stillwater River Area, about 25 miles northwest of the Quad Creek region have also been the subject of recent reinvestigation. The Stillwater igneous complex, described in detail by Hess (1960) is intruded into the Beartooth group which have been described by A. Poldervaart (personal communication) to consist of some quartzite and ironstone members within a main mass of metamorphosed potassic shales. A *K-Ar* date on biotite from the metamorphic aureole bordering the intrusion was found to be 3.2 b.y. (J. L. Kulp, personal communication). In addition to dating the intrusion, this date establishes at least a minimum age for the deposition of the original Beartooth sediments whose composition here again implies an earlier sialic source.

In the investigation of ancient rock ages in northwestern Wyoming, to the south of the Beartooth Range, Giletti and Gast (1961) and Bassett and Giletti (1963) report *Rb-Sr* ages up to 2.7 b.y. on muscovite from pegmatites that cut highly metamorphosed rocks. These authors conclude that these ages, which represent terminal metamorphism of a sedimentary sequence, are extensive in western and central Wyoming. The metasediments of Quad Creek, northwest Wyoming and the Stillwater area appear to be a uniform geologic realm. The first two seem to be correlative with the Rice Lake, Bulawayan and upper Katarchean. The Stillwater may be older, possibly corresponding to the still older rocks in Africa.

Australia

According to Wilson, Compston, Jeffery and Riley (1960) the oldest rocks in Australia show essential unity in structure and age in a region of about 500,000 square miles in western Australia. Although the most accurately dated area is at Boya, near Perth, where the total rock method on granite gives an age of 2.7 b.y. for the emplacement of the granite, *Rb-Sr* and *K-Ar* age determinations over the vast area referred to above also give 2.7 b.y. (within a 4 percent spread) at many localities. This latter age was determined on lithium-bearing pegmatites which inject the Kalgoorlie greenstones and thus indicate the date of

metamorphism of this widespread rock system. The greenstones were derived from basaltic and andesitic lavas, pyroclastics, basic and ultrabasic intrusions, banded iron formations and ill-sorted classic sediments.

The greenstones occur in long narrow belts surrounded on all sides by granite or granite gneiss which are regionally concordant with the greenstones. The gneisses, which are in part at least, "remetamorphosed" into a complex containing charnockitic rocks of all types, are considered by Wilson (1958) to be the oldest rocks present, and to represent the more acid crust on which the original greenstone source rocks were laid down. No dates on the ancient gneisses have been given although age determinations are planned. At present, therefore, any tentative correlation with rock groups of great antiquity on other continents is difficult.

One of the clastic units included in the greenstones from Southern Cross has more recently been described by Marshall, May and Perret (1964) to be a fine-grained quartzite consisting of angular quartz grains.

Direct Conclusions from the Geologic Data

The data on the oldest rock sequences provide the basis for establishing certain limits regarding conditions and events in the earliest geologic phase of earth history. In the interpretation of these data certain assumptions or generalizations are involved. Although further study may alter or refute some of the conclusions, the method of analysis seems valid.

The terminal date for the earliest known geosyncline cycles is about 3.5 b.y. In all cases it is necessary to assume a preceding time interval sufficiently great to accumulate geosynclinal piles and raise them to a high degree of metamorphism. It seems possible to estimate the length of this interval by comparison with the interval of later cycles whose time limits are better known.

As noted earlier, the next major diastrophic events in Southern Rhodesia and the northern Kola Peninsula occurred at about 2.6 to 2.8 b.y. In view of the long time interval between successive terminal events it seems reasonable to conclude that the earliest cycle culminating at 3.5 b.y. began at least 4 billion years ago. This argument is given strong support in a later section which emphasizes the probable slow rate of bedrock erosion in an early geologic time as a result of low temperature, low atmospheric water vapor content and absence of organic acids.

This line of reasoning leads to the conclusion that subaerial erosion, involving running water, was in operation at least 4 billion years ago. Because these estimates are based in part on the *K-Ar* method of isotropic dating, they may be considered minimal owing to the possible loss of argon as noted earlier. It may also be concluded that at least a portion of the continental crust undergoing erosion about 4 billion years ago consisted of quartz-bearing sialic rock material.

The timing of events for North America is not as definitive but nevertheless leads to conclusions of great antiquity regarding the age of the first erosional cycle. The terminal event of the first clear-cut sedimentary cycle in Manitoba is about 2.6 to 2.7 b.y. If the granite inclusions in the Rice Lake conglomerates are considered to be primordial crust, the first cycle would have begun about 3.5 billion years ago. If, however, this granite represents the culmination of a preceding geosynclinal cycle, then the first cycle could also be extrapolated back to at least 4 billion years. In the Beartooth region, if the estimated minimum age of 3.5 b.y. for the Beartooth zircons is valid, then a similar history for this region can be argued, particularly in view of the quartz-bearing sediments which must certainly have been derived from sialic material. The Stillwater date certainly establishes the existence of a sedimentary pile at 3.2 b.y. which may have begun about 3.5 b.y. As the Stillwater sediments indicate a sialic source they may represent the erosion of a primordial granite crust or an earlier cycle granitized mass.

Evidence for an initial acid crust over at least a large part of Australia is also strong in view of the granite and granite gneiss basement in the western part of the continent, and the quartzite composed of angular particles in the overlying greenstones. The latter must be greater in age than 2.7 b.y., the time of pegmatite injection and metamorphism. Because the greenstones are mostly igneous in origin, it is difficult to estimate the time of initiation of this system as is possible with geosynclinal deposits. Certainly the remetamorphosed gneisses, described as the basement, are

considerably older. If first cycle, they probably represent primeval acid crust; if second cycle, they must represent geological activity involving erosion of preexisting acid rocks at least 3.5 billion years ago, and possibly 4.

A summary of our direct conclusions from the geologic data are (1) at least parts of three major continents were present about 4 billion years ago; (2) quartz-bearing sialic material existed in these continents which must have been larger than the areas in which rocks of this antiquity have been found fortuitously, (3) subaerial erosion by water transport was accumulating sediments in geosynclinal troughs about 4 billion years ago; and (4) above-freezing temperatures must have prevailed over at least part of the earth's surface 4 billion years ago.

GEOLOGICAL AND ASTRONOMICAL IMPLICATIONS OF THE OLDEST ROCKS

Solar Luminosity

The data and interpretations given above lead to the conclusion that running water required for rock erosion and sediment transport existed at a number of places having a wide distribution over the earth's surface about 4 billion years ago. Consequently the temperature of much of the surface atmosphere must have been above freezing for much of the year. This leads directly to a consideration of the source and maintenance of the atmospheric heat energy and an evaluation of astrophysical theory of solar evolution.

The ultimate source of this energy is the sun and the level of this energy is fundamentally determined by solar luminosity, which has been slowly increasing according to astrophysical theory. If we consider the present atmosphere and neglect that portion of the solar constant lost through reflection by the earth and atmosphere (about 43 percent), only one-fourth of the isolation is directly absorbed by the atmosphere and the remaining three-fourths by the earth's surface. This results from the transparency of the atmosphere to the visible spectrum which composes about 90 percent of the solar constant. For the most part, the lower atmosphere is directly heated from below in order of importance by (1) absorption of long wave (infrared) reradiation from the earth's surface, (2) release of latent heat of condensation from water originally evaporated through the energy of the short radiation by the oceans, and (3) direct conduction from the surface followed by turbulent (convective) transfer.

Infrared absorption in the atmosphere is accomplished chiefly by water vapor and carbon dioxide with the former being much more important at present in view of its greater atmospheric abundance and its much more effective absorption over a broad spectral range. The composition of the atmosphere thus plays a very important role in its heat budget. This composition must be considered for the primitive atmosphere before solar luminosity can be directly related to early surface temperature conditions.

We can make a good estimate of the present greenhouse effect of the atmosphere from the infrared absorption just described. The radiation temperature of the earth's surface is 246°K for a terrestrial albedo of 40 percent. As the average surface temperature of the atmosphere is 288°K (International Standard Atmosphere), the present greenhouse effect of 42°K is quite significant.

To consider water vapor first, a mutual interaction exists between air temperature and water vapor content. The temperature of the air determines the vapor density of water whose greenhouse effect further increases the heat budget of the atmosphere. With a fairly unlimited oceanic supply and a given lumi osity, equilibrium air temperature and water content will tend to form as at the present time. Unless the air temperature were higher than that at present, from the effect of radiation absorption by other constituents, the water vapor density could never have exceeded the present. Even the present atmosphere, with an available water supply covering 70 percent of the earth's surface is not saturated.

If the oceans accumulated slowly through exhalation from the earth's interior, as discussed by Rubey (1951) and supported by Kulp (1951), the their early volume and surface area must have been quite limited. Hutchinson (1954) also estimates the prebiological ocean volume to be no more than 5 to 10 percent of the present oceans. On the basis of a probable slow accumulation of the hydrosphere together with the dependence of temperature on solar luminosity, we must regard water vapor as unimportant in affecting the temperature in the primitive atmosphere.

At present these is also incomplete agreement about the composition of the early atmosphere as regards the other volatiles, including those which might strongly affect the atmospheric heat budget. Urey (1952, 1959) considers an early atmosphere as consisting of water vapor, hydrogen, methane and ammonia with the quantities of each being uncertain. Although methane has some absorption bands in the infrared, the intensity and spread of this absorption is very small compared to water vapor, and even to carbon dioxide. Further, as discussed by Hutchinson (1954), oxygen, produced by photo-decomposition, would have oxidized methane to carbon dioxide, which is suggested as an important source of the latter. If exhaled slowly during geologic time, as suggested for other volatiles, the concentration of methane may never have been great. Urey (1952) also notes that in the presence of water carbon dioxide pressure must remain low because of reactions with silicates. (Apparently carbon dioxide would have had a low concentration in the early atmosphere and therefore would have been of little importance in the atmospheric heat budget.)

Rubey (1955) rejects Urey's estimate of the composition of the early atmosphere on the basis of geochemical observations and reasoning, proposing instead that nitrogen and carbon dioxide were the dominant gases present. Rubey examines two primitive atmospheric models having high and low densities of original volatiles. He concludes from the geologic record that the carbon dioxide concentration could not have been excessive having accumulated gradually during geologic time.

Ammonia is the only other volatile suggested for a primitive atmosphere that is effective in the absorption of infrared in the band important in the greenhouse effect. However, the high solubility of ammonia in water would prevent the accumulation of an ammonia atmosphere significantly denser than the aqueous content of the present atmosphere. Presumably, the production of large quantities of ammonia would involve the simultaneous generation of large quantities of water into which the ammonia would dissolve indicating that it could not cause a large greenhouse effect in the primitive atmosphere.

In his three-stage model for the evolution of the atmosphere Holland (1962) proposes that methane and possibly hydrogen were the major constituents in the first stage, lasting about 0.5 b.y. (or not less than 4 b.y. ago). In his second stage, which lasted about 3 b.y. during which the pressure probably never exceeded one atmosphere, nitrogen became the dominant component, with water vapor and carbon dioxide important minor components, and with methane and ammonia being trace constituents. Holland's first and early second stages would embrace the interval important to this investigation.

The most reasonable conclusions we can make at this time from the observations and deductions of geochemistry are that the early atmosphere was probably no more, and very likely less, absorbent in the infrared region than the present atmosphere. Surface air temperatures must therefore have been controlled primarily by the direct influence of solar luminosity rather than the greenhouse effect. As such, the time of earliest detectable liquid water able to cause erosion and transportation of sediments (about 4 billion years ago) establishes the earliest time at which solar luminosity reached a value necessary to sustain above-freezing temperatures.

In applying this conclusion to astrophysical theory of solar evolution, we can utilize the luminosity calculations of Haselgrove and Hoyle (1959) which lead to a solar age of 5.3 b.y. In view of the uncertainty of nuclear data and theory and initial solar composition, Hoyle (1960) has estimated the uncertainty in solar luminosity calculations to be about 25 percent. The geologic results may thus be of considerable value in establishing permissible values for these calculations.

Table 1, which has been developed from the age calculations of Haselgrove and Hoyle, shows a time scale of solar evolution and resulting terrestrial surface temperatures according to a choice of initial conditions. Time before the present is shown in the first column, the ratio of past to present solar luminosities in the second column, the ratio of past to present black body temperatures in the third column (based on the fourth root of the luminosity) and three sets of values of resulting surface air temperatures in the last three columns.

In the column headed T_1, the ratio $T-T_0$ is applied to the present average surface air temperature of 288°K. Because studies of Cenozoic

TABLE 1.—*Variation in solar luminosity and related terrestrial surface air temperatures*

Time b.y.	$\frac{L}{Lo}$	$\frac{T}{To}$	Surface Air Temperature °K		
			T_1	T_2	T_3
0	1	1	288	295	246

−3.0	.80	.95	272	279	233
−4.0	.74	.93	267	273	288
−4.5	.72	.92	265	271	226

climate indicate a slow cooling which culminated in the Pleistocene Ice Age, preceded by a warmer and more equable global climate, it may be more correct to use an estimated pre-late Cenozoic average of 295°K. Column T_2 is based on this value. As noted earlier, the present radiative equilibrium temperature of the earth (which omits the present greenhouse effect) is 246°K. Column T_3 indicates past temperature based on this value.

If terrestrial surface temperatures crossed the freezing threshold 4 billion years ago, the values in Column T_2 seem to give the most compatible fit between obsevration and theory. We must emphasize that the assumptions involved in determining T_2 are the most favorable for producing an early crossing of the freezing threshold. As a consequence of the flatness of the luminosity curve in Figure 2, the change in a billion years is only 3 degrees so that the theoretical resolution of the time—temperature points is rather coarse. Small changes in the theoretical $L-L_0$ can shift the freezing threshold over a long time interval. According to Column T_1 (based on present temperatures) the freezing point would not have been crossed until about 2 billion years ago. Although the data in Column T_3 do not apply directly to recent air temperatures, which, as noted earlier, are controlled by a strong greenhouse effect, they might very well apply to the very early atmosphere. The resulting greenhouse effect could have been considerably less than that of the present. It may therefore be reasonable to trace the surface air temperature curve from the lower part of Column T_3 to the upper

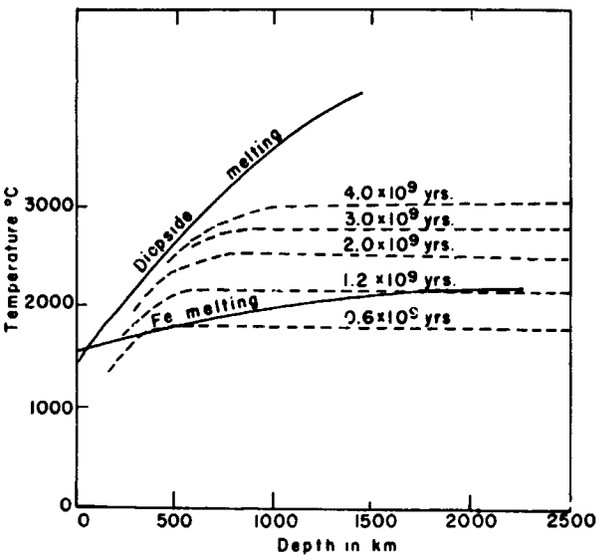

FIGURE 2.—Temperature variation in a homogeneous earth of chondritic composition having an initial temperature of 1300°C. (After MacDonald, 1959)

part of Column T_2 as the greenhouse effect became more important at which time a steepening of the temperature curve would occur.

Before evaluating these temperature relations further, another important consideration must be examined. It was noted previously that the current radiation temperature of 246°K is based on an albedo of 40 percent. However, if the early temperatures were sub-freezing as indicated by present astrophysical theory, then a considerable terrestrial frost coating must have existed, comparable to the probable frost coating responsible for the Martian polar cap. Such a coating requires a very minute amount of water and would have raised the albedo above 40 percent resulting in lower early temperatures in each of the last three columns.

The importance of a highly reflecting primitive frost coating is strongly emphasized from recent theoretical and empirical meteorological observations. For an atmosphere transparent to incident radiation, Budyko (1962) has calculated that a snow and ice cover over the entire earth for a short period would decrease the mean temperature by about 100°C. His work suggests that the present strong contrast in zonal temperatures between low and high latitudes is the result of reflection from the ice cover in both polar regions.

On a more empirical basis, Namias (1963) showed that temperatures over central United

States were as much as 6°C below expected values as a consequence of the additional reflection from somewhat extended snow cover in this region from mid-February to mid-March 1960. In a very similar investigation, Adem (1964) considered the effects of the snow cover of December 1962 which extended several degrees farther south of the normal coverage for northern United States and large parts of Europe and Asia. Observed departures of temperature from normal for January 1963 reached 6°C and 10°C below expected values for North America and Eurasia, respectively.

Although it seems certain to us that a primitive frost coating existed, the time would depend upon the rate of formation of the atmosphere and hydrosphere as well as on solar luminosity. If the atmosphere grew slowly, a higher than predicted luminosity would have been required to produce above-freezing temperatures on the primitive earth. We cannot do more than touch on the problem of the frost coating at present. Temperatures would certainly rise discontinuously at the time the frost disappeared.

Although there is, of course, much uncertainty in the geologic interpretations of the age and composition of the earliest rocks and the implied geologic precesses described earlier, it appears that somewhat warmer conditions probably existed 4 billion years ago than current theory indicates. If the interpretations are valid, alternative hypotheses affecting early temperature must be considered. 1. The composition of the primitive atmosphere may have been such as to produce a much greater greenhouse effect than the present, used in Table 1. As discussed above, we have rejected this possibility based on current information. 2. The zero age of the sun may be greater than that used in current astrophysical calculations, as suggested earlier, in which case the earth may also be older than 4.5 b.y. 3. The model of solar composition may require some modification to permit higher luminosities than the values in Table 1.

Rates of Erosion

The data and deductions given above all lead to the conclusion that rates of weathering and erosion during the early period of earth history must have been distinctly slower than at present. According to the current astrophysical theory described, terrestrial surface temperatures were significantly lower about 4 billion years ago than they are at present. It is also likely that for a long time, running water may only have existed during the summer seasons. Hence, both chemical and mechanical weathering in addition to water erosion and transportation would have operated relatively slowly.

In addition to the temperature effect, the composition of the atmosphere, which was so different from that of the present, would have also acted to slow the rates of weathering and erosion. Owing to the probably absence or low atmospheric density of water vapor, oxygen, and carbon dioxide referred to earlier, rock decomposition must certainly have been very retarded in comparison to the current activity of the hydration, oxidation, and carbonation processes. The importance of the latter has been stressed in the important equilibrium reaction described by Urey (1952) as follows:

$$Ca\ SiO_3 + CO_2 \quad CaCO_3 + SiO_2$$

$$Mg\ SiO_3 + CO_2 \quad MgCO_3 + SiO_2$$

Further, Rubey (1951, 1955) and Turekian (1959) have emphasized the importance of the presence of organic acids in the weathering of silicates. They point out the slowness of the decomposition processes referred to above if such minerals are in contact with water lacking these impurities. Thus when all of these factors—the probable low temperature, the effects of atmospheric composition on rock weathering and the lack of organic acids early in earth history—are taken together, it seems reasonable that early weathering and erosional processes must have been relatively slow, and must have increased in tempo during geologic time. This reasoning has led in part to the estimate of 0.5 b.y. for the duration of the earliest geosynclinal cycles, referred to in an earlier section, and also leads to the conclusion that the duration of individual geosynclinal cycles should have decreased with time.

Formation of the Continents

All of the direct conclusions from the oldest rocks lead directly to a consideration of the mechanism of formation of the earth's continental crust. It would seem that the presence of

early continental platforms must have been the product of a low density crust approximating the composition of granite just as is true of the present continents. This leads directly to the age old question of how these early granitic continental masses originated. Also, how different were they from the present continents, which have a volume of about 6×10^9km^3 and a mass of about 1.7×10^{22}Kg, 95 percent of which are composed, exclusive of sediments, of granites and grandiorites or their metamorphic derivatives.

It is commonly held (e.g., Barth, 1962, p. 352) that "most continental rocks are simply recycled, modified sediments." And we now see evidence for the existence of granitic continental material prior to the earliest recognizable sedimentary cycle. The major problem in this connection is whether the granite was secondary, having been derived by differentiation or granitization, or whether this granite was in a sense an original part of the earth's crust.

Closely involved with this problem is the time scale available for primeval terrestrial processes. The most fundamental information related to the time scale comes from studies on the thermal history of the earth. MacDonald's comprehensive study (1959) considers a large number of models which include a spread of initial temperatures and a different distribution of heat sources, all for an earth of chondritic composition. Of particular interest here is his model 14 using an initially homogeneous earth with a uniform temperature distribution of 1300°C after accumulation. The discussion given earlier on the origin of the earth suggests a model similar to this but probably at a lower temperature. In any case, as we discussed, the surface must have been well below the melting point.

MacDonald finds, even for the high initial temperature of model 14, that 10^9 years would be required to reach the melting point of the metallic phase. The mantle temperature would never exceed the melting point of silicates during this time. According to these results, the separation of the earth into core and mantle would hardly have begun by a billion years after formation. Elsasser (1963, p. 2) notes that the separation of the iron would not occur until the silicate matrix becomes sufficiently soft as its temperature approaches the melting point. MacDonald's calculations (Fig 2) show that below the 1000 km the temperature after a billion years is about 1500°C below the silicate melting point. Although the upper 500 km remained at about a constant temperature, that of the deeper portion are shown to have been warming nearly uniformly.

The thermal history of the earth developed by Lubimova (1958) is essentially in agreement with the somewhat more comprehensive treatment of MacDonald. The separation of the earth into a metallic core and silicate mantle must be concluded to have been a slow process based upon the arguments and conclusions given here. Segregation in the upper mantle would also be delayed until about a billion years after accumulation.

In the light of the data and conclusions given so far, we will now examine mechanisms which have been proposed for the development of the continents.

1. The generation of secondary granite by the extreme differentiation of a basaltic magma presents several problems. First, such a basaltic magma can develop only about five percent of granite. We do not find the rocks that would represent the remaining 95 percent in the regions where granites are prevalent. Second, the residual differentiates of most rocks are retained within their masses rather than being excluded to form a granite body. Barth (1962, p. 121–125) discusses this problem further and expresses the difficulty involved in the derivation of the great bulk of granite by differentiation of basaltic magma.

Metasomatic granitization has been called upon to explain the origin of granites by many authors (summarized by Barth, 1962, p. 349–357). The mechanism proposed involves the upward migration of K, Na, Al, and Si and the downward migration of Ca, Mg, and Fe. We do not see how there could have been enough time for this process to have generated the primordial continental masses between the times of aggregation of the earth and of the earliest demonstrably geosynclinal cycle especially in view of the time scale developed from the thermal history. This is supported by the geologic data from Southeastern Africa which indicates the presence of a relatively large amount of granitic material during the earliest sedimentary cycle. It therefore seems hard to escape the conclusion that a substantial primordial continental crust of granitic composition

existed in at least the regions described and that this crust provided much of the source material for earliest erosion.

Further, the conclusions of Rubey (1951) and Kulp (1951), and Holland (1962) that the hydrosphere and part or all of the atmosphere accumulated slowly and continuously during geologic time, tend to refute the possibility of a fairly rapid separation of sialic components from the mantle to form the early continents. If the volatiles were released from the interior slowly, the rapid rise of the mineral constituents required for continental formation would hardly have been possible.

Engel (1963) has reworked somewhat the concept of continental growth by accretion through the development of granitic material in orogenic processes within island arcs. It seems to us that the instability related to geosynclines and island arcs is the result of the presence of continents, rather than the cause of them. Further, sialic intrusive and extrusive masses within modern and ancient arc complexes may represent in large part at least, the recycling of material already present in the margins of continental blocks. The andesite zone may simply represent the region of mixed continental and oceanic material. If we try to visualize the primitive earth before the development of sialic material, it is difficult for us to imagine the development of geosynclinal piles without the presence of blocks of significant relief resulting from original differences in density.

(2) The convectional process involves the cellular motion of the mantle resulting in the accumulation of a granitic differentiate into localized masses at the earth's surface. This is often visualized as occurring from an originally uniform surface scum of sialic composition and seems more readily explainable under the condition of an original molten earth than under the conditions of cold accumulation stressed in this report.

Convection within the hot mantle has been proposed as an explanation of the continents by Vening-Meinez (1962) and has been elaborated by himself and others. Urey (1952b) suggests that continuous segregation of metal and silicate phases may supply energy for convection through the gravitational energy released in building the metallic core. However, the existence of viscous flow in the mantle basic to any convective process has been questioned by Jeffreys (1959), and more recently by MacDonald (1963) and Knopoff (1964).

On the basis of the known thermal gradient the rate of surface creep from convection has been estimated by Scheidegger (1958) and Dietz (1961) to spread over an order of magnitude from about 2.5 mm to 2 cm per year. In the application of recent experimental and theoretical results from upper mantle processes of the present and relatively recent past, Orowan (1964) has concluded that a convectional velocity of the order of 1 cm per year is possible. In the Pacific Ocean this would mean, for a value of 2 cm, that the crust could have been displaced from the center of the ocean to the shores of the Americas and Asia (about one-quarter cycle of the convection cell) since early Mesozoic. Four to five complete cycles could have occurred since 4.5 b.y. ago, the estimated age of the earth's crust, if the rate has been fairly constant.

Differentiation in the earth was certainly an inefficient process. If we assume only one cycle was sufficient, the accumulation of a continental crust would have taken about a billion years at the above rate. To this must be added the time to heat the earth sufficiently for convection to occur. According to the results of both MacDonald and Lubimova given above, the thermal gradient of the mantle has been steepening with time, so that present convection, if occurring, could hardly have begun until about a billion years after the earth accumulated. Convection does not seem therefore to be a valid mechanism for the accumulation of the continents. Evidence presented in the section on solar luminosity leads to a possible interpretation of a much greater age for the sun, and consequently of the earth. If true, a longer time interval would become available for the initial warming of the interior.

In addition to the arguments above, we therefore do not see how differentiation or metasomatic granitization or convection could have produced discrete continental masses within the required time limits despite recent proposals by Engel (1963) and MacDonald (1963). To accomplish this within the currently accepted age of the earth of 4.5 b.y. we are led into the problem of the accumulation of this granitic crust by some mechanism other than by geologic processes. An

alternative mechanism that seems worth considering at this time is the impact of large-size sialic bodies.

3. The origin of the continents from the impact of one or more continent-size bodies of low density would avoid many of the problems arising from their origin by differentiation of original terrestrial material. If the volume of the sialic continents is taken as 6×10^9 km^3 (30 km in thickness; 208×10^6 km^2 in area), the radius of the equivalent single body is about 1.13×10^3 km. The present distribution of the continents suggests that if such an origin occurred, it was more likely from several large bodies, with the larger continents resulting from an overlapping effect. Australia and Antarctica would thus require the infall of bodies with dimensions of about the largest of the asteroids, Ceres, which has a radius of 370 km.

In considering this mechanism of continental origin, Howell (1959) advanced as objections the lack of known sialic meteorites and the probability that complete vaporization would occur from the energy if impact.

Although the first objection raises a real problem, two ways around it exist. The moon has more than the required radius to produce the largest continents and has very nearly the right density. Why the moon's density is so low we do not know and indeed Urey (1962) has struggled with this difficulty for a long time. But if we accept the moon as forming separately from the earth then we have demonstrable evidence that continent-forming objects did exist.

Further, one should not equate the composition of the present crust with that of the impacting objects. The latter would have been modified by mixing with surface material during the collision as well as by subsequent geologic processes particularly involving invasions from the mantle.

The second objection offered by Howell to the impact theory does not seem very strong, especially if the impact was not higher than the escape velocity. If complete fusion occurs, the process would be aided by greater ease of both mixture with the mantle and differentiation of petrologic components. At the present time it cannot be said with great certainty what proportion of the energy of impact will be involved in the processes of melting, vaporization and shattering.

Some fraction of the material must have spread over the surrounding region to a considerable distance. Geologic activity over 4 billion years would have erased any initial structural details. The question to be answered is whether sufficient material would remain to serve as primeval continents. In view of the difficulties with gradual formation of the continents raised by this study and the fact that continents do exist, an affirmative answer appears to be a reasonable working hypothesis.

If formed in this manner, geological processes within the crust and upper mantle would certainly have modified the original shapes, dimensions and composition of the continents. If convectional processes have operated in the mantle as postulated by so many, then continental deformation would have been restricted to the outer rather than the inner portions of continents. The recycling of sediments in the border region while rock from the interior was carried outward almost continuously might give the impression of continental growth by accretion at the margins. At first glance this accretion picture looks much better for North America with its central shield than it does for the other continents. And even in North America, one of the oldest rock occurrences so far recognized occurs in the Northern Rocky Mountains which show recycling and new orogenic activity as recently as late Cretaceous, while in Africa and Eurasia, the oldest rocks occur near continental margins.

The impact hypothesis does not provide immediate explanations for the apparent differences in the nature of the continental and oceanic mantle to a depth of several hundred kilometers. The most cogent differences are those related to differences in seismic velocities. MacDonald (1963) summarizes the seismic results and offers other evidences for differences between continental and oceanic mantle based on conclusions from gravity and thermal observations. Although we cannot at present evaluate the effects of impact on the mantle to a depth of some hundreds of kilometers, it may be expected that some differences would develop during several billions of years.

The small differences in heat flow between the continental and oceanic crust, the data for which are also summarized by MacDonald, cannot be readily explained by the impact hypothesis except

to note that original differences may have been minimized by geological processes involving interactions between the crust and mantle. It should be noted however that the many locations of high heat flow on the continents are considered anomalous and excluded from comparisons.

Unless the age of the earth is substantially higher than 4.5 b.y. a terrestrial mechanism of origin seems unlikely in view of the presence of continents and normal geological processes as remote as 4 billion years ago. Without a substantial revision of the age of the earth we submit that the impact hypothesis of origin is as cogent as any other so far offered. The only alternative seems to be an accumulation temperature closer to the silicate melting point which is contrary to the evidence for cold accumulation discussed previously.

CONCLUSIONS

A number of geological and astrophysical inferences can be made from the nature and ages of the oldest rocks, especially when considered in the light of conclusions regarding the age and accumulation of the earth and the evolution of the sun. We wish to emphasize that many of these conclusions must be considered tentative pending further investigation, but we believe the conclusions to be of value in setting up guide lines and certain limiting conditions.

1. Radioisotope dates lead to the inference that at least parts of three major continents were present at least 4 billion years ago.

2. Since the finding of the oldest rock record is in part fortuitous and in part the result of subsequent geologic history, the primitive continents must have been considerably larger than the regions of oldest rock occurrence.

3. Quartz-bearing sialic rocks must have existed in the early continents in at least sufficient quantities necessary to provide the observed sediments and granite gneiss complexes.

4. Subaerial erosion by running water probably existed 4 billion years ago.

5. The surface temperature must have been above freezing over much of the continents about 4 billion years ago, with solar luminosity being the major factor in controlling terrestrial surface temperatures. According to current models of solar evolution the surface temperatures would probably have been sub-freezing at this time.

6. Aqueous erosion was probably present 4 billion years ago. To account for this, it may be in order either to push back the ages of the earth and sun or to modify the models used.

7. Rates of erosion of bed rock are proportional to temperature, humidity and organic acids. As these all increased during geologic time, it seems that sedimentation rates should also have increased with consequent decrease in the length of geosynclinal cycles. (N.B. This argument refers to the weathering of bed rock rather than mantle rock which may become more coherent through the binding action of plants.)

8. From published calculations on the thermal history of the earth it can be concluded that the melting of silicates in the mantle would not have occurred during the first billion years of earth history. This seems to obviate the possibility that continents formed by any segregation process from the mantle unless the earth were considerably older than 4.5 billion years.

9. The alternative proposal is offered that the continents originated from the impact of a swarm or swarms of low density meteoritic material. Fusion and admixture with mantle material by geologic processes would have modified the original material into the present continents, which for the most part seem to consist of recycled sedimentary rocks. The unstable continental margins would tend to suffer fairly continual orogeny creating the impression of accretion around a central nucleus or craton.

LOW INTENSITY DECAMETER EMISSIONS FROM JUPITER*

J. K. ALEXANDER AND R G. STONE

Observations of Jupiter with the 26.3 Mc/s Christiansen-type array of the Clark Lake Radio Observatory have been analyzed with a view towards the determination of how the noise storm morphology might be altered when very weak activity (flux $< 10^{-23}$ w/m²/cps) is included. Analysis of the distribution of activity with system III central meridian longitude shows the same general shape as reported by other workers. Although the occurrence-probability histogram peaks are somewhat broadened in comparison to other less sensitive surveys in this frequency range, the region from 330° to 45° longitude still appears completely void of activity. Analysis of the intensity distribution at 26.3 Mc/s suggests two components of the emission. One component is comprised of a large amount of weak activity of flux density between 10^{-23} and 10^{-22} w/m²/cps. The other, secondary component is comprised of strong activity of flux density greater than 7×10^{-22} w/m²/cps and may correspond to the radiation commonly observed by workers at lower frequencies.

During September and October, 1963, and February and March, 1964, the 26.3 Mc/s radiation from Jupiter was systematically observed with the University of Maryland decametric antenna at Clark Lake, California. In view of the particularly high sensitivity of this instrument ($<5\text{x}10^{-24}$ w/m²/cps) special attention was given to the determination of how the apparent properties of the Jovian decameter radiation might be modified by the ability to detect emission considerably weaker than that observed by most other workers. A report of the results of this study follows.

The antenna is a Christiansen-type array consisting of 8 elements spaced at intervals along a two-mile E–W base line. Each element is an N–S colinear array of 91 full-wave dipoles. The response pattern of the array is multilobed—the individual lobes having half-power widths of 10′E–W by 3°N–S and E–W spacing of 1.5°. The declination of the response pattern can be set between 3°N and 63°N by adjusting the phase difference between the individual dipoles of the array. Therefore as a discrete radio source moves across the sky at sidereal rate it passes through one of the lobes of the grating response every six minutes. This feature simplifies identification of the emission since the times at which activity from the planet is detected must correspond to the passage of the source across one of the lobes of the response pattern. We note in this regard that the average difference between the observed and calculated lobe crossing times was about ±18 sec. which corresponds to apparent angular shifts in right ascension of about 4′. Since ionospheric refraction normally causes position shifts of this order in the case of "radio star" observations, we can say that within the limits of our system the noise storm did indeed originate at the planet. A typical record of a Jovian noise storm is shown in Figure 1.

The receiving system is a Ryle-Vonberg radiometer having an integration time of 2 sec. The receiver bandwidth was 35 kc/s during the 1963 observations and 800 kc/s during the 1964 observing period.

The 1963 observations were made nightly from September 19 to October 11, inclusive, with an average observing time of 3.3^h per night. Since meridian transit occurred between 00^h and 02^h local time, the observations were free from interference due to solar noise, and man-made interference was at a minimum. The 1964 data were collected between Feburary 13 and March 14, inclusive, with an average daily observing time of 2.5^h. Jupiter was near conjunction during this period, and hence, meridian transit occurred in mid-afternoon. As a result, interference from

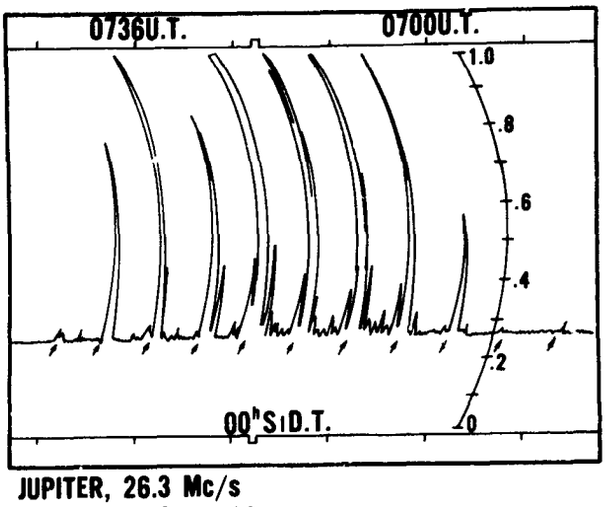

FIGURE 1.—Tracing of a typical Jovian noise storm as observed with the Clark Lake array. The short arrows indicate the calculated lobe-crossing times for the optical planet.

communications traffic and occasional solar noise reduced the total number of daily observations acceptable for analysis to 17.

The variation of the 26.3 Mc/s noise storm activity with system III central meridian longitude is shown in Figure 2. The histogram gives the longitudinal distribution of occurrence probability which is found by taking the ratio of the number of times Jupiter activity was observed to the number of times the planet passed one of the lobes of the grating response for each 10° longitude interval. Although the observations may not be sufficient to insure that the data are statistically complete one can still distinguish the three regions discussed by Douglas (1960): Region 1, 70° to 190°, Region 2, 190° to 265°, and Region 3, 265° to 330°. The distribution of total observations with longitude plotted in Figure 3 serves to show that at least all longitudes were nearly equally sampled during the study. One notices that the probability histogram peaks of Figure 2 are somewhat broadened in comparison to the results of other workers who have found the peaks grow narrower toward higher frequencies. In confirmation of a suggestion by Barrow (1962), it appears that detection of activity at all longitudes within the three main regions only requires sufficient sensitivity at the higher frequencies. On the other hand, this result does not lend support to a theoretical prediction by Ellis and McCulloch (1963) that the 26 Mc/s histogram peaks should be confined to narrow longitude bands. The significance of weak emission will be discussed in more detail later.

It is significant that the quadrant from 330° to 40° is completely void of activity. Although some workers have reported observing a few weak bursts in this region, especially below 18 Mc/s, Douglas and Smith (1963) report that the Yale workers have never detected storms at 22.2 Mc/s having flux greater than 10^{-21} w/m²/cps between longitudes 350° and 70°. In the case of our observations, no activity of flux greater than 5×10^{-24} w/m²/cps was detected. (On only one occasion did we observe any activity below 70° longitude.) All flux measurements were made relative to the discrete source Hercules A (3C 348)

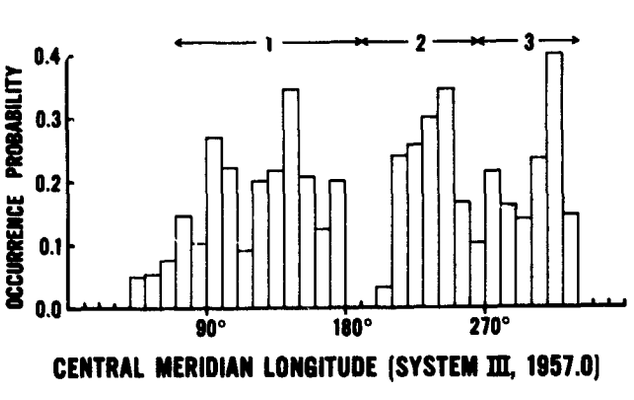

FIGURE 2.—Variation of 26.3 Mc/s activity occurrence with system III central meridian longitude. Arrows indicate location of the major regions at 22.2 Mc/s according to Douglas (1960) for comparison.

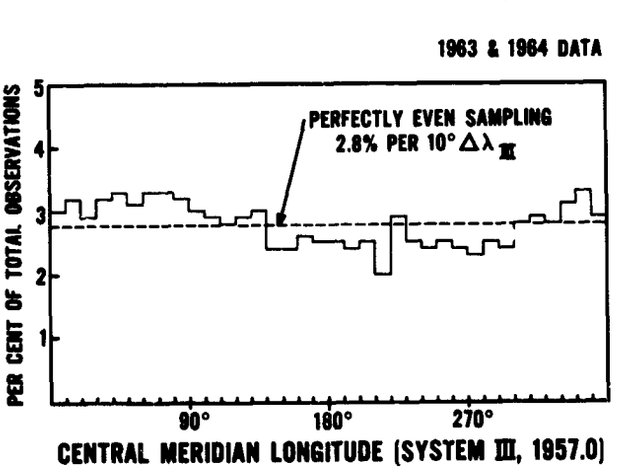

FIGURE 3.—Longitude distribution of total observations.

which has nearly the same declination as did Jupiter during these observations. The 26.3 Mc/s flux of Hercules A was taken to be 2×10^{-23} w/m²/cps (Conway, Kellermann, and Long, 1963).

One of the primary objectives of this study was to determine the number-intensity distribution of emission and to find, within instrumental limits, if there was a threshold below which activity did not occur. We must emphasize that here "activity" is defined as an abrupt increase in antenna temperature occurring at the time Jupiter transits one of the lobes of the antenna response pattern. No attempt has been made to further analyze any fine structure within the 40 seconds required for a source to drift between the half-power points of a single lobe. Furthermore, only activity detected when the planet was between the half-power points of the N–S envelope of the antenna response pattern were considered for this analysis. This condition was satisfied for an average of 1.8^h per night in 1963 and 2.5^h per day in 1964.

The histogram in the upper half of Figure 4 shows the intensity distribution for all storm activity observed in the 1963 series. One division on the abscissa corresponds to approximately 10^{-22} w/m²/cps. The most striking features of this diagram are the large concentration of activity at low intensities and the secondary peak at the high intensity end of the figure. This result would suggest that at 26.3 Mc/s the Jupiter storms are composed primarily of "weak" activity (flux less than 10^{-22} w/m²/cps) and a smaller amount of "strong" activity (flux greater than 7×10^{-22} w/m²/cps), with only rare activity at intermediate intensities.

We examine the intensity distribution of the weak activity in more detail in the lower half of Figure 4. Now the major portion of the activity is clustered at intensities just above 10^{-23} w/m²/cps

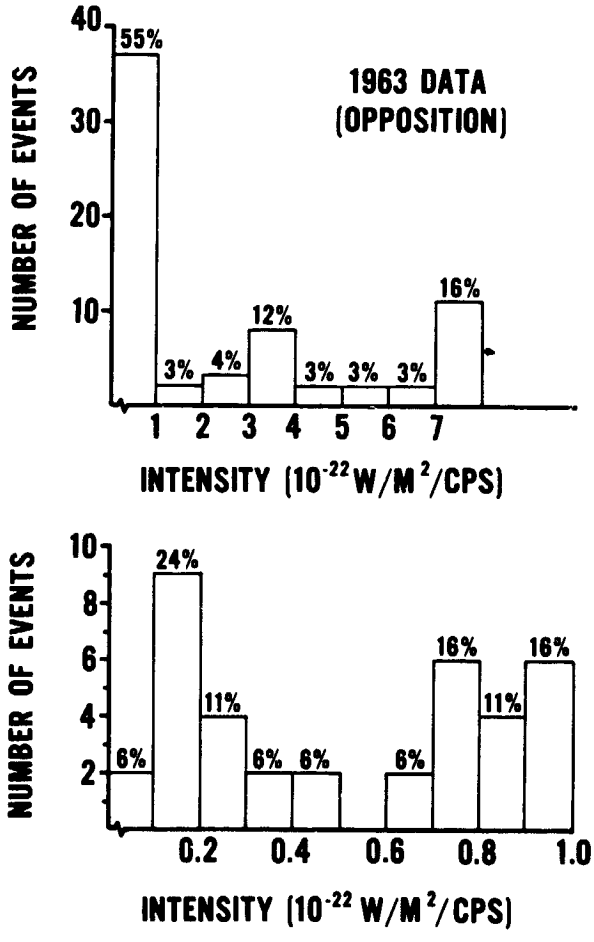

FIGURE 4.—(Upper half) Number-intensity distribution of 1963 events. (Lower half) Distribution of activity falling in first interval of upper histogram.

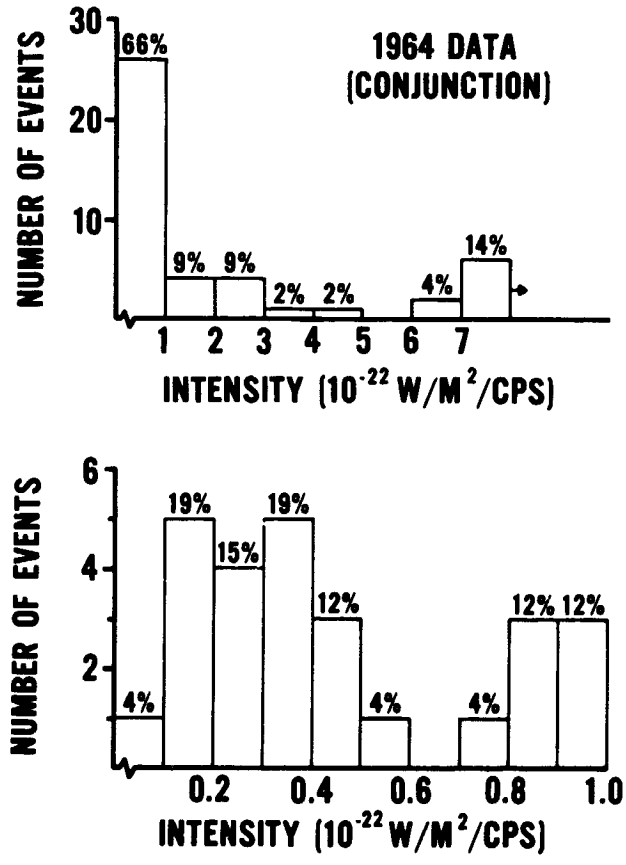

FIGURE 5.—(Upper half) Number-intensity distribution of 1964 events. (Lower half) Distribution of activity falling in first interval of upper histogram.

or at least two times the sensitivity of our antenna. A secondary peak appears around 9×10^{-23} w/m^2/cps.

The results of the same analysis for the 1964 data are shown in Figure 5. Again the intensity distribution of all activity observed is plotted in the upper half of the figure and the detailed distribution of activity falling in the first interval of the upper plot is shown in the lower half of the figure. As before, the data show a concentration of activity between 10^{-23} and 10^{-22} w/m^2/cps.

The combined results of the 1963 and 1964 measurements are given in Figure 6. The intensities of the individual events from the 1964 series were first doubled to correct for the fact that the Earth–Jupiter distance was greater by a factor of $\sqrt{2}$ than during the 1963 observations. Using the intensity distribution data of Figure 6 we may now make some general assumptions regarding the flux spectra of "typical" noise storms. Since

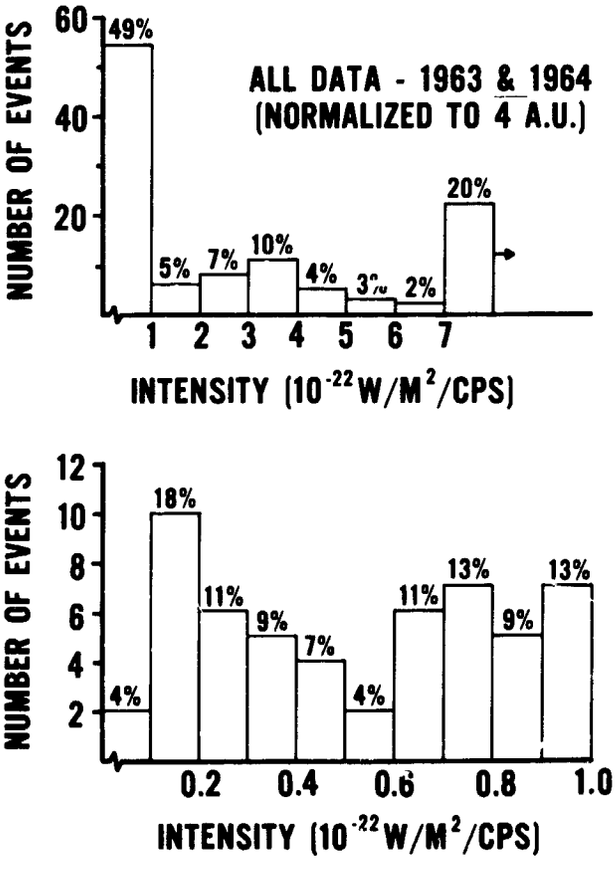

FIGURE 6.—(Upper half) Combined number-inte··· dis-tribution for 1963 and 1964 observations norma· ·o 4 A.U. (Lower half) Distribution of activity falli. first interval of upper histogram.

the Florida workers (Smith, et al.; 1963) have suggested that the flux density falls faster than f^{-5} as frequency, f, increases above 17 Mc/s, we shall assume a spectral index of -5.5. If the flux spectra obtained by extrapolation of the 26.3 Mc/s data to lower frequencies are indeed typical, then they offer an explanation of the fact that several observers report that the noise storms are generally well in excess of the sensitivity limits of their equipment. Taking the flux density for strong activity to be 8×10^{-22} w/m^2/cps, we find that at 18 Mc/s a flux density of about 6×10^{-21} w/m^2/cps in rough agreement with other reports (e.g., Smith, et al; 1963). The weak activity having a 26.3 Mc/s flux density less than 10^{-22} w/m^2/cps, however, would not exceed 9×10^{-22} w/m^2/cps at 18 Mc/s, and, therefore, would not be detected by many of the instruments presently used for Jupiter studies.

When the intensity distribution for all 26.3 Mc/s activity is determined separately for each of the three major longitude regions as shown in Figure 7, the same general shape is found with one

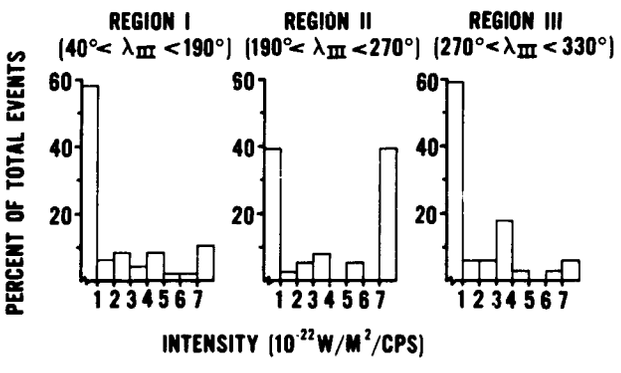

FIGURE 7.—Number-intensity distribution as a function of major longitude region. (1963 and 1964 data combined.)

interesting exception. In regions 1 and 3 the concentration of weak activity is pronounced. In the middle region, however, the weak and strong events are equally divided—each comprising 39.4 percent of the total activity observed. Such a result might have been expected from the fact that the greatest probability of occurrence for activity at frequencies nearer 20 Mc/s is found in region 2.

SUMMARY

When the 26.3 Mc/s radiation from Jupiter is observed with sufficient sensitivity to detect emission as weak as 5×10^{-24} w/m^2/cps, the variation of occurrence with system III longitude is found to have the same general shape as reported by other workers. Although the occurrence probability histogram peaks are somewhat broadened in comparison to other less sensitive surveys in this frequency range, the region from 330° to 40° longitude still appears completely void of activity. Analysis of the intensity distribution at 26.3 Mc/s suggests two components of the emission. One component is comprised of a large amount of weak activity of flux densities between 10^{-23} and 10^{-22} w/m^2/cps. The other, secondary component is comprised of strong activity of flux density greater than 7×10^{-22} w/m^2/cps and may correspond to the radiation commonly observed by other workers at low frequencies. It now remains to supplement these data with further observations at 26.3 Mc/s and new observations with comparable sensitivity at lower frequencies. If the suggestion of two components to the decameter emission is supported, then one must consider the possibility of radiation in two modes, from two radiation belts, or even by two different mechanisms.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the continued guidance and assistance of Professor W. C. Erickson who first suggested parts of this work and offered the facilities of the Clark Lake Radio Observatory for its realization. They also express their appreciation to Miss Lynn Jones who assisted in reduction of the observations. The Clark Lake Radio Observatory is operated by the University of Maryland through the support of the National Science Foundation.

AN ANALYSIS OF TIROS II RADIATION DATA RECORDED OVER NEW ZEALAND AT NIGHT*

LEWIS J. ALLISON

Infrared radiation measurements in the 8–12μ, 8–30μ, and 6.0–6.5μ wavelength regions taken by Tiros II on its initial orbit over New Zealand are examined in detail. A subjective analysis of the synoptic situation confirmed the two broad-scale frontal systems clearly outlined by the Tiros II radiation data recorded over the Tasman Sea at night. The equivalent blackbody temperatures measured in the 8–12μ region were found to be 6° to 12°K colder than the sea water temperatures in warm radiation source areas. In the 6.0–6.5μ region the equivalent blackbody temperatures, when converted to "effective radiation height," averaged 8705 feet below the tropopause at five upper air stations.

INTRODUCTION

The Tiros II meteorological satellite (1960 β I) was launched from Cape Canaveral, Florida, on November 23, 1960. It was spin-stabilized and space-oriented in a nearly circular orbit (apogee 454.4 statute miles, perigee 385.6 statute miles) with a period of 98.3 minutes. Tiros II was the first satellite to be equipped with a five-channel scanning radiometer to measure reflected solar radiation and infrared emission from the earth and its atmosphere, in addition to the two-television-camera system.

The radiation data selected for this analysis were obtained during Orbit Zero as the satellite initially viewed the New Zealand area. This study is a preliminary attempt to analyze the radiation data to delineate nighttime cloud cover over a remote oceanic area where meteorological information is at a minimum.

A brief description of the scanning radiometer and its regions of spectral sensitivity precedes the subjective analysis of the storm area. A comparison of frontal clouds with satellite radiation patterns and a preliminary tropopause height relationship with Channel 1 radiation data are presented.

THE SCANNING RADIOMETER

The five-channel scanning radiometer (Figure 1) measures the terrestrial and reflected solar radiation in selected regions of the infrared spectrum.

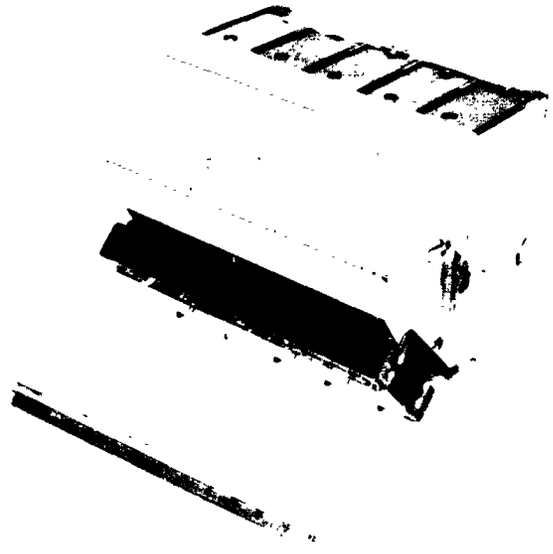

FIGURE 1.—External view of the 5-channel scanning radiometer showing the view apertures in one direction.

The five spectral regions and their characteristic functions[1] are:

- Channel 1: 6.0-6.5μ—water vapor absorption band
- Channel 2: 8–12μ—atmospheric window
- Channel 3: 0.2–6μ—reflected solar radiation band
- Channel 4: 8–30μ—thermal radiation from the earth and atmosphere
- Channel 5: 0.55–0.75μ—visible reference and daytime cloud cover

*Published as *NASA Technical Note* D-1910, March, 1964.

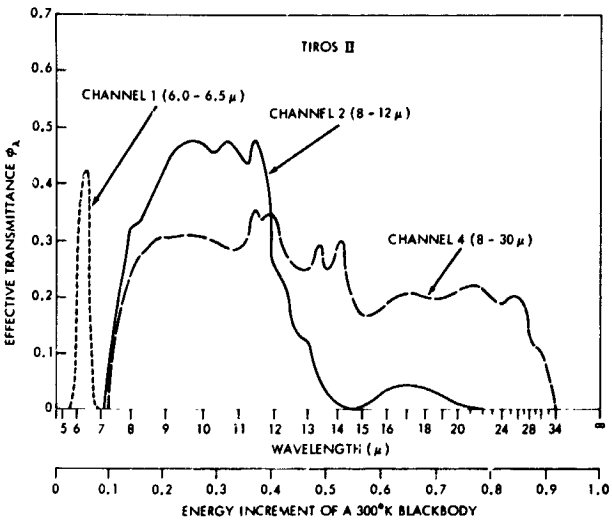

FIGURE 2.—Spectral response characteristics of channels 1, 2, and 4 of the 5-channel scanning radiometer.

The approximate transmission characteristics of the three long-wave channels (1, 2, and 4) are shown in Figure 2.

Channel 2 primarily measures the radiation (8–12μ) from the earth's surface if there are no clouds, or from the tops of clouds if they exist. The relationship between the cloud layers and the emitted infrared radiation has been expressed[2] as follows: "An overcast of dense middle and high clouds whose tops are cold, emits relatively little energy. By contrast, nearby areas of lower clouds or broken clouds or cloudless areas emit more energy. If the radiating surface is opaque, the energy emitted by the surface and measured by the satellite is related to the temperature of the surface; otherwise, the radiation is a complicated function of cloud amount and structure". A preliminary estimate of overcast cloud top heights can be made by relating the Channel 2 equivalent blackbody temperatures to nearby radiosonde temperature-height data.

Channel 4, which covers the 8–12μ window region as well as the 8–30μ region, is characterized by strong absorption bands of carbon dioxide and water vapor.

Channel 1 responds to radiative contributions, depending upon the water vapor, temperature, and pressure profiles, from a broad region in the middle and upper troposphere.

The radiometer detects the radiation energy flux viewed during a scan by means of an optical system designed to chop the radiation and apply it to five thermistor detectors. A filter system separates the five spectral regions.

The radiometer's 5 degree view angle results in a field of view encompassing approximately 40 × 40 statute miles on the earth when the sensor's nadir angle is zero. An increase in the nadir angle elongates the field in the direction viewed. The optical axes of the five channels are all parallel and inclined to the satellite spin axis by 45 degrees. Three earth-scanning modes or patterns of the radiometer (Figure 3) may be described[3] as follows:

Closed Mode: All scan spots throughout a number of spin cycles of the satellite are earth-viewed, either through the "wall" (side) sensor or the "floor" (baseplate) sensor.

Single Open Mode: Some scan spots of a spin cycle are space-viwed and the remainder are earth-viewed through the wall sensor only or through the floor sensor only.

Alternating Open Mode: The scan spots of a spin cycle are a combination of space- and earth-viewed, alternately through the wall sensor and the floor sensor.

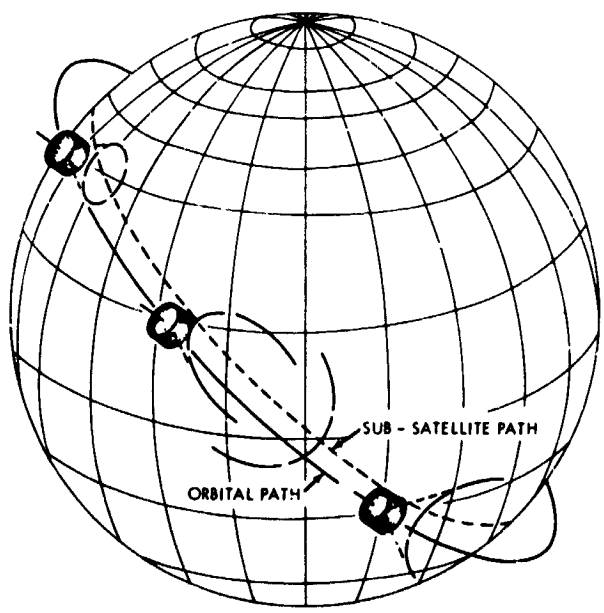

FIGURE 3.—The scan patterns of the Tiros II 5-channel medium resolution scanning radiometer. (The closed, single-open, and alternating-open modes are illustrated from left to right.)

The satellite's 8–12 rpm rotation provides the radiometer with a scan sweep that alternately views outer space (near zero radiation) and the earth's surface. The sensors measure the difference in energy flux over the scanned field of view. The sensor's output is recorded and transmitted to the ground stations where it is converted electronically into usable form. A detailed description of the data handling and conversion process has been published elsewhere.[4]

The output of the radiometers[5] can be described in terms either of equivalent blackbody temperatures (°K) or of radiant emittance (w/m²) within the spectral response curve of each channel (Figure 4). The relative accuracies of Channels 1

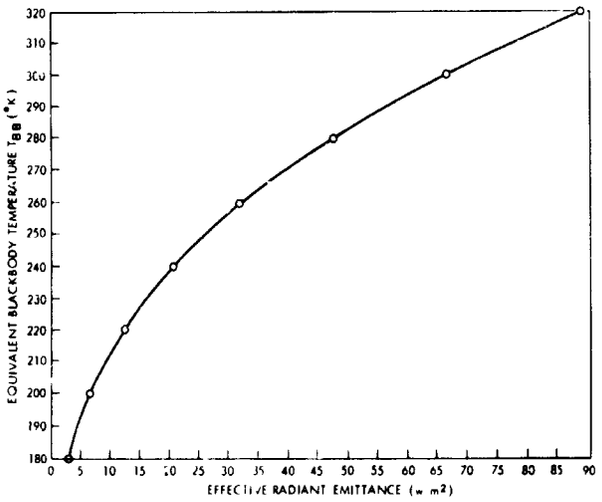

FIGURE 4.—Equivalent blackbody temperature versus effective radiant emmittance for channel 2 of the Tiros II scanning radiometer.

and 2 were estimated to be ±2°C while the absolute values may vary by ±5°C as a result of second-order effects in the calibration procedure.[6]

The radiation data for Channels 2, 4 and 1 were recorded during a 7 minute period at approximately local midnight and were reduced to usable form[5] with the aid of an IBM 7090 computer. The satellite was spinning at 8.0 rpm at swath 1 (1223 GMT), 700 miles southeast of Australia. The camera nadir angle was 127 degrees at swath 1 and slowly changed to 159 degrees at swath 74 (1232 GMT). The swath (radiation viewing path) changed from a parabolic arc to a nearly circular sweep pattern during this period.

ANALYSIS OF THE TIROS II RADIATION DATA

Four independently analyzed surface charts for 1200 GMT, November 23, 1960, were requested and received from the New Zealand and Australian Meteorological Services, the Commander of the U. S. Naval Support Force in Antarctica, and the International Antarctic Analysis Center at Melbourne, Australia, by courtesy of the U. S. Weather Bureau representative. A final composite synoptic chart and nephanalysis (Figures 5 and 6) were made from the above charts with the assistance of Lt. Comdr. John D. Ploetz, Wintering Over Officer 1960, U. S. Naval Weather Service, Washington, D. C.

The two cold-type surface meridional occlusions shown in Figures 5 and 6 had moved east and southeast off the east coast of Australia, and had intensified in the Tasman Sea, within the preceding 24 hours (November 22–23, 1960). A long north-south band of low equivalent blackbody temperatures (cold radiation sources) in the Tasman Sea (Figures 7, 8 and 9) 240° to 258°K,

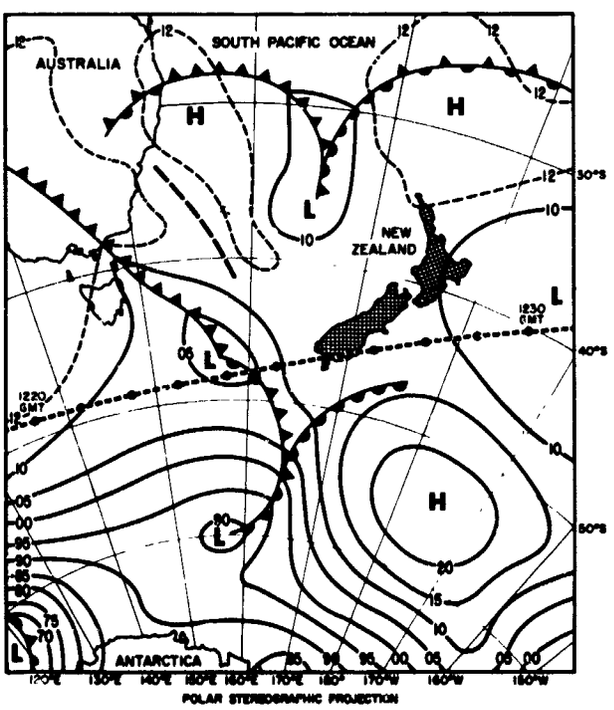

FIGURE 5.—Surface synoptic chart for the New Zealand area, showing sea-level isobars and fronts at, 1200 GMT, November 23, 1960. The satellite track during orbit 0 is shown by a heavy dashed line, with a dot indicating every minute of time.

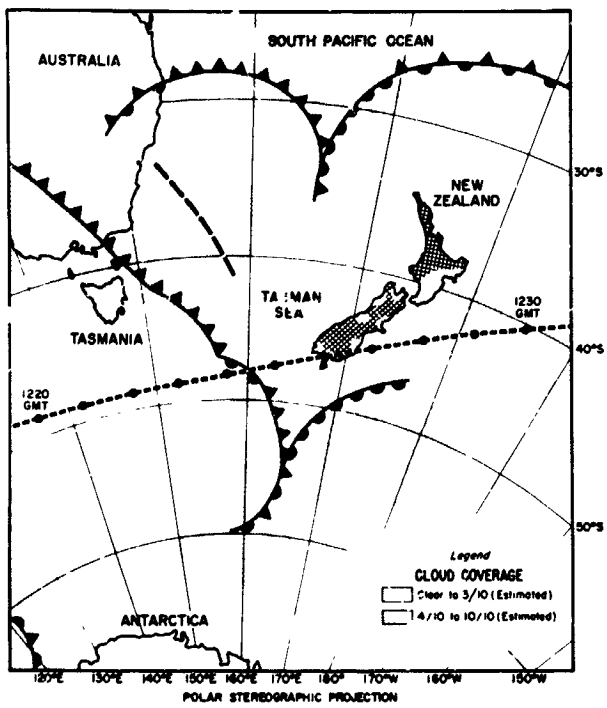

FIGURE 6.—Nephanalysis of the surface synoptic chart for 1200 GMT, November 23, 1960, on orbit 0 or Tiros II.

233° to 255°K, and 225° and 237°K, for channels 2, 4, and 1 respectively—clearly outline these well-developed occluded fronts. The shading indicates areas of cooler equivalent blackbody temperatures. By relating the above mentioned Channel 2 temperatures to nearby radiosonde data, it was estimated that the dense high overcast cloud layers in the meridional occlusions extended to heights of 5-7 kilometers.

Fritz and Winston[2] estimated the heights of the cloud tops over the United States during Orbit 4 (daytime) by use of upper air constant pressure charts, radiosonde reports, and the conversion to height of Channel 2 equivalent blackbody temperatures. It was noted that the Channel 2 blackbody temperatures recorded over thin cirriform clouds over surface fronts related to the infrared emission of the less opaque cirriform clouds and the denser (warmer) altiform and/or stratiform cloud layers below. Thus, the presence of thin high cloud layers can only be deduced by an intelligent analysis of the radiation data, synoptic situation and from climatological data.

Smaller cold radiation areas over the rugged mountain ranges of New Zealand indicate orographic-type clouds while larger cold radiation sources at 173°E longitude and 50°S latitude probably indicate alto- or cirriform-type clouds on the west side of a maritime 1022-mb surface high. Broad areas of warm equivalent blackbody temperatures 265° to 282°K, 261° to 273°K, and 237° to 246°K for channels 2, 4 and 1—occur over two surface high pressure regions. Warm radiation sources indicate areas that are: (1) cloudless, or (2) covered by warm low clouds, or (3) covered by scattered or broken clouds over a warm surface.[2] The first and third weather condition best describes the synoptic cloud cover over the weak surface maritime highs.

An air temperature and air-sea temperature difference chart for 1200 GMT, November 23, 1960 was drawn and analyzed. The waters within 10° to 15° latitude of Christchurch showed a negligible ($\pm 1°-2°$K) air-sea temperature difference both for the 1200 GMT synoptic period and for a Marsden Square oceanographic summary for November[7] (Figures 10 and 11). On air

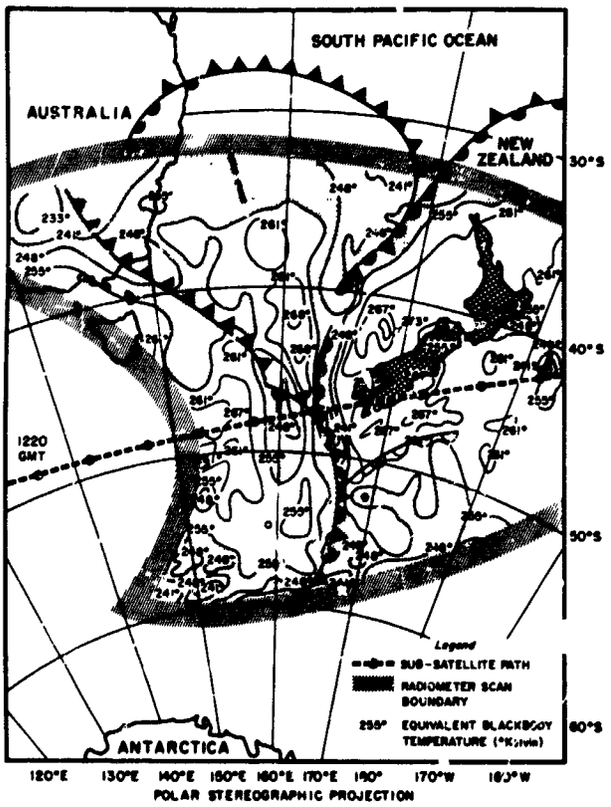

FIGURE 8.—Radiation maps from the Tiros II 5-channel scanning radiometer: Channel 4, orbit 0, 1220–1230 GMT, November 23, 1960. Equivalent blackbody temperatures of 255°K or less are shaded.

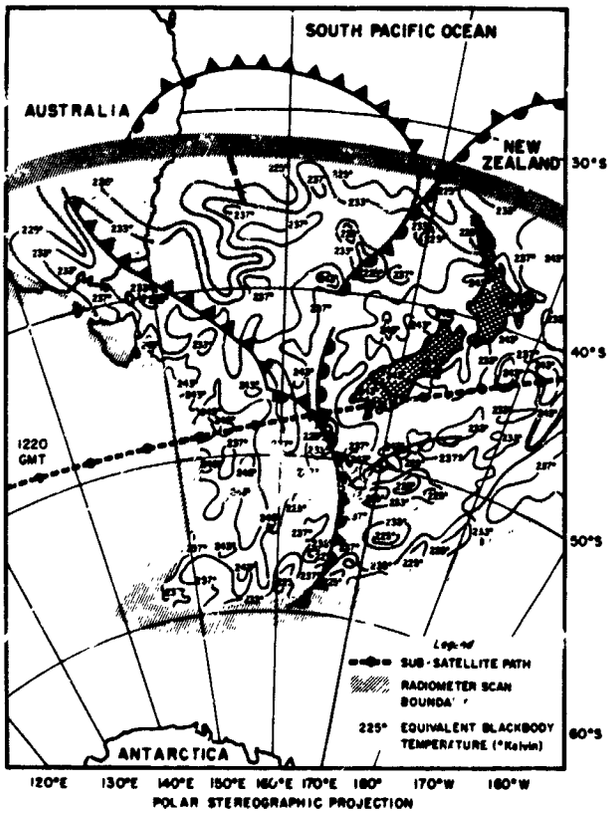

FIGURE 9.—Radiation map from the Tiros II 5-channel scanning radiometer: Channel 1, orbit 0, 1220–1230 GMT, November 23, 1960. Equivalent blackbody temperatures of 237°K or less are shaded.

temperature and air-sea temperature comparison was made where the warmest Channel 2 equivalent temperatures (282° and 278°K) had occurred. At 168°E, 42°S, the Channel 2 equivalent temperatures were noted to be 6° to 12°K colder than the sea water temperatures (Figure 10). This temperature difference was probably caused by the presence of low clouds and/or by the fact that some energy is still received in Channel 2 from atmospheric water vapor and ozone; i.e., this channel is not an entirely transparent "window."[8]

Aircraft weather reports[9] plotted from 0013 GMT, November 23, 1960 (Figure 12) helped to verify the 1200 GMT surface synoptic analysis (Figure 5). Multiple layers of low clouds (stratiform and cumuliform, with bases at 3000–5000 and tops at 6000–8000 feet), middle clouds (altostratus-altocumulus, with bases at 8000–11,000 and tops at 18,000 feet), and high clouds (cirrostratus with bases at 25,000 feet), and linse of thunderstorms (cumulonimbus—0351 GMT) were reported in the area of the meridional occlusion between 160° and 170°E and 30° and 40°S. Broken altostratus and cirrostratus cloud layers were reported by aircraft at 0612 and 0627 GMT in the same area. The presence of these dense, opaque cloud decks with tops at 18,000–25,000 feet is confirmed by the 240°–258°K equivalent blackbody temperatures recorded 6 hours later by Channel 2 (Figure 7) in the Tasman Sea.

Pilot weather reports, aided by aircraft radar, were considered to be among the most valuable sources of cloud information at night over this remote maritime area.

The most detailed upper air information for the 850 mb up through the 200 mb constant pressure level was available at 0000 GMT, November 23 and 24, 1960. The 300 mb chart (Figure 13) for 0000 GMT, November 23 was selected to show the strong circulation pattern which persisted from the 700 mb to the 200 mb level for the 24

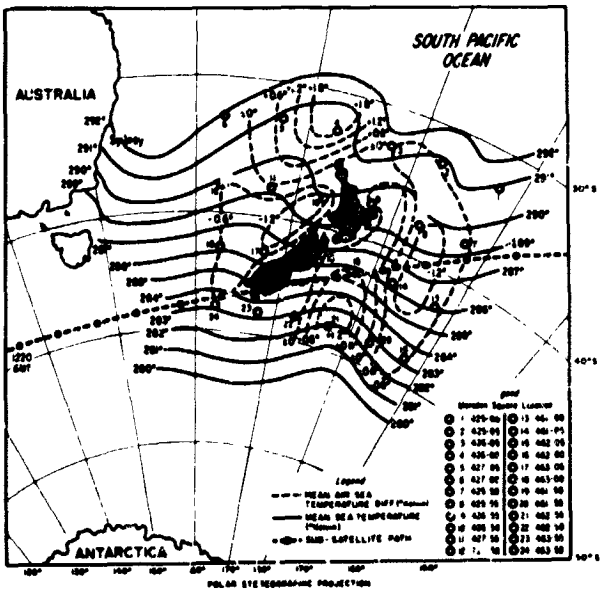

FIGURE 11.—Mean air-sea temperature difference and sea temperature chart for November (1000–1956) for the New Zealand area.

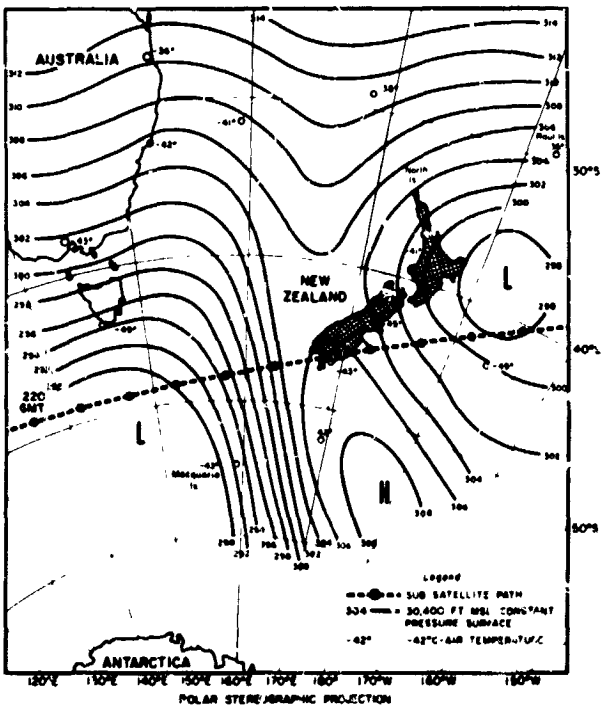

FIGURE 13.—300 mb constant pressure chart for the New Zealand area at, 0000 GMT, November 23, 1960. Tiros II, orbit 0.

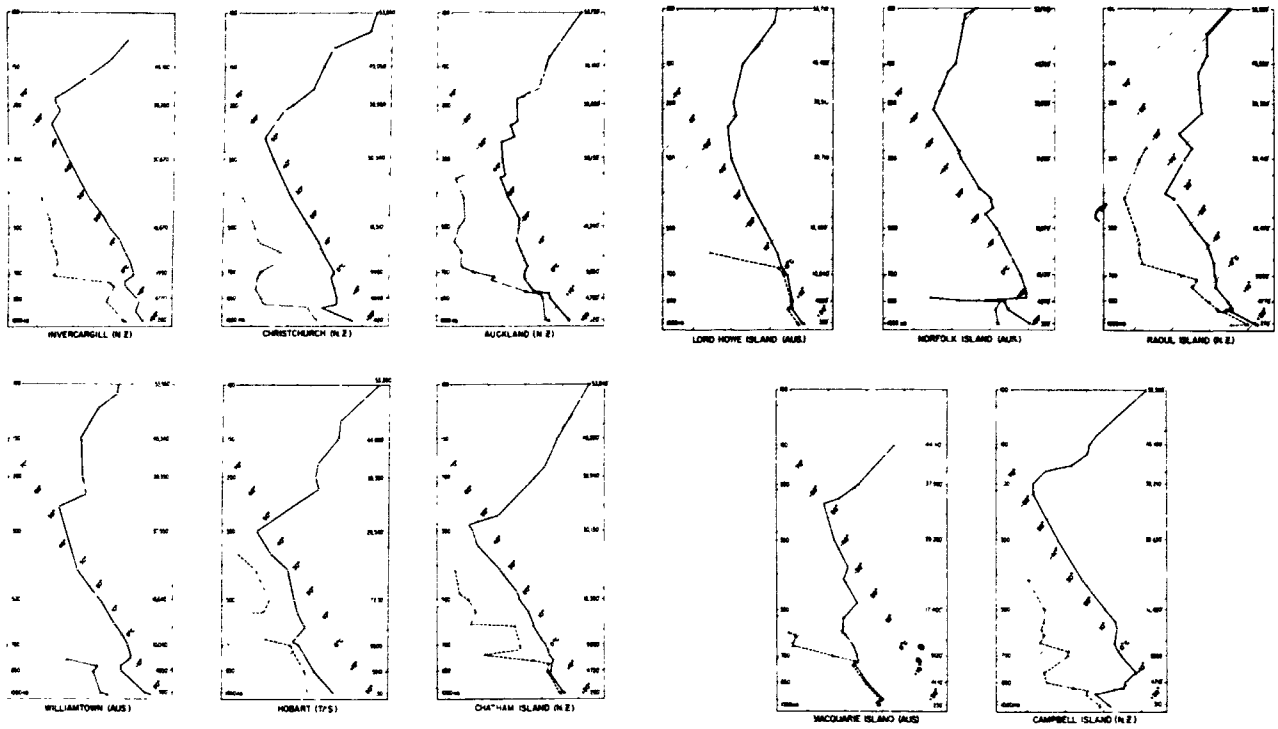

FIGURE 14.—Radiosonde soundings, at 0000 GMT, 23 November, 1960. The solid line shows temperature distribution; the dashed line, dewpoint distribution.

hour period. A strong jet stream (140 knots maximum) was oriented SSE/NNW over Macquarie Island, approximately 5 degrees west of the surface front. An 80 knot isotach maximum was located over the northeast tip of North Island, New Zealand. The 300 mb chart was included in order to complete the upper air analysis for the area.

On the basis of the subjective interpretation of the three well correlated sets of radiation data (Channels 2, 4, and 1) and all synoptic charts, the warm front originally drawn south of New Zealand was redrawn as an upper warm front and the surface portion was placed meridionally to the west of South Island, New Zealand (Figures 7, 8, and 9).

Thus, the meterorologist, through the judicial combination of Tiros II radiation data, aircraft weather reports, and all available surface charts and upper air information, can obtain a reasonably detailed nocturnal description of the horizontal and vertical cloud distribution in the stormy Tasman Sea.

TROPOPAUSE HEIGHT ESTIMATION

Widger and Touart[10] and House and Blankenship[11] have indicated that the Channel 1, 6.0–6.5μ radiation data may be useful in estimating tropopause heights. Hanel and Wark[6] have shown that Channel 1 responds to water vapor emission

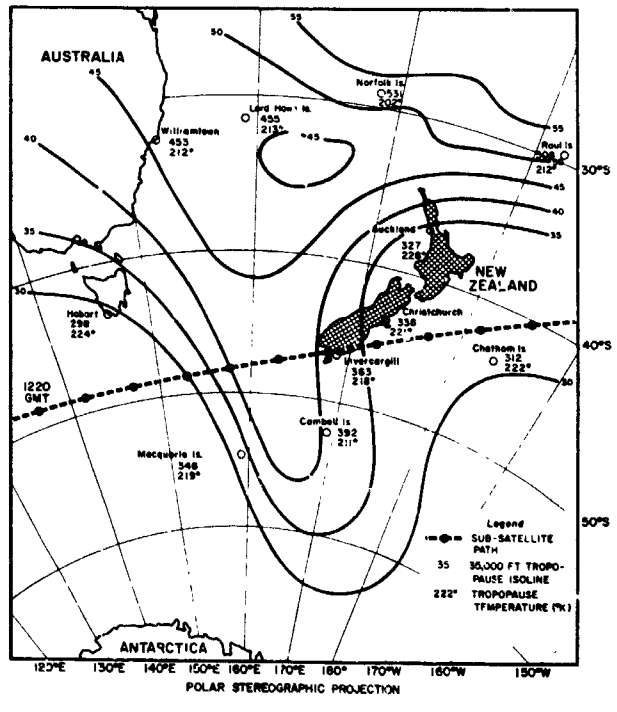

FIGURE 15—Tropopause height chart, for the New Zealand area, 0000 GMT, November 23, 1960.

in a broad region of the middle and upper troposphere, the maximum contributions emanating from the vicinity of 400 mb.

In order to verify this height estimate, the tropopause heights for the New Zealand area were determined in accordance with World Meteorological Organization definitions[12] from Figure 14 and drawn in Figure 15. Channel 1 equivalent blackbody temperatures over 5 radiosonde stations were converted to "effective radiation heights" by means of Figure 14. The effective "heights" were subtracted from the actual tropopause sounding heights at 0000Z on November 23, 1960 and averaged (Table 1). The base of a lower inversion at 36,350 feet at Invercargill was used in Table 1, because it closely approximated the WMO definition for a conventional tropopause. The lower polar tropopause height (32,700 ft) was used at Auckland, which exhibited a multiple tropopause structure.

Table 1 indicates that the Channel 1 (6.0–6.5μ) maximum integrated radiation level averaged 8705 feet below the tropopause; this qualitatively confirms the work of Hanel and Wark. The T_{BB} for Channel 1 averaged 18°K warmer than the tropopause temperatures, in this study.

W. R. Bandeen, (Private communication, September 1962) suggested an empirical equation to obtain a closer tropopause height estimate from the Tiros Channel 1 data:

$$\text{Tropopause Height} = 55{,}000 - 530\,(T_{BB}\ \text{Chan. 1-200}). \quad (1)$$

A comparison of the tropopause height from the same radiosonde soundings with the tropopause heights estimated by use of Equation 1 is shown in Table 2. The difference between the radiosonde and estimated tropopause heights ranged from +1010 to −2690 feet at radiosonde stations with single and multiple tropopauses.

Defant and Taba,[13] in their worldwide hemispheric investigation of tropopause heights and temperatures, stated: "With the exception of the very northern latitudes (75° to 90°N), the close relationship between tropopause height and tropopause temperature seem to be almost perfectly fulfilled in the sense that an increase in height goes parallel with a decrease in temperature or vice versa (compensation principle)." One can presume that the same relationship holds for the southern hemisphere.

Since tropopause temperatures and heights are operational requirements for the stratosphere flights of military and civilian aircraft,[14] more comprehensive studies of these parameters with Tiros radiation data will be made in the future.

Table 1

Comparison of Heights and Temperatures at the Tropopause as Determined from Radiosonde and Tiros Channel 1 Data.

Station	Radiosonde Tropopause Data (Figure 13)			Channel 1 "Effective" Height			Height Diff. (ft)	Temp. Diff. (°K)
	Height (ft)	Pressure (mb)	T_{BB} (°K)	Height (ft)	Pressure (mb)	T_{BB} (°K)

							AVG: 8,705	18

Table 2

Comparison of Tropopause Heights Estimated by Use of Equation 1 with Those Obtained from Radiosonde Data.

Station	Tropopause Height (feet)			Tropopause Characteristics
	Radiosonde	Eq. 1 Est.	Difference	
Auckland	32,700	35,390	-2,690	multiple
Invercargill	36,350	33,800	-2,550	single
Campbell Is.	39,200	39,100	- 100	single
Macquarie Is.	34,800	32,740	-2,060	single
Christchurch	33,850	34,860	+1,010	single

CONCLUSION

The results described in this study point to the important meteorological potential of satellite infrared radiation data in synoptic observation of frontal and air mass movement, interpretation of large scale upper air flow patterns, and investigation of the atmospheric heat budget.[15,16,17]

ACKNOWLEDGMENTS

The author wishes to express his thanks to Dr. R. A. Hanel, Mr. W. R. Bandeen, and Dr. W. Nordberg of Goddard Space Flight Center; Lt. Comdr. John D. Ploetz of the U. S. Navy; and Mr. Thomas Gray of the U. S. Weather Bureau for their instructive comments and encouragement during the course of this service-interrupted study.

LATITUDINAL DISTRIBUTION OF CLOUD COVER FROM TIROS III PHOTOGRAPHS*

ALBERT ARKING†

Television pictures from the Tiros III satellite have been analyzed on a computer to give the latitudinal distribution of cloud cover during the summer of 1961. The results, which will be useful in studying the heat balance of the atmosphere and in the determination of vertical motion, show good agreement with the long-term average cloudiness derived from data accumulated during 50 years of ground observations.

The global distribution of cloud cover is now being investigated by the analysis of photographs from Tiros meteorological satellites. The aim of this cloud-cover study is to derive basic information on the radiation energy balance of the atmosphere, and on the vertical atmospheric motions which are revealed by the existence of clouds The type of information yielded by this analysis is important for studies of climate and for investigations of the general circulation of the atmosphere.

The energy input which sets the atmosphere in motion is given by the difference between the incoming solar energy, consisting of radiation primarily in the visible part of the spectrum, and the outgoing energy, consisting of radiation from the earth and the atmosphere in the far infrared part of the spectrum. The main control over the incoming solar radiation is provided by clouds, which can reflect up to 80 percent of the incident visible radiation, depending upon their thickness and type. Reflection by the atmosphere and the underlying surface is much less; it is about 8 to 10 percent for the atmosphere, from 3 to 20 percent for most terrains, and, in general, only a few percent for large bodies of water. Calculations of the available solar energy are thus strongly dependent on knowledge of the cloud-cover distribution.

The most important factors which govern the distribution of the outgoing infrared radiation are the ground temperatures, the amount of water vapor in the atmosphere, and particularly the extent and height of the clouds.

It is thus seen that the distribution of cloudiness plays an important role in the determination of both the inflow and the outflow of energy through the earth's atmosphere. Thus far, the distribution of clouds—amount, types, and approximate heights—have all been taken from ground-based observations. Satellite observations enable us to obtain extensive cloud-cover data on a global scale in a relatively short period of time.

Each Tiros satellite contains two television camera systems which photograph the cloud cover. Some satellites (Tiros II, III, IV, and VII) contain, in addition, radiometers to measure emitted infrared radiation and reflected visible radiation from the earth, atmosphere, and clouds. The data from the visible and infrared radiometers would ordinarily be sufficient for deriving the energy balance, but only on Tiros VII did the visible radiometer channel work successfully. From the cloud-cover distribution, however, one can estimate the reflected radiation in the visible spectrum and hence, the incoming solar radiation.

Use of the radiation data in determining the energy balance is discussed in a simultaneous publication by Rasool (*1*) in which references are made to other studies of the radiation data. Although the cloud-cover pictures have been used extensively for their synoptic value in the detection and tracking of storms and in present methods of weather forecasting, the analysis of the pictures

*Published in *Science*, 143(3606):569–572, February 7, 1964.
†Goddard Space Flight Center and New York University, New York.

to obtain statistical data on cloud cover, for application to energy-balance studies, has not been undertaken previously.

The analysis of the cloud-cover photographs was performed on an I.B.M. 7090 computer. Photographs are converted into digital form for insertion into the computer by dividing the photographic image into 250,000 picture elements to form a matrix of numbers, 500 by 500, each number representing the brightness of the corresponding picture element.

The main problem in the computer analysis of cloud pictures is the choice of a criterion, suitable for machine execution, which will distinguish clouds from clear areas. The brightness of the picture element should be a suitable criterion, since clouds will have higher reflectivities than clear areas except in snow-covered regions. The analysis is complicated by the fact that a cloud of given reflectivity can have a range of brightness depending on the relative angles of the sun and camera with respect to the surface appearing in the photograph, the structure and thickness of clouds, and the nature of the underlying terrain. In addition, there may be variations in the characteristics of the vidicon tube and associated

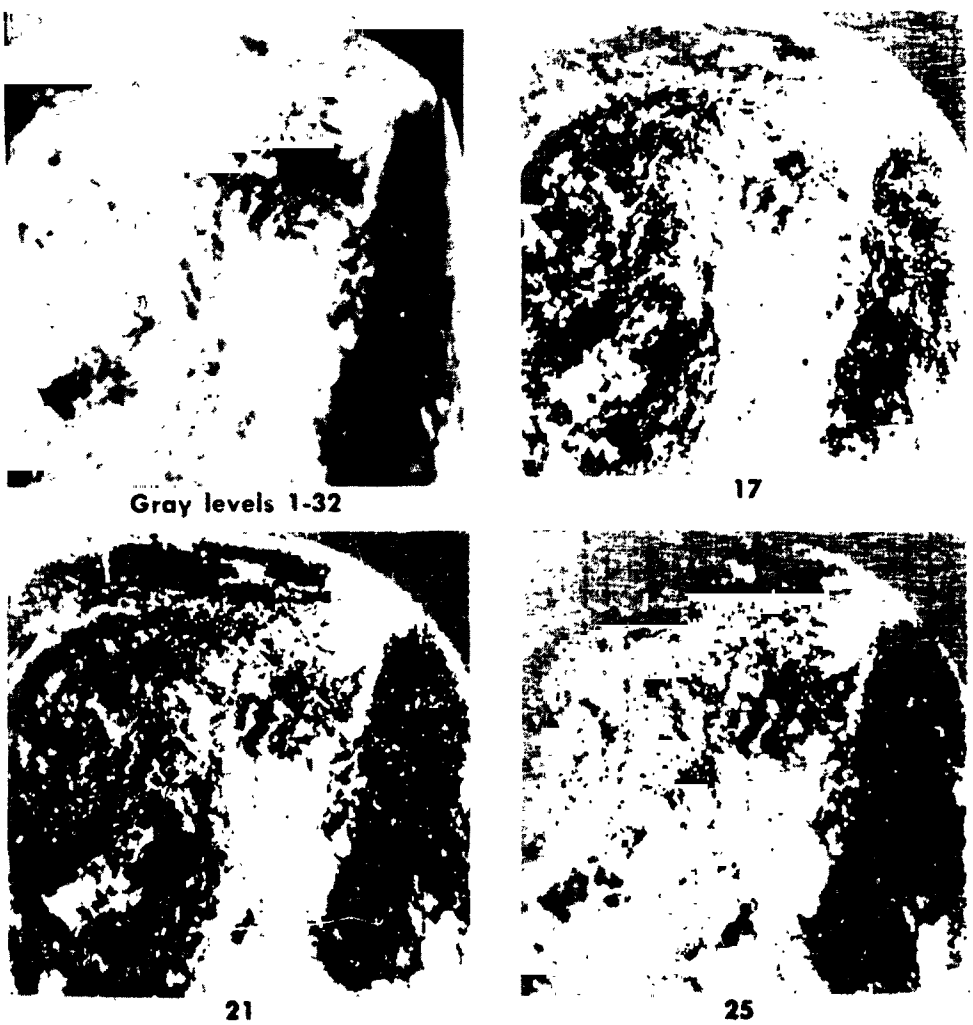

FIGURE 1.—Determination of brightness threshold of clouds (criteria for discriminating clouds from clear areas). A series of two-level images, in which intensities greater than a given threshold appear white and all others black, are produced for a number of thresholds, three of which are shown here. The number underneath each two-level image is the brightness level used as the threshold for the discrimination. The original full-tone image (gray levels 1–32) is compared with each two-level image to find the threshold which most closely reproduces the cloud boundaries reported by the human observer in the original image, in this case 21.

electronics after the satellite is put into orbit. Nonetheless, it was found, by analysis of sample pictures, that the differncee between the reflectivities of clouds and the underlying terrain is great enough so that it is possible to choose a brightness threshold which defines the cloud boundaries reliably (Fig. 1). It was further found that the threshold may vary considerably for pictures taken during different orbits, but it varies only slightly from picture to picture within an orbit. It was therefore necessary to determine a new threshold for each orbital sequence but not for each picture. This method does not distinguish between clouds and snow-covered terrain, and, furthermore, it may result in an overestimation of the cloudiness over regions of bright sand. However, only a very small fraction of the earth is covered by bright sand, and the season and regions covered by Tiros III rule out extensive snow-cover.

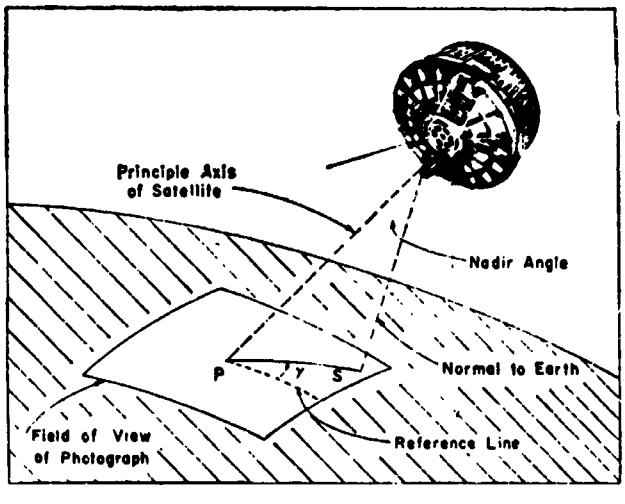

FIGURE 2.—Geometry of Tiros photography. The two television cameras point along the principle or spin axis of the satellite, which is fixed in space. The angle between the principle axis and the normal to the earth, the nadir angle, changes as the satellite orbits the earth. The intersection of the principal axis with the earth is call the principal point, denoted by P, and the point immediately below the satellite, called the subsatellite point, is denoted by S. As the satellite rotates, the image on the vidicon tube appears to rotate about the point P. The angle between PS and a fixed reference line on the vidicon tube defines the roll angle, γ, the value of which is required, in addition to the geographic positions of P and S, to transform from picture coordinates to geographic coordinates.

The location of cloudy and clear areas on a world map requires precise knowledge of the satellite's position and angular orientation at the time the photograph was taken (see Fig. 2). These data were supplied by the Meteorological Satellite Laboratory of the Weather Bureau and the Aeronomy and Meteorology Division of the Goddard Space Flight Center. The transformation from the image plane of the photograph into geographical coordinates is described by Frankel and Bristor (*2*) and by Mach (*3*).

There were 1447 Tiros III photographs available on video tape which were free from excessive noise and for which we were able to obtain all the data required for the transformation to geographical coordinates. All the pictures were processed on the 7090 computer and form the basis of the results presented here.

The end product of the computer analysis is a magnetic tape which contains a summary of every picture analyzed. A computer program interrogates this tape to provide the mean percentage of cloud cover over any specified geographic region during any interval of time. For the purposes of this introductory note, however, we will present only the latitudinal distribution of cloud cover for the summer of 1961.

The geographical distribution of the pictures is shown in Fig. 3; each asterisk on the map represents a single photograph. All were taken during daytime between 12 July and 30 September 1961, between latitudes 60°S and 60°N. The number of pictures in the Southern Hemisphere is appreciably less than in the Northern Hemisphere and, consequently, errors due to statistical sampling will be greater for southern latitudes. There may also be some statistical bias in northern latitudes due to the sparseness of photographs over Asia.

The average latitudinal distribution of cloud cover is shown in Fig. 4 for the period 12 July to 30 September 1961. The solid horizontal bars give the mean percentage of earth area covered by clouds in intervals of 10° of latitude as determined from the Tiros III photographs. The vertical lines passing through the bars indicate the uncertainty estimated to arise in the threshold determination. Possible errors due to statistical sampling are not shown.

The results in Fig. 4 show that the cloud cover in middle latitudes is the same in the Northern

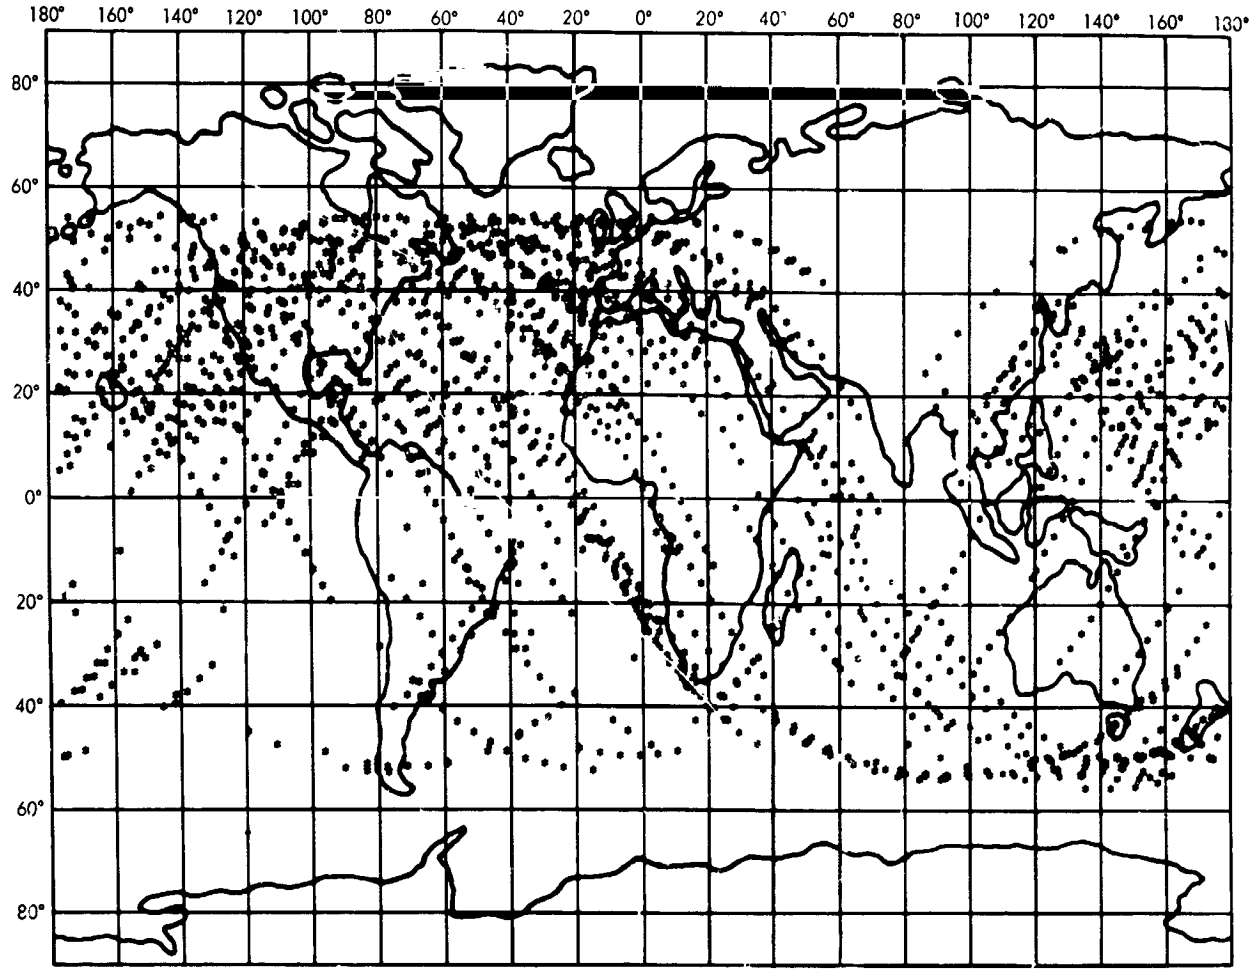

FIGURE 3.—The geographical distribution of the 1447 Tiros III pictures taken between 12 July and 30 September, 1961, which were used in the analysis.

and Southern Hemispheres. However, in tropical latitudes there is an asymmetry, with a local maximum of the cloud cover in the tropics centered at 10°N latitude. This is the average position of the "thermal equator" during the period 12 July to 30 September.

The broad features of the latitudinal distribution of cloud cover obtained from the Tiros photographs are consistent with the known pattern of the general circulation (*4*). Air rising at the thermal equator produces condensation and a relative maximum in the cloud cover, while on the average there is downward motion of cool, dry air at 30°C, which explains the relative minimum of cloudiness. The relationship between cloud-cover distribution and vertical air currents suggests that the Tiros cloud-cover statistics may have an important application in the determination of vertical motions in the atmosphere.

It is of considerable interest to compare the Tiros observations for the summer of 1961 with the climatological distributions of cloudiness found in the literature for the same season. Such distributions have been published by Haurwitz and Austin (*4*), Landsberg (*5*), and others for the globe; and, based on more extensive data, by Telegadas and London (*6*) for the Northern Hemisphere. The climatological results for the period July through September are shown by the dashed histogram in Fig. 4. The Northern Hemisphere data are taken from Telegadas and London (*6*); the Southern Hemisphere data are taken from Landsberg (*5*).

The Tiros results for 1961 are seen to be in good agreement with the long-term mean of cloud-cover distribution obtained from ground observations. The degree of correspondence between our results and the ground-based data gives us confidence in

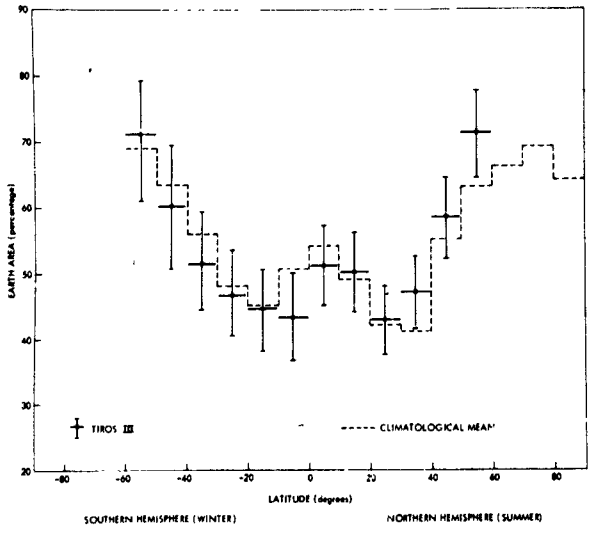

FIGURE 4.—The latitudinal distribution of cloud cover. The solid horizontal bars are the results derived from Tiros III photographs from 12 July to 30 September, 1961. The vertical lines show the estimated uncertainty due to threshold determination. The dashed histogram represents the climatological mean cloud cover based upon ground observations, taken from Telegadas and London (6) for the Northern Hemisphere and from Landsberg (5) for the Southern Hemisphere.

this method of analysis of satellite photographs. The availability of more data from subsequent satellites will permit the determination of the geographical distribution of cloud cover over short intervals of time, for which no reliable information is now available. An increase in the density of observations, coupled with improvements in the techniques for picture analysis now being developed, should eventually lead to the use of cloud-cover pictures, automatically analyzed on a computer to provide the cloud-cover distribution as a function of time for use in studies of atmospheric dynamics and long-term changes in climate.

A RADIATION CLIMATOLOGY IN THE VISIBLE AND INFRARED FROM THE TIROS METEOROLOGICAL SATELLITES*

W. R. BANDEEN, M. HALEV, AND I. STRANGE

Radiometric measurements in the visible and infrared have been made intermittently since 1960 by the meteorological satellites, TIROS II, III, IV and VII. Measurements of reflected solar radiation have been acquired within filtered passbands of approximately 0.2−6μ and 0.55−0.75μ and, of emitted long wave radiation, within passbands of approximately 8−12μ, 8−30μ, 6−6.5μ, and 14.8−15.5μ. The TIROS VII satellite has acquired continuous radiometric data over the earth for more than one year, increasing significantly the potential of its data for climatological studies, compared to the earlier experiments which lasted for shorter periods of time.

A limited climatology of the spatial and temporal variations of the total outgoing long wave radiation and of the planetary albedo is derived from the essentially beam measurements within the 5° field of view of a five-channel, scanning radiometer. The results show essential agreement with previous studies of the planetary heat balance, based upon conventional data. However, several interesting differences appear. The satellite data indicate that a disproportionately high amount of radiation is emitted from the subtropical anticyclones, while the meridional gradient of the mean zonal albedo is larger than indicated in several recent studies.

In addition to the heat balance results, the relative planetary distribution of atmospheric moisture is inferred from measurements made within the 6.3μ band of water vapor, and the seasonal changes of mean temperatures in the stratosphere between about 15 and 35 km are shown from measurements made within the 15μ band of carbon dioxide.

I. INTRODUCTION

Climatological investigations by means of radiation data from the TIROS meteorological satellites have been hindered, at least in part, by the relatively short lifetimes of the early experiments flown on TIROS II, III, and IV. The medium-resolution scanning radiometer flown on TIROS VII, however, has acquired continuous data over the earth for more than one year, increasing significantly the potential of the radiometric measurements for climatological studies.

The design of the radiometers, their calibration, the information flow, and the data reduction techniques have been described previously (Bandeen et al., 1961; Nordberg et al., 1962; Kondratiev, 1963), as have the physical significance of the experiment and its synoptic use potential (Hanel and Wark, 1961; Fritz and Winston, 1962; Bandeen et al., 1964). In this paper we shall discuss three climatological applications of radiation data from TIROS VII, and from TIROS IV for one type of measurement (in the 6.3μ H_2O band) that was not made by TIROS VII.

The radiometer measures essentially beam radiation within a 5° field-of-view from five channels, each made sensitive to a different part of the spectrum by means of filters and other optical elements. The nominal wavelength limits of the sensors flown on the various satellites are shown in Table I.

II. CALIBRATION

The calibration of the infrared channels is carried out in the laboratory by viewing a blackbody cavity, and the primary calibrated quantity is the "equivalent blackbody temperature, T_{BB}(°K)". It follows that the "effective radiant emittance, W (watts m^{-2})" and the "effective radiance N

*Only four channels were used on TIROS IV.
The parenthetical numbers indicate the approximate number of months of usable data for each channel.
**The radiometer on TIROS VII, launched 19 June 1963, is still operating as of this writing.
Detailed characteristics of all experiments are found in their respective Users' Manual (Staff members, 1961, 1962a, 1963, 1964).

(watts m^{-2} ster^{-1})" to which a sensor responds is given by

$$\bar{W} = \pi \bar{N} = \int_{\lambda=0}^{\infty} W_\lambda(T_{BB})\phi_\lambda d\lambda \qquad (1)$$

where $W\lambda$ (T_{BB}) is the spectral radiant emittance from a blackbody at temperature T_{BB} (i.e., Planck radiation) and ϕ_λ is the effective spectral response function for the particular channel. The constant π transforms Planck radiance (intensity) to blackbody radiant emittance (flux).

The calibration of the short-wave channels is carried out in the laboratory by viewing a diffuse sheet of white paper of known spectral reflectivity, ρ_λ, illuminated at normal incidence by a standard lamp of known spectral radiant intensity, J_λ (watts ster^{-1} micron^{-1}), at a known distance R (meters). The reflectance of the white paper is *assumed* to be ideally diffuse (i.e. Lambertian). The effective radiant emittance and radiance to which a sensor responds, then, are

$$\bar{W} = \pi \bar{N} = \frac{1}{R^2} \int_{\lambda=0}^{\infty} J_\lambda \rho_\lambda \phi_\lambda d\lambda \qquad (2)$$

In order to interpret the short-wave measurements in terms of reflectance of solar radiation from the earth and atmosphere, one must know the "effective solar constant, $\bar{W}^*$ (watts m^{-2})", i.e., the measurement which would result if the radiometer field-of-view were completely filled by an ideally diffuse reflector of unit reflectivity when illuminated by one solar constant at normal incidence, expressed by

$$\bar{W}^* = \int_0^{\infty} S_\lambda \phi_\lambda d\lambda \qquad (3)$$

where S_λ is the spectral irradiance of the earth by the sun at unit distance. The solar constant

$\int_0^{\infty} S_\lambda d\lambda$ equals 1395 watts m^{-2}

$= 2.0\ \varsigma$ cal cm^{-2} min^{-1}.

The reflectance of solar radiation, r_o, assuming that the reflectance is *independent of wavelength* and that the radiation is *reflected isotropically* is given by

$$r_0 = \frac{\bar{W}}{\bar{W}^* \cos \zeta} (R_s)^2 \qquad (4)$$

where ζ is the solar zenith angle and R_s is the distance of the earth from the sun in astronomical units. Equation (4) was used to calculate reflectance (and, assuming isotropy, albedos) in this paper, although there is evidence that appreciable errors may result if the angular dependence of the backscattered radiation is not included (Arking, 1964). The maximum allowable solar zenith angle, to insure adequate illumination, was $\zeta = 70°$.

III. THE PLANETARY HEAT BALANCE

We shall only investigate the heat balance at the top of the atmosphere, and not consider the more complicated study of the heat budget of the atmosphere alone at this time. In our study we shall use data obtained over a full year from TIROS VII. A number of problems have arisen concerning the interpretation and treatment of the satellite data. We shall discuss the most important of these below.

a. Coverage

The orbit of TIROS VII is nearly circular, at a mean height of 635 km, and inclined to the equator by 58°. For this reason, the polar regions cannot be observed (Figure 1). The maximum allowable angle of the sensor optical axis from the nadir (the "nadir angle") was 45° for data to be accepted. Therefore, the coverage was extended beyond the subsatellite track to latitudes 63.5°N. and S. For our purposes this broad zone of coverage, which includes 89.5 percent of the world's surface area, shall be termed the "quasi-globe." The two "V-shaped" gaps near Asia and South America (Figure 1) result from the combined constraints of the location of the three Command and Data Acquisition Stations in the United States and the limit of the storage capacity of the satellite tape recorder to one orbit of data. In addition, there is a temporal coverage problem. Because of the orbital regression and the motion of the sun, a period of 76 days (the "orbital synodic cycle") is required for the orbital nodes to move through one complete cycle relative to the sun and, hence, for all latitudes to be sampled at all local times. Figure 2 shows the heliocentric views of the TIROS VII orbit at launch and at four quarters throughout a 76-day cycle.

b. Selection of Spectral Intervals

Ideally the best inference of total long-wave radiation should derive from measurements by the 8–30 micron channel and the best inference of total reflected solar radiation should derive from

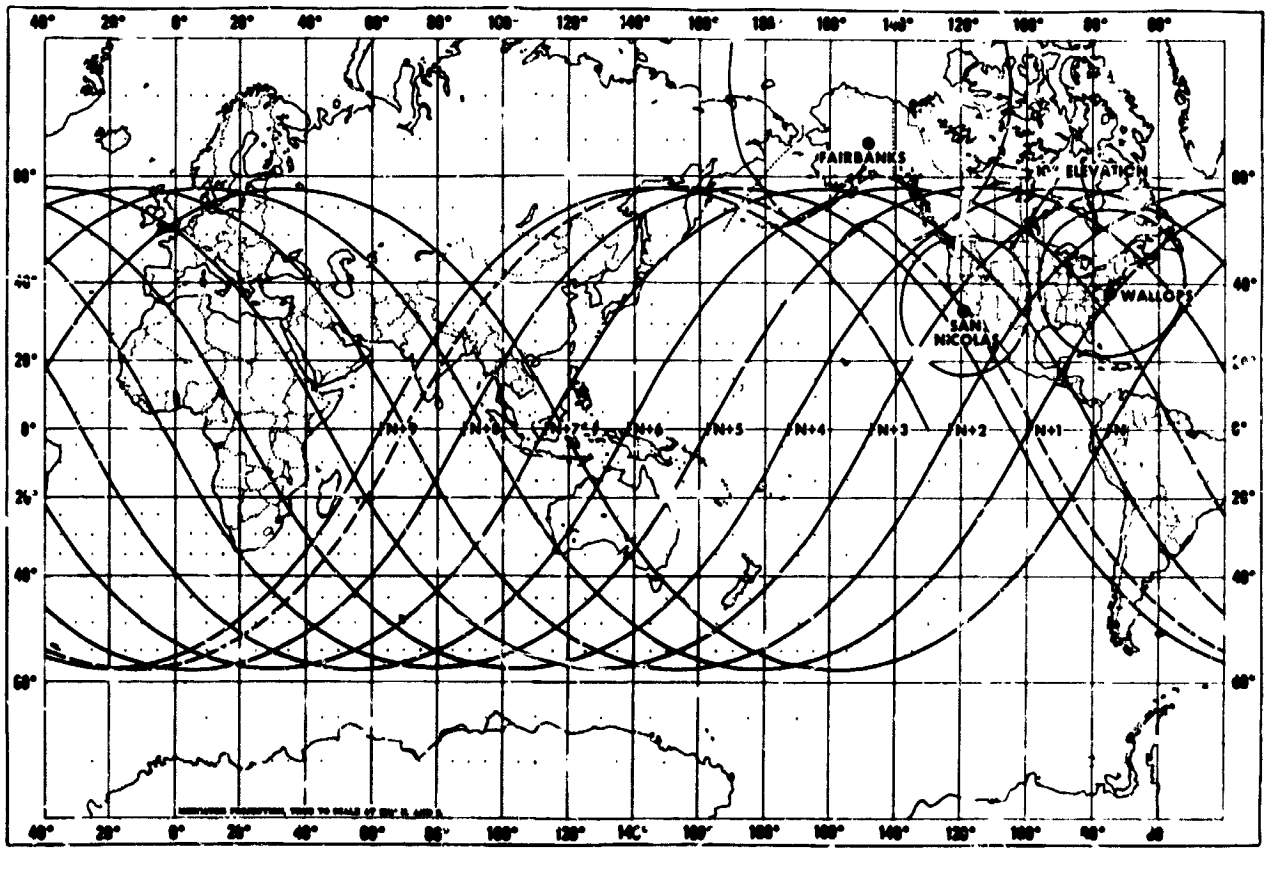

FIGURE 1.—Nominal world-wide radiation data coverage for the Tiros VII satellite.

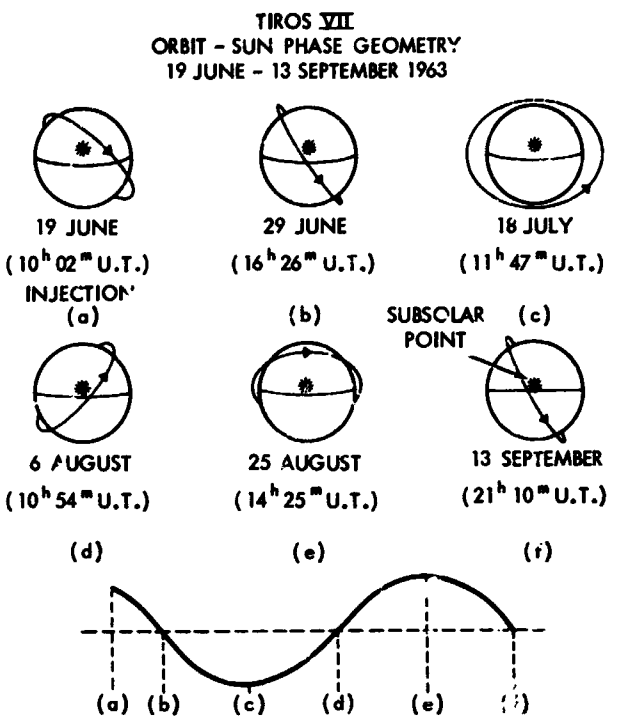

FIGURE 2.—Heliocentric views of the Tiros VII orbit, illustrating the 76-day orbital synodic cycle. The sinusoid shows the convention for indicating the orbit-sun phase geometry in Figures 5 and 6.

measurement by the 0.2–6 micron channel. However, because of engineering problems and the long-term stability of the sensors, it was decided to use the 8–12 micron and 0.55–0.75 micron channels instead (cf. Staff members, 1964).

c. Method of Converting T_{BB} Measurements to Total Outgoing Long-Wave Flux, W

The method of Wark, Yamamoto, and Lienesch (1962) was adopted for converting the essentially beam measurements of the 8–12 micron channel to total outgoing flux. Plots of W vs. T_{BB} (and $\bar{W}$) calculated for three zenith angles are shown in Figure 3. The linear fit

$$W(\text{ly min}^{-1}) = 0.141 + 0.00907\ \bar{W}\ (\text{watts } m^{-2}) \quad (5)$$

was adopted for manually applying second-order corrections for observed degradation in the instrumental response to the data printed out by an electronic computer (cf. IIIe. below).

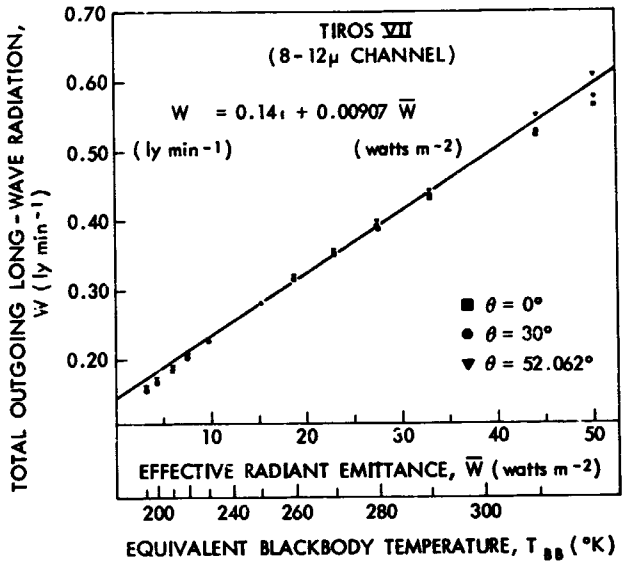

FIGURE 3.—Total outgoing long-wave radiation as a function of equivalent blackbody temperature (and effective radiant emittance) for the 8–12μ channel of Tiros VII for three zenith angles, θ. The straight line approximation was adopted for applying corrections for observed instrumental degradation.

d. Modification Factor for Limb Darkening

The theoretical limb darkening contained in the work of Wark et al. (1962) was determined under ideal conditions of either completely clear or completely overcast skies. The actual limb darkening was investigated using a two-dimensional distribution matrix containing 30 increments of radiance and 10 increments of zenith angle. The curve shown in Figure 4 was developed from the 50th percentile value of radiance in each of the zenith angle increments (after correcting for instrumental degradation; cf. TIROS IV Catalog-Manual: Staff members, 1963), calculated by a computer from nearly 1.3×10^6 measurements by the 8–12 micron channel of TIROS IV. The corresponding theoretical limb darkening, calculated for the same vertical outgoing radiance, i.e., $\bar{N}(T_{BB}=268.18°K)$, is noticeably less in Figure 4. The ratio of the integral incorporating the empirical curve to that incorporating the theoretical curve, calculating the total fluxes from an arbitrary radiance measurement, N', at an average zenith angle, $\theta_{ave}=35.5°$, yielded the value

$$\frac{W_{\text{EMPIRICAL}}}{W_{\text{THEORETICAL}}} = \frac{N'/E(\theta=3.35°)\int_0^{\pi/2}E(\theta)\sin\theta\cos\theta\,d\theta}{N'/T(\theta=35.5°)\int_0^{\pi/2}T(\theta)\sin\theta\cos\theta\,d\theta} = 0.986 \quad (6)$$

where $E(\theta)=[N(\theta)/N(0)]_{\text{EMPIRICAL}}$ and $T(\theta)=[N(\theta)/N(0)]_{\text{THEORETICAL}}$.

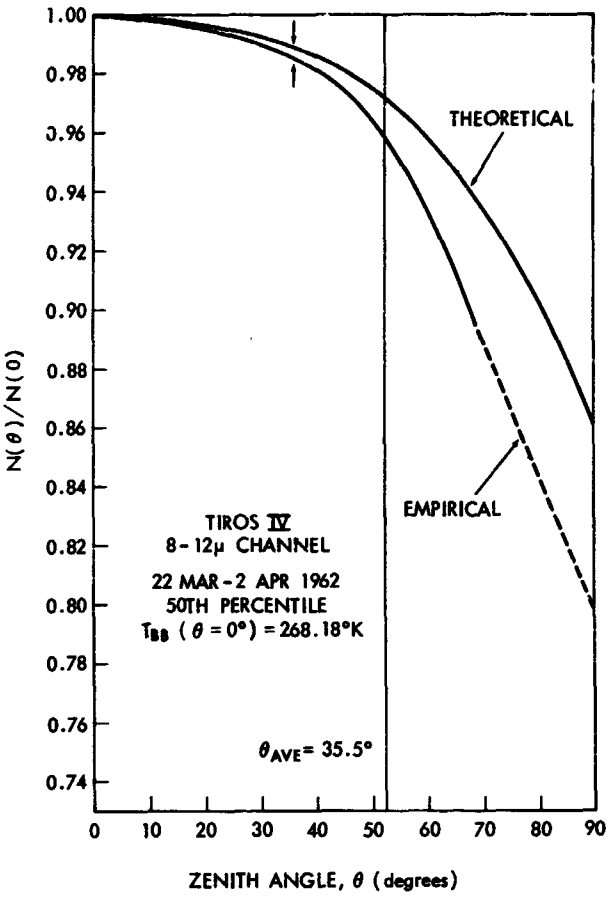

FIGURE 4.—Theoretical vs. empirical limb darkening for the 8–12μ channel of Tiros IV.

Values of total flux calculated by the computer, then, were reduced by the factor 0.986 as a first approximation to correct for the greater observed limb effects compared to the theoretically determined limb darkening.

e. Data Processing and Degradation of the Instrumental Response

An electronic computer was employed to process the data contained on magnetic tape (Final Meteorological Radiation Tapes, FMRT; cf. TIROS VII Catalog-Manual: Staff members, 1964) to a grid print map format (cf. Staff members, 1962b). Briefly, a square-mesh grid containing 2376 elements was superimposed on a Mercator map base of the quasi-globe, and measurements were accumulated in appropriate grid squares by the computer over a period of about seven days. Then averages of all measurements in each grid square were taken resulting in a weekly map of data. In producing the weekly map the computer also calculated and printed out the average of all individual measurements processed (the "map average").

In Figure 5, the effective radiant emittances, $\bar{W}$, calculated by means of Equation (5) from the map average values of total outgoing long-wave flux, are shown for each of 19 weekly periods during the first year of TIROS VII (dots with bars). The 19 periods are numbered along the upper abscissa, and the sinusoid indicates the orbit-sun phase geometry (cf. Figure 2). The Roman numerals at the top of the figure indicate the calendar months making up the four seasons, each of which is represented by averages of data from four weekly periods, equally spaced every 19 days over a 76-day synodic cycle. The lengths of the bars indicate the number of days making up the data period, usually seven. A least-squares quadratic curve is shown for the map averages. The decrease with time is interpreted as indicating a degradation in the response of the instrument while in orbit. There are unavoidable gaps in the quasi-global coverage, caused by such factors as noise and engineering considerations preventing the successful acquisition and reduction of every possible orbit, which might bias the quasi-global map averages. Upon close examination of the data, such biases were ascertained in

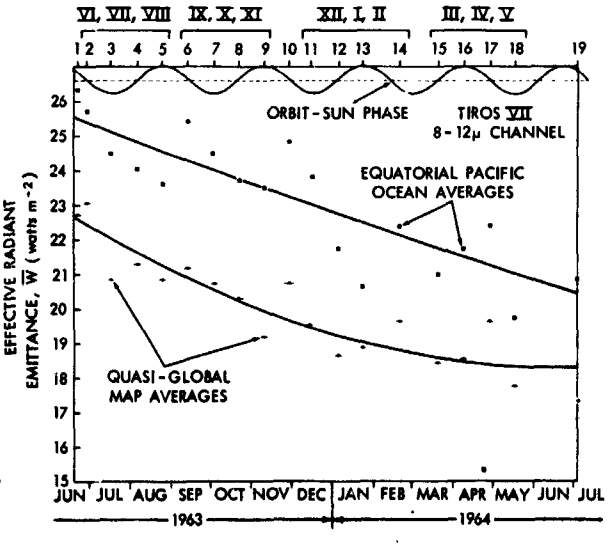

FIGURE 5.—Effective radiant emittances, $\bar{W}$, vs. time from "quasi-global" map averages and equatorial Pacific Ocean averages, indicating a degradation of the instrumental response. Tiros VII, 8–12μ channel.

the map averages of Figure 5. Therefore, values of W were calculated by means of Equation (5) for averages of the data over an equatorial region of the Pacific Ocean which was uniformly covered by all 19 weekly maps. The squares in Figure 5 refer to these values. A least-squares quadratic [illegible] for the Pacific Ocean averages is shown in Figure 5 (top curve), and was adopted as representing the true instrumental degradation. Based upon this curve, then, correction factors, $h_2(t)$, were calculated to correct for degradation in the instrumental response. Because of the linear response characteristic of the radiometer, a degradation-corrected value, $\bar{W}'$, can be expressed by

$$\bar{W}' = h_2(t)\ \bar{W} \tag{7}$$

where $\bar{W}$ is the uncorrected value. Since no degradation in the instrumental response of the 8–12 micron channel is presumed to exist at the time of launch ($t=0$), $h_2(0)=1$. The value of $h_2(t)$ increases throughout the year, reaching 1.250 at the midpoint of period 19 on 5 July 1964.

Finally the values of total outgoing flux calculated by the computer, W, were corrected manually for (1) instrumental degradation and (2) an empirically determined increase in limb darkening. From Equations (5) and (7) we have for the degradation-corrected value of flux, W'

$$W' = 0.141 + 0.00907\ h_2(t)\ \bar{W} \tag{8}$$

Combining Equations (5) and (8) to eliminate $\bar{W}$, we have

$$W' = h_2(t)\ W - 0.141\ [h_2(t) - 1] \tag{9}$$

Finally from Equations (6) and (9) we have for the outgoing flux, W'', corrected for both instrumental degradation and an empirically determined increase in limb darkening

$$W'' = 0.986\ \{h_2(t)W - 0.141[h_2(t) - 1]\} \tag{10}$$

where W is the value of flux calculated by the computer.

Quasi-global averages of reflectances calculated by the computer using Equation (4) from measurements made by the 0.55–0.75 micron channel for each of 17 weekly periods processed during the first year of TIROS VII are shown in Figure 6. Because of an unfavorable orbit-sun geometry,

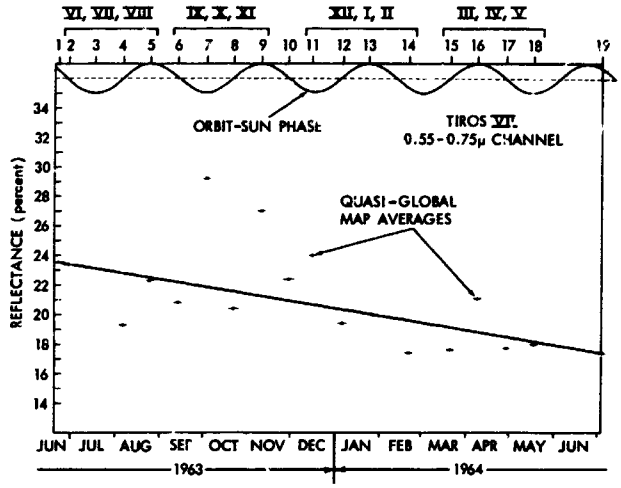

FIGURE 6.—"Quasi-global" map average reflectances vs. time, indicating a degradation of the instrumental response. Tiros VII, 0.55–0.75μ channel.

only very small amounts of data were acquired for periods 3 and 13, and these were rejected as being unrepresentative. A least-squares linear curve was calculated for the quasi-global map averages, showing again, a decrease with time. After some comparisons of reflectances calculated over "constant" targets (e.g., the Sahara Desert) for several periods throughout the year, the curve of Figure 6 was adopted as representing the *apparent* degradation of the instrumental response, and was used in determining the factor $h_5(t)$ for correcting the reflectances printed out by the computer. A reflectance value, corrected for apparent instrumental degradation, r_0', becomes

$$r_0' = h_5(t)\ r_0 \tag{11}$$

where r_0 is the uncorrected value.

In initially treating the data using Equations (10) and (11), it was found that the annual planetary albedo required to balance the annual long-wave flux determined from the 8–12 micron channel was 32.2 percent (cf. IIIf. below). On the other hand the annual planetary albedo inferred from values of reflectance calculated by Equation (11) was only 20.1 percent. If planetary radiative equilibrium exists over one year (and we presume that it very nearly does), there is a glaring inconsistency between the two types of data. There has been a history in the previous TIROS radiometers of abnormally low reflectances and of observed decreases in instrumental

response *even before launch* (Bandeen, et al., 1963). On the other hand there have been no instances where the long-wave channels were observed to degrade before launch or yield "abnormal" results immediately after launch. Therefore, we shall accept the long-wave fluxes as modified by Equation (10), and multiply the reflectance values, r'_0, calculated by Equation (11) by a factor required to satisfy annual radiative equilibrium. This factor is

$$\frac{32.2}{20.1}=1.60 \qquad (12)$$

Finally, from Equations (11) and (12) we have for the reflectances (equivalent to albedo under our assumption of isotropy), corrected for an apparent instrumental degradation and further increased by factor 1.60 to effect annual planetary radiative equilibrium,

$$r_0''=\text{albedo}=1.60\ h_5(t)r_0 \qquad (13)$$

The additional 1.60 factor is presumed to be due to (1) uncertainties in the backscattered fluxes resulting from not including possible angular dependencies, (2) uncertainties in the original calibration, (3) unobserved deterioration of the instrument between the last check-of-calibration on 5 June 1963 and the first orbit of data on 19 June 1963, (4) the assumption that the reflectance of radiation is independent of wavelength, or (5) some combination of the foregoing. This problem is very puzzling and is under continuing study, but to date no satisfactory explanation has been found.

Zonal averages of the weekly maps were "corrected" in accordance with Eqs. (10) and (13), and averages from the applicable set of four weekly maps constituted the data for each season. Meridional integrations were accomplished graphically by means of a planimeter, using "energy diagrams" like those of Figs. 7–11 for long-wave and Fig. 12 for short-wave radiation.

f. Results

The final values of outgoing long-wave radiation and albedo are summarized in Table II.

The seasonal values of long-wave radiation and albedo are shown in Figures 7, 8, 9 and 10 and the annual values are shown in Figures 11 and 12. Vertical lines at latitudes 63.5°N. and S. mark the boundaries of the quasi-globe. Dashed lines indicate an extrapolation of the curves beyond (or near) these boundaries where satellite data were not acquired. Dots show the scatter of the short-wave seasonal data at high latitudes where the population of the data samples becomes increasingly smaller. Data from London (1957) are shown in Figures 11 and 12 for comparison.

Two maxima in the long-wave radiation, associated with the subtropical high pressure regions, show up clearly in all figures as does a tropical minimum, associated with the cloudiness of the Intertropical Convergence Zone (I T C). The location of the long-wave tropical minimum remains in the northern hemisphere in all seasons except in December-January-February, clearly pointing up the asymmetry between the hemispheres. Similarly, the long-wave maximum occurs over the subtropical high of the northern hemisphere in all seasons except June-July-August, when the long-wave radiation over the subtropical high in the southern hemisphere becomes only slightly larger. Generally more long-wave radiation is emitted from the extratropical latitudes of the northern hemisphere than from the same latitudes of the southern hemisphere in

TABLE II.—*Final Seasonal and Annual Values of Long and Short-Wave Radiation*

Season (Months)	Planetary Long-Wave Radiant Power (10^{15} cal min^{-1})	Solar Radiation		Planetary Albedo (%)
		Reflected (10^{15} cal min^{-1})	Incident on Planet (10^{15} cal min^{-1})	
J-J-A	1725.2	699.0	2457.8	28.4
S-O-N	1725.2	922.2	2574.8	35.8
D-J-F	1712.2	859.7	2609.8	32.9
M-A-M	1746.5	796.0	2544.2	31.3
Annual	1727.3	819.4	2546.7	32.2

corresponding seasons. However, in the tropics the situation is reversed where less radiation is emitted from the northern hemisphere than from the southern hemisphere in corresponding seasons. This characteristic tends to equalize the total radiation emitted from the two hemispheres annually. The albedo minimums occur in the tropics of the winter and spring hemispheres but are lowest when they occur in the northern hemisphere.

The tropical annual minimum in the long-wave radiation (and, hence, the approximate mean annual position of the ITC) is located at latitude 5°N, whereas the maximum long-wave radiation is located at latitude 20°N (Figure 11). The emission is smaller in the northern hemisphere between the equator and latitude 15° but larger between latitude 15° and the pole than in the southern hemisphere. The overall long-wave radiation is slightly larger than London's (1957) as would be expected from a comparison of the TIROS-inferred albedo of 32.2 percent with London's 35.2 percent.

The tropical maximum in the albedo of Figure 12 occurs at latitude 5°N, consistent with the long-wave minimum, but the minimum albedo occurs at latitude 16°N, slightly south of the position of the long-wave maximum. The albedo in the northern hemisphere generally is larger between the equator and latitude 12° but smaller at higher latitudes than in the southern hemisphere. It is interesting to note the greater meridional gradient of the TIROS-inferred albedo compared to London (1957) in Figure 12. The consequences of this characteristic is a larger required poleward flux of heat across latitude circles.

The maximum poleward flux of heat (Figure 13) is 9.8×10^{16} cal min^{-1} across latitude 36°S, whereas in the northern hemisphere the maximum is only slightly smaller at 9.6×10^{16} cal min^{-1} across latitude 36°N. A somewhat surprising result is that the poleward flux curve crosses zero near the equator at latitude 0.4°S whereas previous studies (e.g., Simpson, 1929) placed the crossover at about latitude 4.0°N. The annual curve given by London (1957) is shown for comparison.

The seasonal variations of albedos inferred from TIROS VII are shown in Figure 14. Monthly averages of the stellar magnitudes of measurements of earthlight reflected from the moon made

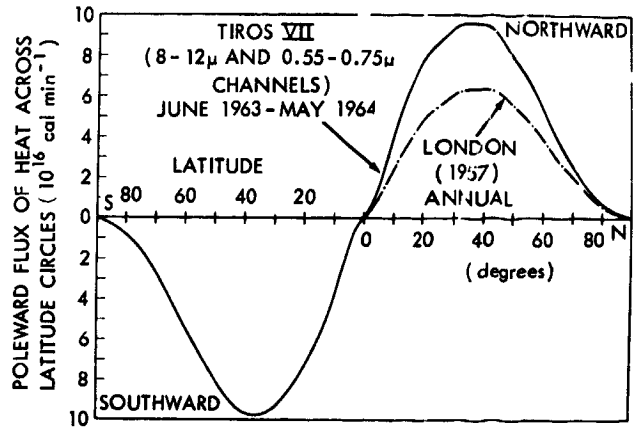

FIGURE 13.—Annual required poleward flux of heat across latitude circles. The corresponding values of London (1957) for the northern hemisphere are shown for comparison.

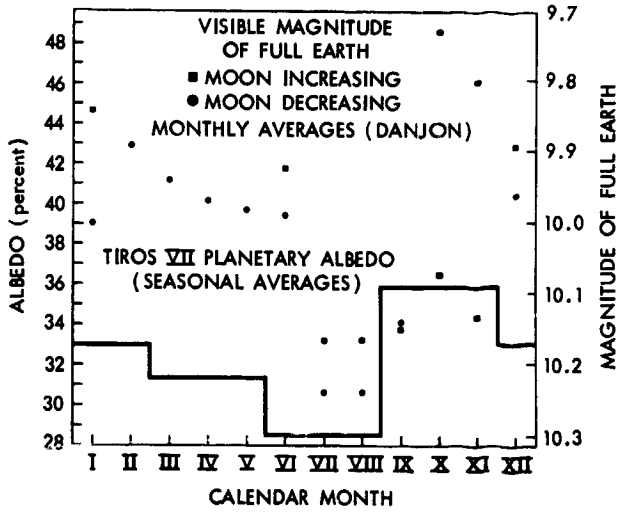

FIGURE 14.—Tiros VII seasonal albedos compared with monthly averages of the magnitudes of earthlight reflected from the moon (after Danjon).

during the years 1926–1935 by Danjon (1936, 1954) are also plotted. There is an approximate correspondence between the albedo and magnitude ordinates. Danjon found a seasonal minimum in the visual albedo of 32 percent in July and a maximum of 52 percent in October. Fritz (1949) pointed out that Danjon's measurements did not include the Pacific Ocean. More recent measurements of this type made by Dzhasybekova, Kazachevskii, and Khari. ov (1960) in the Kazakh SSR during the years 1957-1958 showed considerable variations in the visible albedo (between 31 percent and 48 percent) but did not

show any clear seasonal fluctuations. However, the data of Figure 14 do seem to give further evidence of a minimum around July and a maximum around October.

IV. DETERMINATION OF THE MEAN RELATIVE HUMIDITY AND WATER VAPOR MASS OF THE UPPER TROPOSPHERE

Möller (1961 and 1962) developed a method for the determination of the mean relative humidity of the troposphere and of the surface temperature of clouds or of the ground from radiation data of the TIROS meteorological satellites, and Möller and Raschke (1963/64) have further developed the method. We shall apply the method to data from the 6–6.5 micron and 8–12 micron channels of TIROS IV during the week 11–18 April 1962, and we shall extend the method to include the inference of the mass of water vapor above 500 mb.

The principle of the method is illustrated in Figure 15. Since approximately the same lapse rate exists in all atmospheres ($\gamma \sim 6.5°C/km$), and

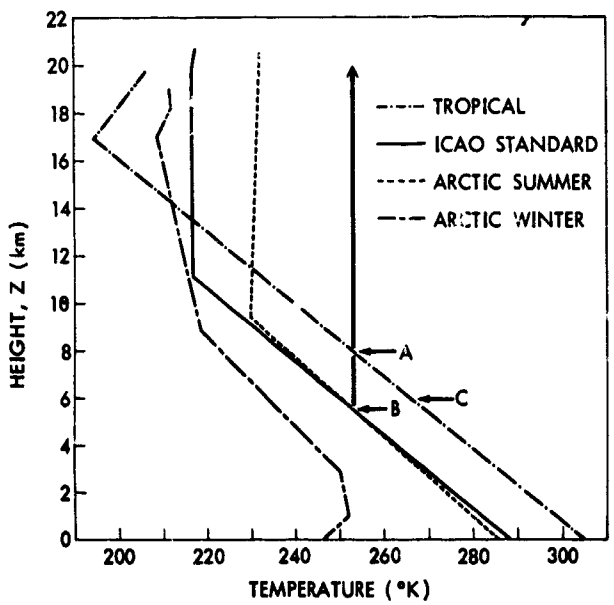

FIGURE 15.—Schematic illustrating that radiation of a given temperature is emitted from approximately the same optical depth in all atmospheres with the same relative humidity (after the method of Möller).

the saturation water vapor pressure is a function only of temperature, it follows that the same water vapor mass exists above the same temperature in all atmospheres having the same relative humidity. The water vapor mass, u, above height, z, can be expressed by

$$u = \int_z^\infty \frac{e_s(T(z))r(z)}{T(z)R^*/m_w} dz \qquad (14)$$

[(a) in Fig. 15]

where e_s is the saturation water vapor pressure, T is temperature, r is relative humidity, R^* is the universal gas constant, and m_w is the molecular weight of water vapor. Thus in Figure 15 Equation (14) would calculate approximately the same water vapor mass above height A in the tropical atmosphere as it would above height B in the ICAO standard atmosphere for the same relative humidities. The reduced mass of water vapor

$$u^* = \int_0^u \left(\frac{P}{P_0}\right)^n du \qquad (15)$$

[(b) in Fig. 15]

which is required for the radiative transfer problem, would be slightly different above the two heights of the previous illustration because of the term $(P/P_0)^n$ which takes into account the pressure broadening of the spectral lines in the absorption band. However, Möller (1961 and 1962) has shown that for the same relative humidity and a lower boundary (ground or cloud) at the same temperature, the outgoing radiance in the interval 6–6.5 microns is nearly the same for all atmospheres. Therefore, to a good approximation one can apply the calculations for one atmosphere to all atmospheres. The evaluation diagram in Figure 16 is designed to determine the mean relative humidity and the surface temperature (of the ground or of clouds) from simultaneous measurements of the 6–6.5 micron channel ("channel 1") and the 8–12 micron channel ("channel 2") (see Möller, 1962 for a detailed discussion of the construction of the diagram). The evaluation diagram in Figure 16 was constructed for the tropical atmosphere of Figure 15 for TIROS III, using the radiation tables of Elsasser (1960) with a pressure dependence exponent of $n = 1$ in Equation (15). No attempt was made to "correct" the 6–6.5 micron data, but the 8–12 micron data were corrected for instrumental degradation in accordance with the nomogram given in the TIROS IV Catalog-Manual (Staff members, 1963). The maximum allowable nadir angle was set at

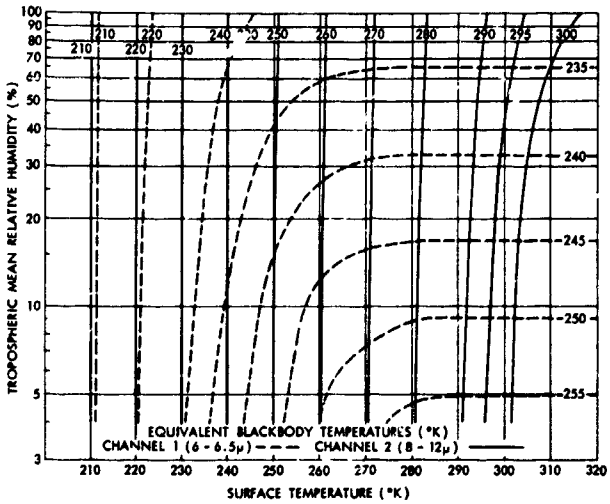

FIGURE 16.—Evaluation diagram for determining tropospheric mean relative humidities and surface temperatures of the ground or of clouds.

40° to eliminate excessive limb effects. We merely state that the spectral response functions of the 6–6.5 micron and 8–12 micron channels of TIROS III and TIROS IV are very nearly the same as a justification for using the TIROS III diagram with TIROS IV data. Also, the pressure dependence exponent, n, should probably be somewhat less than 1. These items notwithstanding, maps of the 6–6.5 micron and 8–12 micron data of TIROS IV were produced by a computer (similar to the maps used in the heat balance study) for the week 11–18 April 1962, and the conversion to relative humidities was carried out by hand using Figure 16. The resultant "quasi-global" relative humidities are shown in Figure 17.

However, if one is interested in the actual water vapor mass, relative humidities can be misleading (i.e., a high relative humidity over the winter arctic may involve much less water vapor than a low relative humidity over the Sahara Desert). To determine the water vapor mass above a given level of a particular atmosphere, having already determined the mean relative humidity, we merely computed the integral of Equation (14) above the temperature in the tropical atmosphere corresponding to the temperature at the given level of the atmosphere in question. For example, suppose that "B" and "C" in Figure 15 are both at the 500 mb levels of their respective atmospheres. Then the water vapor mass above 500 mb in the tropical atmosphere would be determined by insert-

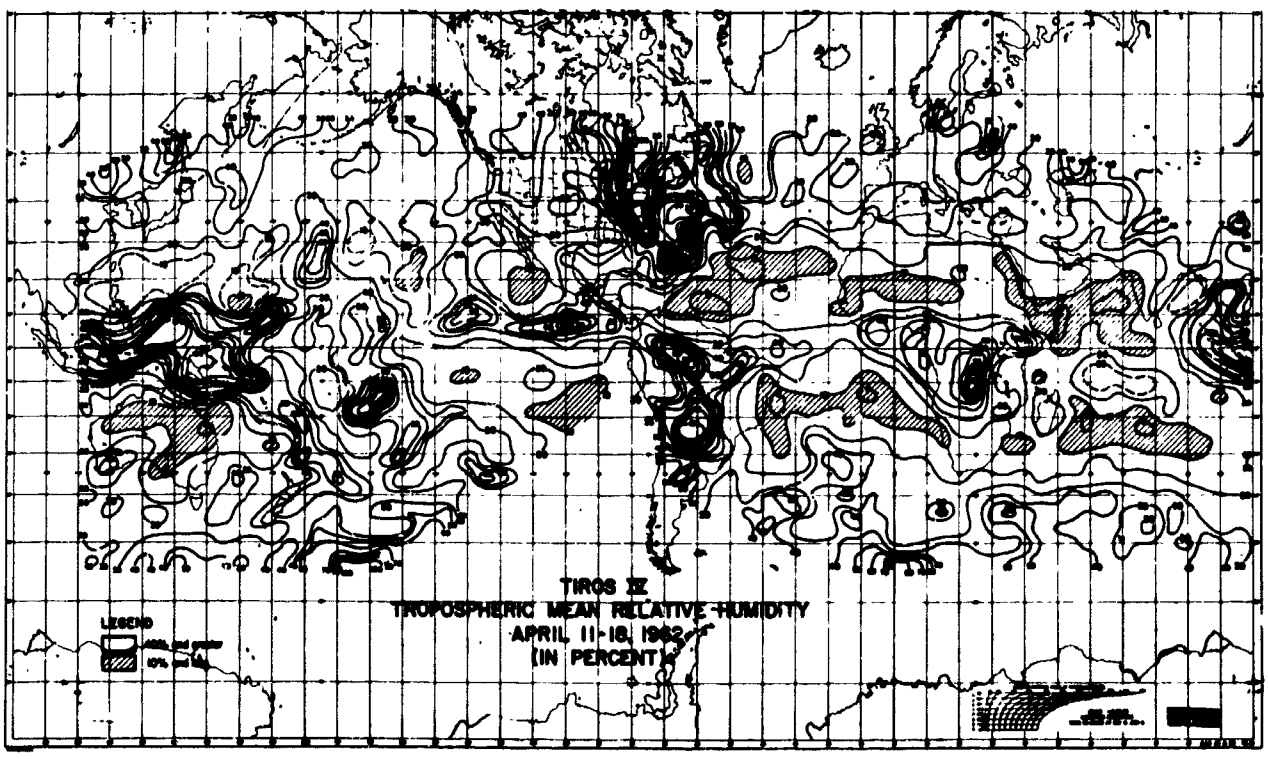

FIGURE 17.—Mean tropospheric relative humidities determined from simultaneous 6.0–6.5 micron and 8–12 micron measurements by Tiros IV during the period 11–18 April 1962, in percent.

ing the measured relative humidity in Equation (14) and integrating over the tropical atmosphere from level "C" to infinity. The water vapor mass above 500 mb in the ICAO standard atmosphere would be determined by inserting the measured relative humidity in Equation (14) and integrating over the tropical atmosphere again, but from level "A" (at the same temperature as "B") to infinity. It was decided to make the determination of water vapor mass above 500 mb because the greater part of the radiation sensed by the 6–6.5 micron channel originates above 500 mb (Hanel and Wark, 1961), and it was convenient to compare the results with a previous study using conventional data by Bannon and Steele (1960).

A world map of 500 mb temperatures was constructed from radiosonde and climatological data for the week of 11–18 April 1962. Using this map and the relative humidities of Figure 17, calculations of water vapor mass were carried out using the technique described above.

The results of the calculations are shown in Figure 18. The agreement with the results of Bannon and Steele (1960) shown in Figure 19 is generally good. Three major concentrations of water vapor are located over Indonesia, South America, and Africa, comparing favorably both in position and magnitude with Figure 19, although there are smaller included areas of much higher concentrations indicating near-saturation. Two additional indicated moist regions over 6°N, 100°W and 15°S, 60°W (which are not seen in Figure 19) are located near the position of the ITC in April and were found to persist in an analysis of additional data two weeks later. Hence, they too may be semi-permanent in nature, but conclusions cannot be drawn without more extensive analyses. The marked dry tongue over the Sahara Desert extending westward to the Caribbean Sea and the relative dryness everywhere near latitude 20°N, with the consequent decrease in atmospheric absorption and emission, corroborates the long-wave peak near this latitude in Figure 10. Considering the many approximations used, it is not possible at this time to fully assess the validity of the results, but the patterns are encouraging for additional work in this area.

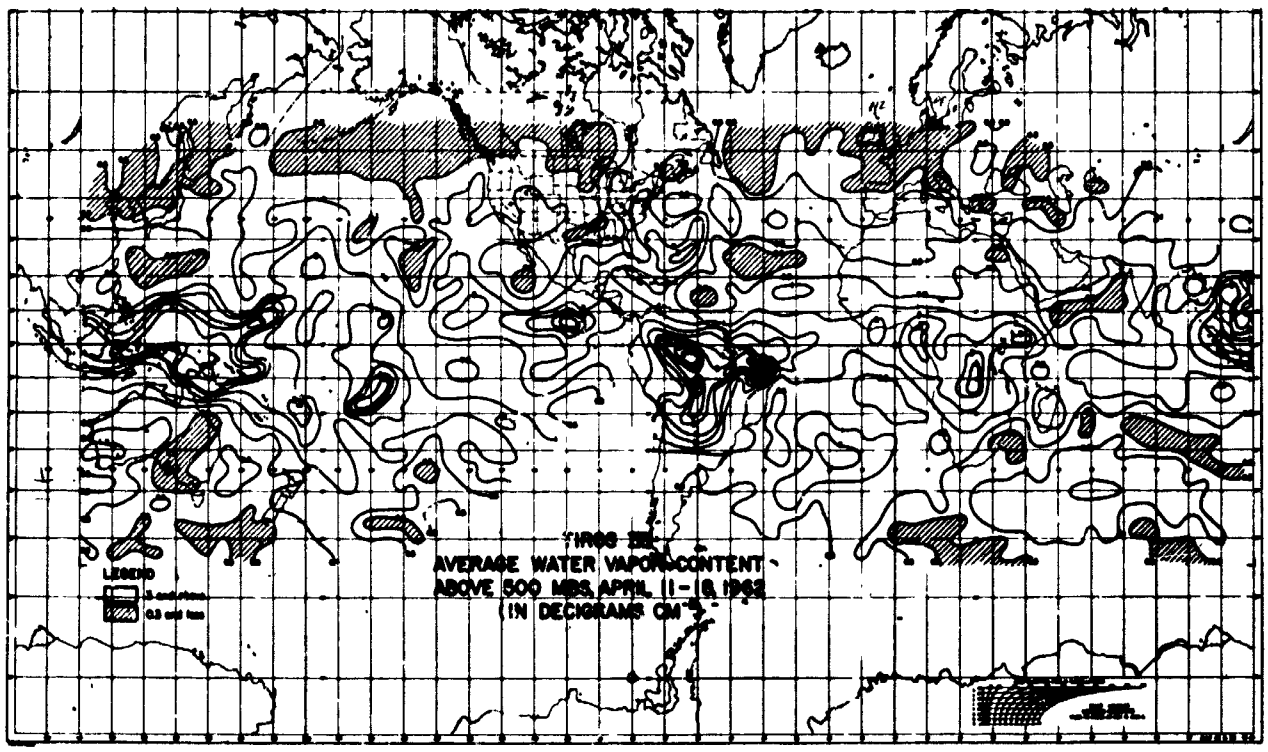

FIGURE 18.—Average water vapor content above 500 mb determined from simultaneous 6.0–6.5 micron and 8–12 micron measurements by Tiros IV and 500 mb temperatures from radiosonde data during the period 11–18 April 1962, in decigrams cm^{-2}.

V. MEASUREMENT OF STRATOSPHERIC TEMPERATURES

One of the optical channels of the TIROS VII radiometer measured infrared radiation emitted mainly by carbon dioxide in the earth's atmosphere at wavelengths ranging from 14.8 to 15.5 microns. A detailed discussion of the physical significance of the measurements in this spectral interval and of the temperature patterns mapped during the first nine months of TIROS VII has been given by Nordberg et al. (1964). We shall only demonstrate by a few examples the ability of this channel to map the mean temperatures of the lower stratosphere on a global scale, and we refer the reader to the original paper for a complete discussion.

The outgoing effective radiance, $\bar{N}$, in the direction of the satellite can be expressed by

$$\bar{N} = \frac{1}{\pi} \int_{\lambda=0}^{\infty} \int_{\lambda=0}^{\infty} B_\lambda(T(h)) \phi_\lambda \frac{\partial \tau_\lambda(h)}{\partial h} dh \, d\lambda$$

$$\bar{N} = \frac{1}{\pi} \int_{\lambda=0}^{\infty} \Psi(h) \, dh \tag{16}$$

$$\Psi(h) = \int_{\lambda=0}^{\infty} B_\lambda(T(h)) \phi_\lambda \frac{\partial \tau_\lambda(h)}{\partial h} d\lambda$$

where

B = Planck function (flux)

ϕ_λ = spectral response function of channel

τ = atmospheric beam transmittance in the direction of the satellite

h = height above the surface

The spectral response function of the channel is shown in Figure 20. Four model atmospheres are shown in Figure 21(a). A homogeneous distribution of CO_2 of 0.00031 fractional parts by volume was assumed in the atmosphere. Using the radiation tables of Elsasser (1960) and a pressure-dependence exponent of $n=1$, the $\Psi(h)$ functions for the four model atmospheres were computed for nadir angles of 0° and 58° (equivalent to a zenith angle of 69°) and plotted in Figures 21(b) and (c). From Figure 21 it may be seen that about 65 percent of the integrated radiance reaching the satellite originates in the region from 15 to 35 km for a nadir angle of 0° and that the weighting curves are shifted upward about 2.5 km for a nadir angle of 58°. Thus even though there are contributions from higher and lower layers, it

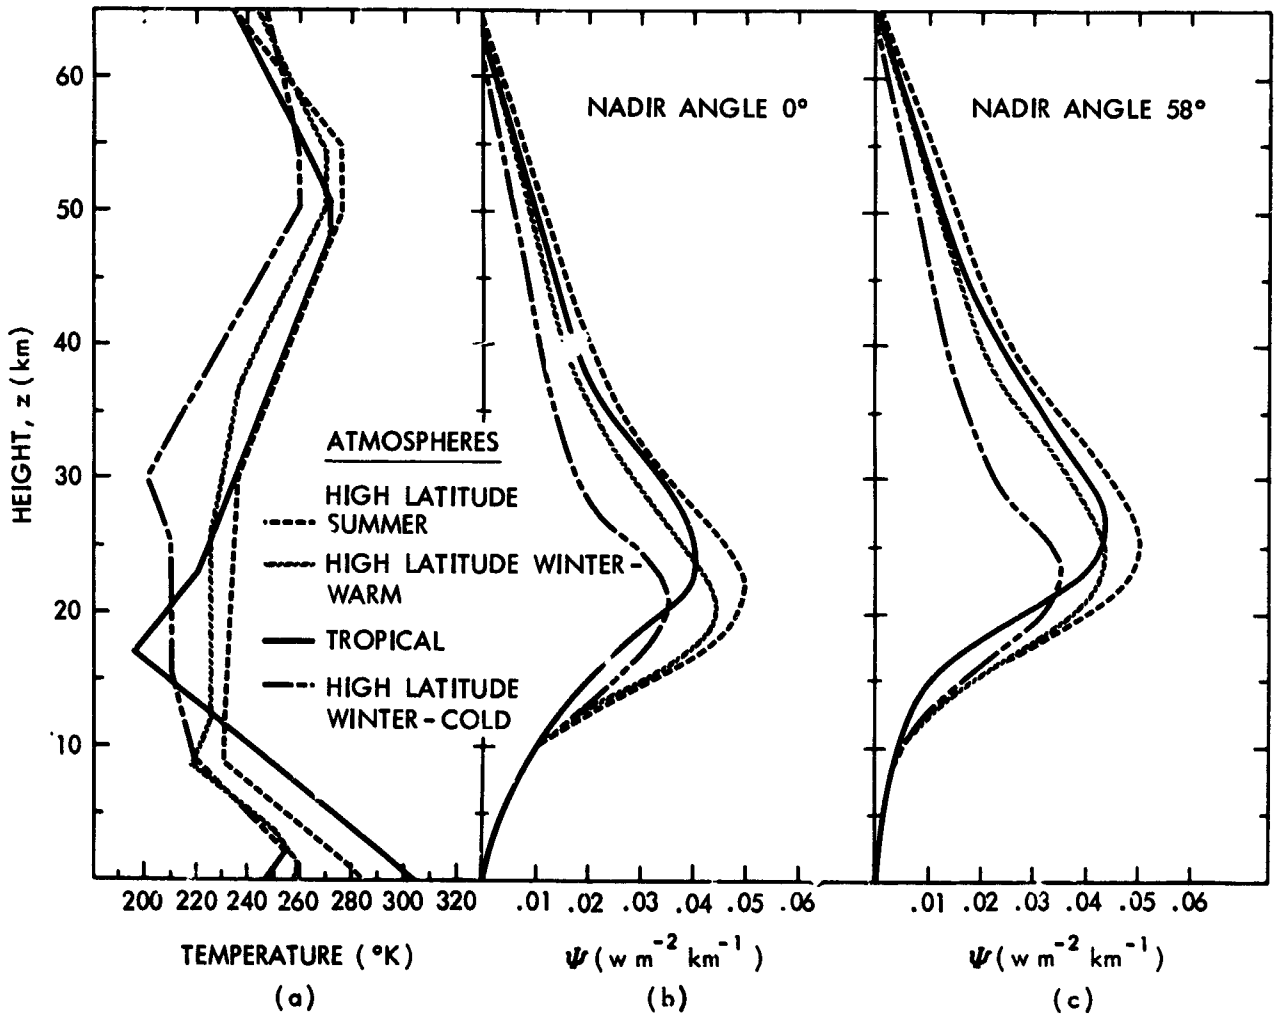

FIGURE 21(a).—Typical temperature profiles based on proposed supplements to the "U. S. Standard Atmosphere 1962" for 60° North summer, 60° North winter (warm and cold) and 15° North. The "warm" and "cold" temperature profiles for 60° N ("high latitude winter") can be considered typical at these latitudes depending on the state of the stratosphere in these regions.

FIGURE 21(b).— Weighting functions Ψ (h), applying to the measured outgoing radiance N; nadir angle = 0°.

FIGURE 21(c).—Weighting functions Ψ (h); applying to the measured outgoing radiance N; nadir angle = 58°.

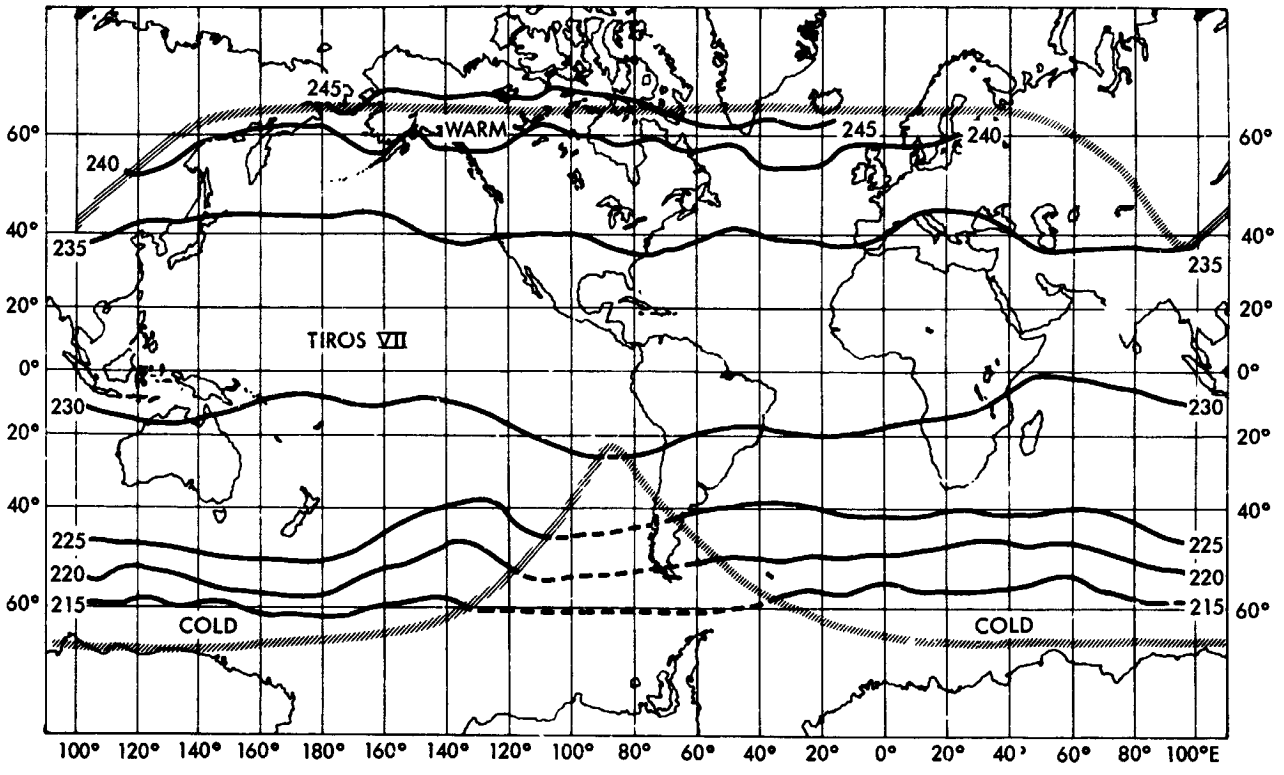

FIGURE 22.—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 19–25 June 1963; nadir angle 0°–40°.

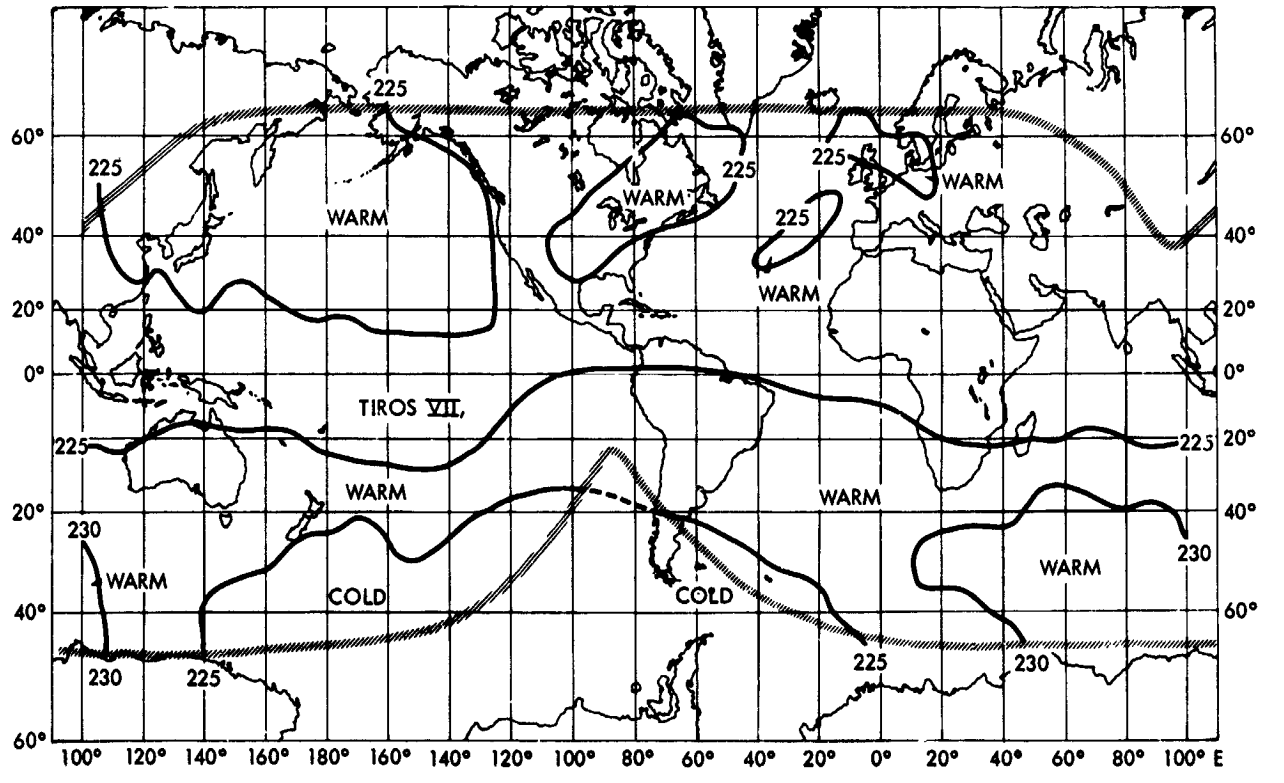

FIGURE 23.—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 25 September-1 October 1963; nadir angle 0°–40°.

is seen that the measurements may primarily be interpreted in terms of temperatures of the lower stratosphere.

A typical temperature pattern at the start of the northern hemisphere summer and southern hemisphere winter is shown in Figure 22. Stratospheric mean temperatures averaged over the week immediately after the launch of TIROS VII, 19–25 June 1963, range from 240°K near latitude 60°N to 215°K near 60°S. The generally zonal structure of the temperature pattern confirms the established knowledge of the lower stratosphere, namely, the existence of a very strong cyclonic circulation system around the cold low pressure core centered near the winter pole and an anticyclonic circulation system around the warm high pressure system centered over the summer pole.

The map for the period 25 September–1 October 1963 illustrates the transition period. It is important to point out that due to instrumental degradation, all temperatures shown in Figure 23 and all succeeding maps are about 7°K too low, inasmuch as the degradation seemingly leveled off in July and August after an initial rather rapid decline. In Figure 23 the southern winter vortex has broken down and the temperature gradients between the two hemispheres have reached thier minimum during the transition period.

The map for the period 15–22 January 1964 (Figure 24) illustrates the state of the stratosphere in opposite seasons to those depicted in Figure 22. The southern hemisphere summer pattern is very much like its northern hemisphere counterpart in Figure 22. However, a striking difference is seen in the northern hemisphere winter. The "Aleutian Anticyclone", a regular climatological feature, displaces the cold stratospheric cyclone from the position of symmetry that one might expect it to have. The strong Aleutian Anticyclone established itself in the first week of December and remained throughout the entire winter.

During the last week of January 1964 a stratospheric warming of apparently moderate intensity occurred over the region of the Caspian Sea. The situation is summarized in Figure 25 which shows that on 27 January the radiation temperatures had increased by 15°K over the averages for the week of 9–15 January near the center. During the

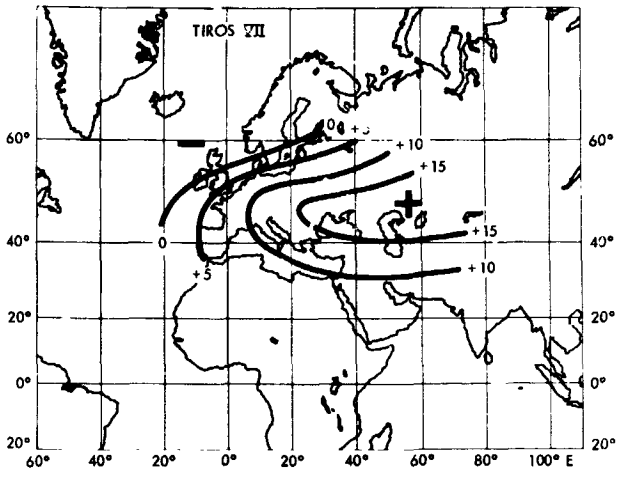

FIGURE 25.—Regional map of the differences between the 15μ equivalent blackbody temperatures measured on 27 January 1964 and those averaged over the week 9–15 January; nadir angle 0°–40°. The effects of a stratospheric warming over Eastern Europe are illustrated.

following week, 31 January–8 February, the warming passed its climax and dissipated soon thereafter.

The global temperature structure undergoes a major change during the period from early February to the period around the Vernal Equinox in Figure 26. The strong zonal winter temperature patterns, particularly over the eastern hemisphere, as well as the zonal summer pattern in the southern hemisphere have disappeared. The southern hemisphere has cooled considerably, resulting again, as in September, in an almost constant temperature, 223°+7°K, prevailing over the entire globe.

VI. SUMMARY

Studies involving satellite radiometric data have been carried out in three areas of climatological interest—the planetary heat balance, the upper tropospheric content and distribution of water vapor, and the temperature and associated circulation patterns of the lower stratosphere. Even though difficulties exist in certain areas, such as instrumental stability, and interpretations of the essentially-beam measurements, the results give a new insight into the large-scale, long-term radiative characteristics of our planet and the physical processes which can be derived from them. The comparative relationships indicating hemispheric asymmetries and seasonal fluctuations in the various parameters appear to be valid.

Finally, the potentialities of climatological investigations from future satellites—in polar orbits and with improved instrumentation—have been clearly demonstrated, we believe, by the studies reported in this paper.

VII. ACKNOWLEDGEMENTS

We gratefully acknowledge the contributions of the many persons, too numerous to mention individually, who have contributed to the success of the TIROS series of meteorological satellites. We are particularly indebted to Mr. Robert Hite and his group for their computational efforts in reducing the vast amount of radiation measurements and to Mr. Lewis Allison for his significant contributions in regard to the water vapor analyses.

TIME CORRELATION OF EXTREME ULTRAVIOLET RADIATION AND THERMOSPHERIC TEMPERATURE

R. E. BOURDEAU, S. CHANDRA† AND W. M. NEUPERT

Thermospheric temperatures deduced from satellite drag observations are compared with the intensity of extreme ultraviolet radiation measured on the first Orbiting Solar Observatory (OSO–1). The comparison leads to a conclusion that, for the two complete solar rotation periods during which the EUV data are available, the 27-day periodic variation in upper atmospheric density was due to corresponding changes principally of ultraviolet rather than corpuscular radiation.

INTRODUCTION

It generally has been accepted that the absorption of solar extreme ultraviolet (EUV) radiation constitutes an important mechanism for atmospheric heating. The possibility of an additional heat source of importance comparable to the EUV effect has been introduced by many investigators to explain semi-annual, diurnal and 27-day variations in atmospheric densities deduced from satellite drag observations. However, the need for a heat source as important as EUV radiation in order to explain temporal density changes does not appear to be conclusive.

Paetzold and Zschörner (1960) first suggested that semi-annual variations in atmospheric density could be associated with corresponding changes in geomagnetic activity and thus with possible slow changes in a second heat source associated with the solar wind. However, they depended on correlating satellite deceleration data for the period 1958–1961 with geomagnetic indices for the corresponding months averaged over the previous solar cycle. According to Bartels (1963), a positive correlation is not obtainable if the satellite deceleration data are compared with simultaneously-observed geomagnetic indices. This sheds doubt on the need for a solar wind effect to explain semi-annual density variations.

Harris and Priester (1962), by solving the heat balance equation have proposed that the EUV effect should result in a diurnal maximum in atmospheric density at 17^h local time. The observed maximum deduced from satellite drag studies occurs at about 14^h local time (Jacchia, 1963). To account for the difference between the observed and their theoretically-computed time for the diurnal maximum, Harris and Priester empirically introduce a second heat source equivalent to the EUV effect and which they identify with the solar wind. However, an alternative explanation for the phase shift is that the heat source is entirely EUV but a transport mechanism exists which shifts the absorbed energy toward the west. (Priester, private communication).

MacDonald (1963) has suggested that there is a systematic 56-hour phase delay between the 27-day cycles in observed decimetric solar flux and satellite-drag inferred densities, a delay corresponding to a straight line velocity from the sun of 750 km sec^{-1}. Since 750 km sec^{-1} is characteristic of solar wind velocities, MacDonald concludes that the 27-day period in atmospheric density is entirely due to corpuscular rather than EUV radiation.

In this paper daily averages of 170–400Å radiation measured by use of the first Orbiting Solar Observatory during March–May 1962 are time-correlated with satellite drag observations and with geomagnetic activity. The comparison leads to a conclusion that for the two complete solar rotation periods during which the EUV data are available, the 27-day periodic and the day-to-day

†Goddard Space Flight Center. Mr. Chandra is a NAS-NASA Postdoctoral Resident Research Associate.

variations in upper atmospheric density are principally due to EUV radiation, a conclusion which is not in harmony with MacDonald's.

MEASURED ULTRAVIOLET SPECTRUM

The solar radiation data used in our analyses were obtained by the use of a grazing incidence spectrometer pointed at the center of the solar disk within several minutes of arc. In this orientation the spectrometer analyzed radiation from the entire solar disk and inner corona, covering the nominal spectral range from 10Å to 400Å with a resolution of 0.85Å once every 8.5 minutes. Variations in several of the more intense lines in the observed spectrum have already been associated with solar flares (Behring, et al., 1963) and the slowly varying component of solar activity (Neupert, et al., 1964). In this paper, we present time variations of the EUV flux representing the sum of the intensities of the twenty-two most prominent lines in the range 170–400Å. These lines are identified by asterisks in the two spectral scans shown in Figure 1.

Since an absolute calibration of the OSO–1 spectrometer has not yet been completed, an indirect method of calibration has been used to derive flux from measured counting rates. This method consists of comparing the counting rates obtained from the OSO–1 instrument with fluxes

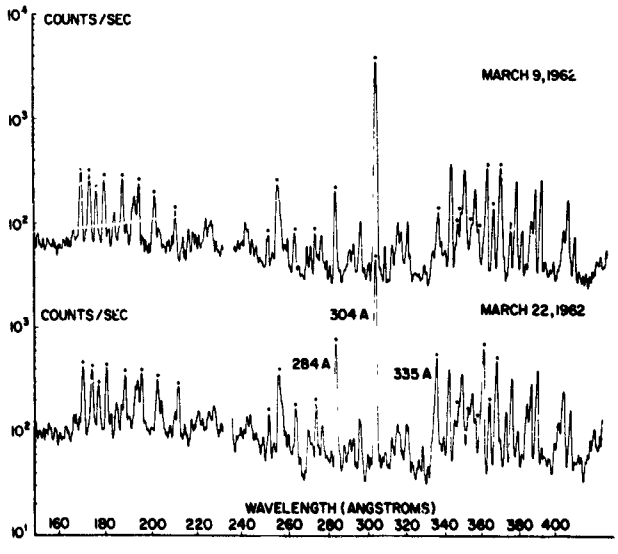

FIGURE 1.—Spectra obtained by OSO–1, grating spectrometer for two days of different solar activity. The lines marked by asterisk were used in the present analysis. Unmarked lines above 340A represent second order images of lines observed at shorter wavelengths.

measured by Hall et al., (1963) who used a calibrated rocketborne spectrometer. The comparison could only be made in the spectral region for which the two instruments overlapped, 250Å to 400Å. Furthermore, the comparison is meaningful only if the solar radiation on the day of the rocketborne measurement was indeed the same as on the days of OSO–1 observations chosen for comparison. The mean daily solar radio flux at 2800 Mc, measured by the National Research Council, Ottawa, Canada, was used as a measure of solar activity to obtain equivalent days of OSO–1 observations. Calibration of the instrument was extrapolated below 250Å using the measured reflectivity of the grating and an estimate of the detector sensitivity.

Each of the spectral lines used in the intensity estimate was observed 75 to 100 times during each day of observation, thereby yielding an accuracy of about one percent in the determination of the counting rate for each line, assuming a constant line intensity throughout the averaging period. The estimated error of the sum of intensities of the twenty-two brightest lines is therefore significantly smaller than the observed day-to-day variations. It has been found that the details of the time variations are relatively insensitive to likely changes in the assumed calibration of the instrument and also to the inclusion of numerous fainter lines in the sum of intensities. The daily averages of the sum of the intensities of the twenty-two discrete lines are illustrated in Figure 2a. Because of the uncertainties in calibration, the absolute value of the overall curve should not be taken as reliable but the time variations should be valid.

PHASE COMPARISON BETWEEN ATMOSPHERIC TEMPERATURE AND MEASURED ULTRAVIOLET RADIATION

Altitude variations in EUV spectra obtained by use of rocket-borne nomochromators (Hinteregger and Watanabe, 1962) establish that the portion of the spectrum which contributes most heavily to thermospheric heating lies between 1026 and 170Å. A summary of these and other EUV measurements (Watanabe and Hinteregger, 1962) indicates that the twenty-two discrete lines identified in Figure 1 represent approximately one-third of the pertinent ultraviolet radiation. Thus

conclusions derived from the EUV data presented here will depend on the reasonable assumption that the entire spectrum between 1026–170Å exhibits the same temporal variation as the sum of the intensities of these twenty-two discrete lines. Conclusions drawn from the EUV data additionally will depend on the assumption that the contribution of the twenty-two individual lines to thermospheric heating is proportional to their respective intensities. One weakness in such an assumption arises from uncertainties in our knowledge of the absorption and photoionization cross sections of the atmospheric constituents as a function of wavelength. However, a review (Watanabe and Hinteregger, 1962) does suggest that the cross sections of the important atmospheric constituents (O, O_2 and N_2) individually are reasonably independent of wavelength for the spectral region considered here.

Plotted in Figure 2b are the daily values of the temperature (T) representative of diurnal maximum conditions in the isothermal altitude region. These values of T were computed by Jacchia and Slowey (1963) from their observations of the deceleration of the Explorer 9 satellite and a theoretical model (Nicolet, 1961) of atmospheric density profiles as a function of temperature. It should be emphasized that, although the absolute value of T and the EUV intensity may be somewhat uncertain, we are interested here only in the validity of the time variation.

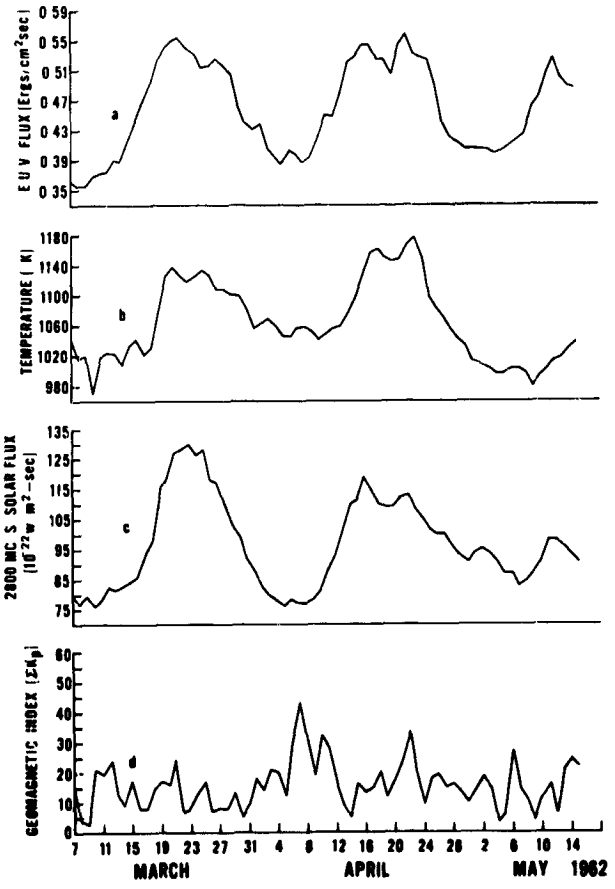

FIGURE 2.—Comparison of the EUV flux with the atmospheric temperature, the 2800 Mc/s solar flux, and the geomagnetic index ΣK_p.

By comparing Figures 2a and 2b, we conclude both from visual inspection and from a least-square fit performed by a computer analysis that the phase difference between T and the measured EUV radiation for the March and April solar rotations is of the order of one day. A one day delay can be explained either by the uncertainty of the satellite deceleration data or by the relaxation time of the atmosphere. Thus, it can be considered that there is a positive correlation between T and the EUV flux, leading to the conclusion that the day-to-day and the 27-day periodic variation of T are due principally to the EUV effect, at least for the months of March and April, 1962. It should be noted that despite the uncertainty in the individual T points, the short term variations in the atmospheric temperature correlate quite well with corresponding EUV radiation changes. Note, for example, the existence of double peaks in both the T and the EUV data during the maxima of the March and April solar rotations.

The 10.7 cm decimetric radiation has been plotted in Figure 2c. Comparison with Figure 2a shows that decimetric flux is an approximate but not precise index of the EUV effect. MacDonald (1963) has suggested that there is a systematic 56-hour delay between the emission of solar decimetric radiation and the response of the atmosphere. Since this corresponds to typical velocities of the solar wind, this delay led him to conclude that the 27-day density fluctuations are entirely due to interaction of the upper atmosphere with the solar wind. It should be noted that Jacchia (1963) reports that there was no appreciable lag between 10.7 cm solar flux and atmospheric density for the same period analyzed by MacDonald.

It also is possible to conclude that the two 27-day cycles in T considered here are not significantly associated with the solar wind from

simultaneously-measured indices of geomagnetic activity. Snyder et al., (1963) have measured the velocity of the solar wind and have quantitatively related this parameter to the geomagnetic index, Σk_p. Consequently, we have plotted the Σk_p index for each day of the pertinent period in Figure 2d. Using the relationship between solar wind velocity and Σk_p established by Snyder and et al., we estimate that if the solar wind is entirely responsible for the 27-day variation of the upper atmosphere temperature there should be an average phase delay of 4 days between the EUV flux and T, a delay much in excess of the average value derived from Figures 2a and 2b. Thus, we conclude that the solar wind was not significantly effective in heating the upper atmosphere during March and April, 1962. This does not contradict the findings of Jacchia (1963) who has associated significant transient increases in atmospheric density with geomagnetic activity generally much more intense than what was characteristic of the time interval studied here.

There is a suggestion of a significant enough phase delay between T and the EUV radiation during the May rotation to support the need for another heat source. However, it would be dangerous to draw any firm conclusion from this cycle without data throughout the complete solar rotation.

COMPARISON BETWEEN DIURNAL AMPLITUDE OF ATMOSPHERIC TEMPERATURE AND MEASURED ULTRAVIOLET RADIATION

It is important to compare the respective amplitudes as well as the phases of the 27-day temperature and EUV variations. In Figure 2, even though the amplitudes of the two complete EUV cycles are approximately the same, the amplitudes of the corresponding T cycles differ significantly from each other. Due to the motion of the perigee of the satellite under study with respect to the sun-earth line, the diurnal temperature variation shows up in the data of Jacchia and Slowey in addition to the day-to-day variation. For our purposes, we should have temperatures reduced to the same local time. For this reason we will now compare the differences between diurnal temperature maximum (T) and minimum (T_0) with heat source variations. It will be shown that the amplitudes of the 27-day variation of ($T-T_0$) and of the EUV cycles present a consistent picture. Jacchia (1963) has suggested the following empirical formula which relates day and night temperatures deduced from drag observations:

$$T = T_0\left(1+0.33\cos^n\frac{\Psi}{2}\right), \qquad (1)$$

where T_0 corresponds to the nighttime temperature minimum, Ψ is the angular distance between satellite perigee and a point 30 degrees east in longitude of the subsolar point and where $n=4$.

In Figure 3, we have set $n=1, 2, 4$, and compare the three resultant $T-T_0$ curves with the EUV data, using observed values of Ψ applicable to the Explorer 9 satellite. It is seen that by the use of $n=4$, one tends to overcorrect for the change in Ψ

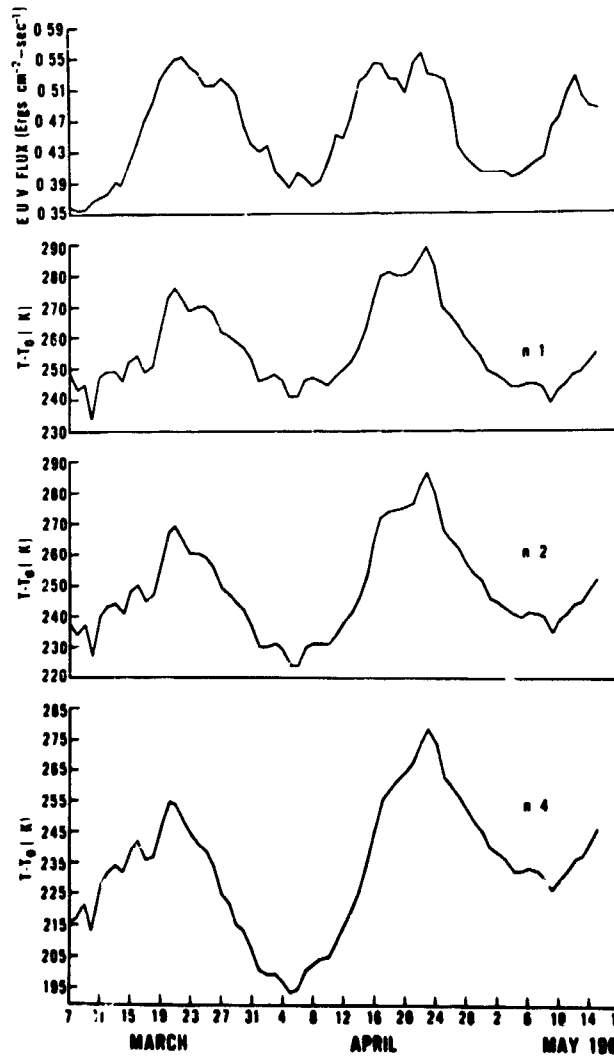

FIGURE 3.—Comparison of the EUV flux with the diurnal amplitude as computed from Equation 1 for $n=1$, 2 and 4.

with time in that now the amplitude of the second temperature cycle is larger than the first. An appropriate value for n seems to be between 1 and 2, as demonstrated by the very favorable comparison between the relative amplitudes of the two EUV cycles with the relative amplitudes of the two temperature cycles for $n=1$ and 2. Jacchia (private communication) independently concludes that a much lower value of n than was previously used is more consistent with satellite drag observations.

CONCLUSIONS

Daily values of atmospheric temperature have been compared with EUV radiation data and also with indices of geomagnetic activity. The analysis which includes both a phase and amplitude study favors the EUV rather than the solar wind effect as principally responsible for the 27-day variations in atmospheric temperature at least for the months of March and April 1962. The question as to whether this conclusion applies at all times and whether a second source of heating is required to explain semi-annual and diurnal temperature variations remains open.

ACKNOWLEDGEMENTS

DETAILED BEHAVIOR OF THE MIDLATITUDE IONOSPHERE FROM THE EXPLORER XVII SATELLITE*

L. H. BRACE, N. W. SPENCER AND A. DALGARNO†

Measurements of electron temperature and ion density by electrostatic probes on the Explorer XVII satellite have revealed the detailed diurnal and latitudinal behavior of the summer ionosphere near the altitude of the F_2 maximum over the eastern United States at the time of solar minimum. The electron temperature at 40° North magnetic latitude is observed to rise rapidly from a nighttime value of about 1100°K to a mid-morning maximum of 2700°K followed by an afternoon plateau of 2000°K. The electron temperature always exceeds accepted values of neutral gas temperature and thus reflects the existence of heat sources in both the daytime and nocturnal ionosphere. The ion density displays a maximum value about three hours after local noon. A strong degree of latitude control, evident near the F_2 maximum, causes the temperature to increase and the density to decrease with increasing latitude. The electron temperature is relatively independent of altitude between 260 and 450 kilometers in the forenoon but displays a slight increase with altitude at night. The diurnal variations found over stations at 10° and 60° North magnetic latitude display general characteristics similar to those found at 40° N and also reveal the inverse gradients of temperature and density with latitude. Calculations based on the measurements show that the ion temperature begins to exceed the neutral temperature significantly above 300 kilometers and approaches the electron temperature near 600 km. The ratio of electron to ion temperature at 300 km is between 2 and 3 in the daytime and about 1.5, but highly variable, at night. The measurements are also employed to calculate the amount of electron heating in the F region. It appears that heating by solar ultraviolet radiation is adequate to explain the daytime results below 300 kilometers, and that the available flux of ionizing photoelectrons is adequate to account for the heating at higher altitudes. The heating at night is consistent with a corpuscular flux of soft electrons with a total energy of about 1×10^{-2} ergs cm^{-2} sec^{-1}.

INTRODUCTION

Between 1959 and 1961 a series of measurements of electron temperature using rocket-borne electrostatic probes at Ft. Churchill, Manitoba and at Wallops Island, Virginia, established that there are marked differences between the electron temperature and the heavy particle temperature in both daytime and nighttime ionospheres (Boggess, Brace and Spencer, 1959),[1] (Spencer Brace and Carignan, 1962),[2] (Brace, Spencer and Carignan, 1963).[3] The data show also that the magnitude of the temperature difference increases with latitude, a conclusion in harmony with later observations from the Ariel satellite (Willmore, Henderson, Bowen and Boyd, 1964).[4]

It was clear that further measurements were desirable to determine more precisely the extent of non-equilibrium for a wide variety of ionospheric conditions, especially since the degree of thermal non-equilibrium is a sensitive indicator of atmospheric energy sources. Theoretical studies (Hanson and Johnson, 1961),[5] (Dalgarno, McElroy and Moffett, 1963),[6] (Hanson, 1963),[7] (Dalgarno, 1963)[8] had demonstrated the close relationship of the charged particle temperature and densities to the composition and structure of the neutral particle atmosphere, and thus had emphasized the need for simultaneous measurements of ionospheric and neutral particle parameters. Accordingly, cylindrical electrostatic probe experiments, similar to that employed in the rocket flights, were included with the neutral partical mass spectrometer and total density gauge experiments in the Explorer XVII satellite, (Reber, Nicolet, 1965)[9] (Newton, Horowitz, Priester, 1965).[10] A brief description of some of the satellite probe measurements has been given

*Published as *Goddard Space Flight Center Document X-651-64-368*, November 1964.

†The Queen's University of Belfast, North Ireland.

(Brace and Spencer, 1964).[11] In this paper, we shall report the probe results in more detail and discuss their significance in the context of the heat balance in the ionosphere.

THE ELECTROSTATIC PROBE EXPERIMENTS

The cylindrical probes employed for the measurements of electron temperature T_e and ion density N_i were dimensioned to operate in an orbital-motion-limited mode (Mott-Smith and Langmuir, 1926).[12] Each collector was 23 cm in length and 0.056 cm in diameter. A guard electrode, 10 cm in length, was employed to prevent the collection of charged particles within the ion sheath surrounding the satellite. Both the collector and guard were made of stainless steel. The location of the sensors is discussed in an accompanying paper (Spencer, 1965).[13]

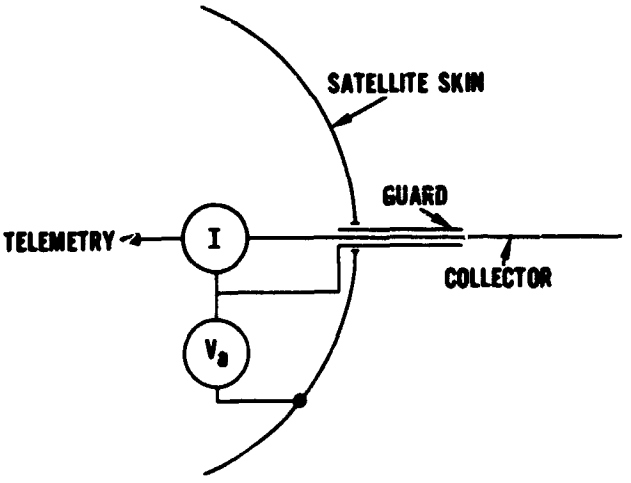

FIGURE 1.—Functional diagram of either the electron temperature (T_e) or the positive ion density (N_i) probe experiment.

Figure 1 is a functional block diagram which applies for either the T_e or the N_i experiment. The electronic circuitry associated with each sensor provided suitable sawtooth sweep voltages and current measuring sensitivities to optimize one experiment for the determination of N_i and the other for the measurement of T_e. The experiments operated simultaneously throughout each 4-minute satellite pass and provided simultaneous point by point measurements of both T_e and N_i along the satellite path.

The Ion Density Measurement

The voltage applied between the N_i probe and the satellite was swept both negative and positive (−3 v to +2 v) so that both the ion and electron saturation regions of the volt-ampere characteristics were observed. Since the satellite potential was normally about −0.5 v, the probe potential V relative to the plasma was −3.5 to +1.5 v. The ion saturation region of a cylindrical collector (when employed on a satellite) is particularly useful for determining the local charged particle density because the flux of ions intercepted by the probe is determined largely by the satellite velocity and the collector orientation, which are known factors. Because of the high satellite velocity the ion current I_i is relatively insensitive to the thermal velocity of the ions and the accelerating potential of the collector, factors which are less well known.

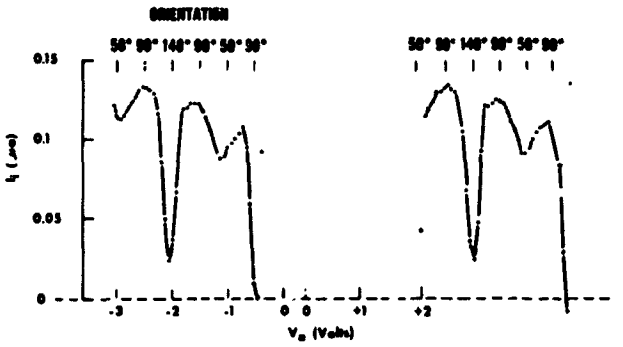

FIGURE 2.—Raw telemetry data (points) for two consecutive volt-ampere characteristics of N_i probe. The ion saturation regions, modulated by the changing probe orientation, display maximum ion current when the probe is perpendicular to velocity vector (90°) and minimum current when the probe looks forward (50° in this case) and aft (140°).

Figure 2 shows a machine-plot of raw telemetry data points representing two consecutive volt-ampere characteristics from the N_i probe. At positive applied voltages the measured current is off-scale negative due to the predominance of electron current, and only the ion saturation regions are visible. The sweep period (2 seconds) was made several times the spin period (0.7 seconds) so that the effects of changes in orientation upon collection area and wake effects could be studied through the manner in which they modulate the

ion saturation current. Maxima in the ion current (I_{max}) occur twice per satellite spin, corresponding to those times when the probe axis is perpendicular to the velocity vector. At this orientation the collector presents its maximum projected area to the plasma stream. In addition, a major minimum of ion current is observed each time the probe is rotated into the wake region behind the satellite. A secondary minimum occurs 180° later when the sensor is ahead of the satellite and presents its minimum projected area to the stream.

The relatively small effect of the applied voltage is evident in the slight decrease of I_{max} between successive maxima. This decrease corresponds to a voltage change of about 1 v. Curves such as those shown in Figure 2 permit one to derive empirically the functional dependence of I_{max} upon V, a relationship which is needed for an accurate evaluation of N_i from the measured ion currents. Using the slope of I_{max} versus V derived from a representative selection of probe data, I_{max} was found to be about 20 percent ± 3 percent higher than would be observed at $V=0$, where no acceleration of the ions occurs. Neglecting a very small enhancement of the current due to the thermal motion of the ions (<4 percent), the current at $V=0$ is simply the charge per unit time swept out by the frontal area of the collector. Therefore the ambient positive ion density is given by:

$$N_i=\frac{0.8I_{max}}{\ell d e v_s}=V=0 \qquad (1)$$

where ℓ is the length and d is the diameter of the collector, e is the unit charge and v_s is the satellite velocity.

Because I_i is always measured at the same orientation, the relative accuracy of the N_i measurements depends primarily upon the current detection error, which does not exceed 5 percent for $N_i>5\times10^4$ cm^{-3}. The absolute accuracy of N_i is better than 10 percent when 0^+ ions predominate (below 600 km).

The Electron Temperature Measurement

Between the extremes of ion and electron saturation, the probe current characteristic exhibits an exponential shape whose curvature permits a direct interpretation of the curves in terms of the electron temperature (Mott-Smith and Langmuir, 1926).[12] The analysis of individual curves is carried out by the log-plot technique in which T_e is given by the slope of $\log_e I_e$ with respect to V, as given by (2)

$$\frac{d\log_e I_e}{dV}=-\frac{e}{kT_e} \qquad (2)$$

Based on the experience gained with identical probes on ejectable rocket-borne instruments (Spencer, Brace and Carignan, 1962),[2] the T_e experiment was designed to permit high resolution of the exponential portion of the volt-ampere characteristics, with primary emphasis on thermal electrons in the $0-1$ eV range. To permit ample voltage resolution through a wide range of T_e, two saw-tooth sweeps were employed (0 to +0.75 v and 0 to +1.5 v). The telemetry sampling rate assigned to the experiment (180 samples/sec) was sufficient to permit a sweep rate of 10 curves per second. The necessary current resolution was provided by two linear current detectors of 1 μa and 5 μa full scale sensitivity which time-shared the assigned telemetry channels on a 10-second-on, 10-second-off basis. Each detector recorded 100 consecutive volt-ampere curves during its on-period.

Figure 3 is a computer plot of 1 μa and 5 μa raw telemetry data at the beginning of two consecutive 10 second on-times recorded during a nighttime Blossom Point pass. The temperature and density at this time were moderately low ($T_e\simeq1200°$ K, $N_i\simeq1\times10^5$ cm^{-3}). The inflight current calibrations at the left were obtained by substituting appropriate known resistances for the probe sensor at the beginning of each 10 second series of curves. The 5 μa data taken with a 1.5 v sweep permit a "coarse" measurement of the characteristics. A "high resolution" measurement is provided by the 1 μa detector with a 0.75 volt saw-tooth applied. This combination of sensitivities and voltages permitted high resolution measurements of T_e between 500° and 5000° K, when N_i exceeded 3×10^4 cm^{-3}. The satellite spin period is apparent in Figure 3 in the modulation envelope of the electron current curves (not particularly marked in this example). This modulation stems from both the reduction of

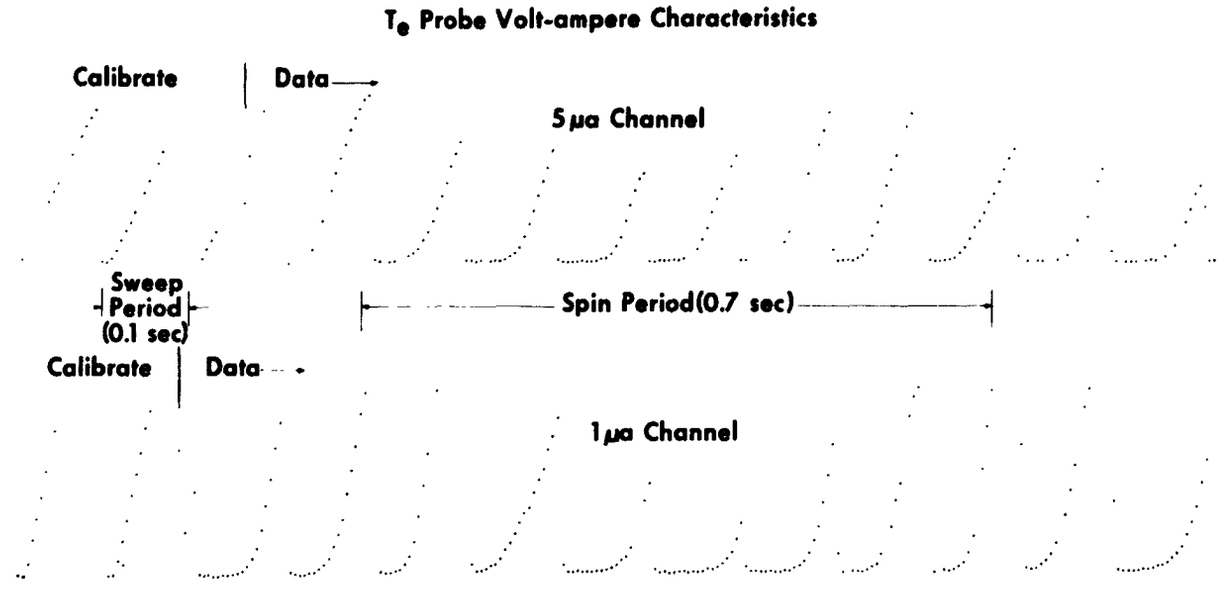

FIGURE 3.—Raw telemetry data showing a series of 5μa (0 to 1.5 v applied) and 1μa (1 to 0.75 v) current characteristics, each preceded by an inflight current calibration. The 1μa channel provides the high resolution necessary to permit accurate determination of the low electron temperature in nighttime passes such as this one.

charged particle density in the wake region immediately behind the satellite and the modulation of probe voltage by the induced $\vec{B}\times\vec{v}_s$ voltage caused by motion of the satellite through the Earth's magnetic field, $\vec{B}$. Measurement error due to these easily recognized effects has been avoided by selecting for analysis only those non-wake curves which correspond to the minimum rate of change of induced voltage. Following this criterion for curve selection, the relative accuracy of the T_e measurements within a given satellite pass is better than 5 percent. The absolute accuracy depends upon the maintenance of the linearity and amplitude of the saw-tooth sweep voltage throughout the life of the satellite. Frequent checking of inflight calibrations has shown no detectable change and the absolute accuracy is believed to be better than 5 percent on most passes.

Figure 4a and 4b help to demonstrate the computer methods employed in the T_e analysis. Figure 4a is a computer printout arranged to display a single volt-ampere characteristic as it appeared on the 1 μa channel, and 4b is a log-plot of the same characteristic. Because of a limited plotting interval imposed by the printer, the plotting accuracy shown is only 1/10th the accuracy of the actual data. The computer is programmed to make a best straight-line fit to the linear part of the log plot and then print out the corresponding T_e according to equation (2). Plots of this type are made by the computer for each curve of a group of 15 consecutive curves. Several groups are chosen from each satellite pass to permit hand verification of the computer values of T_e. All temperature data presented in this paper have been verified in this manner.

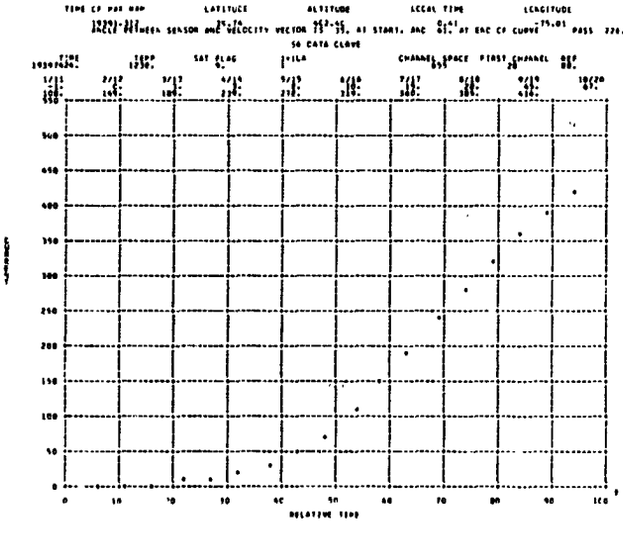

FIGURE 4a.—Computer plot of single current characteristic demonstrating the computer analysis procedure. Telemetered points (current) and plotted versus time (voltage, 0→0.75 v) to permit visual identification of exponential portion of curve (0 to 60 milliseconds).

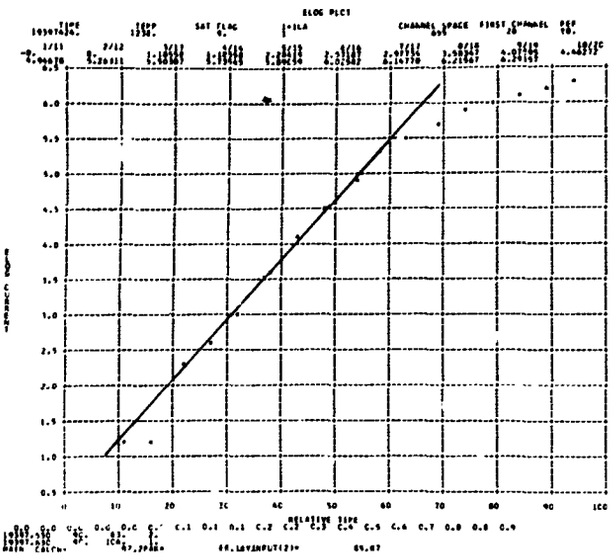

FIGURE 4b.—Computer plot of natural log of currents in Figure 4a showing the linear portion which is related to T_e. Line drawn by hand permits manual check of computer value of T_e printed automatically above.

RESULTS

Motion of the Satellite

The inclination of a satellite orbit simultaneously determines the precession rate of the orbit plane and the movement of perigee, so that a given satellite may sample the atmosphere at only unique combinations of local times and altitudes over each telemetry station. Thus, the orbital inclination determines the aeronomic coverage which a particular satellite can provide. For example, in its 100 day lifetime, Explorer XVII's inclination of 58°, combined with apogee and perigee altitudes of 927 and 258 km, provided the coverage over Blossom Point shown in Figure 5. Each pair of points connected by a line represents the beginning and end of a particular satellite pass. Although the pattern of coverage was similar at other latitudes, perigee and apogee occurred at other local times.

Figure 5 aids in selecting those Blossom Point passes in which diurnal and altitude effects can be most effectively separated. For example, the southbound set of passes provides an excellent opportunity to study the diurnal variation of T_e and N_i at a fixed altitude (perigee) through the daylight hours.

In processing the data from each telemetry station we derived a single value of T_e and of N_i

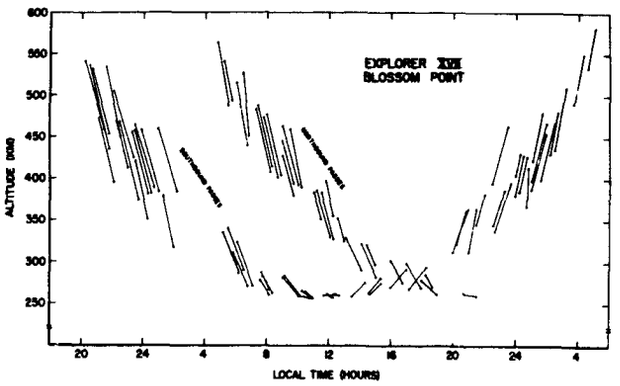

FIGURE 5.—Altitude and local solar time coverage over blossom point produced by the precession of the orbit plane and the movement of perigee during the 100-day active lifetime of Explorer XVII. The points joined by lines represent the positions of the satellite at the beginning and end of each pass.

from groups of volt-ampere curves taken at one-minute intervals through each satellite pass and plotted the beginning-of-pass and end-of-pass values of T_e and N_i against local solar time. Although the gross variations evident in the resulting local time plots for each station may reflect some altitude and seasonal variations in the atmosphere, the rapid precession of the orbit plane ensures that local time effects will predominate. Variations of T_e and N_i within a particular pass, however, are controlled by latitude or altitude changes in that pass because the local time change within a pass is small.

Blossom Point Data

Table 1 contains the values of T_e and N_i measured at the beginning and end of each Blossom Point pass, with the corresponding positions of the satellite and concurrent values of the solar index ($F_{10.7}$) and of the magnetic index (a_p).

To permit the local time, altitude, latitude and season of each measurement to be identified, data from southbound and northbound passes have been plotted separately in Figures 6 and 7, respectively. The points joined by lines are the beginning and end-of-pass values and the figures show the average altitude and the month of the pass.

Latitude and Local Time Effects

In order to show the effects of latitude, smoothed curves have been drawn in Figure 6 through the values measured at magnetic latitudes

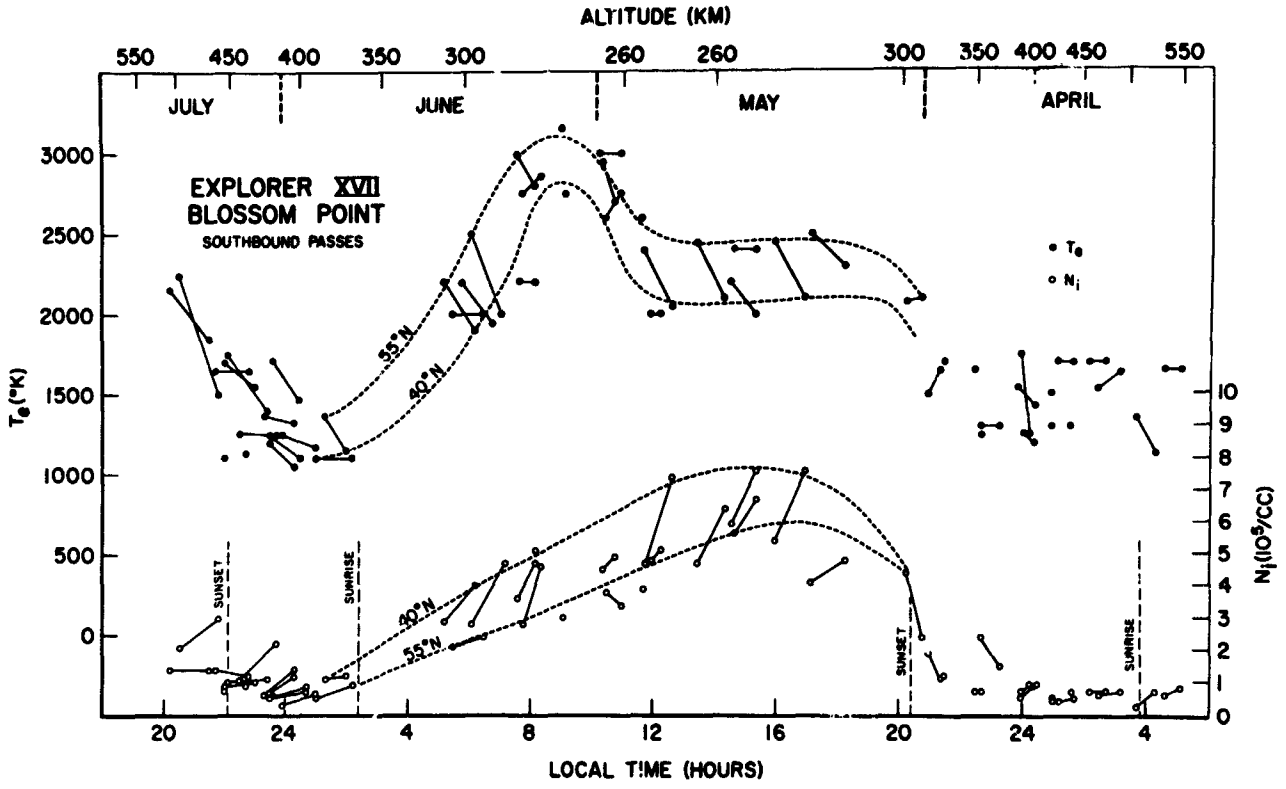

FIGURE 6.—T_e and N_i data from southbound Blossom Point passes identified with the altitude, month, and local times. The points joined by lines represent beginning-of-pass and end-of-pass values. The latitude gradient in T_e and N_i, evident in the daytime, made possible latitude identification of the data as well.

of 40° N and 55° N, the extremes of latitude observed from Blossom Point. The smoothed curves therefore represent an averaged diurnal variation of T_e and N_i near F_2 maximum at the indicated magnetic latitudes. The major characteristics of the diurnal variation of electron temperature are a nighttime minimum, a steep rise to a mid-morning maximum, and an afternoon plateau, followed by a decline to a lower, more variable, value at night. This behavior is very different from the diurnal variation of the neutral gas temperature (T_g), which exhibits a maximum in the afternoon rather than the morning. The values of T_e are clearly much in excess of T_g, even at night. The diurnal variation in N_i is characterized by a gradual morning rise, an afternoon maximum and a sharp decrease at sunset.

It is particularly significant that in all southbound daytime passes the satellite was near perigee and therefore was changing altitude very little. Thus the changes in T_e and N_i observed within each of these passes must reflect the latitude control which was first evident in the smoothed diurnal variation curves for 40° and 55° N magnetic latitude. The average temperature gradient is about 25° K/° latitude, at this latitude and altitude.

Seasonal Effects

A major seasonal effect which may be seen in Figure 6 is made evident by the longer time T_e remained low in the April night passes as compared to the June-July night passes when nights were shorter. The less rapid decay of T_e at sunset in July than at sunset in April may also be a seasonal effect, or it may simply reflect the greater influence of heat conduction in the electron gas at the higher altitude of the July sunset passes.

Altitude Effects

The night-time passes in April (Figure 6), where altitude is the most important variable, suggest that there is a slight positive gradient of T_e with altitude at night of the order of 1° K/km between 350 and 550 km.

As noted earlier, a comparison of northbound passes (Figure 7) and southbound passes (Figure

Tabulation of T_e and N_i from Blossom Point Passes (Explorer XVII)

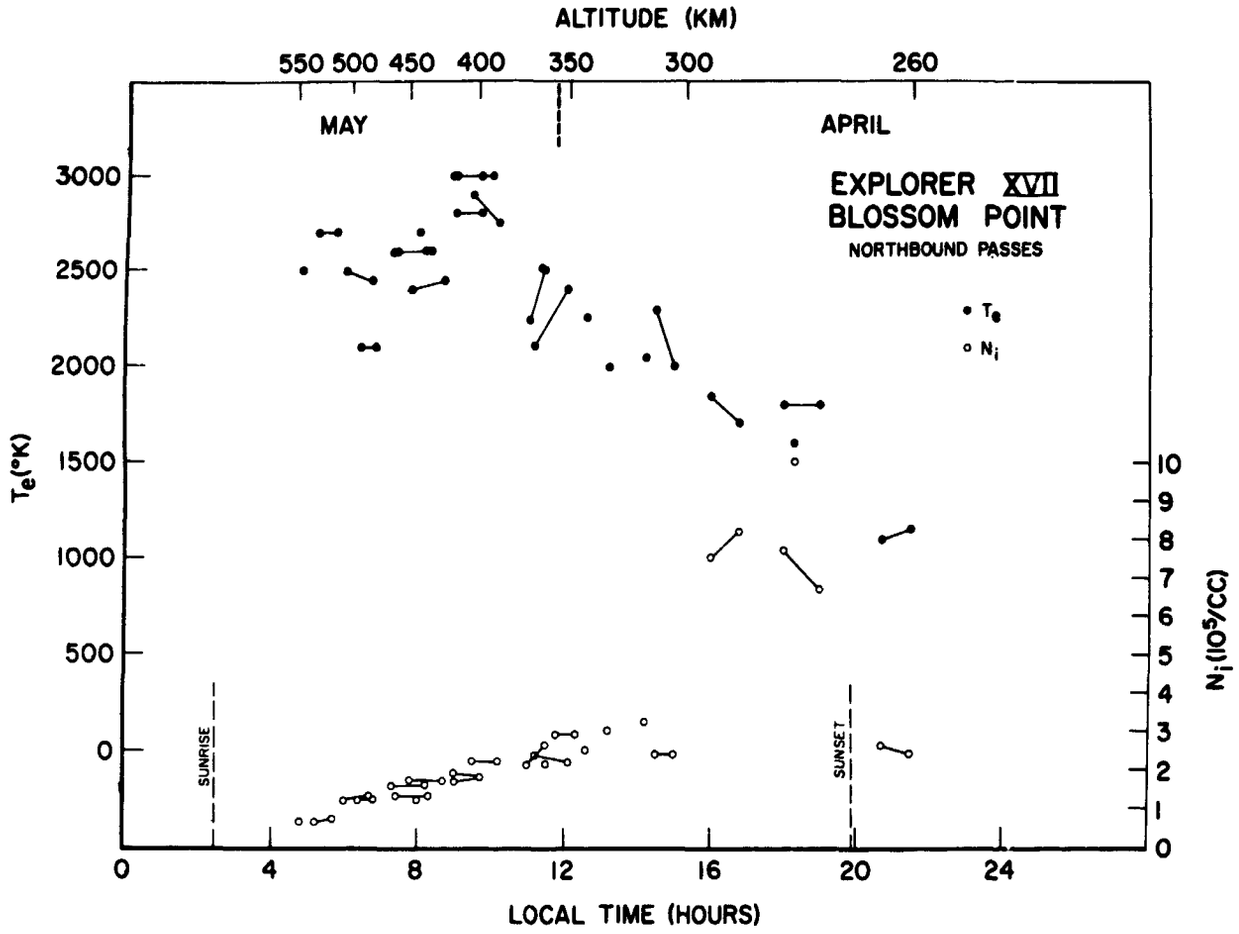

FIGURE 7.—T_e and N_i data from southbound Blossom Point passes.

6) permits the effect of altitude to be evaluated for the morning hours. Such a comparison reveals no systematic gradient of T_e with altitude between 0600 and 1200 hours.

Inverse Relationship Between T_e and N_i

In nearly all daytime passes where beginning and end values of T_e and N_i have been derived, T_e increased and N_i decreased with increasing latitude, the changes being especially marked in the southbound passes which were at lower altitudes. A few exceptions occurred in the early morning, higher altitude, passes when neither T_e nor N_i changed significantly within individual passes.

Data from Other Latitudes

Graphs of the measurements of T_e and N_i during passes at Quito, Equador (10° N magnetic) and at College, Alaska (60° N magnetic) have been prepared. The smoothed diurnal variations of T_e and N_i derived from all three stations are shown in Figure 8. These curves refer to the region between 260 and 400 km containing the F_2

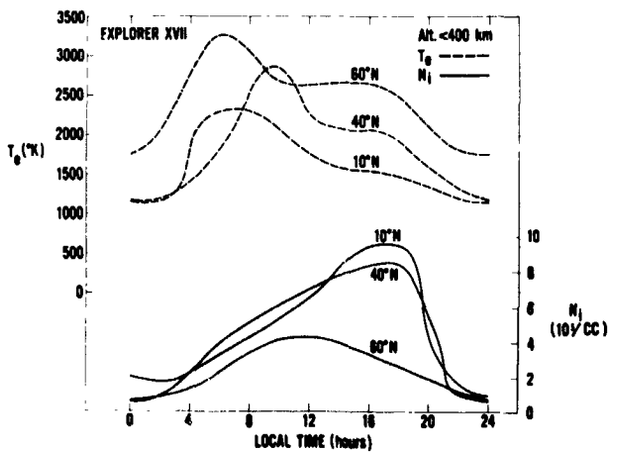

FIGURE 8.—Smoothed diurnal variations in T_e and N_i at three latitudes (10°, 40°, and 60° north magnetic) for altitudes below 400 kilometers.

maximum. Although the general behavior of the F-region at Blossom Point, Quito and College is similar, the times of the morning maxima of T_e and afternoon maxima of N_i and the magnitudes of the temperatures and densities differ considerably. Not all the differences can be ascribed to magnetic latitude alone, for the T_e maximum at College may occur earlier because of the earlier sunrise there in summer, which is a result of the higher geographical latitude. Indeed, the Blossom Point results at 40° and 55°N magnetic latitude suggest that magnetic latitude has little control over the time of occurrence of the maxima in T_e. Differences in magnetic longitude may also be of importance.

The higher nocturnal electron temperatures of the College passes also may be related to the higher geographic latitude (58° N) at which they were measured. The mid-summer F_2 region at 58° N is always illuminated, although the zenith angle of the sun exceeds 90° near midnight.

ION TEMPERATURE AND HEAT SOURCE

If we assume that the temperature of the electron gas is in equilibrium such that the rate at which it gains heat equals the rate at which it loses heat, the heat source Q necessary to maintain a temperature difference can be calculated from the cooling rates. Only elastic processes contribute significantly to cooling in collisions with the positive ions, and the rate at which the electron gas loses heat to a positive ion gas mixture of 0^+, He^+ and H^+ at a temperature T_i is given approximately by

$$Q_e=\frac{5\times10^{-7}(T_e-T_i)n_e}{T_e^{3/2}}\{n(0^+)+4n(He^+)+16n(H^+)\}eVcm^{-3}\,\mathrm{sec}^{-1} \quad (3)$$

(cf. Spitzer 1956),[14] (Hanson and Johnson, 1961).[5] Equation (3) demonstrates that simultaneous measurements of temperature and density are required for an accurate calculation of the energy source responsible for the temperature difference. The strong inter-dependence of temperature and density require that the measurements be essentially point measurements.

The Positive Ion Temperature

The heat gained by the positive-ion gas causes its temperature to rise above that of the neutral

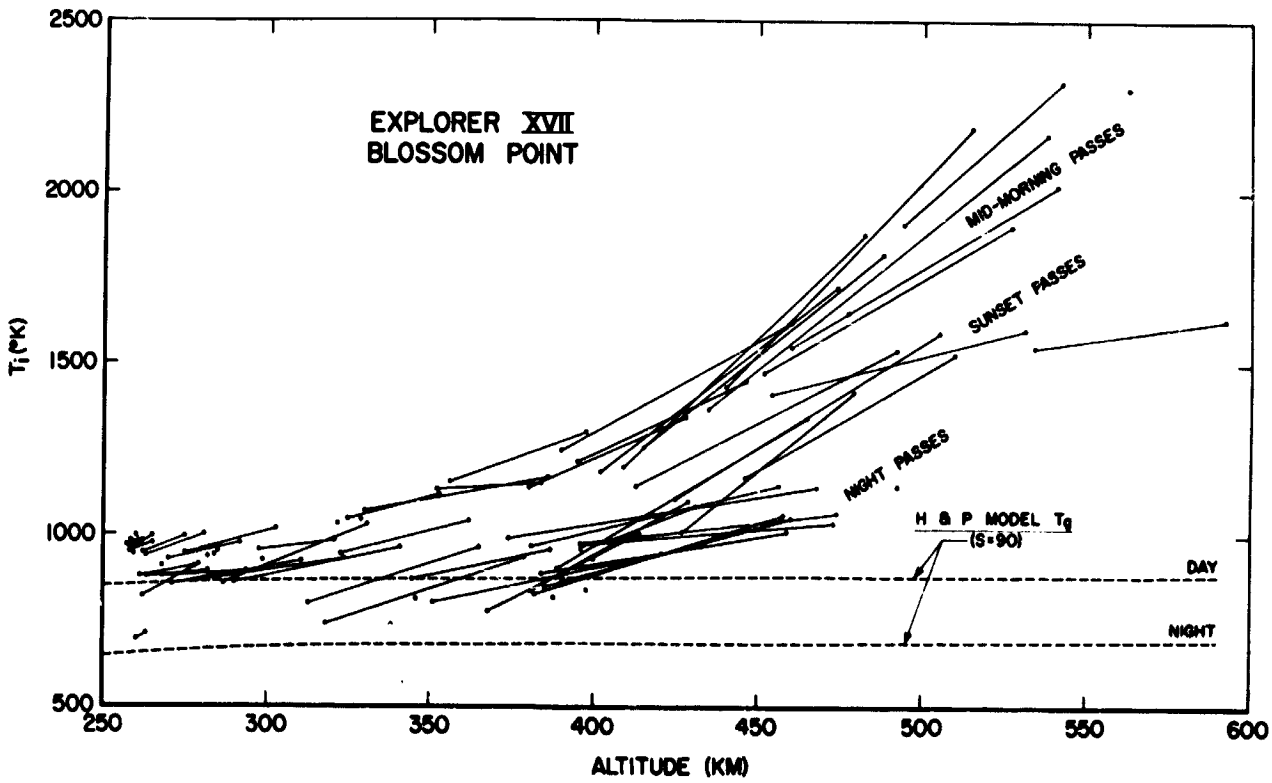

FIGURE 7.—Calculated ion temperature (T_i) for all Blossom Point passes. The Harris and Priester models, used with measured T_e and N_i for computation, are also shown.

particle gas (Hanson, 1963)[7] (Dalgarno, 1963).[8] The positive ions cool mainly by resonance charge transfer collisions with the parent atoms and by elastic collisions with unlike atoms and molecules. The rates of heat loss from the positive ions to the neutral gas at a temperature T_g may be derived from the collision frequencies (Dalgarno, 1958,[15] 1961,[16] 1964[17]) and there results

$$Q(0^+)=n(0^+)\ \{9\times10^{-14}n(0)+6\times10^{-14}n(N_2)+6\times10^{-15}n(He)+2\times10^{-15}n(H)\}(T_i-T_g)\text{eV cm}^{-3}\text{ sec}^{-1}, \quad (4)$$

$$Q(He^+)=n(He^+)\ \{6\times10^{-14}n(0)+4\times10^{-14}n(N_2)+2\times10^{-13}n(He)+1\times10^{-14}n(H)\}(T_i-T_g)\text{eV cm}^{-3}\text{ sec}^{-1} \quad (5)$$

and

$$Q(H^+)=n(H^+)\ \{3\times10^{-14}n(0)+3\times10^{-14}n(N_2)+5\times10^{-14}n(He)+4\times10^{-13}n(H)\}(T_i-T_g)\text{eV cm}^{-3}\text{ sec}^{-1}. \quad (6)$$

In equilibrium,

$$Q_e=Q(0^+)+Q(He^+)+Q(H^+), \quad (7)$$

an equation which determines T_i in terms of T_e, n_e and the neutral particle and positive-ion concentrations.

The altitudes of the Blossom Point measurements were usually such that 0^+ was the major ion and thus (7) can be simplified to yield

$$T_i-T_g=\frac{6\times10^6 n_e(T_e-T_i)}{n(0)T_e^{3/2}}. \quad (8)$$

We have substituted the satellite measurement of $N_i=n_e$ and of T_e into (S) together with the number densities of atomic oxygen given by the model of Harris and Priester (1962)[18] for the local time of the measurement. The resulting values of T_i and of T_e/T_i for Blossom Point are shown in Figures 9 and 10 as a function of altitude. In Figure 9 the passes divide naturally into those occurring in mid-morning (when T_e reaches its

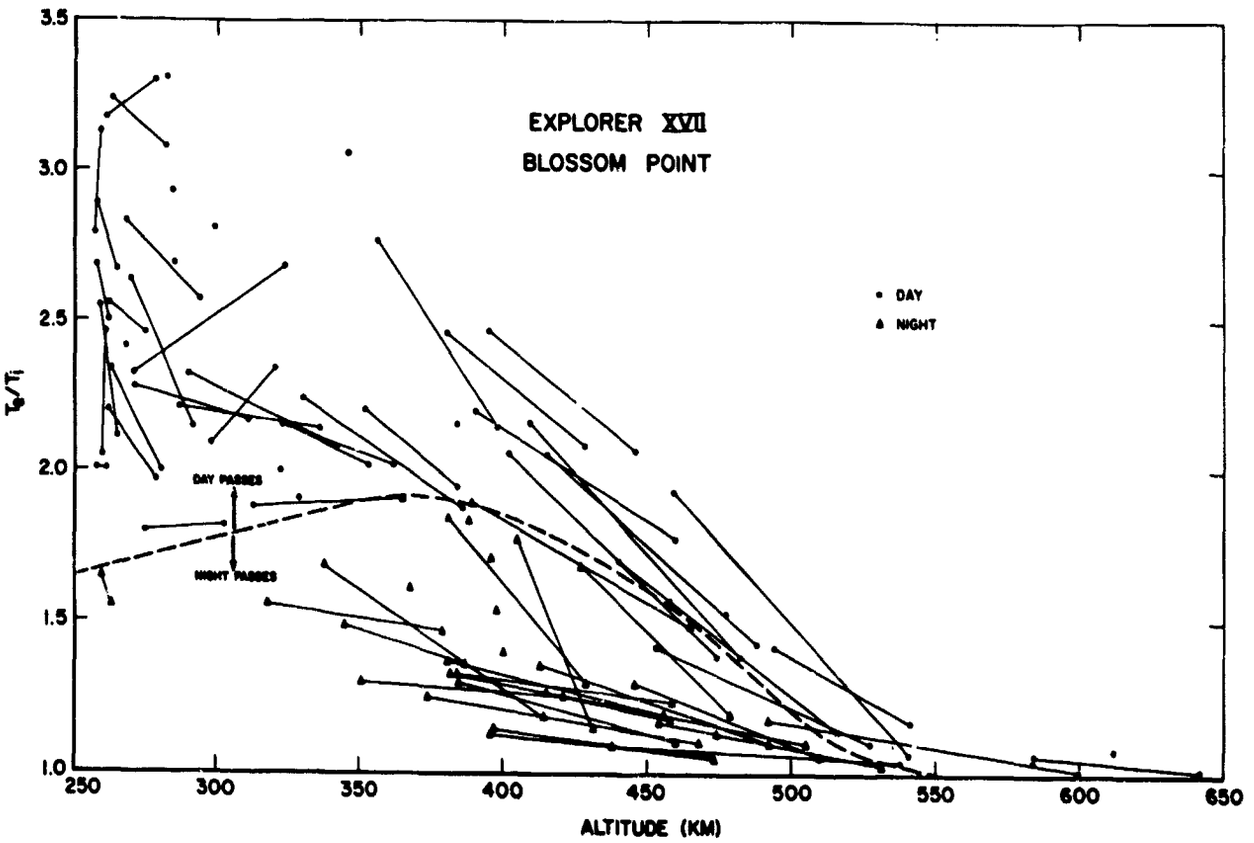

FIGURE 10.—T_e/T_i at Blossom Point.

maximum), near sunset and at night. Figure 9 reveals a positive-ion temperature increasing with altitude, a difference between T_i and T_e first emerging in the region of 300 km. The positive-ion temperature is larger during the day than at night but even at night it appears to exceed T_e at high altitudes. Local time effects are distinguished in Figure 10 only between day and night but the data are probably sufficiently numerous to establish that during the day T_e/T_i passes through a maximum value of between 2 and 3 at an altitude near 300 km and approaches unity at high altitudes. Similar descriptions of the average T_e variations with altitude and of T_e/T_i have been given by Evans (1964)[19] and by Evans and Lowenthal, (1964)[20] in analyses of ground-based radar observations made at the latitude of the Blossom Point passes.

The Heat Source

Having determined T_i, the rate of heat loss of the heated electrons to the positive ion gas may be computed. The heated electrons also cool in collisions with the neutral particle gas, the most significant processes being excitation of atomic oxygen to the 'D level at high altitudes and rotational and vibrational excitation of molecular nitrogen at low altitudes. Cooling by excitation of oxygen to the 'D level is of special importance since it may be responsible for the variability in the intensity of the red arc in the dayglow (Noxon 1964),[21] (Dalgarno and Walker, 1964).[22] The cooling rates have been tabulated by Dalgarno and McElroy (1964)[23] and a comparison of the contributions of the various processes at an altitude of 250 km is given in Figure 11.

The accuracy of the cooling rates is not yet adequate to warrant the use of the neutral particle densities and temperatures measured by the other Explorer XVII experiments (Newton, et al, 1964),[10] (Reber, et al, 1964).[9] To calculate the heat necessary to produce the measured electron temperature we have instead adopted the model distributions of Harris and Priester (1962)[18] appropriate to the local time of the measurement. The results for the southbound passes over Blossom Point are shown in Figure 12 as a function of local time and altitude. Local time effects dominate during the daytime southbound passes and it appears that the heat input is roughly symmetrical about local noon, a variation in marked contrast to the asymmetries in T_e and N_i. The heat input at 260 km has a maximum value of 4×10^3 eV cm^{-3} sec^{-1}. The nighttime values, presented in Figure 13, depend more strongly on altitude. They show clearly a non-vanishing heat source decreasing with increasing altitude with a value of not less than 20 eV cm^{-3} sec^{-1} at an altitude of 400 km. The importance of using calculated ion temperatures is shown by a comparison of Figures 13 and 14. No clear pattern for Q emerges from Figure 14, which is based upon the assumption that $T_i = T_e$.

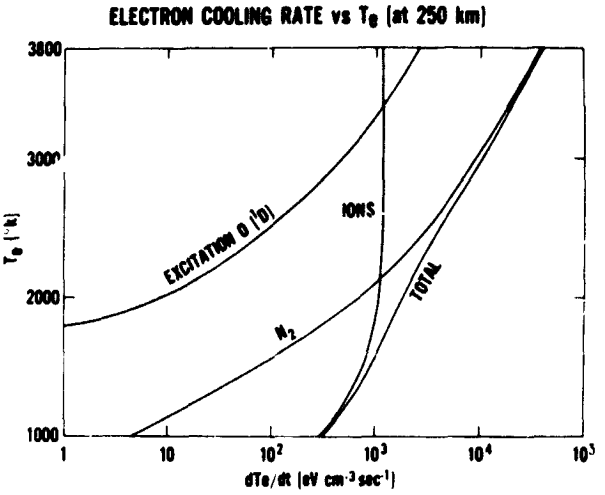

FIGURE 11.—Electron cooling rates at 250 kilometers demonstrating their sensitivity to the electron temperature.

The calculated values of Q for the northbound passes are shown in Figure 15. Local time and altitude effects are mixed and we have attempted to remove the dependence on local time by adopting for the northbound passes the diurnal variation suggested by the southbound passes. The corrected values of Q, normalized to noon, are given in Figure 16. They show a heat input decreasing with altitude with an apparent change in the gradient in the region of 350 km.

DISCUSSION

The probe measurements of T_e from the Explorer XVII satellite confirm the conclusions of the rocket flights (Boggess, Brace and Spencer 1959),[1] (Spencer, Brace and Carignan, 1962),[2] (Brace, Spencer and Carignan, 1963),[3] (Nagy, Brace, Carignan and Kanal, 1963)[24] that the difference between the temperature of the electrons

in the F region of the ionosphere and the neutral particle temperature is large during the daytime and small but non-vanishing at night. These conclusions are in harmony with measurements on the Ariel satellite (Willmore, Henderson, Bowen and Boyd, 1964)[4] and on the Discoverer satellite (Sagalyn and Smiddy, 1964),[25] with observations of incoherent backscatter (Bowles, Ochs and Green, 1962),[26] (Evans, 1962),[27] (Pineo and Hynek, 1962),[28] (Evans, 1964),[19] (Evans and Lowenthal, 1964),[20] (Greenhow, Sutcliffe, Watkins)[21] and with a recent analysis of density profiles (Bauer, and Blumle, 1964).[30]

There are significant differences between the various data. In particular, Willmore, et al do not find the morning maximum in T_e which is a

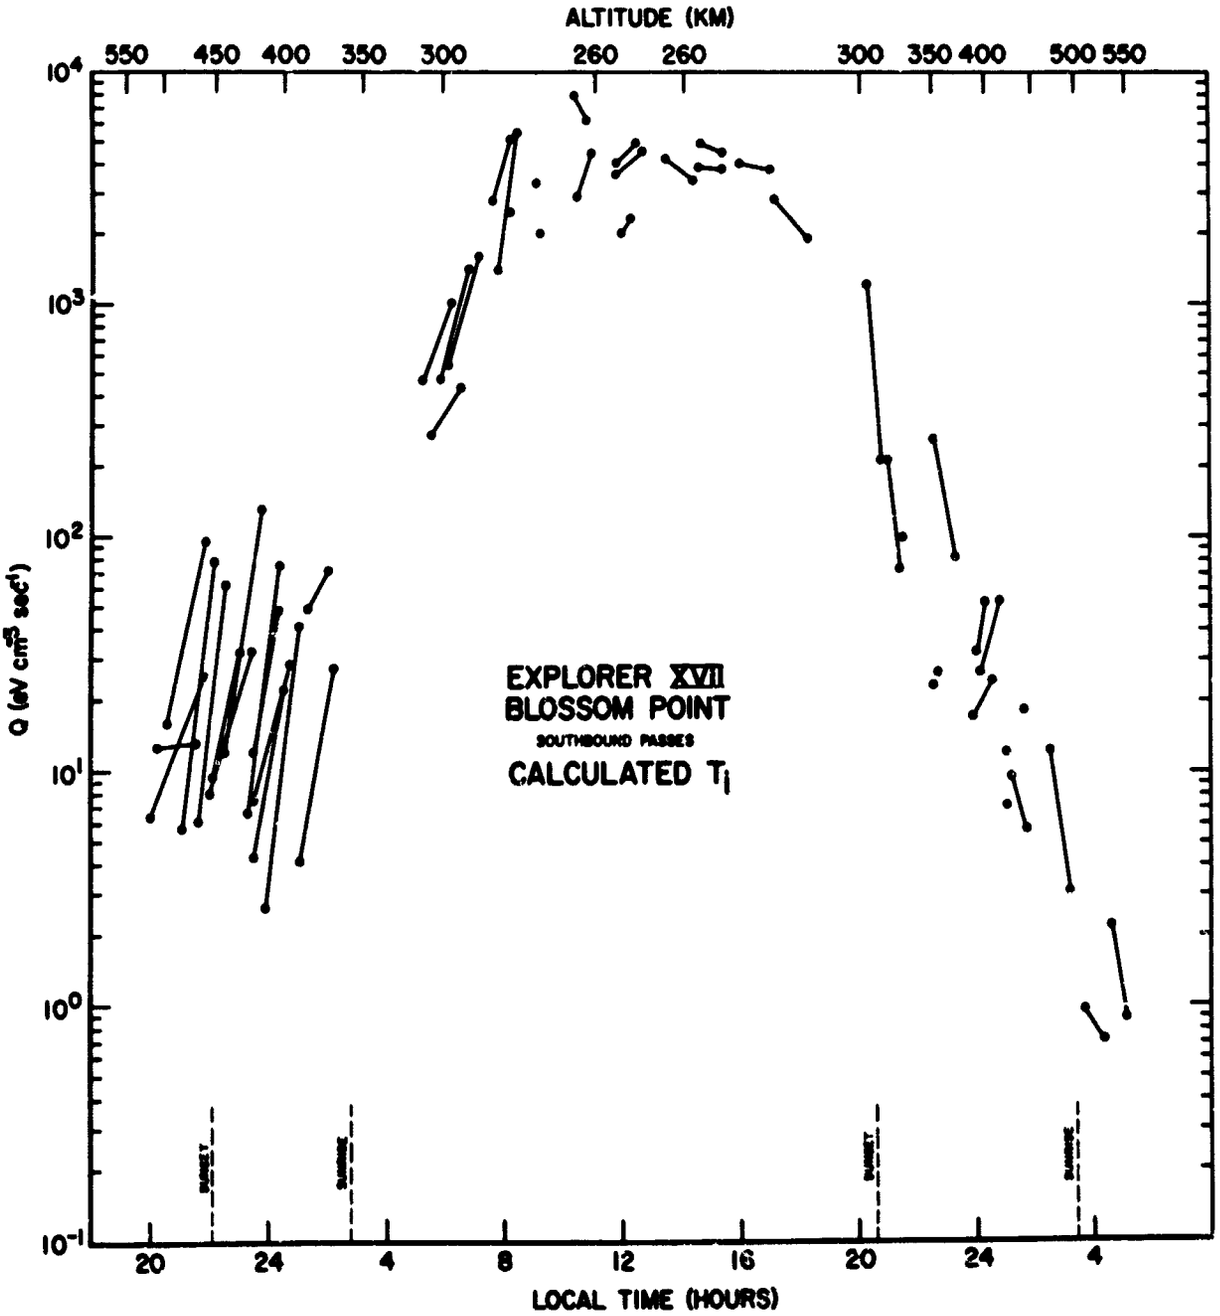

FIGURE 12.—Locally absorbed energy (Q) calculated for southbound passes. Local time effects predominate in the daylight passes and altitude effects control the variations in the nighttime values of Q.

feature of the Explorer XVII data and which also appears in the backscatter observations of Evans and Loewenthal, the satellite data of Sagalyn and Smiddy and the density profile analysis of Bauer and Blumle. Bowles, et al, observing at the Equator, find a maximum at sunrise. As discussed earlier, Figure 8 shows that the time of the maximum depends at least partly upon geographic latitude.

Again in harmony with the rocket flight data, the Explorer XVII data show that T_e increases with latitude, a phenomenon also observed by Willmore, Henderson, Bowen and Boyd (1964).[4] The inverse relationship between T_e and n_e described in Equation (3) strongly suggests that the increase in T_e is caused by the decrease in n_e, a possibility noted by Dalgarno (1963).[8] The temperature may not continue to increase at high latitudes and a preliminary analysis of passes over Grand Forks at a latitude of approximately 65°N magnetic indicates that T_e had passed through a maximum (and n_e through a minimum).

Strong evidence that the positive ion temperature is also higher than the neutral particle temperature at altitudes above 300 km has been advanced by Evans (1964)[19] and by Evans and Loewenthal (1964)[20] and the averaged profiles of T_e and of T_e/T_i that they present are consistent with those given in Figures 9 and 10, which are based upon Equation (8). The magnitudes of T_i at 400 km are in harmony with those measured by Boyd and Raitt (1964)[21] and it seems that over a considerable altitude extent $T_e > T_i > T_g$ with T_e/T_i approaching unity at high altitudes, a possibility to which Hanson (1963)[7] and Dalgarno (1963)[8] drew attention.

The heating effect of absorbed solar ultraviolet radiation has been investigated by Hanson and Johnson (1961),[5] by Dalgarno, McElroy and Moffett (1963),[6] by Hanson (1963)[7] and most recently by Dalgarno and McElroy (1964)[23] whose calculations make use of the improved photoionization calculations of Dalgarno, Henry, and Stewart (1964).[22] The assumption that the heat

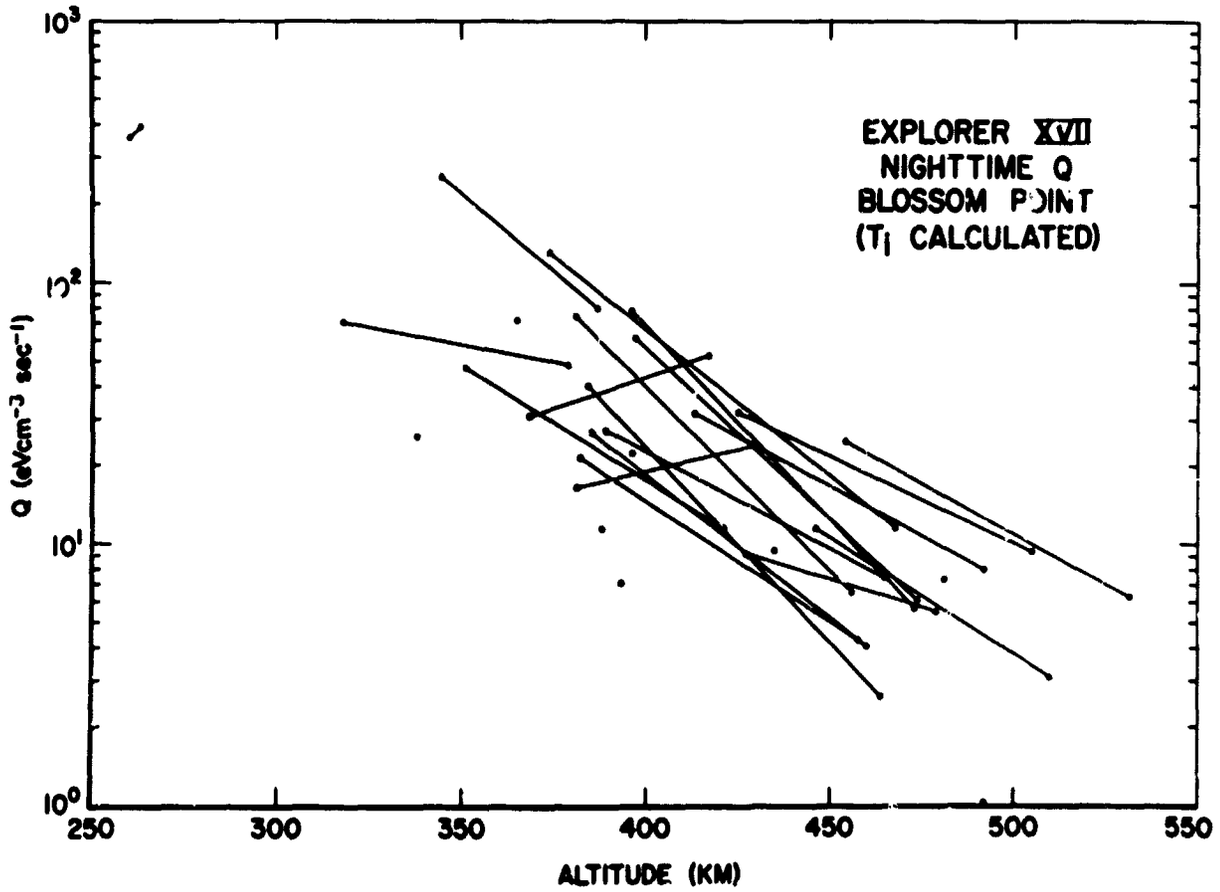

FIGURE 13.—Q vs. altitude in the nighttime ionosphere using the calculated values of T_i.

is deposited locally leads to the predicted euv heating shown in Figure 16, which is in agreement with the heating derived from the Explorer XVII measurements at altitudes below 300 km. Because of the escape of fast photoelectrons (Hanson, 1963)[7] the assumption of local heating is not valid above 300 km.

The gradient of the heat deposition from solar extreme ultraviolet radiation is equivalent to the neutral particle scale height, which is also shown in Figure 16 to emphasize the change in gradient near 350 km. This change in gradient demonstrates that absorption of energy by neutral particles is not the controlling process at great altitudes, and it suggests that the controlling process may be absorption by the ambient electrons, a typical gradient for which is also shown in Figure 16. Such a heat flux is to be expected at great altitudes from the escaping photoelectrons which lose energy by elastic collisions with the ambient electrons.

If j cm^{-2} sec^{-1} is the upward flux of photoelectrons and we adopt a mean of 10 eV for their energy, the rate of heating is given by

$$Q = 2j\, n_e \times 10^{-13} eV \text{ cm}^{-3} \text{ sec}^{-1} \tag{9}$$

If the electrons cool by collisions with the positive ions 0^+,

$$\frac{T_e - T_i}{T_e^{3/2}} = \frac{4\times10^{-7}}{n_e} j, \tag{10}$$

and if by collisions with He^+

$$\frac{T_e - T_i}{T_e^{3/2}} \quad \frac{1\times10^{-7}}{n_e} j. \tag{11}$$

It follows that an upward flux of about 5×10^8 cm^{-2} sec^{-1} may be sufficient to explain the Explorer XVII data, and it appears from the report of Hinteregger, Hall and Schmidtke (1964)[33] on the intensities of the extreme solar ultraviolet

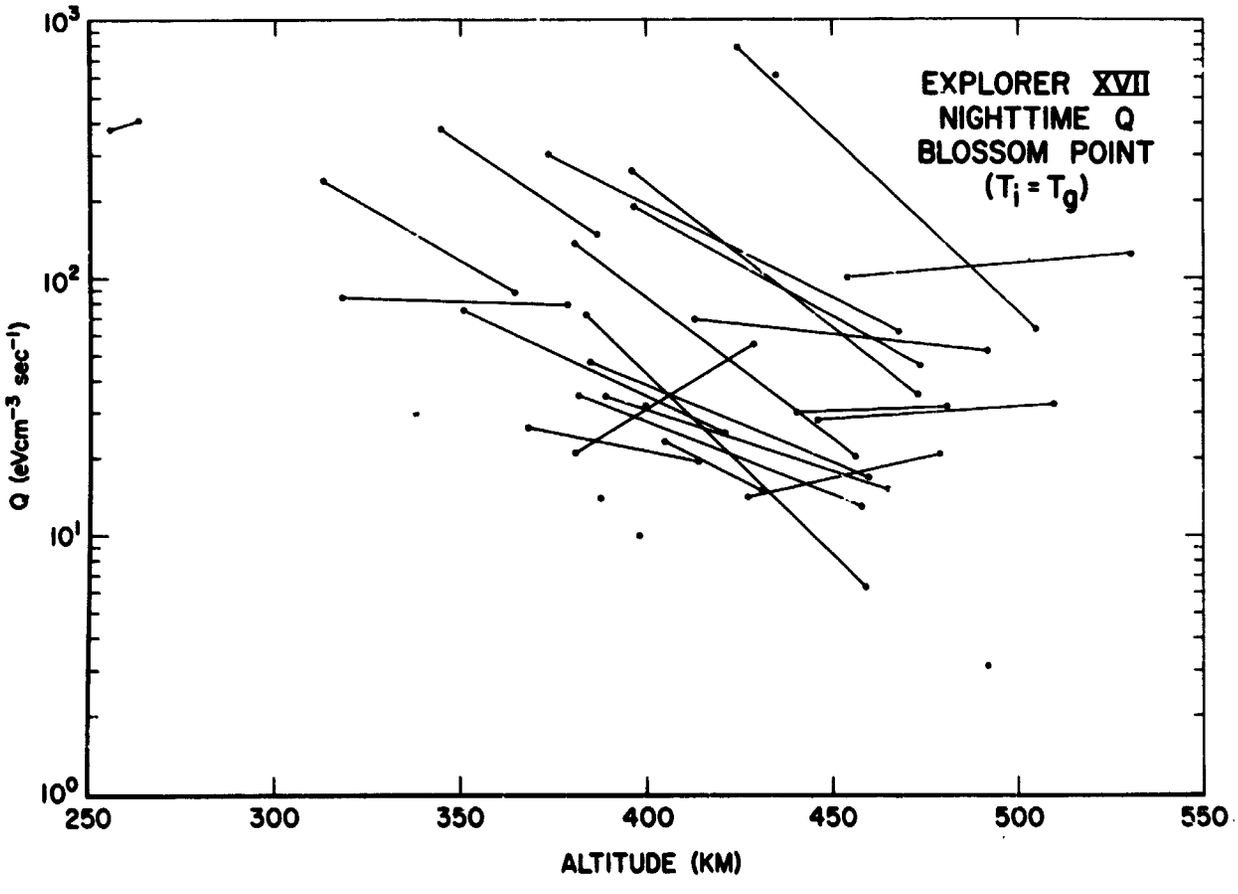

FIGURE 14.—Q vs. altitude in the nighttime ionosphere assuming $T_i = T_e$. Note the greater scatter and lack of pattern resulting from this assumption.

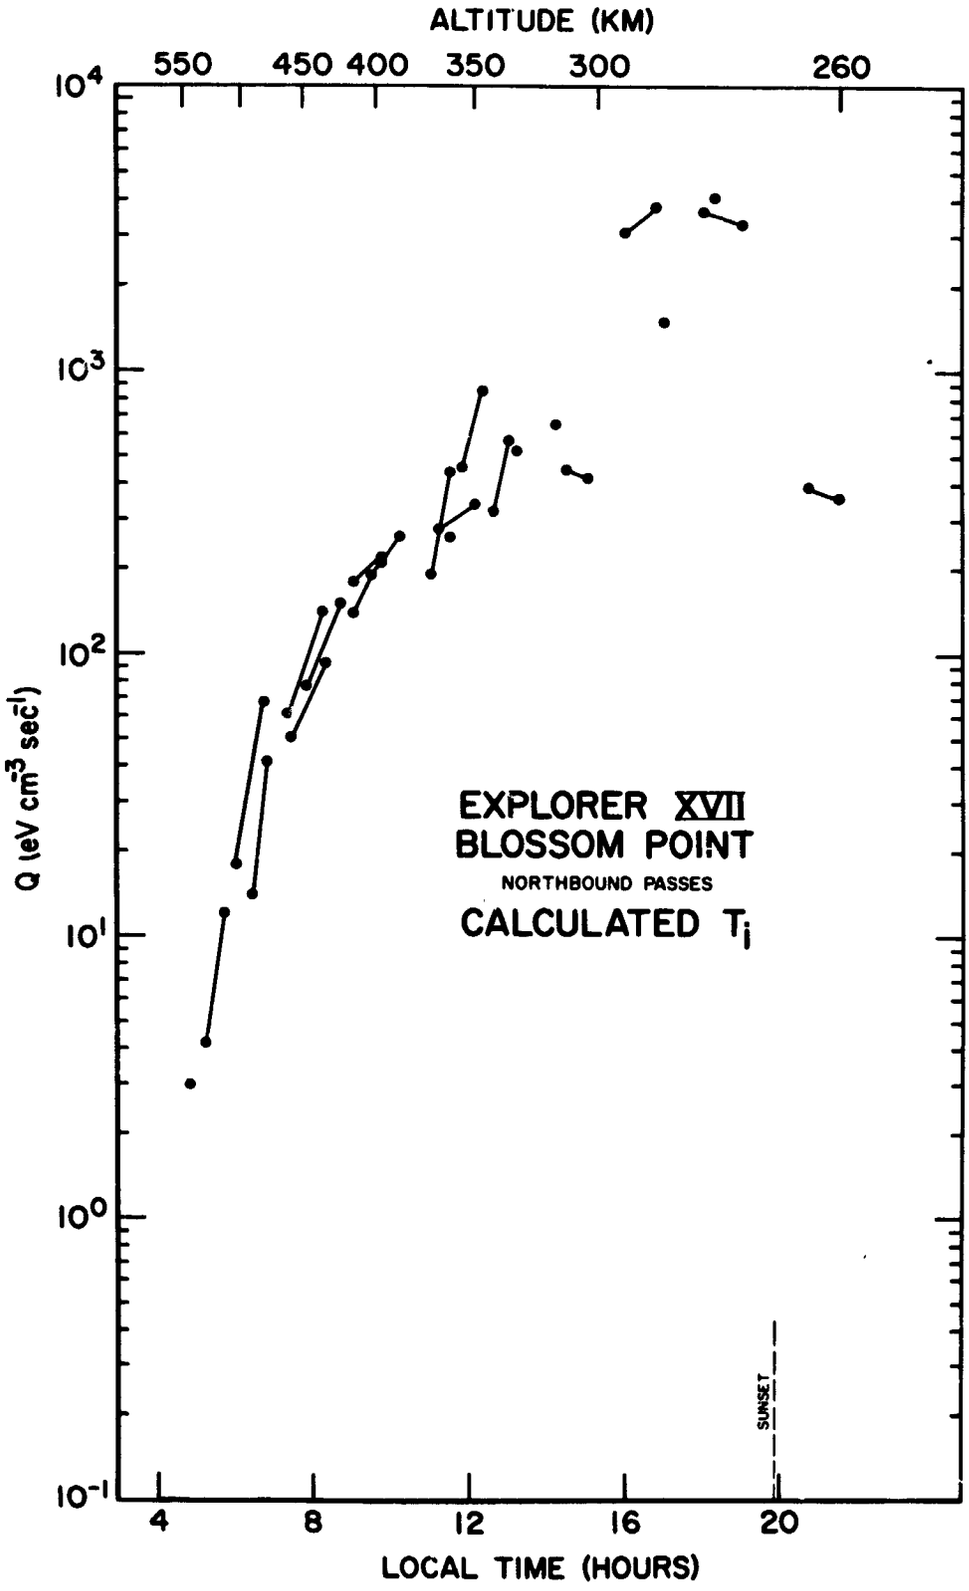

FIGURE 15.—Q calculated for northbound passes. Local time and altitude effects are strongly mixed in these passes, particularly in the early morning.

radiation, and from observations on Cosmos 3 and Cosmos 5 satellites (Mularchik and Vaisberg, 1964),[34] that such a flux is available.

Similar arguments have been advanced by Willmore (1964)[35] in a discussion of the Ariel measurements which were carried out a year earlier than Explorer XVII measurements, but which lead to daytime heat inputs smaller by a factor of two or three.

The fact that the electron temperature does not fall to the neutral particle temperature at night is of great interest, since it reveals the presence of an energy source in the nocturnal ionosphere. The heat input at an altitude of 400 km is about 20 eV cm^{-3} sec^{-1}, which is about five times larger than that derived from Ariel data. Willmore (1964)[35] has suggested that the energy source responsible for the Ariel observations can be identified with the fluxes of 2–3 kev electrons of about 8×10^{9} cm^{-2} sec^{-1} observed by Vernon, Savenko, Shavrin, Nesterov, Pisivenko (1963).[36] This is an energy flux of 30 ergs cm^{-2} sec^{-1}, which is an order of magnitude larger than that of the solar ultraviolet radiation. If these electrons were precipitated into the atmosphere, they would give rise to 6 kilorayleighs of 3914 Å emission (c.f. Dalgarno, 1964)[37] whereas O'Brien, Allum and Goldwire (1964)[38] observe 5 rayleighs or less above 85 kilometers.

The difficulties presented by the large energy flux postulated by Willmore can be avoided by arbitrarily invoking instead a flux of soft electrons of, say, 100 eV energy. Assuming a heating efficiency of 0.1, the Ariel data require about 2×10^{-3} ergs cm^{-2} sec^{-1} and the Explorer XVII data require about 1×10^{-2} ergs cm^{-2} sec^{-4}. Fluxes of this order do not contradict any of the limits that have been derived from spectroscopic observations (c.f. Dalgarno, 1964)[37] and the resulting altitude variation in the heat deposition would be similar to that indicated by the data in Figure 16.

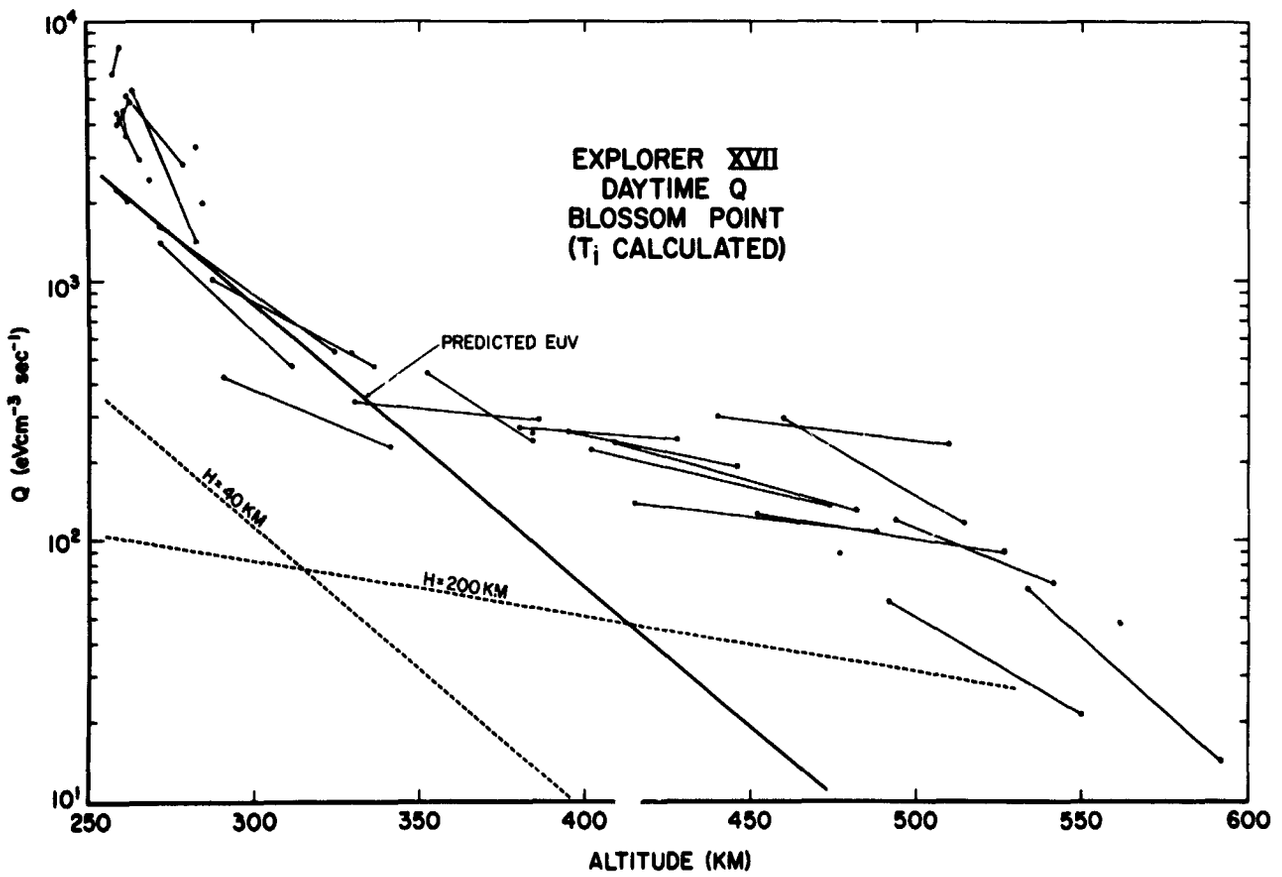

FIGURE 16.—Q vs. altitude normalized to noon. This altitude variation of Q was obtained from northbound passes by removing the diurnal variation suggested by southbound passes.

ACKNOWLEDGMENT

The authors are indebted to Mr. G. Carignan, University of Michigan, and Mr. J. Findlay, Goddard Space Flight Center for their outstanding efforts toward making the experiment successful and to G. Dunham for his aid in the analysis of data.

FIRST ELECTROSTATIC PROBE RESULTS FROM EXPLORER 17*

N66 37964

L. H. BRACE AND N. W. SPENCER

INTRODUCTION

On April 3, 1963, the Explorer 17 satellite was launched into a 58° inclination direct orbit having perigee and apogee altitudes of 258 and 927 km, respectively. In addition to the neutral particle instruments [*Spencer and Reber*, 1963, *Newton et al.*, 1963], two cylindrical electrostatic probes were used, one for the measurement of electron temperature (T_e) and the other for determining the positive ion density (N_i). The purpose of this letter is to report the variations in T_e and N_i observed above the Blossom Point, Maryland, telemetry station (latitude 38°N, longitude 77°W) and to briefly discuss the more immediate conclusions that can be drawn from the data.

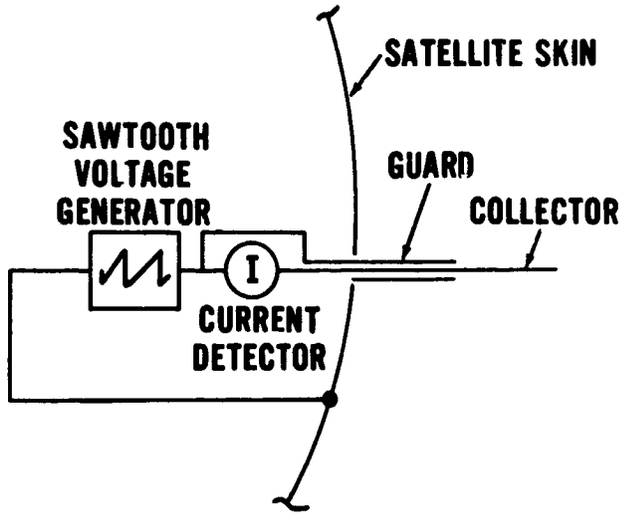

FIGURE 1.—Functional block diagram of either the T_e or N_i probe experiment. A sawtooth voltage applied to the guard and collector produces a volt-ampere characteristic from which either T_e or N_i can be derived, depending on the current sensitivity and sweep magnitude employed.

*Published in the *Journal of Geophysical Research*, 69(21):4686–4689, November 1, 1964.

THE EXPERIMENTS

Figure 1 is a block diagram illustrating either of the two independent probe instruments. Both instruments employ a two-element sensor consisting of a 10-cm-long guard electrode, concentric with a collector electrode 0.056 cm in diameter and 23 cm long. The collector and guard electrodes were insulated from each other and from the satellite, which served as the reference electrode. An appropriate sawtooth voltage was applied to both collector and guard elements, but only the current to the collector was measured and telemetered. Voltage sweep rates, current sensitivities, and telemetry sampling rates were optimized to permit a measurement of T_e in approximately 50 msec, corresponding to negligible translational and rotational motion of the satellite. The volt-ampere characteristics resulting from operation of the instruments thus permitted computation of electron-temperature and ion-density values that can be considered measurements at a point.

Figure 2 shows a series of raw telemetry points from the T_e experiments which demonstrate the measurement resolution. The computational technique employed has been reported [*Langmuir and Mott-Smith*, 1924; *Taylor et al.*, 1963; *Nagy et al.*, 1963].

To permit greater confidence in the measurement accuracy of the Explorer 17 probe technique, a rocket (NASA 6.07) carrying an ejectable instrumentation employing a probe sensor identical to that of Explorer 17 was launched concurrent with a satellite pass at Wallops Island, Virginia. An ionosonde was also operating simultaneously nearby. The ionosonde and rocket probe data agree with the satellite data within a few percent, confirming that the satellite motion did not perturb the temperature and density measurements. A more detailed documentation of the rocket-

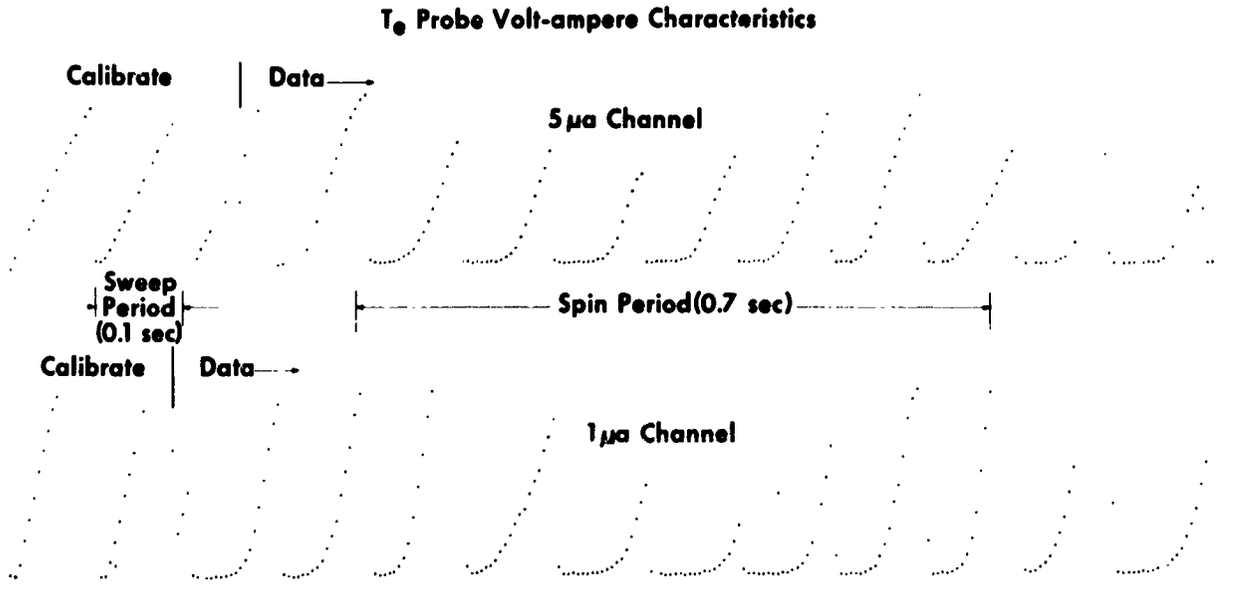

FIGURE 2.—Plot of raw telemetry data from T_e experiment during nighttime perigee pass at Blossom Point. The upper set of volt-ampere characteristics were measured by the 5-μa detector with a sweep of 0→+1.5 volts. The lower set, recorded a few seconds later, were measured by the 1-μa detector with a sweep of 0→+0.75 volts applied to the probe.

satellite experiment will be provided in a later paper.

THE BLOSSOM POINT DATA

During its 100-day operational lifetime (April 3 to July 10, 1963), Explorer 17 was interrogated successfully about 650 times, most responses providing 4 minutes of measurements along the satellite path. The Blossom Point (BP) passes, to be discussed here, provided dense coverage over the eastern United States. During the active lifetime of the satellite, the latitude of perigee, initially 38°N, moved to its maximum northward excursion of 58°, then moved southward, reaching 22°S at the time of battery exhaustion. Accordingly, most of the BP measurements were made near perigee and thus generally represent the F_2 region between 258 and 400 km. Changes in T_e and N_i during these passes reflect latitude and/or local apparent time effects (approximately 10° of latitude and 1 hour of local time) and not altitude change. These changes within passes are evident in Figure 3, which shows data measured over a three-month period. The individual points connected by solid lines are the values of T_e and N_i measured at the beginning and end of some of the individual 4-minute passes. Most of these data are from southward passes during which a consistent decrease in T_e and an increase in N_i were observed. The reverse changes are observed within the northward passes, confirming that the change observed within the pass is a latitude effect. By drawing smooth curves through the end values of T_e and N_i from the individual passes in Figure 3, the gross diurnal variation at the extremes of latitude reached in the BP passes (40° to 55° north magnetic) is made evident.

Several general characteristics of the ionosphere are also evident in Figure 3:

1. A steep morning rise in T_e and a more gradual rise in N_i.
2. A morning maximum in T_e (about 5 hours after local sunrise) and a continuing gradual rise in N_i during the day.
3. A decrease of T_e to an afternoon plateau (its value depending on latitude) and a late afternoon maximum of N_i.
4. A possible minor maximum of T_e during late afternoon.
5. A steep decline of both T_e and N_i at sunset.
6. A nighttime plateau of T_e at about 1150°K, but moderately variable, and a relatively constant value of N_i.

Although the data from other sites have not been completely analyzed, they appear to exhibit the same gross characteristics as the data from Blossom Point, the major differences being in the

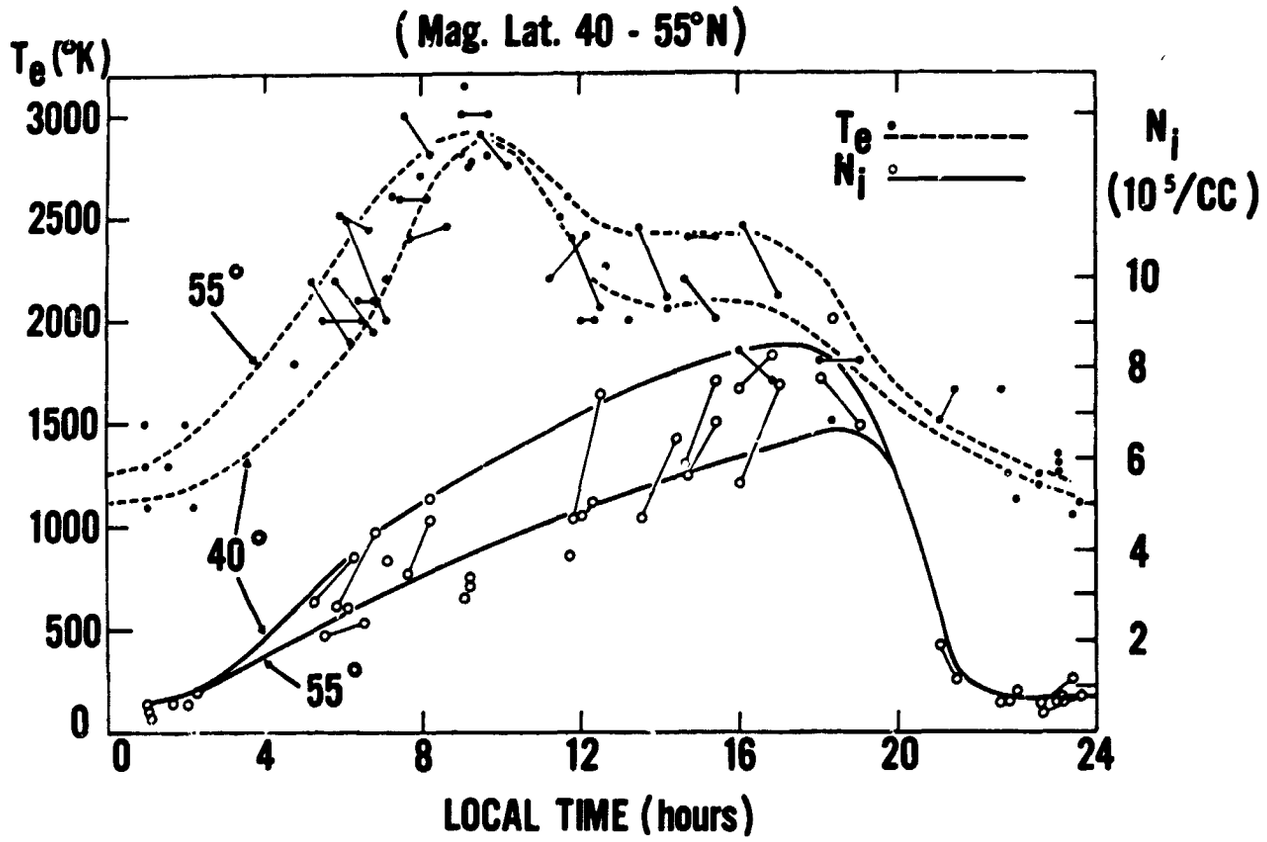

Figure 3.—Blossom Point results in the 260- to 400-km altitude range. The points connected by lines represent values recorded at the beginning and end of particular passes. The inverse variation of T_e and N_i within individual passes has been identified with the latitude change in the pass.

time of the morning T_e maximum and the value of T_e during the afternoon plateau.

GEOPHYSICAL IMPLICATIONS OF THE BLOSSOM POINT DATA

If we consider the neutral gas temperature (T_g) to be between about 700°K (at night) and 1000°K (daytime), the Figure 3 data show that thermal nonequilibrium is the normal condition near the F_2 maximum, both day and night. Thus, the Explorer 17 data confirm our earlier conclusions which were based on rocket probe data [*Boggess et al.*, 1959; *Spencer et al.*, 1962; *Brace et al.*, 1963] that (*a*) the ionosphere is not in thermal equilibrium and (*b*) the degree of nonequilibrium is greater in the auroral zone than at midlatitudes.

The major implication of the nonequilibrium is that significant sources of local heating for the electrons are present and that some of these sources exist at night as well as during the day. This is borne out by calculations of the local electron heat flux density (Q) using the equation given by *Hanson* [1963];

$$Q = -\frac{3kN_e}{2}\left[\left.\frac{dT_e}{dt}\right|_{O} + \left.\frac{dT_e}{dt}\right|_{N_2} + \left.\frac{dT_e}{dt}\right|_{O_2} + \left.\frac{dT_e}{dt}\right|_{+}\right] \quad (\text{ev cm}^{-3}\,\text{sec}^{-1}) \quad (1)$$

where the derivatives represent the cooling rates of electrons to ions and to the indicated neutral species. In a calculation using the measured values of T_e and N_i and the Harris and Priester model values ($S=90$) for the neutral particle concentrations and temperatures, the locally deposited energy (Q) at 400 km was determined to be approximately 250 ev cm^{-3} sec^{-1} at midday and 15 ev cm^{-3} sec^{-1} at night [*Brace et al.*, 1964]. The daytime value is in reasonable agreement with the predictions of both *Hanson* [1962] and *Dalgarno et al.* [1963], but differs significantly from Ariel satellite data given by *Willmore* [1964], who finds about

100 ev cm^{-3} sec^{-1} at 400 kilometers. The nighttime value of 15 ev cm^{-3} sec^{-1} indicates a significant heating source, not yet identified.

The calculations further show that both the diurnal and latitudinal variations of electron temperature in the daytime ionosphere (Figure 3) are primarily reflections of corresponding variations in the local electron density [*Willmore*, 1964]; thus there is no reason to believe that the observed latitude variation of T_e in the daytime is related to atmospheric heating by particles as a function of latitude [*Willmore et al.*, 1962; *Spencer et al.*, 1962; *Brace et al.*, 1963].

It is particularly useful to compare BP data with the radar backscatter data of *Evans* [1964], because the measurements are from essentially the same latitude, longitude, and altitude. In March 1963, a month before Explorer 17 was launched, Evans found that T_e/T_i, at 330 km reached a maximum value of 3 at midmorning, exhibited an afternoon plateau of about 2.3, and was variable between 1.3 and 2 at night. The satellite results at Blossom Point, expressed in terms of T_e/T_p, provide an essentially identical picture.

Inherent in this comparison of T_e/T_i and T_e/T_p is the assumption of equilibrium between ions and neutrals ($T_i = T_p$). In the altitude region below 400 km where these data are compared, it is reasonable to make this assumption. However, as *Hanson* [1963] has pointed out, because the neutral particle scale height is less than the ion-electron scale height, the thermal contact between ions and electrons will predominate above some altitude and the ion temperature will approach that of the electrons. *Hanson* [1963], using an assumed model atmosphere, has calculated that T_i will exceed T_p above about 600 km and will approach T_e at 900 km. Accordingly, T_i was predicted to lie about midway between T_e and T_p at 750 km. Similar calculations using Explorer 17 BP data show that this transition occurs near 500 km rather than 750 km (*Brace et al.*, 1964].

In summary, Explorer 17 measurements of T_e and N_i in the F_2 region above Blossom Point have shown that thermal nonequilibrium ($T_e > T_p$) is the normal condition both day and night and, further, that the degree of nonequilibrium is strongly latitude dependent in the daytime and moderately variable at night. The data also reveal a strong inverse relationship between the local values of T_e and N_i (or N_e), which is consistent with the equations Hanson and Dalgarno used in their studies of ionospheric heating. There is no evidence that the observed latitude dependence of T_e, seen in previous rocket flight data and apparent in Ariel satellite measurements, is related in an important way to particle fluxes at higher latitudes. Instead, the data suggest that the latitude dependence of T_e primarily reflects the global distribution of electron density and its controlling mechanism.

ACKNOWLEDGMENT

We thank Dr. A. Dalgarno of the Queen's University of Belfast for enlightening discussions of the experimental data and its geophysical implications and for his participation in the calculations of ion temperature and electron energy input.

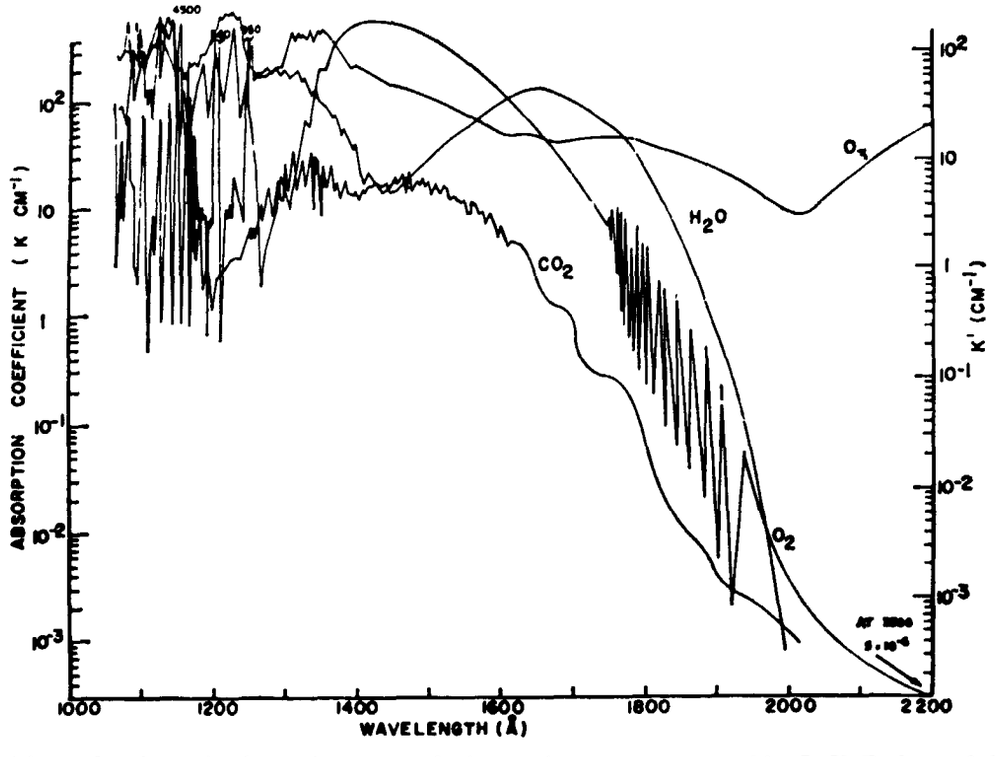
ORIGIN AND EVOLUTION OF ATMOSPHERES AND OCEANS*

A. G. W. CAMERON, P. J. BRANCAZIO, AND N. W. PANAGAKOS

In recent years it has become evident that the atmosphere and oceans have been produced by the outgassing of volatile materials from the earth's interior, principally from volcanoes. In 1950 W. W. Rubey presented geological evidence indicating that sea water has progressively accumulated in this way. At about the same time, Harrison Brown pointed out that the very low abundances of the noble gases in the earth's atmosphere constituted compelling evidence that at least the atmospheric oxygen and nitrogen were almost entirely of secondary origin, having been outgassed, possibly in different chemical form.

The main purpose of the 1963 conference was to consider new evidence for mechanisms which might add to or subtract from the contents of the atmosphere and oceans, and to consider mechanisms which could contribute to the origin of atmospheres of other planets. H. H. Hess opened the discussion with a consideration of the problems of convection currents in planetary mantles. The important factor is the time between nucleosynthesis and the formation of the solid planet. The protoplanet will contain radioactive materials which generate heat, and the rate at which it is generated will decrease as the activity of the radioisotopes decreases. A planet may or may not have convection, depending on whether enough radioactive materials remain in the mantle to cause vigorous heating at the base.

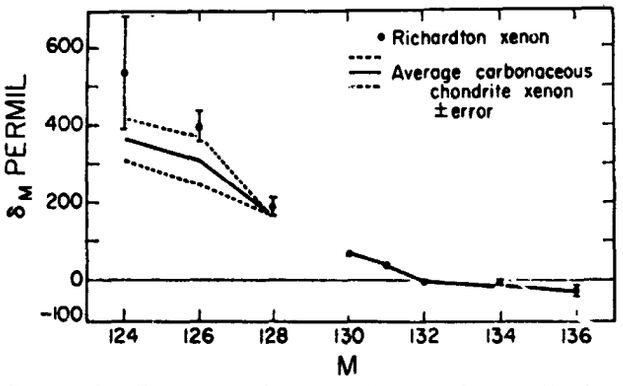


K. K. Turekian of Yale University discussed some models for the degassing of argon from the earth. He showed that at least eighty percent of the argon now in the atmosphere must have come from the mantle. He proposed that the most useful degassing model appeared to be one with continuous degassing of the earth as a whole. Turekian pointed out, however, that one should be careful in applying the results thus obtained to the escape of the other rare gases from the earth.

L. V. Berkner of the Southwest Center for Advanced Studies, Dallas, Texas, discussed the origin of oxygen in the earth's atmosphere. According to Berkner, the existence of an appreciable atmosphere of oxygen implies the presence of life. He pointed out that the production of oxygen in the primitive atmosphere from the photochemical dissociation of water would in turn lead to a layer of ozone in the atmosphere. The ozone layer is a buffer against the destruction of terrestrial life as we know it by the ultraviolet rays of the sun. If the amount of oxygen in the atmosphere were very small, the ozone layer would occur at ground level, and the sun's ultraviolet radiation would penetrate to the surface. In such a harmful environment, life would be unable to emerge from the seas onto land.

Tracing the history of the earth's atmosphere, Berkner pointed out that a sufficiently long period of time had to elapse for marine life to produce sufficient oxygen to change the composition of the atmosphere and produce high-lying ozone layers. When this took place, life was able to emerge—first in plant form, then in animal form in perhaps a few million years.

The helium problem was examined by G. J. F. MacDonald of the University of California at Los Angeles. He pointed out that if it is assumed that the escape of gases from the earth's atmosphere is due only to temperate effects, then the rate of influx of helium by outgassing is larger than the rate of escape. The helium in the earth's atmosphere should be building up at a rapid rate, but this is not the case. MacDonald noted that analyses of satellite drag data by I. Harris and W. Priester showed that an additional heat source derived from the solar wind is necessary to account for the time variations in the temperature of the



*Published in *Physics Today*, :19–22, February 1964.

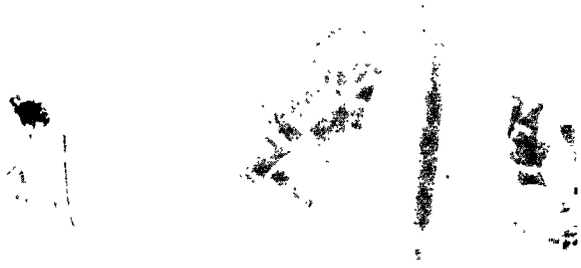
SKETCH 1.—Ultraviolet absorption by various atmospheric constituents, as presented by L. V. Berkner of the Southwest Center for Advanced Studies. The absorption beyond 2000 angstroms is almost entirely due to ozone.

upper atmosphere. He also noted that if the earth's magnetic field was at one time significantly stronger, as indicated by measurements of ancient baked clay, the interaction between the field and solar plasma could increase the heating of the upper atmosphere. This could account for a greater rate of escape of helium, averaged over a long time scale.

R. O. Pepin discussed some of the recent work done by J. R. Reynolds and his group at the University of California, Berkeley, in the field of "xenology"—the study of the isotopic abundances of the xenon isotopes. These studies are providing considerable information about the early history of the solar system; for example, the anomalously high abundance of ^{129}Xe resulting from the decay of primordial ^{129}I allows us to obtain the formation ages of meteorites. He pointed out that the relative abundances of the xenon isotopes differ for different types of meteorites and, in particular, the isotopic abundances of the xenon isotopes in the earth's atmosphere differ from the abundances found in meteorites. The problem is to account for all these anomalies.

SKETCH 2.—Comparison between the general anomalies in xenon from the Richardton stone meteorite (an ordinary chrondrite) and in xenon from carbonaceous chondrites.

In this respect, Pepin cited the work of W. B. Clarke, who conducted heating experiments on irradiated uranium oxide samples. Clarke found that the xenon evolved at low temperatures was isotopically different from that evolved at high temperatures. The inference is that the isotopic anomalies may be due to temperature fractionation effects on a fissionogenic component of the xenon gas.



Among the studies done by the Berkeley group was an analysis of some deep-seated terrestrial rocks. They found that the xenon evolved from these rocks contained a fission component resulting from uranium spontaneous fission. This suggests the feasibility of a U-Xe dating method, to be used in conjunction with other established dating techniques.

Peter Signer of the University of Minnesota showed that the abundances of primordial gases in meteorites are generally similar to those in the atmosphere or in the sun only when there is a great amount of this gas in the meteorites. If the amount of gas is small, then a very large degree of fractionation can occur among the elements.

In order to understand the composition of the earth's atmosphere, one must be able to explain the differences between the isotopic abundances of xenon isotopes in meteorites and in the earth. A. G. W. Cameron of the Goddard Institute for Space Studies interpreted the differences in abundances of the light "shielded" xenon isotopes as resulting from neutron capture in the sun during the deuterium-burning stage of early solar history. However, this interpretation requires that the bulk of the xenon in the earth's atmosphere should have once been in the sun, and that it has since been captured by the earth from the solar wind.

The composition of Mercury's atmosphere raised considerable discussion among participants at the conference. Mercury is the smallest planet, and, because of its small size, has been generally believed to have no atmosphere, or a very tenuous one at best. George Field of Princeton University discussed measurements of the differential polarization of scattered light from Mercury made by Audouin Dollfus of the Observatoire de Paris, Meudon, France, who had interpreted them as showing the presence of a small atmosphere.

Field suggested that the atmosphere of Mercury may be composed of a considerable amount of radiogenic argon which escaped from the interior of the planet. The observed atmosphere would require that Mercury had outgassed to about the same extent as the earth. However, if the atmospheric constitution is to be nearly pure argon, the temperature of the upper atmosphere should not exceed 1400 degrees. Above this temperature, evaporative escape would take place. A problem arises in that theoretical estimates place the temperature of an upper atmosphere of pure argon at well above 1400 degrees, since argon is a very inefficient radiator of electromagnetic energy. It was agreed that much more study is needed for an understanding of the manner in which an argon atmosphere—if it exists—could be maintained on Mercury.

SKETCH 3.—Seated in the cabin of his balloon observatory, Audouin Dollfus of the Observatoire de Paris prepares for a flight in which he attempted to detect extraterrestrial water.

Important new data concerning the presence of water vapor on Mars and Venus was presented by Audouin Dollfus. Reporting on observations made with a specially designed telescope which he carried aloft in a balloon, and on observations made from an elevated mountain observatory, Dollfus said he measured 0.01 gm/cm² of water vapor for Venus above the cloud-top level.

For Mars, Dollfus found 0.02 gm/cm² of water vapor, enough to cover that planet to a depth of a fifth of a millimeter. This is five times as much as had been generally estimated. The disagreement between Dollfus' observations and those of several other scientists who give lower values for the water-vapor content of the Martian atmosphere raised sharp debate at the conference. Participants concluded that various experiments may have been subject to unforeseen sources of error, and that it is extremely important to make new measurements.

H. D. Holland of Princeton University suggested that pools of molten sulphur, rather than oceans of water, will be found on the surface of Venus. When that planet was formed, much less water was accreted than when the earth was formed, he suggested. The main substance ejected from Venusian volcanoes probably is sulphur dioxide, which would react with carbon

monoxide to form liquid sulphur on the surface.

Thomas Gold of Cornell University suggested that some of the depressions on the moon's surface may be regions of collapse caused by underground rivers which result from an "outgassing" process taking place in the moon.

He reasoned that if there is water in the interior of the moon, radioactivity should produce enough heat to vaporize it. The water vapor would then seek to rise from the interior to the surface, but it would be trapped by a permafrost or ice layer which must exist below the surface at a depth of 150 feet. However, large meteorites striking the lunar surface could form craters extending below the ice layer; the water in the area of the explosion would then flow underground towards the crater. The extensive area that is drained might then collapse, forming the rills that are a common feature in moon photographs. Gold pointed out that these rills or depressions, converging on craters in flat ground from many angles, could hardly be caused by stresses from the craters themselves. Unlike the stress pattern, the rills do not converge in a straight line, but zigzag—sometimes for hundreds of miles.

Gold also suggested that Venus may possibly be covered by water which has escaped from the interior of the planet. The consensus among scientists has been that if there is water on Venus, it is in the planet's atmosphere and does not exist in appreciable amounts. However, Gold cautioned against ruling out the possibility of water on the surface. His contention was that it is too difficult to explain what happened to the water that must have been present on Venus at some time in its past if this were not the case.

Venus resembles the earth closely in many of its properties. Hence, Gold reasoned that water should have been outgassed from Venusian volcanoes to the same extent that this outgassing had occurred on earth. If Venus' surface temperature is somewhat less than that measured by instruments on Mariner II (perhaps a little less than 600° K), then water would be in equilibrium with steam. Hence, Venus should possess a very massive lower atmosphere composed primarily of steam.

Discussing the atmosphere of Venus, [illegible] Sagan of Harvard University reviewed many of [illegible]eat uncertainties in the measured parameters [illegible]e planet. He also discussed some of the chemical equilibria that could influence the composition of gas in the Venusian atmosphere.

Sagan noted that the planet must be extremely hot at the surface, a temperature of perhaps 650° K on the dark side and about 750° K on the bright side. The pressure at the base of the Venusian atmosphere appears to be at least 30 atmospheres, which would indicate that there may be an appreciable amount of water vapor. Nevertheless, because of the high temperatures, the amount of water in the Venusian atmosphere would be enormously less than that in the earth's oceans. Hence, Sagan disagreed with Gold's suggestion that an approximation of the Venusian atmosphere could be obtained by heating the surface of the earth.

Despite the relatively large amount of observational data on Mars, there is still a considerable degree of uncertainty about the abundances of the planet's atmospheric constituents, according to Richard M. Goody of Harvard University. The amount of carbon dioxide could be reliably determined if the atmospheric pressure at ground level were known, but this is uncertain by at least a factor of two. The amount of oxygen is probably very small. One clue to the abundance of oxygen in the Martian atmosphere might be obtained by detecting that element's allotrope, ozone. This raises a problem, however. If there is oxygen on Mars, ozone should be present even at the ground level. Berkner pointed out that ozone formed near the ground may react with anything that can be oxidized, unless the entire surface of Mars is sufficiently covered by an oxide layer that further oxidation is impossible. It is possible that the continual weathering by wind on Mars would expose fresh rock surfaces and that the subsequent loss of ozone would eventually result in a very small amount of oxygen in the atmosphere.

P. J. E. Peebles of Princeton University presented new calculations showing that Jupiter and Saturn have approximately the same composition, predominantly hydrogen and helium, and that the ratio of hydrogen to helium is similar to that of the sun. Using a variety of reasonable values for different mixtures of hydrogen and helium—and with a core of heavier elements near the center of the planet—Peebles found that a helium-hydrogen ratio by number of 0.075 to 0.08 for Jupiter, and

perhaps twice this amount for Saturn, was required in order to reproduce the mechanical properties of these planets. The amount of heavier elements has not been well determined, but it is only a few percent by mass.

Rupert Wildt of Yale University Observatory summarized the results obtained by H. Spinrad of the Jet Propulsion Laboratory, who showed that at times there are clouds of ammonia in the upper atmosphere of Jupiter which have velocities as high as four kilometers per second relative to the underlying atmosphere. This has become known as the "Spinrad effect." Spinrad has also determined some preliminary values for the composition of the Jovian atmosphere. His work indicates that the ratio of carbon to hydrogen on Jupiter is greater than that in the sun, and that it is higher still in the atmosphere of Saturn.

THE RED LINE OF ATOMIC OXYGEN IN THE DAY AIRGLOW*

A. DALGARNO† AND JAMES C. G. WALKER

It is argued from the observations of the red line that the rate coefficient for deactivation of the excited oxygen atoms in collisions with molecular oxygen cannot be much less than 10^{-10} cm^3 sec^{-1} and that the solar flux in the region of 1450Å cannot be as large as the reported measured values. It is further argued that photodissociation of molecular oxygen and recombination of molecular ions are inadequate to explain the observations and that an additional mechanism is operative at high altitudes. The mechanisms of fluorescent excitation and of non-thermal excitation by photoelectrons are briefly examined and it is concluded that although the latter may be a significant source of excited atoms, neither mechanism explains the observed variability. It is suggested that the variability in red line intensities is associated with the presence of hot thermal electrons and sample calculations are presented of the altitude profiles that may result from this source.

1. INTRODUCTION

From a theoretical survey, Bates and Dalgarno (1954) concluded that the red line of atomic oxygen at 6300 Å is one of the strongest features of the dayglow spectrum, and a more quantitative study of the red line by Brandt (1958) yielded an intensity of 50 kilorayleighs (kR), about half arising from photodissociation of molecular oxygen in the Schumann-Runge continuum

$$O_2+h\nu\rightarrow O(^3P)+O(^1D) \qquad (1)$$

and about half arising from dissociative recombination of the molecular ions O_2^+

$$O_2^++e\rightarrow O(^1D)+O'. \qquad (2)$$

The ground-based measurements of the red line in the dayglow by Noxon and Goody (1962) and by Jarrett and Hoey (1963) yielded intensities comparable with those predicted by Brandt, but other ground-based measurements by Noxon (1963) and rocket-based measurements by Zipf and Fastie (1963) and by Wallace and Nidey (1964) have shown that the intensity of the red line is often much less than the predicted value. This variation in intensity is significant for it suggests that the mechanisms leading to the emission of the red line have not been correctly identified and described.

2. MODEL ATMOSPHERES

To describe the structure of the neutral component of the upper atmosphere, we have employed the analytic representation of Bates (1959) which is specified by the temperature, temperature gradient and composition at a reference altitude, z_0, and by the exospheric temperature, $T(\infty)$. For the atmospheric parameters, we adopted the values

$$z_0=120 \text{ km}, \left.\frac{dT}{dz}\right|_{z_0}=20\text{K/km}, \quad T(z_0)=350\text{K}$$

and for the number densities of atomic oxygen, molecular oxygen, and molecular nitrogen at 120 km the alternative sets (i) $n(O)=5\times10^{10}$ cm^{-3}, $n(O_2)=1\times10^{11}$ cm^{-3}, $n(N_2)=5\times10^{11}$ cm^{-3}, which we shall describe as the high O_2 atmosphere, and (ii) $n(O)=5\times10^{11}$ cm^{-3}, $n(O_2)=2\times10^{10}$ cm^{-3}, $n(N_2)=5\times10^{11}$ cm^{-3}, which we shall describe as the low O_2 atmosphere. The models appear to span the possible atmospheres (Nicolet, 1961; Harris and Priester, 1962; Pokhunkov, 1963; Jursa, Nakamura and Tanaka, 1963; Schaefer, 1963; Hall, Schweizer, and Hinteregger, 1963; Nier, Hoffman, Johnson, and Holmes, 1964).

The mass density distribution corresponding to the low O_2 atmosphere with $T(\infty)=750$K and to

*Published in *Journal of the Atmospheric Sciences*, 21(6):463–474, September 1964.

†Queens University, Belfast, Northern Ireland.

high O_2 atmospheres with $T(\infty)=750$K and 1000K are compared in Fig. 1 with the density distributions derived from satellite drag data (King-Hele, 1963; Jacchia and Slowey, 1964; Bryant, 1964). The red line observations that we shall discuss were carried out in 1962 and 1963 and except when otherwise noted our results refer to the low O_2 atmosphere with $T(\infty)=750$K, an atmosphere in harmony with the drag data and an atmosphere more easily reconciled with observations of the red line than are the high O_2 atmospheres. The number density, temperature, and mass density distributions corresponding to the low O_2 atmosphere with $T(\infty)=750$K are presented in Table 1.

At altitudes below 120 km we used an atmosphere similar to the model of Jastrow and Kyle (1961).

3. PHOTODISSOCIATION IN THE SCHUMANN-RUNGE CONTINUUM

At wavelengths between 1300 Å and 1750 Å, ultraviolet radiation is strongly absorbed in the Schumann-Runge continuum of molecular oxygen

$$O_2(X^3\Sigma_g^-)+h\nu\rightarrow O_2(B^3\Sigma_u^-)\rightarrow O(^3P)+O(^1D), \quad (3)$$

the process providing a substantial source of $O(^1D)$

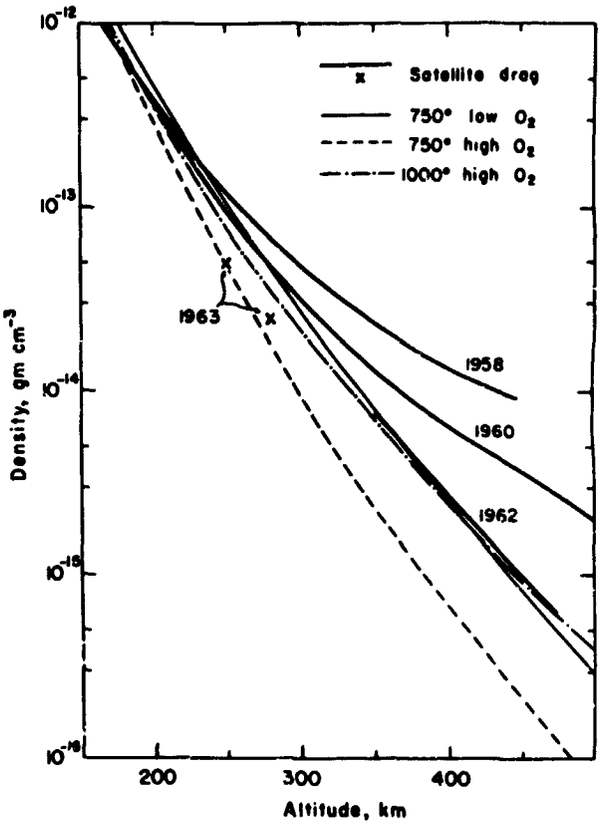

FIGURE 1.—Comparison of the model atmospheres with mid-year daytime maximum satellite drag densities (King-Hele, 1963; Jacchia and Slowey, 1964; Bryant, 1964).

atoms in the upper atmosphere (Bates, 1948). The rate of production of $O(^1D)$ atoms at an altitude, z, and for a solar zenith angle, θ, is given by

$$Q_1(z,\theta) = n(O_2|z)\int_{1350}^{1750} F_\infty(\lambda)\sigma(\lambda)\exp[-\mu(\lambda)]d\lambda \quad (4)$$

where $F_\infty(\lambda)$ is the incident flux, $\sigma(\lambda)$ is the absorption cross section and μ is the attenuation factor,

$$\mu(\lambda) = \sigma(\lambda)\int_{(R+z)\cos\theta}^{\infty} n(Q_2|\{y^2+(R+z)^2\sin^2\theta\}^{\frac{1}{2}})dy, \quad (5)$$

R being the radius of the earth. For the calculation of Q_1 we have used the measurements of $\sigma(\lambda)$ by Metzger and Cook (1964) and we have supposed the solar ultraviolet flux to be that of a black body at a temperature, T_s. The limited data (Purcell, Packer and Tousey, 1960; Detwiler, Garrett, Purcell, and Tousey, 1961; Tousey, 1963) are consistent with a value of 4750K for T_s. The results shown in Figs. 2 to 5 are actually appropriate to a solar temperature of 4500K, but they may all be scaled to a temperature of 4750K by multiplying by a factor of 2.9, the loss of accuracy being negligible.

Values of the production rates of $O(^1D)$ atoms are shown in Fig. 2 for several values of θ. Since the intensity of the red line at 6300 Å in the night airglow is much less than that of the green line at 5577 Å (cf. Chamberlain, 1961a) and since the red line is emitted at a much greater altitude than is the green line (Packer, 1961; Tarasova, 1963), it is clear that severe deactivation of the $O(^1D)$ atoms must occur at the lower altitudes (Bates and

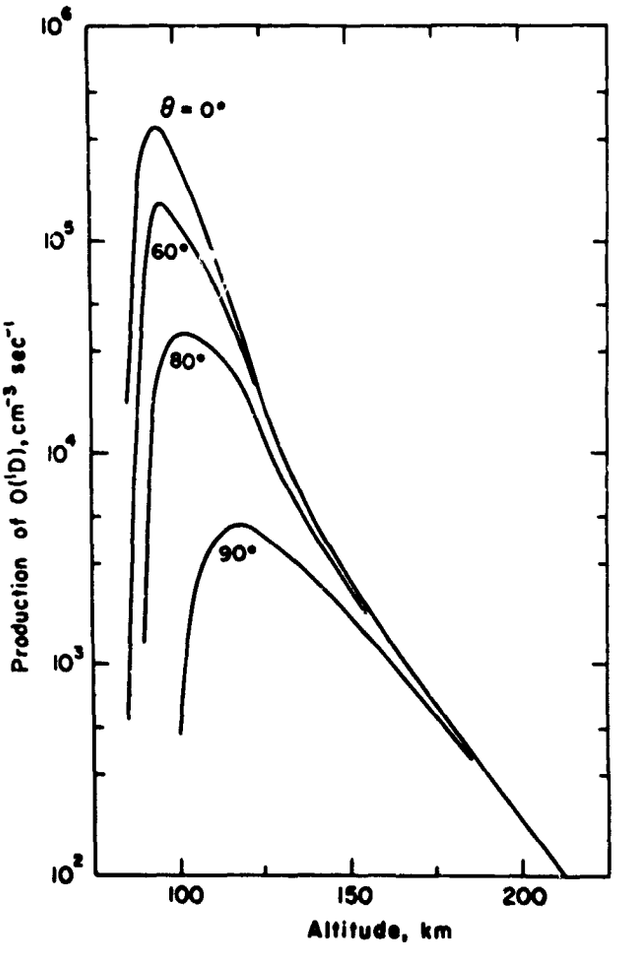

FIGURE 2.—Dependence on altitude of the rate of production of $O(^1D)$ atoms by photodissociation of O_2 for the 750° low O_2 model atmosphere with $T_s = 4500$K. Results are shown for several values of solar zenith angle, θ.

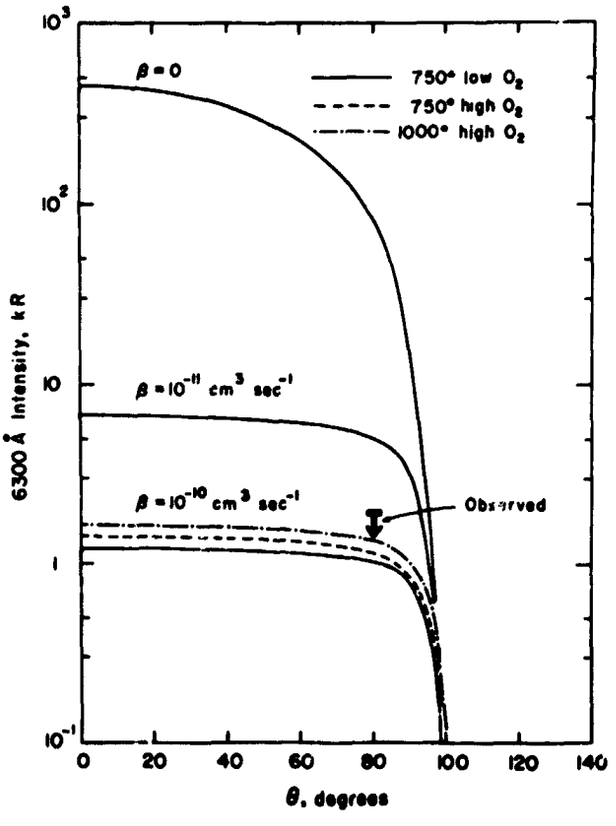

FIGURE 3.—Dependence on solar zenith angle of the intensity which results from the photodissociation of O_2 with $T_s = 4500$K. Results are shown for several atmospheric models and several values of the deactivation coefficient, β. The upper limit imposed by Noxon's (1963) observation is indicated.

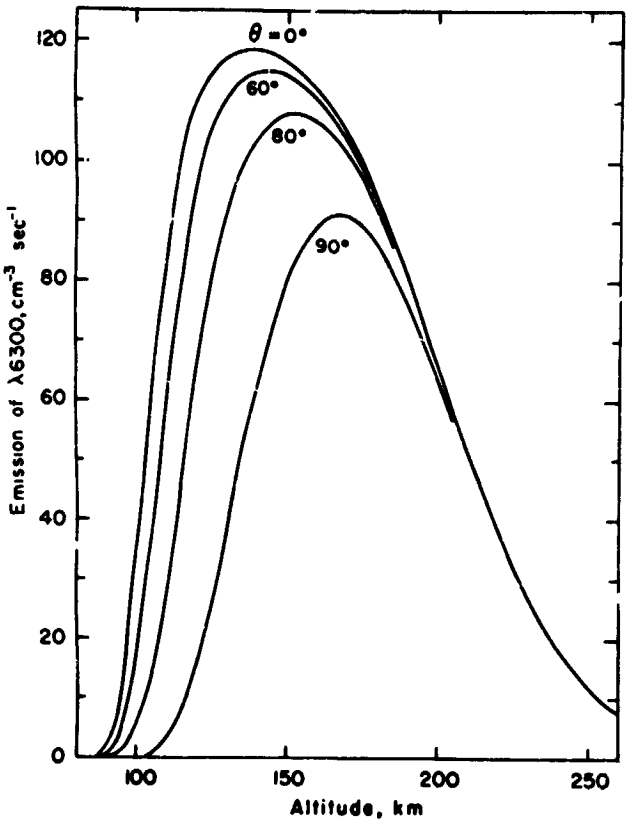

FIGURE 4.—Dependence on altitude of the emission of λ6300 which results from the photodissociation of O_2. The results are for the 750° low O_2 model atmosphere with $T_e = 4500$K and $\beta = 10^{-10}$ cm,³ sec⁻¹.

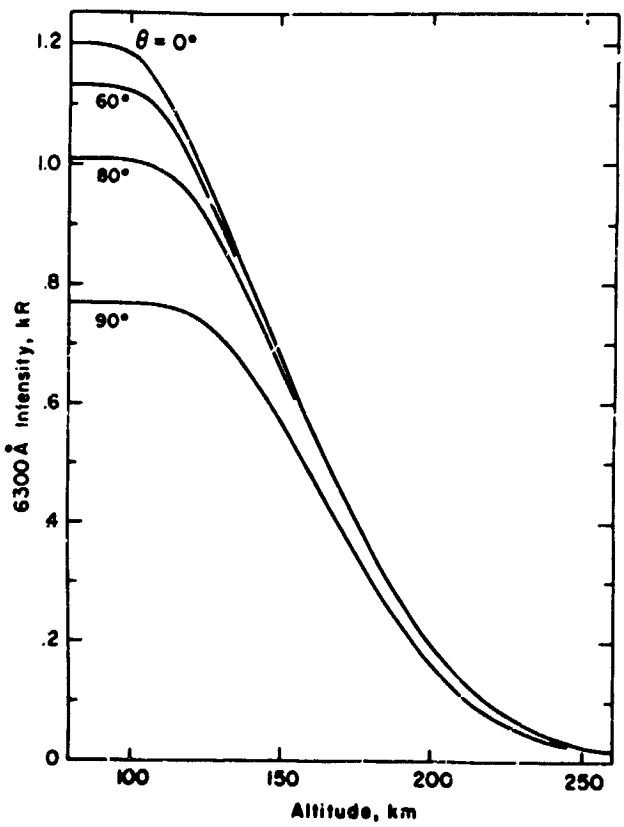

FIGURE 5.—Dependence on altitude of the zenith intensity which results from the photodissociation of O_2. The results are for the 750° low O_2 model atmosphere with $T_e = 4500$K and $\beta = 10^{-10}$ cm³ sec⁻¹.

Dalgarno, 1953; Seaton, 1954). Deactivation by electron impact is negligible (cf. Bates, 1960), and Bates and Dalgarno (1953) and Seaton (1958) have argued that the deactivation probably occurs in collisions with molecular oxygen. With this assumption, Wallace and Chamberlain (1959) have derived from an analysis of auroral observations of the O_2 atmospheric band system a rate coefficient, β, such that

$$4\times10^{-12}\ \text{cm}^3\ \text{sec}^{-1} < \beta < 10^{-10}\ \text{cm}^3\ \text{sec}^{-1}.$$

Despite the fact that the mechanism does not conserve spin, it has been suggested that deactivation of $O(^1D)$ by molecular nitrogen is comparable in efficiency (DeMore and Raper, 1964) and, although the arguments are not convincing, the possibility cannot be excluded. Because the N_2 density profile closely parallels the O_2 density profile, the inclusion of N_2 deactivation would involve no important modification of our subsequent arguments and we shall largely ignore it.

During the day, deactivation by electron impact is still negligible but there occurs the possibility that $O(^1D)$ atoms may be removed by resonance absorption of solar radiation.

There appears to be only one allowed transition, the wavelength of which coincides with a strong solar line, and that is the transition to the $O(2p^3 3s\,^1D)$ state at 1152 Å, the solar flux of λ1152 being about 10^9 photons cm^{-2} sec^{-1} (Hinteregger, 1961; Hinteregger and Watanabe, 1962). Despite the substantial flux and the wavelength coincidence, the mechanism can be discounted because the only allowed transition from the upper state returns the atom to the original ^1D state.

The probability that an $O(^1D)$ atom at altitude, z, will emit a 6300 Å photon is given by

$$p(z) = \left\{1+\frac{A_{6364}}{A_{6300}}+\frac{\beta n(O_2|z)}{A_{6300}}\right\}^{-1} = \{1.32+1.45\times10^2\beta n(O_2|z)\}^{-1}, \quad (6)$$

where A_λ is the radiative transition probability for

the line of wavelength λ (cf. Chamberlain, 1961b). Values of $p(z)$ are given in Table 1 for $\beta = 10^{-10}$ cm^3 sec^{-1}.

The intensities of red line emission for a solar temperature of 4500K and various values of the deactivation coefficient, β, are shown in Fig. 3 as a function of solar zenith angle. The intensity for an overhead sun varies from 433 kR in the absence of deactivation to 1.2 kR if β has a value of 10^{-10} cm^3 sec^{-1}, which is close to the maximum possible for a thermal collision. Fig. 3 includes also the intensities corresponding to two other model atmospheres to show the lack of sensitivity to the details of the number density distribution.

To determine β we note that Noxon (1963) has reported that the intensity of the dayglow red line at noon at Fort Churchill was less than 2 kR on 15 December, 1962, a result in harmony with an observation of Wallace and Nidey (1964). [illegible] Noxon was observing with the sun at a zenith angle of about 80°, it follows from Fig. 3 that, for the low O_2 atmosphere with $T(\infty) = 750$K, $\beta \geq 1.7 \times 10^{-10}$ cm^3 sec^{-1} if $T_e = 4750$K and that $\beta \geq 3.7 \times 10^{-11}$ cm^3 sec^{-1} if $T_e = 4500$K. If deactivation in collisions with N_2 were significant, the implied upper limit on T_e would be increased.

Bates and Dalgarno (1954) pointed out that photodissociation in the Hartley continuum of ozone is an intense source of O(^{1}D) atoms below 100 km, and Cadle (1964) has predicted an intensity of 2 kR for the resulting red line emission, his calculations following Brandt (1958) in using a value of 10^{-12} cm^3 sec^{-1} for β. With either of the two limits derived from Noxon's observations, the actual red line emission below 100 km must be negligible.

Adopting a value of 10^{-10} cm^3 sec^{-1} for β, we show in Figs. 4 and 5, respectively, the emission rate and zenith intensity as functions of altitude for a number of solar zenith angles.

4. IONIC RECOMBINATION

There is usually a good correlation between the nocturnal intensity of the red line and the critical frequency of the F region (Barbier, 1957; Barbier and Glaume, 1962; Barbier, Roach, and Steiger, 1962; Carman and Kilfoyle, 1963; Barbier, 1964), supporting the belief that the main excitation mechanism is dissociative recombination. Originally the molecular ion involved was identified as O_2^+ but it is apparently now believed that NO^+ is the major participant (cf. Wallace and Nidey, 1964). The proposed reaction

$$NO^+(X^1\Sigma^+) + e \rightarrow N(^4S) + O(^1D) \qquad (7)$$

fails to conserve spin. We therefore concentrate on O_2^+ recombination as a source of O(^{1}D) atoms. The ionospheric and airglow data presented by Barbier (1964) indicate that the rate of electron removal in the nocturnal ionosphere exceeds the rate of emission of 6300 Å photons by a factor of about 8, consistent with our suggestion that (7) is not an important mechanism for O(^{1}D) excitation.

The nocturnal intensity of the red line is between 50R and 100R (cf. Chamberlain, 1961a) and considerable daytime enhancement is to be expected. The calculations by Brandt (1958) were based upon a simple sequence of ion-removal reactions and his results were sensitive to the adopted reaction rates. It is now clear that the actual reaction paths in the ionosphere are much more complicated (Nicolet and Swider, 1963; Dalgarno, 1964a). Serious uncertainties remain, the consequences of which can be largely avoided by assuming that local equilibrium prevails between ion production and removal rates, an assumption which is valid below 300 km throughout most of the day but fails at greater altitudes because of the increasing importance of diffusion.

The ion production rates, $q(O^+)$, $q(N_2^+)$, and $q(O_2^+)$ cm^{-3} sec^{-1} have been calculated for a wide range of model atmospheres and solar zenith angles by Dalgarno and McElroy (1964a) and some of their results are reproduced in Fig. 6.

In order to estimate what fractions of the ions, O^+, N_2^+, and O_2^+, lead to (O^{1}D) atoms, it is necessary first to determine what fractions of the ions O^+ and N_2^+ are converted to O_2^+ ions or possibly to NO^+ ions. The fractions depend upon the electron density distribution and we have adopted the distribution measured by Brace, Spencer, and Carignan (1963) in a quiet ionosphere and included in Table 1. The intensity of the red line is insensitive to the details of the adopted electron density profile.

The reactions which remove N_2^+ ions have been discussed by Nicolet and Swider (1963). They are

$$N_2^+ + e \rightarrow N' + N'' \qquad (8)$$

$$N_2^+ + O_2 \rightarrow N_2 + O_2^+ \qquad (9)$$

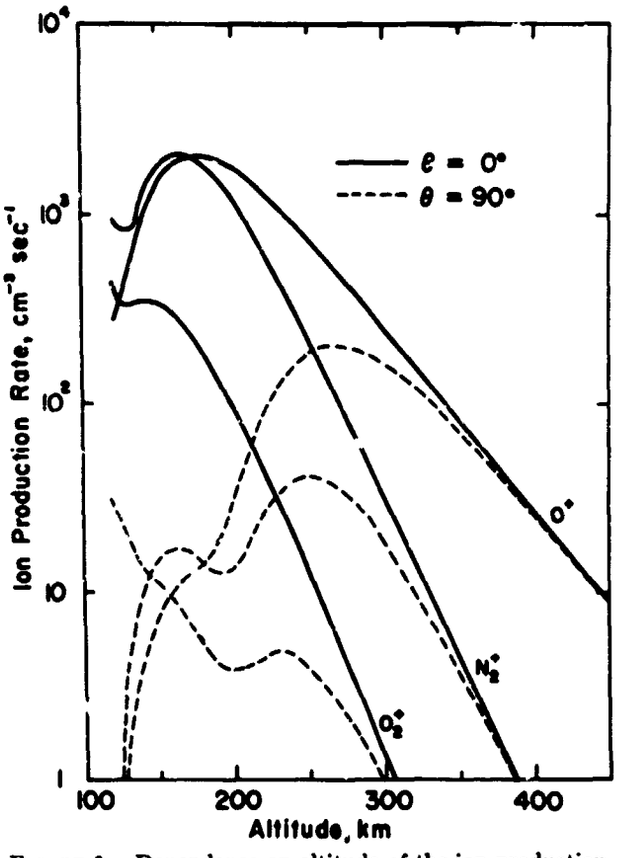

FIGURE 6.—Dependence on altitude of the ion production rates for the 750° low O_2 model atmosphere.

$$N_2^+ + O \rightarrow N_2 + O^+ \qquad (10)$$

$$N_2^+ + O \rightarrow NO^+ + N. \qquad (11)$$

The rate coefficient of (8) has been measured as 2×10^{-7} cm^3 sec^{-1} (cf. Biondi, 1964) and of (9) as 2×10^{-10} cm^3 sec^{-1} (Fite, Rutherford, Snow, and van Lint, 1962). Rate coefficients of 2×10^{-11} cm^3 sec^{-1} for (10) and (11) have been derived by Norton, Van Zandt, and Denison (1963) and by Whitten and Poppoff (1964) from ionospheric data. The analyses of ionospheric data impose arbitrary temperature variations on the rates of the possible processes and the derived coefficients have little quantitative significance. However, the measured concentrations of N_2^+ apparently require that one or both of (10) and (11) be rapid so we assume that each of them has a rate coefficient of 1×10^{-11} cm^3 sec^{-1}. Since, in the atmosphere, (10) is usually followed by

$$O^+ + N_2 \rightarrow NO^+ + N \qquad (12)$$

the distinction between (10) and (11) is unimportant for our purposes.

The O^+ ions are removed by the ion-atom interchange reactions, (12) and

$$O^+ + O_2 \rightarrow O_2^+ + O \qquad (13)$$

(Bates, 1955). For our calculations we have adopted a rate coefficient of 1×10^{-11} cm^3 sec^{-1} for both (12) and (13) (Sayers and Smith, 1964) but the red line intensity depends only upon the ratio of the rates of the two reactions.

The ion, O_2^+, disappears by dissociative recombination

$$O_2^+ + e \rightarrow O' + O'' \qquad (14)$$

throughout the altitude region in which (14) might provide a significant source of emission of the red line. Thus, if f is the probability that (14) produces an $O(^1D)$ atom, the rate of production is given by

$$Q_2 = f\left\{ q(O_2^+) + q(N_2^+)\left[\alpha_9 n(O_2) + \frac{\alpha_{10} n(O)}{1+\frac{\alpha_{12} n(N_2)}{\alpha_{13} n(O_2)}}\right] \times [\alpha_8 n(e) + \alpha_9 n(O_2) + (\alpha_{10}+\alpha_{11}) n(O)]^{-1} + q(O^+)\left[1+\frac{\alpha_{12} n(N_2)}{\alpha_{13} n(O_2)}\right]^{-1}\right\} \qquad (15)$$

The reaction is energetically capable of producing two $O(^1D)$ atoms so that f may be as large as 2. In Fig. 7 $Q_2(z)$ is shown as a function of altitude for several solar zenith angles with f taken equal to 2. The results provide an upper limit to the possible excitation rates consistent with the adopted ultraviolet flux and reaction rates.

Because $n(N_2)$ is much greater than $n(O_2)$ in the altitude region where $q(O^+)$ and $q(O_2^+)$ are comparable, the last term of (15) is important only at high altitudes where the production rates are small. Thus the intensity of the red line is insensitive to the magnitudes of α_{12} and α_{13}. In contrast is the sensitivity to the relative values of α_8 and α_9. Reaction (9) is an important source of O_2^+ ions at the lower altitudes where the production rates are large, whereas the sequence of (10) followed by (13) is important only at high altitudes where the production of $O(^1D)$ is small. Accordingly, we illustrate in Fig. 7 only the sensitivity to the ratio α_8/α_9, the dashed curves of Fig. 7 arising when the value of 2×10^{-10} cm^3 sec^{-1} for α_9 is replaced by zero so that most of the N_2^+ ions disappear by dissociative recombination.

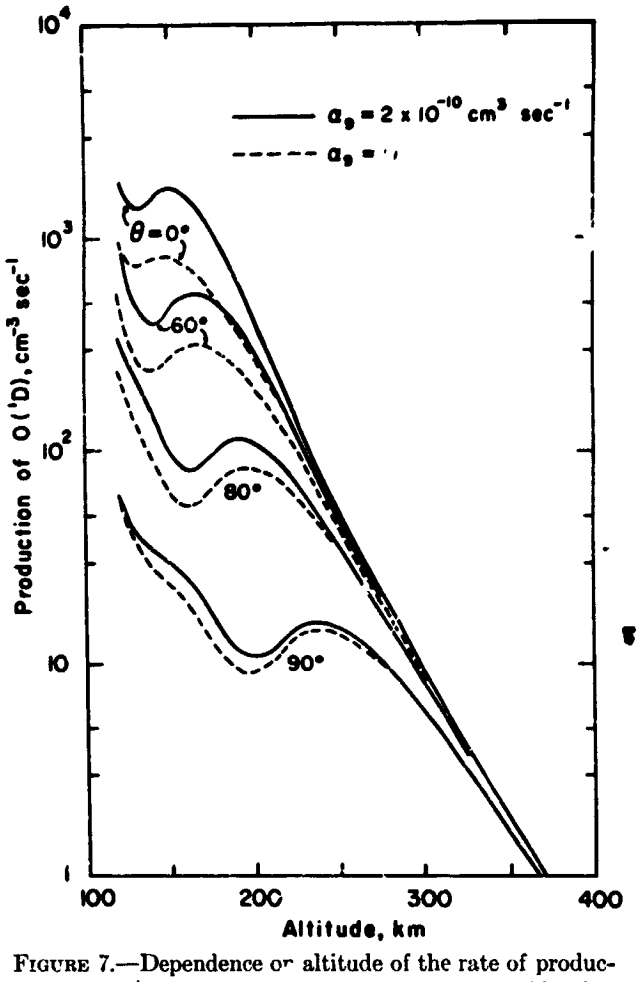

FIGURE 7.—Dependence on altitude of the rate of production of O(¹D) atoms by the dissociative recombination of O_2^+ for the 750° low O_2 model atmosphere.

The possible additional source of O(¹D) atoms provided by the dissociative recombination of NO^+ (7) is shown in Fig. 8 on the assumption that every NO^+ recombination yields an O(¹D) atom. The actual yield is presumably much less than unity.

The rate of emission of 6300 Å photons produced by dissociative recombination of O_2^+ with $\alpha_3/\alpha_9 = 10^3$, $\alpha_8/\alpha_{10} = \alpha_8/\alpha_{11} = 2 \times 10^4$, $\alpha_{11}/\alpha_{12} = 1$, $\beta = 10^{-10}$ cm^3 sec^{-1}, and $f = 2$ is shown in Fig. 9. The corresponding zenith intensities are shown in Fig. 10.

Fig. 11 shows the sensitivity of the predicted intensities to the atmospheric model.

5. PHOTODISSOCIATION AND IONIC RECOMBINATION

A comparison of Figs. 3 and 11, and 5 and 10 shows that the contributions of photodissociation and of ionic recombination to the zenith intensity of the red line may be comparable, depending upon the values of T_s and f, but there are significant differences in the variations with solar zenith angle and with altitude. The zenith intensity has been measured as a function of altitude by Zipf and Fastie (1963) at Wallops Island on 7 May 1964 with the sun at a zenith angle of 60°. We have attempted to reproduce the observational data of Zipf and Fastie by combining the contributions of photodissociation, shown in Fig. 5, and of ionic recombination, shown in Fig. 10, and regarding the solar temperature, T_s, and the excitation probability, f, as disposable parameters subject to $f \leqslant 2$.

Fig. 12 shows the best fits we have been able to obtain by this procedure for three model atmospheres. The results for the 1000° high O_2 atmosphere with $T_s = 4660$K and $f = 2$ agree closely with the observations, the total zenith intensity being 4.8 kR of which 3.1 kR is due to photodissociation and 1.7 kR to ionic recombination. The corresponding intensities appropriate to a zenith angle of 80° are, respectively, 2.7 kR and 1.0 kR,

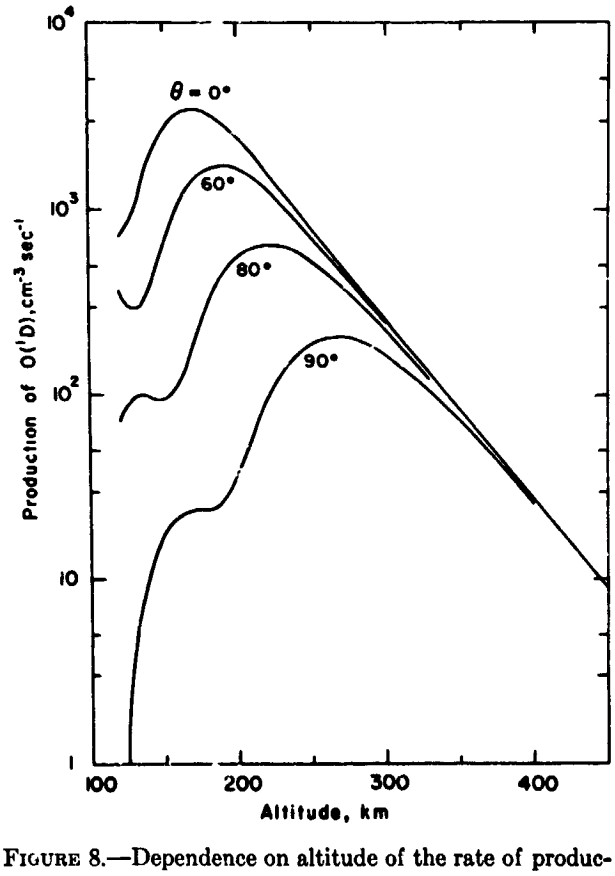

FIGURE 8.—Dependence on altitude of the rate of production of O(¹D) atoms by the dissociative recombination of NO^+ for the 750° low O_2 model atmosphere.

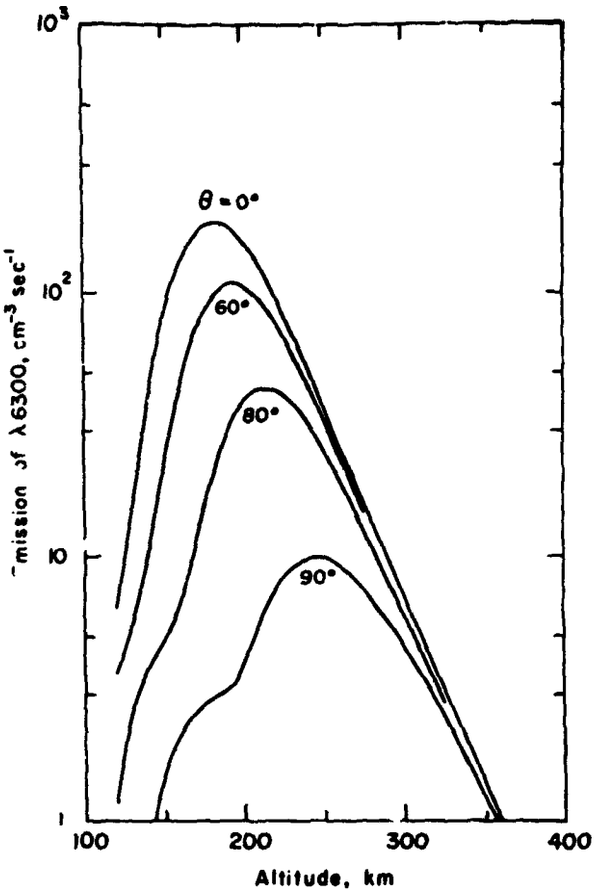

FIGURE 9.—Dependence on altitude of the emission of λ6300 which results from the dissociative recombination of O_2^+ for the 750° low O_2 model atmosphere.

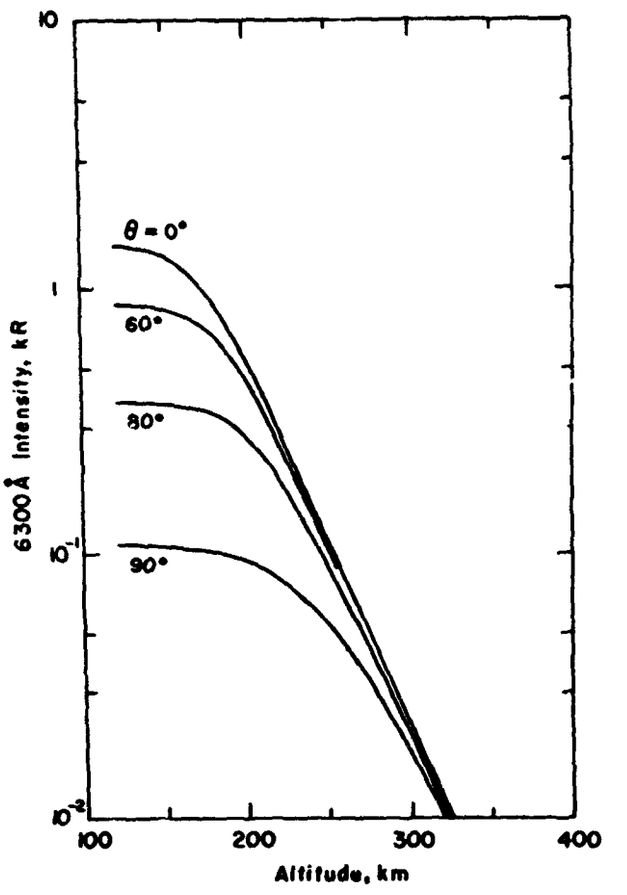

FIGURE 10.—Dependence on altitude of the zenith intensity which results from the dissociative recombination of O_2^+ for the 750° low O_2 model atmosphere.

the sum of which exceeds the upper limit of 2 kR observed by Noxon (1963) at Fort Churchill at noon on 15 December 1962. In order to be consistent with an upper limit of 2 kR at 80°, it is necessary with the 1000° high O_2 model atmosphere to adopt a solar temperature not greater than 4580K, even with $f=0$. The results for the other models shown in Fig. 12 lead to even greater conflict with Noxon's upper limit.

Temporal variations in the solar ultraviolet flux in the neighborhood of 1216 Å are small (Lindsay, 1963), and there is no evidence to suggest that large variations occur in the flux at the longer wavelengths of the Schumann-Runge continuum. Ignoring the possibility of temporal change in T_s, we have determined the values of T_s which give the largest intensities at 60° consistent with the upper limit of 2 kR at 80°. The intensities as a function of altitude for the three model atmospheres are shown in Fig. 13. All of these models lead to intensities which are markedly lower than the Zipf and Fastie results. The situation cannot be improved by using lower values of f and higher values of T_s because, with a deactivation coefficient, β, of 10^{-10} cm^3 sec^{-1}, the photodissociation contribution is nearly independent of θ as θ varies from 60° to 80°, as shown in Fig. 3.

There are also discrepancies in the detailed dependence of emission on altitude, Zipf and Fastie (1963) finding that the emission rate is 2.6×10^2 cm^{-3} sec^{-1} from 120 km to 190 km, increasing abruptly to 5.0×10^2 cm^{-3} sec^{-1} from 190 km to 220 km. The dependence of emission on altitude would be modified if the deactivation coefficient, β, were to change rapidly with increasing temperature. As Bates (1960) has pointed out, O(^{1}D) atoms produced by dissociative recombination initially possess considerable kinetic energy so that the effective temperature controlling β may be higher than the ambient temperature. The effect

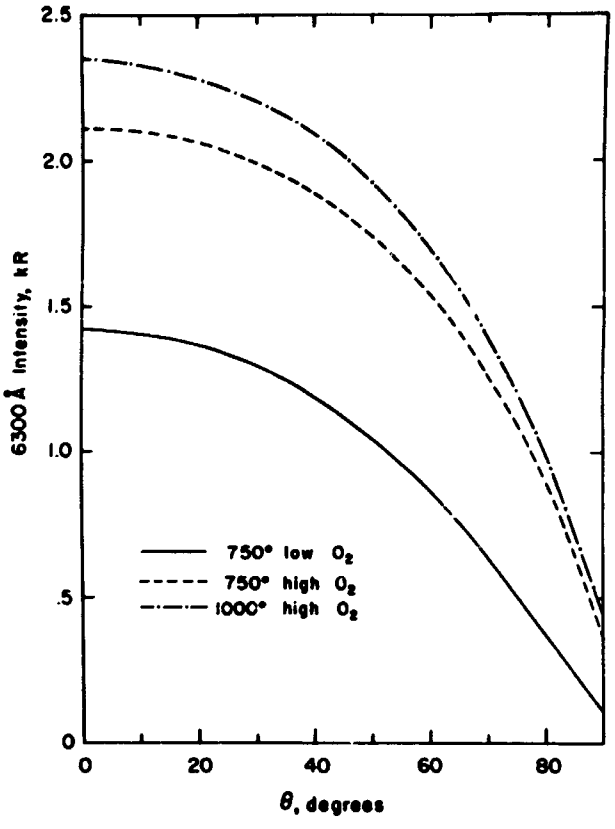

FIGURE 11.—Dependence on solar zenith angle of the intensity which results from the dissociative recombination of O_2^+ for several model atmospheres with $\beta = 10^{-10}$ cm^3 sec^{-1} and $f = 2$.

is probably small since molecular oxygen is a minor constituent at the altitudes of interest and thermalizing collisions with the major constituents, O and N_2, occur more frequently than deactivating collisions with O_2. A rapid change of β with increasing altitude will not, in any case, remove the discrepancy between the predicted intensities of Fig. 13 and the observed intensities. The discrepancy can more plausibly be attributed to an additional excitation mechanism.

6. FLUORESCENT EXCITATION

Bates (1948) and Chamberlain (1958) have shown that resonance scattering of sunlight

$$O(^3P)+\lambda 6300 \rightarrow O(^1D) \qquad (16)$$

does not contribute significantly to the twilight-glow in the red line and it follows from their calculations, but including deactivation, that the yield in the dayglow does not exceed 20R.

Fluorescence through the sequences

$$O(^3P)+\lambda 1304 \rightarrow O(^3S) \qquad (17)$$

$$O(^3S) \rightarrow O(^1D)+\lambda 1641, \qquad (18)$$

or

$$O(^3S) \rightarrow O(^1S)+\lambda 2325 \qquad (19)$$

followed by

$$O(^1S) \rightarrow O(^1D)+\lambda 5577, \qquad (20)$$

may be a more abundant source of dayglow red line emission and incidentally of dayglow green line emission also, for the atmosphere is optically very thick in the triplet centered at λ1304.

The intensity of λ1304 has been measured by Donahue and Fastie (1964) and by Fastie, Crosswhite and Heath (1964). If we assume a Doppler width corresponding to a temperature in the region of 2000K for the line and a value of 4.0×10^{-6} (Garstang, 1961) for the ratio of the transition probabilities for the emission of λ1641 and λ1304 radiation, the measured intensities of λ1304 lead to an estimate of the order of 100R for the red

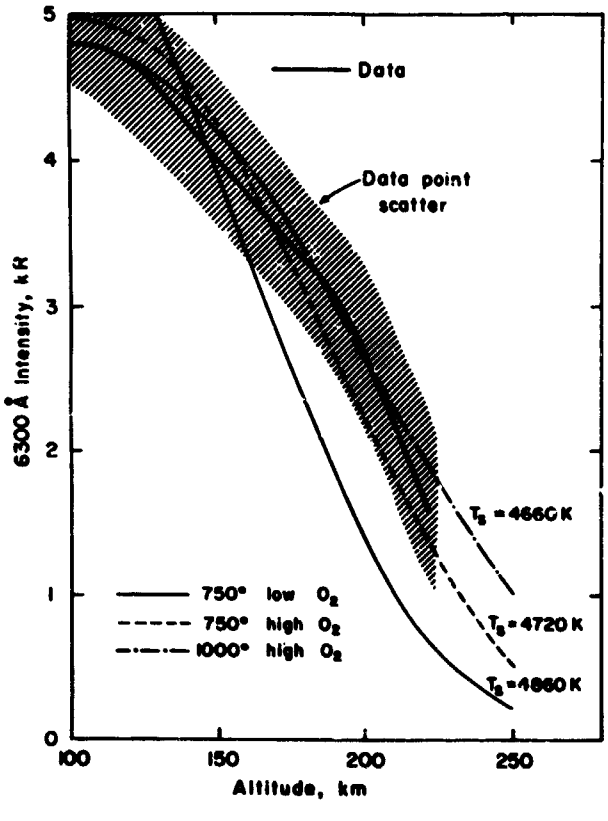

FIGURE 12.—Comparison of the data of Zipf and Fastie (1963) with the theoretical intensities at $\theta = 60°$ which result from photodissociation and ionic recombination. All three models use $f = 2$ and $\beta = 10^{-10}$ cm^3 sec^{-1}.

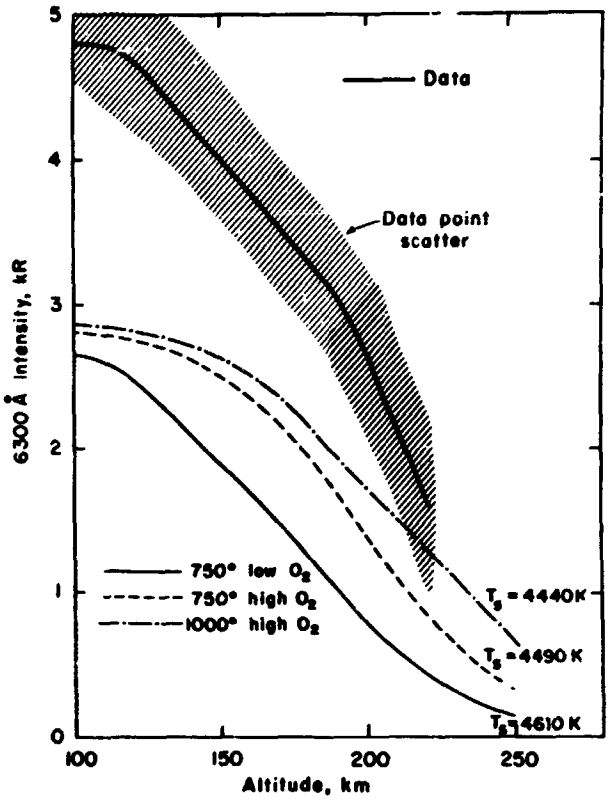

FIGURE 13.—Comparison of the data of Zipf and Fastie (1963) with theoretical intensities at $\theta = 60°$ due to photodissociation and ionic recombination for models which lead to an intensity of 2kR at $\theta = 80°$. The calculations assume $f = 2$ and $\beta = 10^{-10}$ cm^3 sec^{-1}.

line, an estimate which is consistent with the fact that λ1641 radiation has not been detected in the airglow. The contribution of (19) and (20) is much smaller because the ratio of the transition probabilities for the emission of λ2325 and λ1304 is 1.6×10^{-8} (Garstang, 1961).

None of the mechanisms discussed so far explains the great variability of the red line intensity, discovered by Noxon (1964). The electron temperature is markedly higher than the neutral particle temperature in the F region and may well be very variable (Spencer, Brace and Carignan, 1962; Brace, Spencer and Carignan, 1963; Nagy, Brace, Carignan and Kanal, 1963) and the energy source responsible may also be a source of excitation of the red line.

7. ELECTRON IMPACT EXCITATION

7.1 Thermal Excitation

It has been pointed out (Dalgarno, 1964b) that a rise in the temperature of the ambient electron gas will be accompanied by an enhancement of the red line. Spencer, Brace and Carignan (1962) and Brace, Spencer and Carignan (1963) have presented the results of measurements of electron densities and electron temperatures from several rocket flights. If we assume that there is no depletion of the high energy tail of the velocity distribution, the associated red line emission rates may be easily computed using rate coefficients derived from Seaton (1956). The emission rates and intensities as functions of altitude are shown in Figs. 14 and 15 for a deactivation coefficient $\beta = 10^{-10}$ cm^3 sec^{-1}.

In calculating the zenith intensities, it is necessary to estimate the emission at altitudes above those for which electron temperature and density data are available. We have assumed that the electron gas is isothermal and in diffusive equilibrium at these altitudes. The contribution of the high altitudes to the overhead intensity is

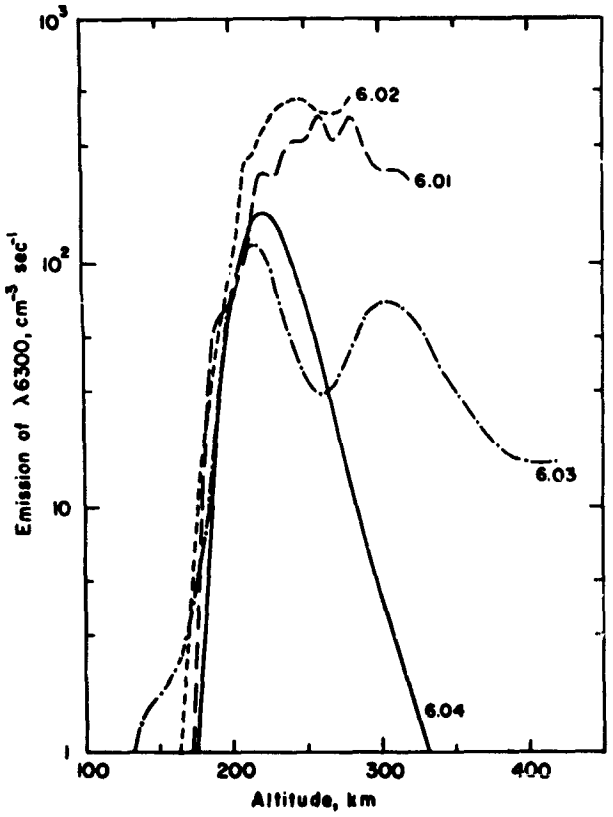

FIGURE 14.—Dependence on altitude of the emission of λ6300 which results from excitation by thermal electrons for four measured profiles of electron temperature and density (Spencer, Brace, and Carignan, 1962; Brace, Spencer, and Carignan, 1963. The results are for the 750° low O_2 model atmosphere with $\beta = 10^{-10}$ cm^3 sec^{-1}.

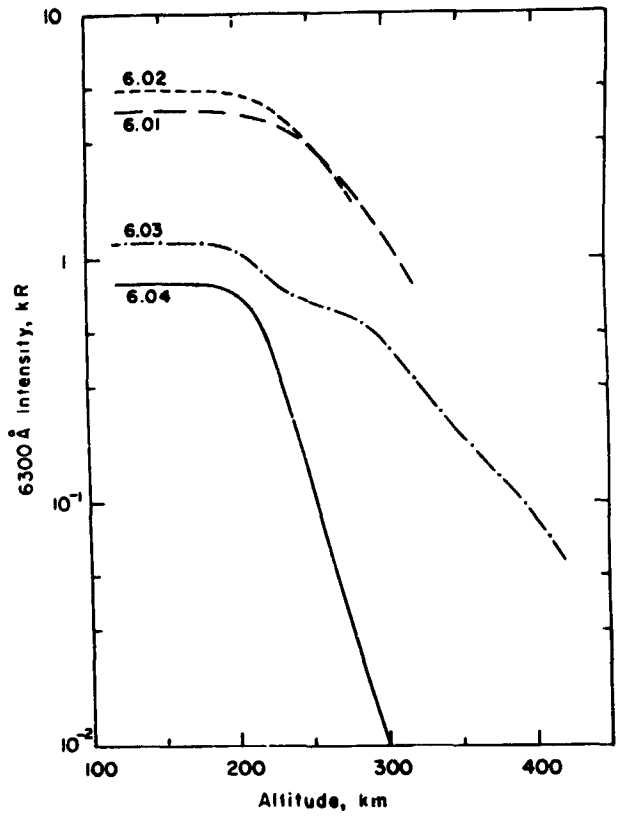

FIGURE 15.—Dependence on altitude of the zenith intensity which results from excitation by thermal electrons for four measured profiles of electron temperature and density (Spencer, Brace, and Carignan, 1962; Brace, Spencer, and Carignan, 1963). The results are for the 750° low O_2 model atmosphere with $\beta = 10^{-10}$ cm^3 sec^{-1}.

about 30 percent for flight 6.02, 20 percent for flight 6.01, 5 percent for flight 6.03, and 0.1 percent for flight 6.04.

Flight 6.01 was fired from Fort Churchill on 16 March 1960, during spread *F* conditions and flight 6.04 was fired from Wallops Island on 3 March 1961, during quiet ionospheric conditions. The red line intensities predicted for thermal excitation are 4.1 kR and 0.79 kR, respectively. The altitude profiles are markedly different, the emission rate for flight 6.04 peaking at 220 km and decreasing rapidly and that for flight 6.01 varying little from 220 km up to at least 320 km.

Flight 6.04 provides an interesting contrast to flight 6.02 which was fired from Fort Churchill on 15 June 1960, also during quiet ionospheric conditions. Flight 6.02 is actually very similar to the spread *F* flight 6.01 with a predicted intensity of 4.9 kR and an emission rate varying little from 225 km up to at least 280 km.

Flight 6.03 was fired from Wallops Island on 3 August 1960, following a period of magnetic disturbance. Below 250 km the results are similar to those for the quiet ionosphere Wallops Island flight 6.04. However, the 6.03 emission rate is enhanced at greater altitudes, with a second maximum at 310 km and a relatively slow decrease above this altitude. The predicted intensity for flight 6.03 is 1.2 kR.

The daytime electron temperature is very sensitive to small disturbances and it appears that the intensity and the altitude dependence of the red line may be still more sensitive. Thus an increase of 10 percent in the electron temperatures measured on flight 6.04 would raise the predicted red line intensity from 0.79 kR to 2.1 kR. The combined profile due to such arbitrary thermal excitation, to Schumann-Runge photodissociation with $T_s = 4610$K and to ionic recombination with $f = 2$

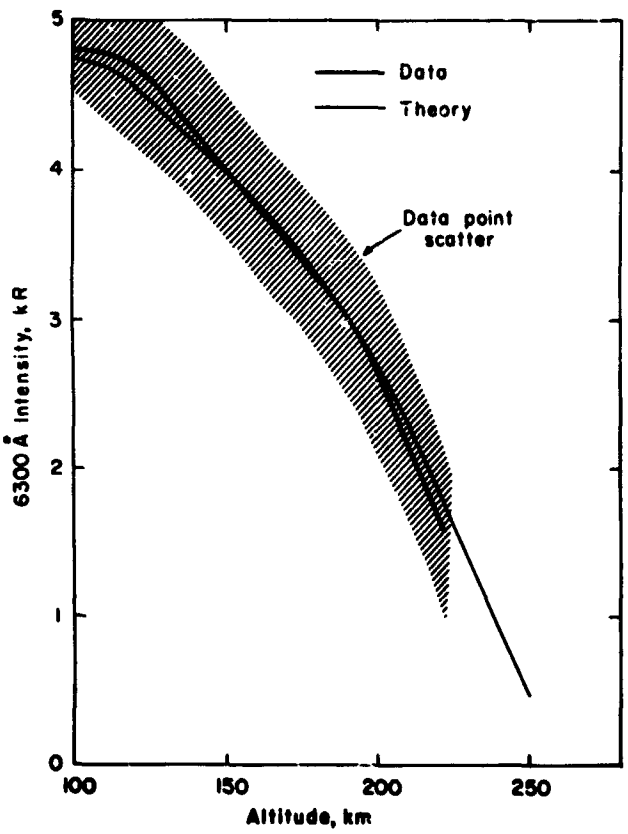

FIGURE 16.—Comparison of the data of Zipf and Fastie (1963) with the theoretical intensity which results from the combination of photodissociation with $T_s = 4610$K, ionic recombination with $f = 2$, and electron excitation given by the profile calculated for flight 6.04 enhanced by a factor of 2.7. The theoretical results are for the 750° low O_2 model atmopshere with $\beta = 10^{-10}$ cm^3 sec^{-1}.

is in harmony with that observed by Zipf and Fastie (1963), as Fig. 16 demonstrates. This model reconciles the observation of Zipf and Fastie with Noxon's (1963) upper limit on the intensity at Fort Churchill if we assume that electron impact excitation was negligible at the time of Noxon's measurement.

The very high intensities of the order of 40 kR observed by Noxon and Goody (1962) and by Jarrett and Hoey (1963) can be ascribed to thermal excitation by electrons with a temperature in the region of 4000K. Such high temperatures have been detected, but only occasionally, on Explorer XVII (Brace and Spencer, 1964) and it is significant that very intense red line emission is also a rare phenomenon (Noxon, 1964).

The Explorer XVII data show an early morning maximum in the electron temperature (Brace and Spencer, 1964), related presumably to the dawn effect (Dalgarno and McElroy, 1964b), and an early morning enhancement of the red line may be a regular feature of its diurnal variation.

Satellite observations (Willmore, Henderson, Boyd, and Bowen, 1964; Brace and Spencer, 1964) show that the electron temperature remains higher than the neutral particle temperature during the night. The temperatures are usually too low to give rise to significant thermal excitation and the intensity associated with the nocturnal rocket flight 6.05 of Brace, Spencer and Carignan (1963) was a fraction of a rayleigh. However, the energy source associated with the heating of the electrons may contribute directly to excitation of the red line and it is interesting to note that Barbier (1964) has suggested that about 20R of red line emission is not directly correlated with the normal ionospheric parameters.

A similar effect may occur during the day.

7.2 Non-Thermal Excitation

A major source of heat during daylight exists in the fast photoelectrons produced by photoionization by solar ultraviolet radiation. The photoelectrons lose energy through a complicated sequence of collision processes, one of which is electron impact excitation of atomic oxygen to the $O(^1D)$ state (Hanson and Johnson, 1961; Hanson, 1963; Dalgarno, McElroy and Moffett, 1963; Dalgarno, 1964b). The resulting altitude profile will be similar to that derived for thermal excitation and the intensity may be of the order of a kilorayleigh in which case the importance of thermal excitation in the interpretation (Fig. 16) of the observed profile (Zipf and Fastie, 1963) must be correspondingly diminished.

8. CONCLUSIONS

Noxon's observation that the intensity of the red line at a zenith angle of 80° is less than 2 kR places severe restrictions upon the contributions from photodissociation of molecular oxygen and from recombination of molecular ions. It appears necessary that the deactivation coefficient for collisions of $O(^1D)$ atoms with O_2 be as large as 10^{-10} cm^3 sec^{-1}, and that the solar flux in the region of 1450 Å be less than the reported values. Then the contributions of photodissociation and of ionic recombination vary from at most 3.4 kR for an overhead sun to at most 1.3 kR for a zenith angle of 90°.

It is difficult to reconcile the limit placed by Noxon with the altitude profile measured by Zipf and Fastie without postulating an additional excitation mechanism effective at high altitude. The additional mechanism may be impact excitation by photoelectrons or it may be thermal excitation by hot electrons. The latter source can tentatively be identified as that responsible for the observed variability of the dayglow intensities. The dayglow red line may therefore provide a means of monitoring the electron temperature and thereby of gaining information about temporal variations in upper atmosphere energy sources. A search for correlations between simultaneous measurements of the red line and the electron temperature would be instructive.

ACKNOWLEDGMENTS

Our study of the emission of the red line in the dayglow was stimulated by Dr. J. F. Noxon's observations and we have enjoyed many discussions with him on the subject. Mrs. O. P. Ko provided valuable assistance in programming and running the computer.

A part of this research was performed while Walker was at Columbia University and was supported by the National Aeronautics and Space Administration under Grant Number NsG–145.

A LATITUDE SURVEY OF THE NIGHT AIRGLOW*

T. N. DAVIS† AND L. L. SMITH‡

A four-color turret photometer has been used for shipboard observations of the night airglow and the aurora. Zenith observations have been obtained during 1962 close to the 70°W meridian from the northern auroral zone to the Antarctic pack ice. Most of the observations were taken during the Southern Winter.

Maximums in the [OI] 5577A intensity were found near 30–40°N and 40°S, with the Southern Hemisphere level being generally lower than that in the Northern Hemisphere. The [OI] 6300A latitudinal variation was similar to that of [OI] 5577A except that maximums in the latitudinal distribution were found near 15° geomagnetic north and south latitudes. In contrast with the [OI] emissions, the sodium group (NaD doublet and OH bands near 5893A) generally increased to the south with maximums near 20–30°N and 40–50°S geographic latitude. The total 5340A background increased from north to south. When the integrated starlight and zodiacal light components were subtracted from the total background, the resultant terrestrial component showed a pronounced minimum at low latitudes and apparent symmetry about the geomagnetic equator.

I. INTRODUCTION

Photometric observations of the aurora and the night airglow made aboard the U.S.N.S. *Eltanin* during the period March/November, 1962. The *Eltanin* departed from New York in late March and moved northward into the Laborador Sea where photometric observations of aurora were made on four nights After returning to New York, the *Eltanin* departed on May 24 on a trip southward and arrived in Valparaiso, Chile on June 27. Clear skies existed throughout most of this cruise and useful airglow observations were obtained on 17 nights. In the period July/ November 1962, the *Eltanin* made several cruises southward from Valparaiso and useful observations (during clear, moonless dark hours) were obtained on 36 nights. See Figure 1 for the positions of the *Eltanin* when the observations were made.

Observations were made in four narrow wavelength bands centered near 5577, 6300, 5893 and 5340A with a turret photometer built by the Fritz Peak Observatory following a design by Purdy, Megill and Roach (1961). This instrument has a 5° diameter circular field of view and was mounted on a free swinging gimbal to assure observation of the zenith. The gimbal mount was effective in reducing the effect of the ship's motion to the extent that the photometer axis pointed to within 5° of the zenith throughout most of the observations. Observations at a given wavelength were obtained at 5 minute intervals.

The two-color method (Roach and Meinel, 1955) was applied to the 5577, 6300 and 5893A observations in an attempt to remove the contributions due to airglow continuum, zodiacal light, and integrated starlight; the method involves subtraction of these contributions as determined by observation through the 5340A filter. Details of the data reduction and calibration procedures together with tabulations of the results are given in a limited circulation report (Davis and Smith, 1964).

A complication to the determination of the intensities of the [OI] 5577, [OI] 6300 and NaD 5893A emissions arises due to contamination from nearby OH band emissions. Figur 2 shows the filter transmission characteristics and wavelengths

*Published in the *Journal of Geophysical Research*, 70(5):1127–1138, March 1, 1965.

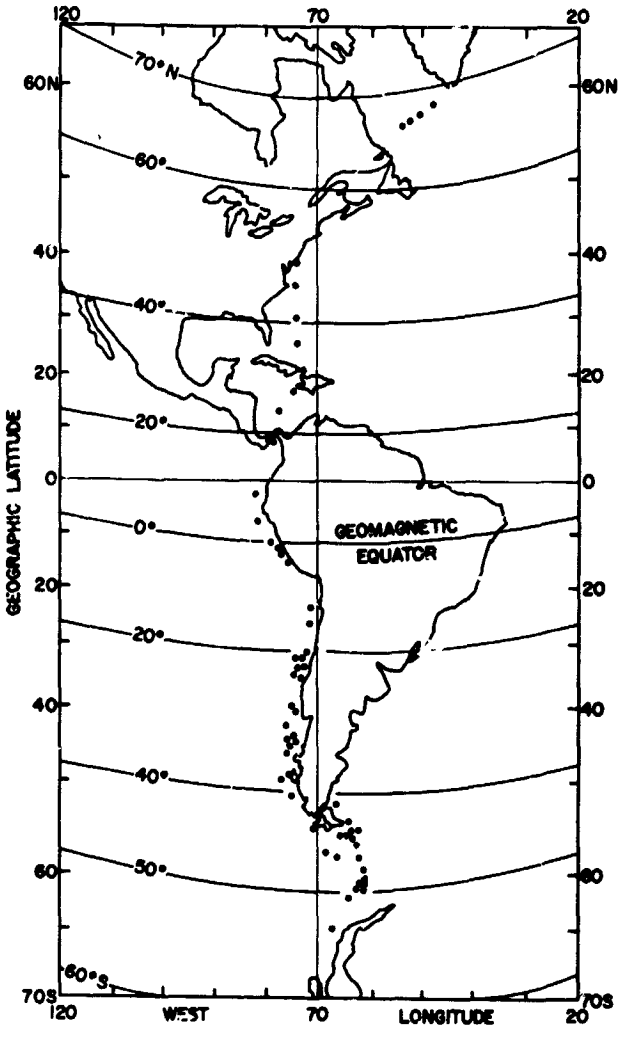

FIGURE 1.—Location of the *Eltanin* on nights when useful nighttime observations were made.

of the [OI] and NaD (doublet) emissions. A correction to the [OI] 5577A intensity is required due to the presence of the OH [7/1] band emissions with the band head at 5562A. Using estimates of the mean zenith intensities of the OH 5562A and [OI] 5577A line emissions given by Roach (1956), 15R and 250R, respectively, or measurements by Krassovsky, Shefov, and Yarin (1962) together with the known transmission characteristics of the 5577A filter, it is estimated that on the average approximately 90 percent of the intensity remaining after correction for continuum sources is due to the [OI] 5577A emission. Although the 6300A filter is quite narrow, contamination from the OH (9/3) band with band head near 6256A is significant. Based on data given by Chamberlain (1961, pp. 555/557) the OH contribution through the 6300A filter is estimated to be in the neighborhood of 10 to 20 Rayleighs. At low levels of [OI] 6300A emission encountered during some of the measurements described below, the OH contamination is especially severe. Serious contamination also occurs through the 5893A filter as a result of the OH (8/2) band near 5386A. The NaD and OH emissions can covary (see Chamberlain, 1961 p. 517) and it is estimated that approximately 70 percent of the line and band emission measured through the 5893A filter is due to the NaD doublet at 5890/5896A. Since the observations reported here are obtained over a wide range of latitude, it must be recognized that there is much uncertainty about the OH contributions. Hence, no attempt has been made to correct the results presented below for OH contamination.

II. RESULTS

Several types of variation occur in the night airglow; these types include latitudinal variation, seasonal variation, diurnal variation, nightly variation and possibly also effects produced by high-altitude explosions. Considering the nature of the data taken so far aboard the *Eltanin*, it is impossible to completely separate the different types of variation. An additional complication arises from inhomogenieties of the data, since on some nights complete observations are obtained, while on others, as little as only an hour of observation may be available.

II. A. Variation of [OI] 5577A

A. 1 *Night-to-night and Diurnal Variations*

The observations show two categories of diurnal variation in 5577A. One type, illustrated in Figure 3A, is one in which little variation in the 5577A intensity occurs during the middle of the night. In the second category are those nights in which an enhancement occurs during some part of the night; see Figures 3B and 3C. Evidently the time at which the enhancement occurs is random, since averaging over a number of nights (Figure 4A) yields a nearly constant level of 5577A emission throughout the night. The data do not indicate any latitude dependence of the character of the diurnal variation, although the quantity of data is not sufficient to rule out such a dependence.

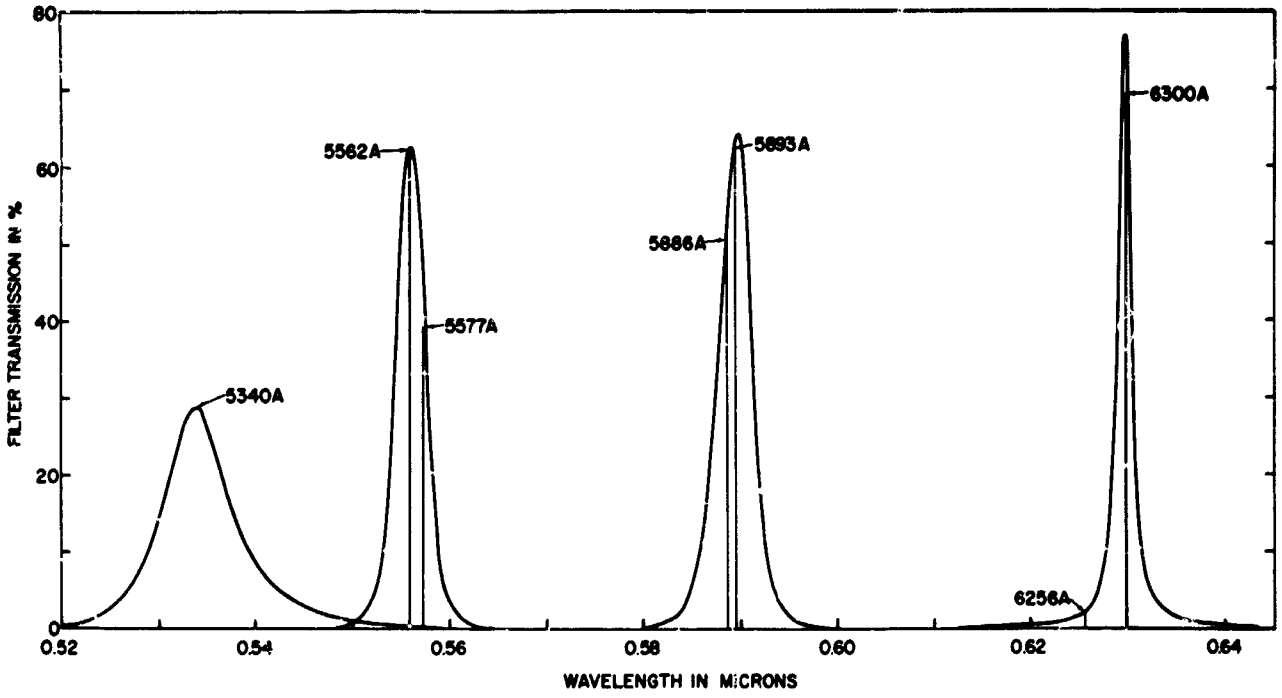

FIGURE 2.—Transmission characteristics of the interference filters and locations of line emissions near the filter peaks.

A. 2 *Latitude and Seasonal Variations*

Figure 5A shows a plot of the nightly average and nightly range of hourly averages of 5577A intensity versus date. The variations here are of several types: latitude, nightly, and seasonal. The same data are plotted in Figure 5B against latitude and those taken during a limited period, May 24/September 1, 1962, are plotted similarly in Figure 5C. An attempt to eliminate part of the nightly variation is shown in Figure 5D, which is compiled by taking the averages of all data in 10 latitude-degree groups. Figures 5C and 5D provide the best indication of both the seasonal and latitude variation in 5577A intensity. The northern hemisphere data are obtained over a short period of time (May 24/June 2) and therefore include only diurnal, nightly and latitudinal variations. These types of variation cannot be separated completely, however Figures 5C and 5D indicate the possibility of a latitudinal maximum near 30/40° geographical latitude and decreasing intensity as the eqator is approached. Moving southward from the equator, there is some increase in the average intensities (Figures 5C and 5D) with a weak maximum occurring near geographic latitude 40°. There appears to be a definite decrease in the 5577A airglow level to the south as far as 65° geographic latitude where the observations end. The data are consistent with a seasonal variation in which there is a maximum summer and minimum in winter.

II. B. Variation of [OI] 6300A

B. 1 *Night-to-night and Diurnal Variations*

Unlike the [OI] 5577A, the [OI] 6300A emission shows a definite variation through the night. The well-known post-twilight decay and the lesser predawn increase are evident in the data taken at all latitudes; see Figure 4B. A nightly variation occurs in [OI] 6300A; for the most part it appears as an over-all change in the level of the emission through the night.

The only exception occurred when the *Ellanin* was near the equator. On the two nights shown in Figure 6, and possibly on a third, an enhancement in [OI] 6300A developed in the hours near midnight. These monochromatic enhancements may be related to the intertropical red arcs described by Barbier, Weill, and Glaume (1961); however, the enhancement is relatively small and apparently restricted in time to the hours near

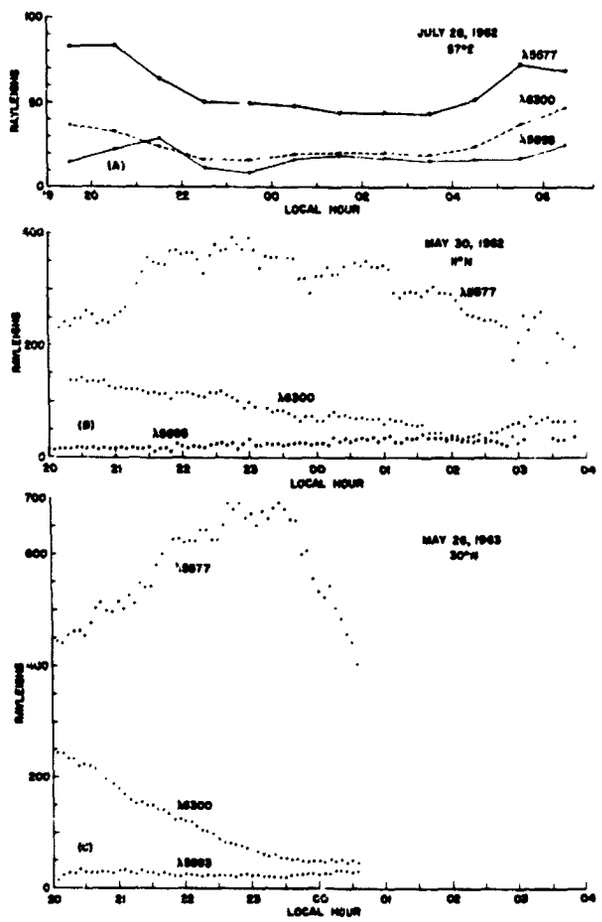

FIGURE 3.—A) Example of a night of relative quiet in the airglow variations (plot of hourly averages); B) and C) are examples of active variations in 5577A.

local midnight. Although the midnight enhancements observed on June 2 and 6, 1962 may not be related to the intertropical red arcs, the zones where the intertropical red arcs appear coincide with the positions of the two maxima on the curve of Figure 7C. There is much similarity between the observed latitudinal distribution of 6300A in the region within 30°N and 30°S magnetic latitude and the F region electron content per vertical column by Duncan (1960). In this calculation, he assumed an initially uniform electron distribution to be modified by electrodynamic lift and subsequent settling down the geomagnetic field lines. Since it has been found that the intensity of the 6300A emission is approximately proportional to the maximum electron density in the F2 region (Huruhata et al., 1959), it appears possible that the processes described by Duncan may contribute to the observed 6300A distribution in the tropic regions.

B. 2 *Seasonal and Latitudinal Variation*

The diagrams showing all data versus latitude (Figure 7A), Southern Hemisphere Winter versus latitude (Figure 7B) and 10-latitude-degree averages (Figure 7C) show generally higher intensities in the Northern Hemisphere and thus may indicate a seasonal variation of [OI] 6300A similar to that of [OI] 5577A; namely, a maximum in summer and minimum in winter. Maximums in the latitudinal distribution of intensity appear near the equator at approximately 15°N and 15°S geomagnetic latitude.

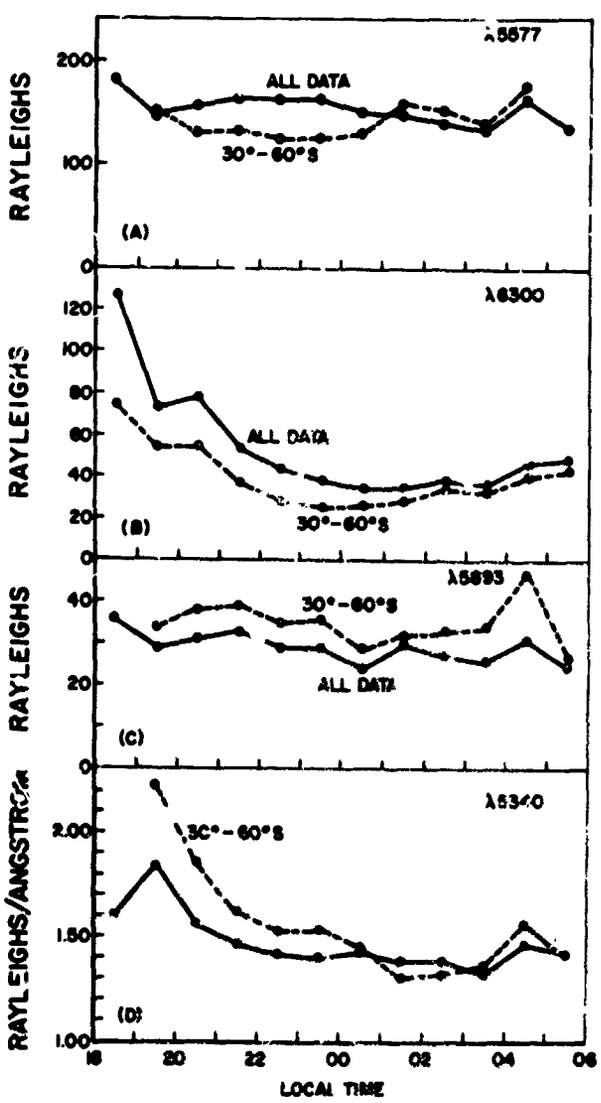

FIGURE 4.—Average diurnal variation of the airglow emissions.

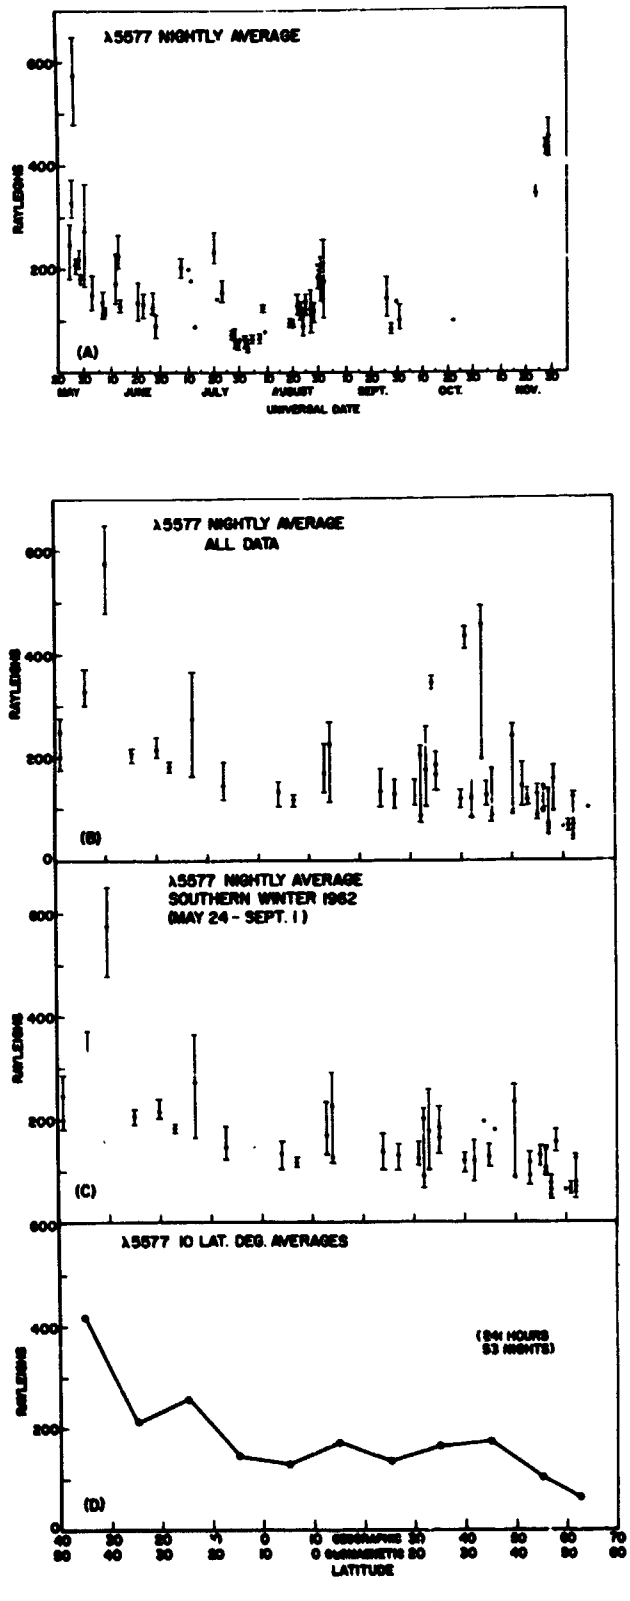

FIGURE 5.—Nightly average and range of hourly average of 5577A: A) versus date, B) all data versus latitude, and C) for data taken May 24 to September 1, 1962. D) ten-degree latitude averages versus latitude, all data.

Another representation of the [OI] 6300A data is shown in Figure 8, where the observations are plotted against latitude and local time and then used to compile isophotes of zenith intensity. This diagram is suggested by a similar one by Barbier (1961) and should be compared with it.

The intensity ratio 6300A/5577A obtained from individual airglow observations is highly variable; ratios averaged over a night's observations range between 0.09 and 0.67. The average ratio of the observations in the region 30/60°S is 0.25.

II. C. Variation of the NaD group

As mentioned previously, the 5893A filter passes both the NaD doublet centered near 5893A and OH emissions including the OH (8/2) emission at 5886A. These emissions will be referred to here as the sodium group. The sodium group intensity remains relatively constant on a given night, and the average diurnal variation curves, Figure 4C, indicate little or no regular variation through the night.

Plots of the sodium group variations versus latitude (Figure 9), show a trend toward higher intensities going from north to south. Superimposed on this trend are irregularities. A maximum appears near 20/30°N, and there is a minimum centered near 0/10°N. Another maximum may exist near 10/20°S, and relatively high intensities are observed over the latitude range 30/[illegible]°S. The intensities observed between 58 and 65°S are relatively low. Overall, the variation with latitude of the sodium group intensity is somewhat less than that of the [OI] 5577A and 6300A emissions. The observed sodium group intensities are consistent with a seasonal variation in which there is a maximum in winter and minimum in summer.

II. D. Variation of the Background near 5340A

Except for some evening twilight contamination or post-twilight enhancement, the background near 5340A averaged over all data remained relatively constant through the night; see Figure 4D. The total background near 5340A, shows a general increase from north to south. This total background includes components from integrated starlight, zodiacal light and airglow continuum. Using integrated starlight intensities given by

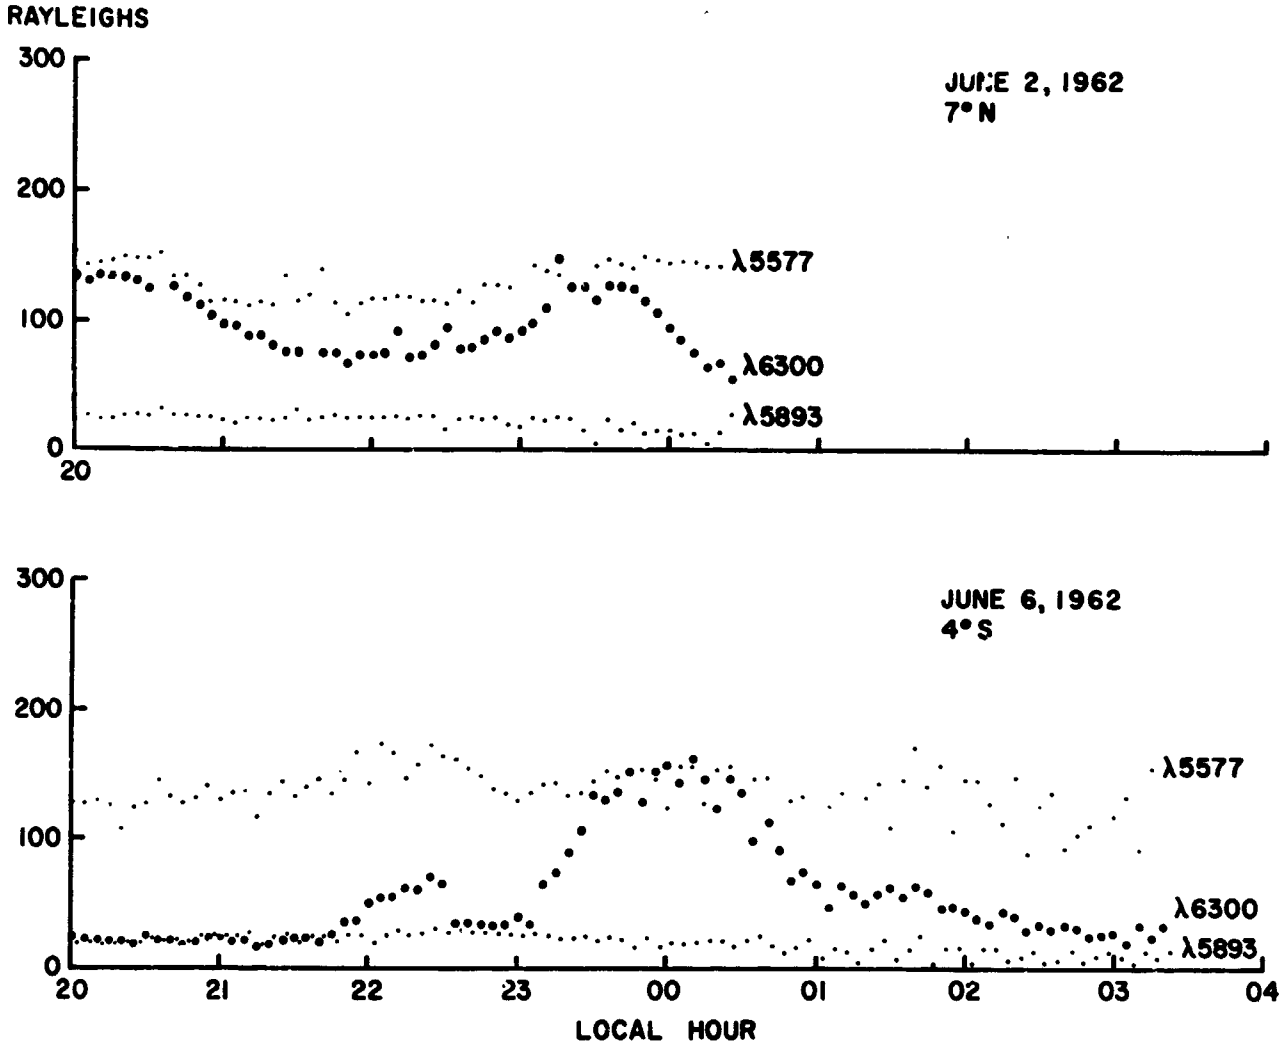

FIGURE 6.—Nights on which enhancements in 6300A occurred.

Roach and Megill (1961) and zodiacal light intensities from Roach and Smith (manuscript in preparation) the contribution of these components to the total background is determined and displayed in Figure 10. The background component due to airglow continuum is obtained by subtraction and is also shown in Figure 10. The airglow continuum determined by this method shows a pronounced minimum at low latitudes and appears to be fairly symmetrical about the goemagnetic equator. For comparison, one-year average values of the airglow continuum obtained by Roach and Smith for two airglow observatories, Fritz Peak, Colorado and Haleakala, Hawaii, are indicated on Figure 10 by the numbers 1 and 2, respectively.

II. E. Auroral Zone Observations

Limited observations of auroras were made during March and April 1962 at the northern auroral zone, however high seas and partial cloudiness during the period of these observations detract from their value. Bright auroral forms were observed in the zenith during part of the observations; 5577A intensities ranged up to 92kR, those of 6300A ranged up to 1.8kR. Although the results may not be meaningful, intensities of the sodium group were not much greater than that observed in the airglow (see Figure 7).

One interesting aspect of the auroral observations is the behavior of the average [OI] 6300/5577 ratio. Individual values of the ratio varied be-

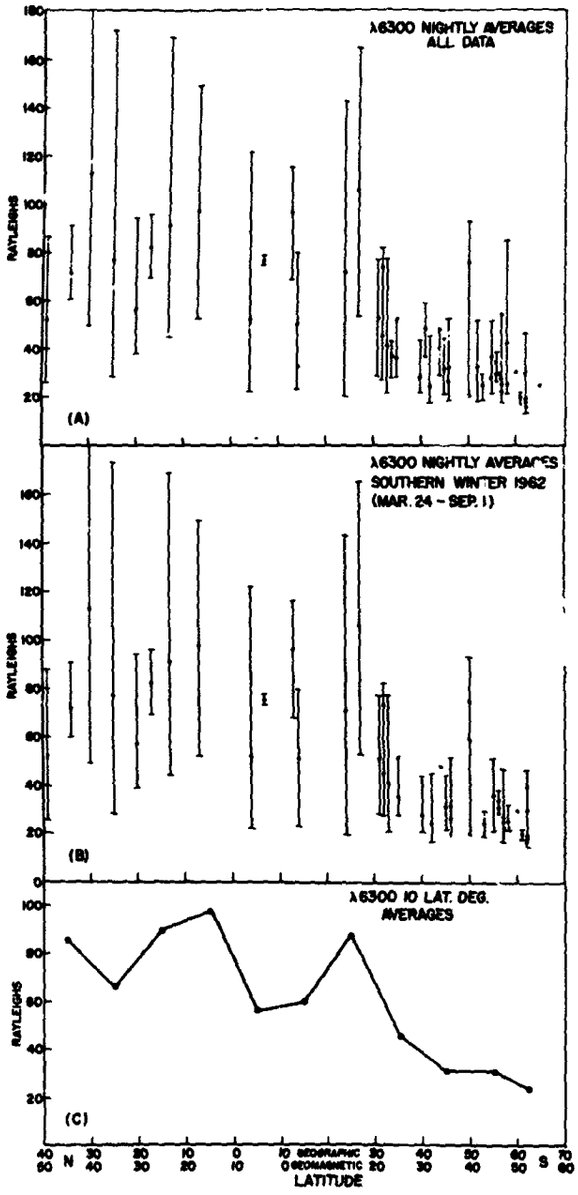

FIGURE 7.—Nightly average and range of hourly averages of 6300A: A) for all data and B) for data taken May 24 to September 1, 1962. C) ten-degree latitude averages versus latitude for all data.

tween 0.007 and 0.5, with the ratio decreasing with increasing 5577A and 6300A intensity: see Figure 11. The higher values of the ratio tend to occur in the hours before midnight, and the lower values after midnight. The tendency for the 6300A/5577A ratio to decrease with increasing 5577A intensity may be due to electron deactivation of the oxygen ^1D level in the brighter

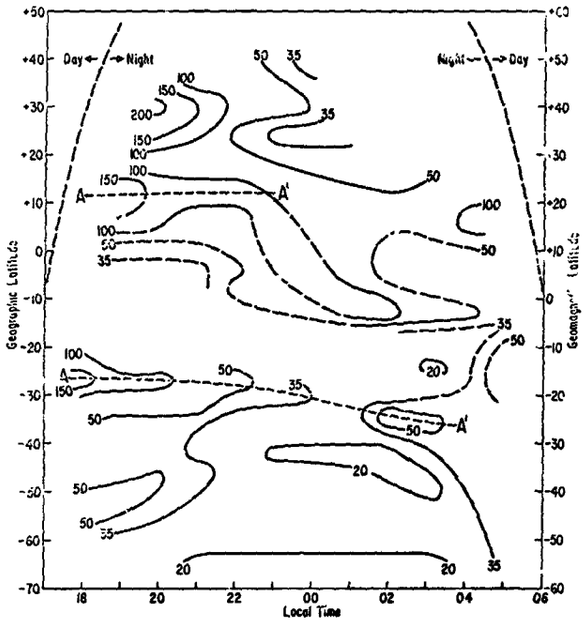

FIGURE 8.—Isophote map giving zenith intensity of 6300A in rayleighs as derived from the *Eltanin* observations during Southern Winter 1962. The dashed lines A–A' indicate possible arc-like zones of enhanced radiation. (Compare with Barbier, 1961)

auroras (Chamberlain 1961, p. 315). Also, molecular deactivation of the ^1D level by collisions with O_2 may be responsible for the results shown in Figure 12 if the brightening of 5577A is associated with increasing auroral exitation at low altitude in the post-midnight hours.

III SUMMARY AND DISCUSSION OF RESULTS

While it is not possible to separate completely the types of variations which influence the results obtained here, these results are compatible with the diurnal, seasonal, and latitudinal variations shown in Table I in summary form. As indicated in the right-hand column of Table I, the observations may be interpreted as suggesting either a rather general seasonal variation or a pronounced hemispherical effect. One aspect of the observations which is evident in the various diagrams but which is not indicated in Table I is the sizable nightly variation observed in each of the airglow components. A comparison of these nightly variations with the global magnetic activity index Kp did not reveal any connection. However, it is interesting that the results of this study do suggest

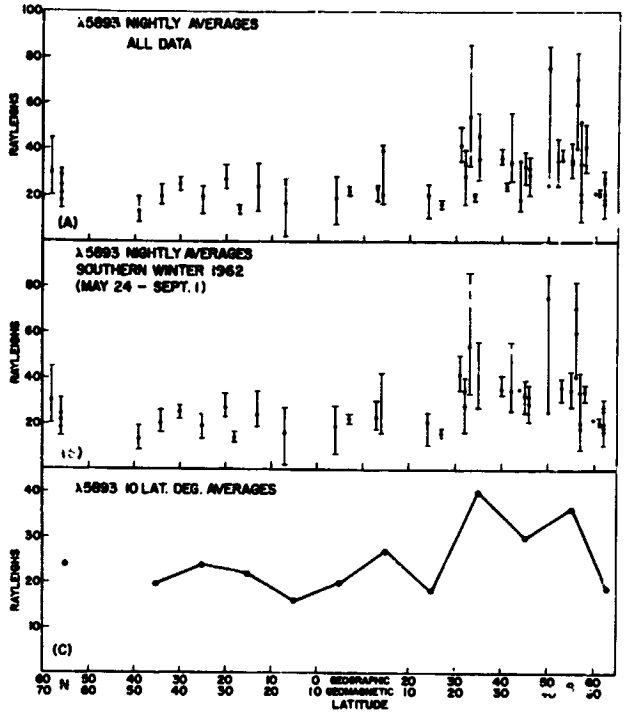

FIGURE 9.—Nightly average and range of hourly averages of the sodium group (NaD 5893A and OH): A) for all data and B) for observations taken May 24 to September 1, 1962. C) ten-degree latitude averages versus latitude, all data.

that the latitudinal distribution of intensity of some airglow emissions may be influenced by the configuration of the geomagnetic field.

The diurnal and nightly variation of 5577A observed on the *Eltanin* in 1962 is somewhat less that that observed in previous years on the *Soya* (Nakamura, 1957 and 1959). Assuming that the calibrations are correct for each set of data, the *Eltanin* observations show lower absolute 5577A intensities as well. Two differences exist in the conditions under which these sets of data were obtained: the observation aboard the *Soya* were made during southern summer and during a period of high solar activity whereas the *Eltanin* observations were made near a minimum in the solar cycle and during southern winter.

Several factors affect the accuracy of the results reported here. One is the uncertainty in the absolute calibration of the comparison source. Another is the problem of OH contamination, which is discussed above. Since the observed 5577A intensities in the southern hemisphere are low, somewhat more than 10 percent of the 5577A intensities reported here may be due to OH. If it is assumed that the NaD and OH emissions

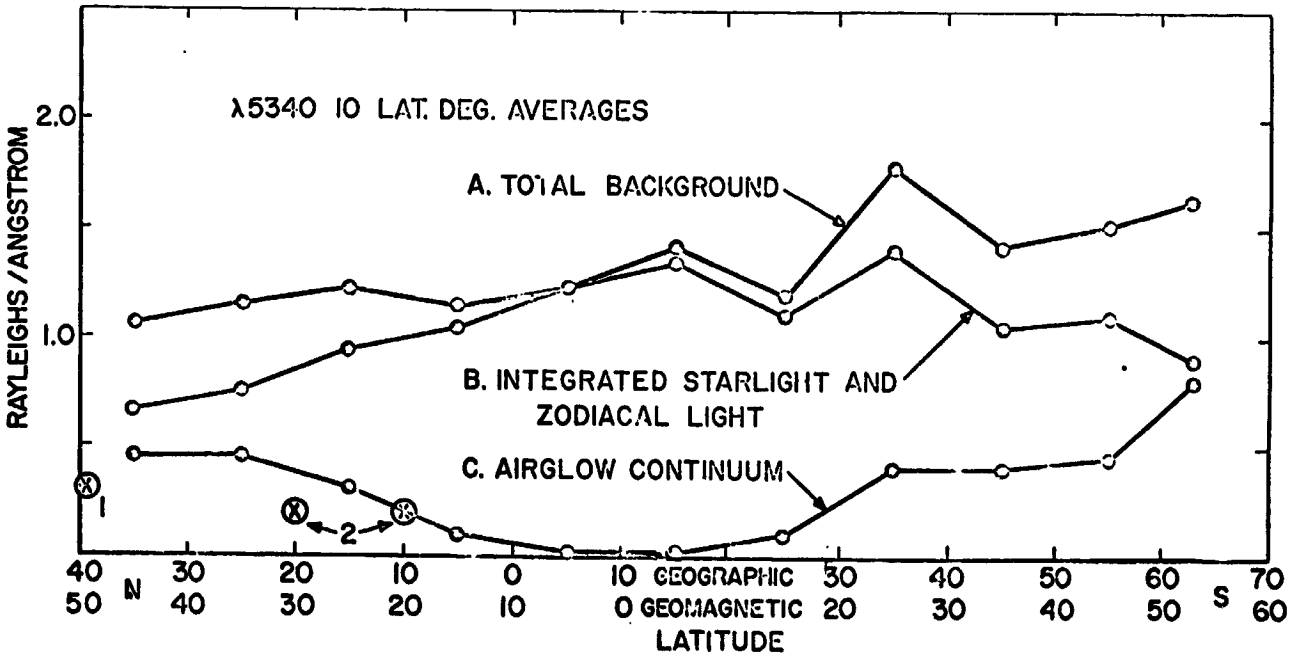

FIGURE 10.—Ten-degree latitude averages of the 5340A background: A) total background, B) the component due to integrated starlight and zodiacal light as computed by Roach and Smith (private communication), and C) the airglow continuum component determined by subtracting curve B from curve A. The point labeled (a) represents the one-year average airglow continuum obtained by Roach and Smith for the Fritz Peak Observation (geographic latitude 40°, geomagnetic latitude 50°) and the points labeled (2) are the same for the Haleakala Observatory (geographic latitude 20°, geomagnetic latitude 10°).

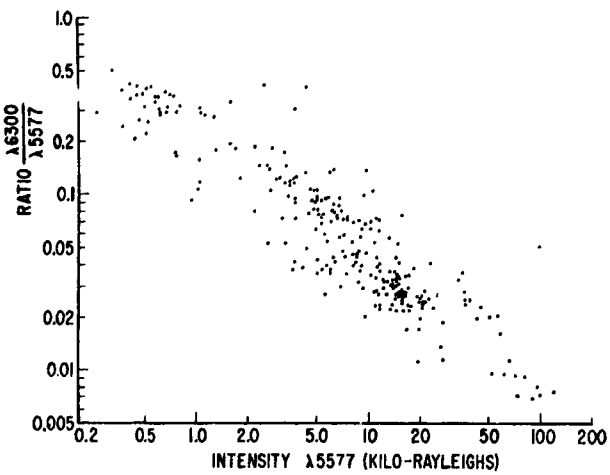

FIGURE 11.—The zenith intensity ratio 6300A/5577A plotted against the zenith intensity of 5577A in the auroral zone aurora.

co-vary, then, at all times, approximately 70 percent of the sodium group intensity observed through the 5893A filter is due to NaD 5893A. It has been found during these observations that these observations that the 2-color method is not a completely satisfactory means of eliminating the astronomical and airglow continuum components from the observations. In using that method it has been assumed that a single proportionality constant relating the contaminants to the 5340A intensity is applicable at all observed light intensities. Observations made during periods of relative stability in the level of the various airglow emissions and in which the astronomical component varied (for example, passage of the Milky Way over the photometer) indicate that the proportionality constant for each wavelength was too low to correct for the astronomical component. On the other hand, if one adopts proportionality constants of sufficient size to give a complete correction when the astronomical components are large, an obvious over-correction occurs at other

TABLE I.—*Summary of* Eltanin *Airglow Observations*

Emission	Diurnal Variation	Latitudinal Variation	Seasonal Variation (or Hemispherical Difference)
[OI] λ5577	No regular diurnal variation irregular activity (sometimes monochromatic) on some nights.	Apparent maximum near 30–40°N, decreasing to minimum near equator, then gradual increase to maximum near 40°S. Decreasing intensity southward as far as 65°S.	Compatible with maximum in summer and minimum in winter. (Or if no such general seasonal variation, the intensities are greater in the northern hemisphere than in the southern hemisphere).
[OI] λ6300	Common post-twilight and predawn variations persist at all latitudes. Monochromatic enhancement observed at local midnight near equator.	Apparent maxima near 15° geomagnetic north and south.	
NaD+ OH near λ5893	No diurnal variation evident.	Apparent maximum near 20–30°N. Shallow minimum near 0–10°N. Irregular increase southward to maximum near 40–50°S and decreasing from 55°S to 65° south.	Compatible with minimum in summer and maximum in winter. (or, as above, higher relative intensity in the southern hemisphere).
Background near λ5340	Possible post-twilight enhancement, otherwise no regular diurnal variation.	Relatively steady increase of total background from 40°N to 65°S. Astronomical components maximize in equatorial region; airglow continuum lowest in equatorial region with apparent symmetry about geomagnetic equator.	

times (the line emission intensities become negative). Consequently, the 2-color method, as used here, must be considered as a very crude means of correction for the atmospheric continuum and astronomical backgrounds. Despite the various uncertainties which influence the absolute values of the emissions reported here, the trends summarized in Table I appear to be real in that they appear in the data prior to and after the application of any corrections.

ACKNOWLEDGMENTS

We are grateful to Dr. Franklin E. Roach for his aid and advice throughout this study. Dr. Manfred H. Rees also has contributed many helpful discussions and several specific suggestions which we have followed. Most of the data presented here were collected through the conscientious shipboard efforts of Mr. F. T. Berkey. Part of the work was accomplished while one of us (T.N.D.) was a Guest Worker at the Fritz Peak Observatory of the National Bureau of Standards. This work was supported by the Office of Antarctic Programs of the National Science Foundation grant number 18704.

THE UPPER ATMOSPHERE OF JUPITER*

S. H. GROSS† AND S. I. RASOOL‡

The properties of the upper atmosphere of Jupiter have been theoretically investigated. The vertical temperature profile in the atmosphere above the clouds and the structure of the ionosphere have been computed for two different model atmospheres: Model I corresponds to a H/He mixing ratio of 20 : 1 by volume (Urey, 1959), and Model II has a H/He ratio as low as 0.03 : 1 (Öpik, 1962). Assuming that the atmosphere of Jupiter above the clouds is in radiative equilibrium, the temperature distribution in the upper atmosphere of Jupiter has been computed. With a cloudtop temperature of 153° K and the total optical thickness of the atmosphere in the far infrared of 0.66, the radiation emitted by the planet is 3.1×10^4 ergs cm^{-3} sec^{-1}. This value of radiation flux is about four times higher than the solar flux received by Jupiter. The equilibrium distribution of electron densities in the ionosphere of Jupiter has also been calculated. The maximum electron densities of $\sim 10^6$ electrons/cc are found to occur at the altitudes of 220 km and 110 km above the cloudtop for the two model atmospheres.

INTRODUCTION

Revived interest in planetary astronomy has provided us with a considerable amount of new data on the temperature, pressure, and composition of the upper atmosphere of Jupiter. These data may now be used to derive coherent and satisfactory models of the structure of the Jovian atmosphere.

In this paper we first derive the two extreme model atmospheres for Jupiter which are consistent with the available data on the relative abundances of gases on the planet. We then derive the thermal structure of the upper atmosphere of Jupiter for these two extreme cases, and study the formation of an ionosphere due to the photoionization effect of the solar ultraviolet radiation.

MODELS OF THE JOVIAN ATMOSPHERE

Based on the recent observational evidence, the following assumptions have been made regarding the composition, temperature, and pressure in the Jovian atmosphere.

Composition and Pressure

The atmosphere of Jupiter, above the clouds, contains 150 m-atm of CH_4 and 7 m-atm of NH_3 (Kuiper, 1952). Recently Spinrad and Trafton (1963) estimated the pressure at the cloudtops to be $\sim$3 atm. This pressure value indicates that the amounts of CH_4 and NH_3 quoted above would account for less than 1 percent of the total atmosphere of Jupiter, indicating that more than 99 percent of the atmosphere may be composed of hydrogen and helium with, perhaps, some traces of neon (Gallet, 1962).

The exact abundances of hydrogen and helium in the atmosphere of Jupiter are, at the present time, a subject of considerable controversy (Kuiper, 1952; Urey, 1959; Öpik, 1962; Spinrad and Trafton, 1963; Foltz and Rank, 1963). The controversy lies in the quantitative interpretation of the quadrupole lines of molecular hydrogen observed in the high dispersion spectra of Jupiter (Kiess, Corliss, and Kiess, 1960; and Spinrad and Trafton, 1963). The estimates of the amount of H_2 present in the atmosphere of Jupiter above the clouds vary from 5.5 km atm (Zabriskie, 1960) to $\sim$200 km atm (Foltz and Rank, 1963).

For the calculations of the structure of the upper atmosphere of Jupiter, therefore, two extreme models for the composition have been considered. In the first, the hydrogen/helium ratio by volume is 20:1 (Urey, 1959), while in the second, it is as low as 0.03:1 (Öpik, 1962). The mean molecular weight of the atmosphere of Jupiter above the clouds in these two models

*Published in *Icarus*, 3(4):311–322, November 1964.
†Airborne Instruments Laboratory, Long Island, New York.
‡Goddard Space Flight Center, and New York University, New York.

would be 2.2 and 3.95. respectively. The pressure at the cloudtop, for both cases, has been assumed to be 3 atm.

Temperature

Murray and Wildey (1963) have recently reported a temperature of 128° K measured in the 8–12 μ atmospheric "window," confirming the older measurements (Menzel *et al.*, 1926) which gave a value of 130° K.

Estimates of the temperature at the Jovian cloudtop have also been made by measuring the radiation emitted by the planet in the microwave regions. Thornton and Welch (1963), from their measurements made at $\lambda = 8.35$ mm, estimate a cloudtop temperature of $144 \pm 23°$ K. Radio-brightness temperatures at cm wavelength regions are contaminated with nonthermal radiation from the planet and therefore cannot be used for a reliable estimate of the cloudtop temperatures.

Because of the presence of 700 cm-atm of NH_3 in the atmosphere of Jupiter (Kuiper, 1952), the levels in the atmosphere to which the infrared and the microwave measurements refer are not reliably known. NH_3 has a strong absorption band in the 8–12 μ interval and therefore the temperatures observed in the infrared may correspond to a level high up in the atmosphere. At $\lambda = 8.35$ mm the absorption due to NH_3 is much less, and therefore the level to which the temperature measured at this wavelength would refer may be deep in the atmosphere and near the cloud level.

Several authors (Öpik, 1962; Kuiper, 1952; Gallet, private communication) have given estimates of the cloudtop temperature on the assumption that the clouds are composed of NH_3 crystals and therefore they are in phase equilibrium with the amount of NH_3 vapor above. On this basis, Öpik has suggested a temperature of 156° K at the cloudtop.

VERTICAL DISTRIBUTION OF TEMPERATURE

In order to calculate the vertical distribution of temperature above the clouds, it is assumed that the atmosphere is in radiative equilibrium. With the Eddington's approximation and assuming a frequency-independent absorption (gray atmosphere), the equation of radiative transfer gives the following expression for the distribution of temperature with altitude:

$$T_z^4 = T_e^4\left(\tfrac{1}{2} + \tfrac{3}{4}\tau_z\right). \qquad (1)$$

Here T_z is the temperature at any level z, T_e is the effective blackbody temperature of the planet, and τ_z is the average infrared optical thickness of the atmosphere above the level z.

In the case of Jupiter, it is assumed that $z = 0$ at the cloudtop where $\tau_z = \tau_0 =$ the total optical thickness of the atmosphere above the clouds.

The absorption in the infrared is due to NH_3 and CH_4. In Fig. 1 is shown the absorption spectrum of NH_3 for the wavelengths between 7 and 60 μ, based on the band intensities for the vibration–rotation bands of ν_2 and ν_4 and the line intensities of the rotation lines recently tabulated by Gille (1964). The absorption has been computed for a mean pressure of 1.5 atm and a mean temperature of 150° K for the total amount of NH_3 of 7 m-atm (Kuiper, 1952). The only absorption band of CH_4 which is significant in this spectral interval is the 7.7-μ vibration–rotation band, and for the measured amount of 150 m-atm, the atmosphere of Jupiter is completely opaque in this spectral interval.

The absorption for the total amounts of NH_3 and CH_4 in the atmosphere has been folded into the 150° K blackbody energy curve and the net energy emitted is shown as the dashed line curve in Fig. 1. The mean transmittance of the Jovian atmosphere over the entire spectral region is 52 percent, giving the total optical thickness of the atmosphere $\tau_0 = 0.66$.

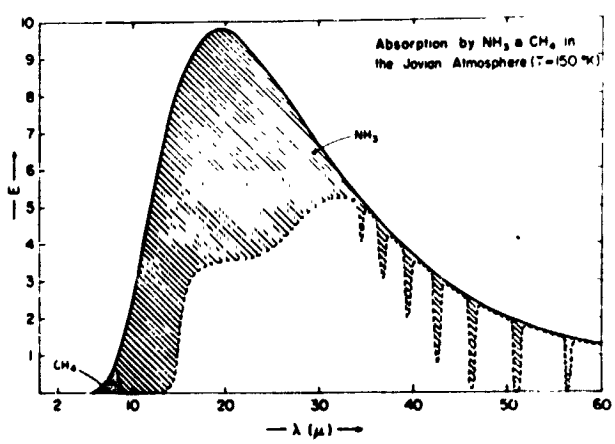

FIGURE 1.—Transmission of infrared radiation through the Jovian atmosphere, composed of 150 m-atm of CH_4 and 7m-atm of NH_3 at 150°K.

Above the cloud level, the opacity (τ_z) will, at any level z, be given by

$$\tau_z = \tau_0 e^{-z/H}, \quad (2)$$

where H is the atmospheric scale height in km, and z is the height in km above the clouds.

We now assume that the 128° K temperature measured by Murray and Wildey (1963) refers to a level high up in the atmosphere where the optical thickness of NH_3 in the 8–12 μ spectral interval has decreased to a value of unity. At this level the total optical thickness of the atmosphere above will be <0.1. We therefore solve Eq. (1) for T_e putting $T_z = 128°$ K and $\tau_z = 0$. The effective temperature of the planet thus calculated is 153° K. Equations (1) and (2) are now combined to obtain the temperature profile of the atmosphere above the clouds.

For the total optical thickness of 0.66, the cloudtop temperature is also found to be 153° K. For the vertical distribution of the temperature, calculations have been made for the two model atmospheres and the results are shown on the left-hand side of Fig. 2.

From this figure it may be noted that the 128° K temperature measured by Murray and Wildey corresponds to the level of 35 or 70 km, depending on which model is being considered. This is consistent with the fact that Murray and Wildey observed a very slight limb darkening, which denotes the existence of a very small temperature gradient at these levels.

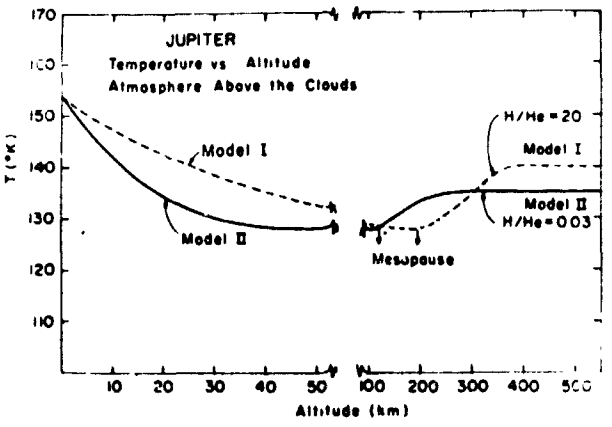

FIGURE 2.—The vertical distribution of temperature in the atmosphere of Jupiter above the clouds for the two model atmospheres.

Also to be noted is the probability that the effective temperature of the planet Jupiter may be about 153° K and not 102° K. The latter should be the effective temperature if the planet were in radiative equilibrium with the incoming solar radiation. The total flux radiated from Jupiter, for an effective temperature of 153° K, is 3.1×10^4 ergs cm^{-2} sec^{-1}. The incoming radiation flux from the Sun for a Jovian albedo of 0.47 is, however, only 0.8×10^4 ergs cm^{-2} sec^{-1}. The difference of 2.3×10^4 ergs cm^{-2} sec^{-1} is probably the radiation being emitted from the interior of the planet.

A rough estimate of the gravitational potential energy released by Jupiter ($3M^2G/5R$, where M and R are the mass and radius of the planet) indicates that if this energy were uniformly distributed over a period of 10^{10} years, the present flux from the interior of the planet could be as high as 3.2×10^5 ergs cm^{-2} sec^{-1}. The rate of the release of energy due to the gravitational contraction of the planet has certainly not remained uniform over this length of time, and the luminosity of the planet is probably much less now than in the earlier period of the planetary history. Our calculations indicate that if the present rate of radiation from the interior of the planet were only 1/12 of its average value, the relatively higher temperatures observed in the atmosphere of Jupiter could be explained by the release of energy due to the gravitational contraction.

In the higher atmosphere of Jupiter, the temperature profile is modified by the deposition of the solar untraviolet energy. We shall therefore assume that the isothermal region extends only up to a level defined as the "mesopause." Above this level the absorption of solar ultraviolet radiation by hydrogen and helium is very significant and part of the energy deposited at that level will heat the atmosphere above the isothermal value of 128° K. This increase in temperature in the "exosphere" gives rise to a positive temperature gradient and permits the energy deposited in the upper atmosphere to be conducted downwards. The "mesopause" is defined as the altitude at which all the energy conducted downwards from the higher atmosphere is radiated away. In the case of Jupiter CH_4 and NH_3 are the radiating molecules.

Following the method described by Bates (1951) and Chamberlain (1962), we find that the mesopause is at a level where the total number density is $\sim 3\times10^{14}$ cm^{-3}. These calculations are made on the assumption that "vibrational relaxation" exists at this altitude, i.e., collisions are rare during the radiative lifetime of the molecules.

The levels at which the number density equals 3×10^{11} cm^{-3} correspond to 104 and 187 km above the clouds for the two model atmospheres as shown in Fig. 2.

Below the level of the mesopause, the atmosphere is thoroughly mixed and the mean molecular weight does not vary with the altitude. Above the level of the mesopause, the atmosphere is assumed to be in diffusive separation and the vertical distribution of each constituent is calculated for its own molecular weight. This assumption is based on the analogy with the Earth, and is supported by the suggestion of Spinrad and Trafton (1963) that strong circulation currents leading to thorough mixing may exist in the atmosphere above the clouds.

The rise in temperature in the atmosphere above the mesopause level is calculated by asuming that 50 percent of the ultraviolet radiation absorbed in the upper atmosphere ($\lambda<912$Å) goes into heating. The method used for these calculations is that described by Nicolet (1959), and for the two model atmospheres, exospheric temperatures of 140° and 135° K, respectively, are obtained (Fig. 2).

This considerably smaller increase in temperature on Jupiter, as compared with the exospheric temperature of the Earth, which is of the order of 1500° K, results because (1) the intensity of solar radiation at Jupiter is 27 times less than at the distance of the Earth; (2) the conductivity for the gaseous mixture on Jupiter is higher than for the O_2–N_2 mixture for the Earth; and (3) the density scale heights in the upper atmosphere are $\sim$5 times less than in the upper atmosphere of the Earth.

IONOSPHERE

Using the temperature distribution in the upper atmosphere of Jupiter shown in Fig. 2, we can now proceed to investigate the properties of an ionospheric layer which may be formed by the photoionization of the atmospheric constituents by the solar ultraviolet radiation.

In an atmosphere mainly composed of hydrogen and helium, the equilibrium electron density in the ionosphere will be determined by a number of ionizing, recombination, and charge exchange processes. The most important of these reactions are shown in Table 1 and have been considered in the present study.

From Table 1 it is readily seen that though only the ions of He and H_2 will be formed by direction photoionization of these gases, H_3^+, H^+, and HeH^+ can also be expected to be produced by charge transfer mechanisms. The reaction (6) to form H_3^+ is very rapid, so that, in equilibrium, little H_2^+ can be expected. HeH^+ is also formed fairly rapidly [reactions (5) and (8)], further decreasing the concentration of H_2^+ and also of He^+ ions. Hydrogen atoms are generated by these reactions at a fairly fast rate and H^+ ions can be produced by direct photoionization. Because of the slow recombination rate of H^+ [reaction (13)], it becomes an important constituent of the ionosphere. We therefore first calculate the distribution of H atoms in the upper atmosphere of Jupiter and then proceed to the computation of equilibrium electron densities in the ionosphere of Jupiter.

Distribution of Hydrogen

Hydrogen atoms generated at higher altitudes are assumed to diffuse downward and recombine by three-body recombination processes [reaction (14)] at lower altitudes, the third body being either H_2 or He depending on the atmospheric model being considered. Since the recombination time is long compared with the time to diffuse through the atmosphere, H atoms may be considered in diffusive equilibrium, distributed exponentially at high altitudes but with the density decreasing rapidly at lower levels where recombination is significant. In equilibrium, the total hydrogen atoms generated each second must equal the total lost due to recombination.

From reactions (5), (6), (8), 10, and (12) of Table 1, it is seen that every ionized H_2 molecule will form two H atoms, and also every ionized He atom will result in two H atoms. The total rate of formation of atomic hydrogen, J(H), can be obtained by integrating the ionization rates of H_2 and He over a vertical column.

Assuming that the solar flux of wavelengths <804Å is completely absorbed above the mesopause in the ionization of H_2 and He, then $J(H)=2\times$ the total number of photons incident on a square centimeter column. At the distance of Jupiter, the solar flux of $\lambda<804$Å can be obtained by reducing by a factor of 27 the observed values of the solar flux at the distance of the Earth recently published by Hinterreger (1961). This gives $J(H)=2\times10^9$ atoms cm^{-2} sec^{-1}.

Having obtained the total rate of production of atomic hydrogen, we can now determine the vertical distribution of this gas following the method described by Zabriskie (1960). This method consists of solving the diffusion equation given by Chapman and Cowling (1939) with the following boundary conditions: (1) At higher altitudes the diffusion current equals the rate of formation of H. This is a reasonable assumption since recombination will occur mainly at lower altitudes. (2) At some lower altitude both the diffusion current and the density of atomic hydrogen must go to zero. This is probably also reasonable since recombination will simultaneously reduce both of these quantities.

Using these boundary conditions, Zabriskie derives a simple expression to compute the vertical distribution of atomic hydrogen. His

formulation has been applied to the two model atmospheres that have been studied, and the resulting distributions are shown in Fig. 3.

It is noted in Fig. 3 that the maximum density of atomic hydrogen is of the order of 5×10^9 cm^{-3} and occurs at a level 10–20 km above the mesopause. It is also noted that the density of atomic hydrogen increases rapidly above the mesopause and then decreases exponentially with a scale height of approximately 44 km for the two cases.

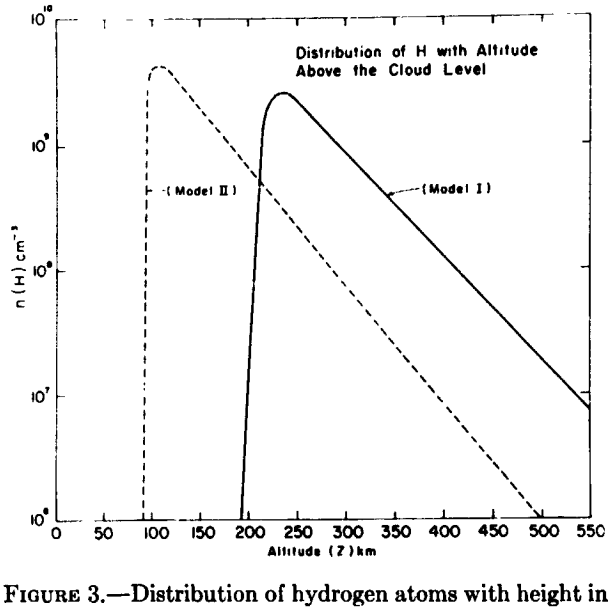

FIGURE 3.—Distribution of hydrogen atoms with height in the upper atmosphere of Jupiter.

Although the two model atmospheres are two extreme cases in which the H/He ratio varies by a factor of 600, it is interesting to note that the equilibrium number density of atomic hydrogen for the two cases is approximately the same. The amount of atomic hydrogen however, even at the level of its peak density, is some 10^4 times less than the total number of particles.

Since it has been assumed that diffusive separation applies above the mesopause, the densities of molecular hydrogen and of helium at these altitudes are readily found from the temperature distribution and they will decrease more rapidly than the density of atomic hydrogen. Consequently, at an altitude of roughly 400 km above the mesopause for Model I, and at 240 km above the mesopause for Model II, atomic hydrogen is the dominant constituent.

Ionization

Having obtained the distributions of He, H_2, and H with altitude, it is now possible to compute the equilibrium ion density distribution as a function of height.

The ionization equations for the reactions listed in Table 1 are as follows:

$$\dot{n}_e = Q_e(H_2)+Q_e(He)+Q_e(H)-\alpha_9 n\ i(H_2^+) - \alpha_{10}n_e n(HeH^+)-\alpha_{11}n_e n(He^+) - \alpha_{12}n_e n(H_3^+)-\alpha_{13}n_e n(H^+) \quad (3)$$

$$\dot{n}(He^+) = Q_e(He)-\alpha_{11}n_e n(He^+) - \alpha_4 n(He^+)n(H_2) - \alpha_5 n(He^+)n(H_2) \quad (4)$$

$$\dot{n}(H_2^+) = Q_e(H_2)-\alpha_9 n_e n(H_2^+)-\alpha_8 n(He)n(H_2^+) - \alpha_6 n(H_2)n(H_2^+)-\alpha_7 n(H)n(H_2^+) + \alpha_4 n(H_2)n(He^+) \quad (5)$$

$$\dot{n}(HeH^+) = \alpha_5 n(H_2)n(He^+)+\alpha_8 n(He)n(H_2^+) - \alpha_{10}n_e n(HeH^+) \quad (6)$$

$$\dot{n}(H_3^+) = \alpha_6 n(H_2)n(H_2^+)-\alpha_{12}n_e n(H_3^+) \quad (7)$$

$$\dot{n}(H^+) = Q_e(H)+\alpha_7 n(H_2^+)n(H)-\alpha_{13}n_e n(H^+) \quad (8)$$

and the total ion density

$$n_e = n(He^+)+n(H_2^+)+n(HeH^+) + n(H_3^+)+n(H^+). \quad (9)$$

In these equations $n(X)$ is the density of constituent X at any altitude z, α_n's are the corresponding values of reaction rates given in Table 1, $Q_e(X)$ is the photoionization rate, and n_e is the electron density in cm^{-3}.

The rate of formation of H^- from reaction (15) is so slow that it has been neglected in the above equations. He_2^+ is also neglected since it is too unstable to contribute significantly. In addition, it is found that there is little He^+ to produce He_2^+ by the three-body reaction.

Since $n(He^+)$ and $n(H_2^+)$ will be small in comparison with $n(H_3^+)$ or $n(HeH^+)$ and n_e with respect to $n(H_2)$ or $n(He)$, we can neglect certain terms in these equations. In Eq. (4) one can neglect the term involving α_{11} and in Eq. (5), the term with α_9. Also reaction (4) is unimportant compared to reaction (6). This is because $n(He^+)$ will not be sufficiently larger than $n(H_2^+)$ to make up for the difference in rate coefficients.

From these equations we find that the contribution of $n(He^+)$ and $n(H_2^+)$ to the total electron

density is relatively small and therefore we can safely neglect these terms in Eq. (9). The total equilibrium electron density is therefore

$$n_e = n(H^+) + n(H_3^+) + n(HeH^+). \quad (10)$$

On solving the resulting set of simultaneous equations and inserting the values of the reaction rates from Table 1, we find

$$n_e = \left\{ 10_8 \left[Q_e(He) + \frac{\{5n(H_2)+n(He)\}Q_e(H_2)}{5n(H_2)+n(H)+n(He)} \right] + 10^{12} \left[Q_e(H) + \frac{n(H)Q_e(H_2)}{5n(H_2)+n(H)} \right] \right\}^{1/2}. \quad (11)$$

In order to evaluate the concentration of electron density as a function of altitude, we first determine the rates of production of H^+, H_2^+, and He^+.

The rate of production of ions is

$$Q_e(X) = \tfrac{1}{4} \int_{\lambda 1}^{\lambda 2} n_z(X)\sigma_\lambda(X)\mathfrak{F}_z(\lambda)d\lambda, \quad (12)$$

where $n_z(X)$ is the number density of the ionizing constituent X at the level z, $\sigma_\lambda(X)$ is the ionization cross section for the constituent at the wavelength λ, and $\mathfrak{F}_z(\lambda)$ is the solar radiation flux at wavelength λ reaching the level z, after having been attenuated by all the ionizing constituents above. The factor 1/4 is due to the fast rotation of Jupiter, so the evaluation of Q_e gives a mean value of the ion production rate over the whole globe. Equation (12) is evaluated by approximating the ionization cross section over the spectral interval and also by taking an average value of the solar radiation $\mathfrak{F}$ over the relevant spectral regions. The values used are shown in the Table 2.

The ionization sections and the corresponding wavelengths for He, H_2, and H are given in Table 2. Although there is a significant overlapping in the relevant spectral regions for the ionization of the individual gases, it may, however, be noted that H_2 is the principal absorber of the far ultraviolet radiation, even when He is the principal constituent, due to the following reasons: (a) The density scale height is large compared to He by a factor of 2, and (b) at altitudes of ~180 km and above, H_2 is the principal constituent. (At much higher altitudes where H is the major constituent, it is optically too thin to be the principal absorber.)

TABLE 2.—*Mean Cross Sections and Fluxes*

$\bar{\sigma}(H_2)$	($\lambda < 504$)	1.7×10^{-18} cm²
$\bar{\sigma}(H_2)$	($804 > \lambda > 504$)	6.1×10^{-18} cm²
$\bar{\sigma}$(He)	($\lambda < 504$)	3.3×10^{-18} cm²
$\bar{\sigma}$(H)	($912 > \lambda > 804$)	5.0×10^{-18} cm²
$\bar{\sigma}$(H)	($804 > \lambda > 504$)	3.0×10^{-18} cm²
$\bar{\sigma}$(H)	($\lambda < 504$)	6.0×10^{-19} cm²
$\bar{\mathfrak{F}}\infty$	($\lambda < 504$)	6.7×10^{8} ph/cm²/sec[a]
$\bar{\mathfrak{F}}\infty$	($804 > \lambda > 504$)	4.0×10^{9} ph/cm²/sec[a]

[a] Hinterreger, 1961.

In Table 2 the values of $\bar{\sigma}$ have been calculated for the relevant spectral interval for the various overlapping bands. $\bar{\mathfrak{F}}\infty$, the total incident solar flux in a wavelength band, is calculated for the distance of Jupiter from the values obtained recently by Hinterreger (1961) at the distance of the Earth.

The ionization cross sections of atomic hydrogen are theoretical and have been obtained from Bates (1962). References for $\sigma(H_2)$ and σ(He) are given in Table 1. From the numerical values listed in Table 2, we calculate the production rates of the H, He, and H_2 ions from Eq. (12), using a mean approximation over the band, and the results are shown in Figs. 4 and 5.

It may be noted that the rate of production of H^+ is 10 times less than the rate of production of H_2^+ in both our model atmospheres. As the recombination rate of H^+ is much slower than that

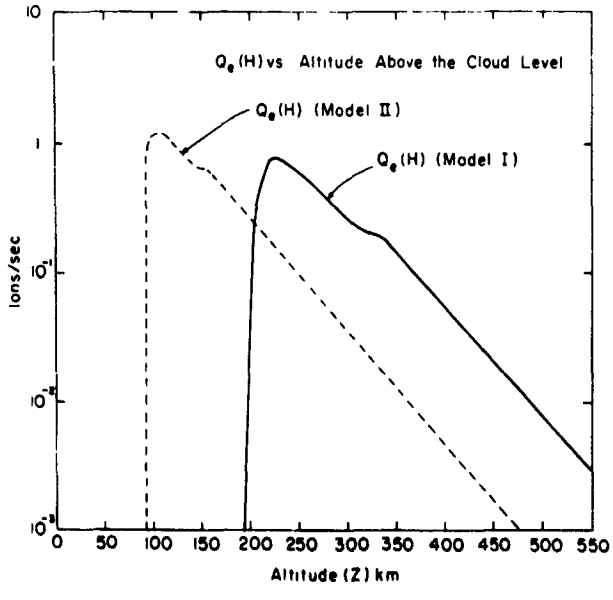

FIGURE 4.—Rate of production of H^+ in the upper atmosphere of Jupiter

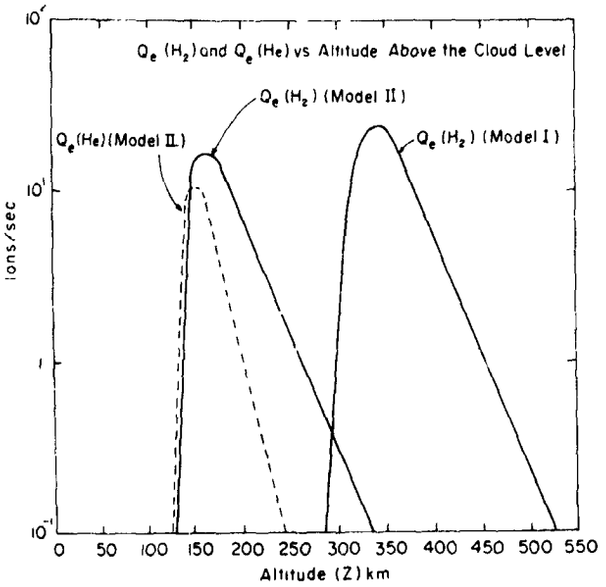

FIGURE 5.—Rate of production of H_2^+ and He^+ for Model I and Model II atmospheres.

of H_2^+ [which is via H_3^+ or HeH^+, or dissociatively via reaction (9), Table 1], it is expected that the atomic hydrogen will be a significant contributor to the total electron density. In the case where He makes up 97 percent of the total atmosphere, Fig. 4 shows that even then the rate of production of He ions is less than H_2^+, though the amount of hydrogen in the atmosphere has been assumed to be only 3 percent. This circumstance is due to the screening of the radiation less than 504 Å by the H_2 above.

Using these computed values of $Q_e(H_2)$, $Q_e(He)$, and $Q_e(H)$, we can now calculate the total electron densities as a function of altitude from Eq. (11). The results are shown in Fig. 6, which is a plot of n_e vs altitude for both models.

When H/He=20, the peak electron density is 7×10^5 cm^{-3} and occurs at ~200 km above the cloud level, with a secondary maximum of about 3×10^5 at ~350 km altitude. In the Model II atmosphere, the maximum electron density occurs at 110 km with a peak value of about 10^6 cm^{-3}. The extent of the ionosphere in the two cases is of the order of ~ 500 km.

The major constituent of the ionosphere for both models is H^+, contributing more than 99 percent of the ions. The maximum concentration of H_3^+ and HeH^+, for the two cases, is ~10^3 to 10^4 cm^{-3}. H_2^+ and He^+ ions have a peak concentration even less, ~10^2 cm^{-3}.

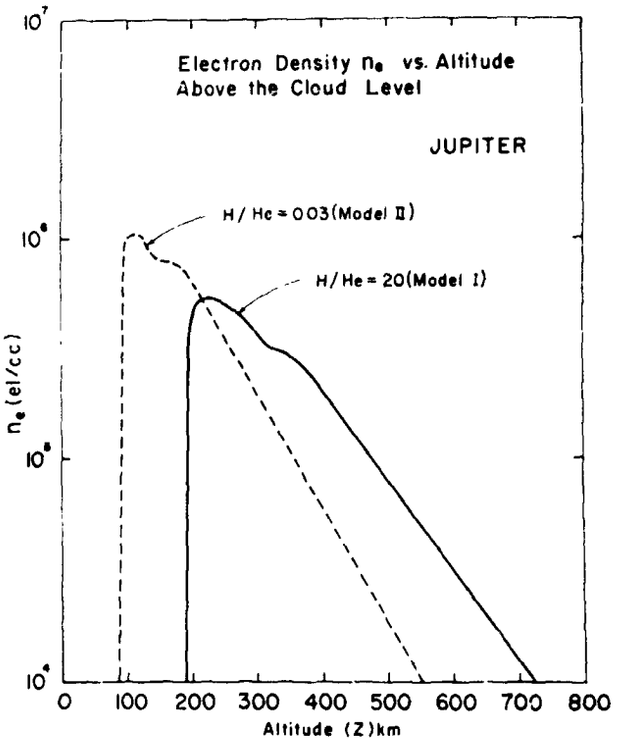

FIGURE 6.—Distribution of total equilibrium electron density as a function of altitude in the upper atmosphere of Jupiter.

RESULTS

The following are some of the important results of the preceding calculations regarding the atmosphere of Jupiter:

(1) If the cloudtop temperature of Jupiter is 153° K and the amounts of NH_3 and CH_4 above the clouds are 700 and 15 000 cm-atm, then the total average optical thickness of the atmosphere in the infrared is 0.66.

(2) Assuming the atmosphere to be in radiative equilibrium, the approximate temperature profile calculated by a simplified version of the equation of radiative transfer for a gray atmosphere indicates that the temperature near the cloudtop decreases with altitude slowly to reach an asymptotic value of 128° K at approximately 35 km for Model II and at approximately 70 km for Model I (Fig. 2). These temperature profiles are consistent with the recently measured temperatures of the planets in the far infrared and in the mm region of the planetary spectrum.

(3) The temperature of the upper atmosphere of Jupiter has been calculated, assuming that 50

percent of the ultraviolet energy deposited in the thermosphere is converted to heat and the energy is conducted downwards to the mesopause to be radiated away by CH_4 and NH_3. The mesopause levels for Model I and II are at 187 km and 106 km, respectively, and the corresponding exospheric temperatures are found to be 140° and 135° K. The results are summarized in Fig. 2.

(4) Calculations of the equilibrium electron density for Model I (H/He=20) result in an ionospheric layer with a maximum density of $\sim 7\times 10^5$ electrons cm^{-3} at an altitude of 200 km above the cloud level. A slightly higher electron density (1.0×10^6 cm^{-3}) is achieved in the second case when H/He=0.03, the peak being at 120 km above the clouds.

(5) The major constituent of the ionosphere in both cases in H^+.

DISCUSSION

Results on the electron density distribution in the upper atmosphere of Jupiter may be compared with the earlier studies of the Jovian ionosphere.

The most comprehensive study to date of the possible structure of the ionosphere of Jupiter has been made by Zabriskie (1960). His main conclusion is that a Jovian ionosphere of peak electron density greater than 10^5 cm^{-3} is highly unlikely. The disagreement of our results with those of Zabriskie is probably due to the following differences in our basic assumptions and approach to the problem:

(1) The exospheric temperatures assumed arbitrarily by Zabriskie were, for his two cases, 600° K and an isothermal atmosphere at 100° K.

(2) Only hydrogen was assumed to be the ionizable constituent of the Jovian atmosphere.

(3) Zabriskie underestimates the ionization of atomic hydrogen by neglecting the ionizing radiation band of 804–912 Å, for which he assumes an ionization cross section of 10^{-20} cm^2. According to Bates (1962), however, it may be $\sim 5.0\times 10^{-18}$ cm^2. This enhances the contribution of H^+ to the total electron density.

(4) The solar flux values for the far ultra-violet adopted by Zabriskie are a factor of 2 less than those recently given by Hinterreger (1961) and used in this study.

(5) Zabriskie neglected the reaction $H_3^+ + H_2 \rightarrow H_3^+ + H$ which contributes significantly in the formation of H.

Rishbeth (1959) has made a very rough study of the ionosphere of Jupiter with the main result that an ionosphere mainly composed of H^+ is formed with a maximum density of 10^6 electrons cm^{-3}. This result is very similar to ours, but it is based on the erroneous assumption that the major fraction of H_2 is directly photodissociated into atomic hydrogen which then ionizes to H^+. From the results of Rishbeth, it is not clear at precisely what altitude this maximum occurs.

The photodissociation of H_2 is a very inefficient process (Bates and Nicolet, 1950) and although we are in agreement with Rishbeth for the maximum electron density, our process of formation of atomic hydrogen is through the dissociative recombination of H_3^+ and H_2^+.

Zhelezniakov (1958) has also briefly discussed the formation of a Jovian ionosphere and quotes a maximum electron density value of 10^7 cm^{-3}. This estimate is based on the assumption that the "effective recombination coefficient in the hydrogen layer" is 4×10^{-14} cm^{-3} sec^{-1}, which is incompatible with the values given in Table 1.

It may be mentioned that in our calculations we have neglected the possible dissociation and ionization of methane and ammonia, which may be quite important at the level of the mesopause and may give rise to a secondary ionization peak at that altitude.

The results of this study may have an important bearing on the validity of those hypotheses which invoke the ionosphere of Jupiter as a direct participant in the generation of the decameter radiation. For example, a mechanism has recently been proposed which required electron densities of the order of 10^8 cm^{-3} in the Jovian ionosphere (Chang, 1963).

ACKNOWLEDGMENTS

It is our pleasure to thank Dr. Alex Dalgarno of Queens College, Belfast, Ireland, and Dr. A. G. W. Cameron of the Goddard Institute for Space Studies for numerous valuable discussions and suggestions during this work. We would also like to thank Professor Edwin Salpeter of Cornell University and Dr. Siegfried Bauer of the Goddard Space Flight Center for critically reading the

manuscript. We are grateful to Allan Liebman who helped us with the computations.

1. SCOPE

The purpose of this report is

to show how significant information on the atmosphere and surface of Mars can be extracted from the thermal-emission spectrum of the planet

to describe the design of an infrared interferometer capable of measuring the thermal-emission spectrum

to document requirements and constraints of the infrared interferometer experiment on a planetary fly-by spacecraft

2. SCIENTIFIC OBJECTIVES

The objective of the infrared interferometer spectrometer (IRIS)‡ experiment is to obtain information on the composition and structure of the atmosphere and surface of the planet Mars. This information will be extracted from the thermal-emission spectrum within the interval of 2000 cm^{-1} (5 microns) to 500 cm^{-1} (20 microns) and possibly to 300 cm^{-1} (33 microns) with a spectral resolution of 5 cm^{-1}. The IRIS experiment is deliberately aimed at a wide spectral range to permit clear identification of many predictable spectral features and, even more important, to allow a search for unexpected phenomena. For a nominal fly-by distance of 5000 km, the resolved area will be a circle of 250-km diameter, approximately equivalent to the resolution now obtained by photographic techniques with ground-based telescopes.

The wide spectral range of the instrument, combined with the relatively high spectral resolution, makes a variety of scientific studies possible; these can be grouped into investigations concerning the atmosphere, and those concerning the planetary surface. In addition, many other inferences can be made from the results of the measurements. The following discussions indicate the wide scope of scientific investigations made possible by this experiment.

2.1 The Thermal-Emission Spectrum

The thermal-emission spectrum of a planetary atmosphere depends on many parameters, of which the most important are the temperature profile, the surface temperature and emissivity, the concentration of atmospheric constituents, and the surface pressure. Under the condition of radiative equilibrium, the temperature profile is completely defined by the parameters mentioned above as well as the solar zenith angle. In theory, if a greater number of measurements of the specific intensity are obtained than the unknown parameters which exist, then all parameters influencing the thermal-emission spectrum can be determined; however, the measurements must be made in independent spectral regions or at different zenith angles. In practice, the extraction of individual parameters is more difficult, and within the limited accuracy of the instruments, different

*Published as *Goddard Space Flight Center Document X-650-64-204*, July 1964.

†University of Michigan.

‡IRIS is the Greek word for rainbow.

parameters can be determined only within certain limits.

To study the influences of the various parameters on the thermal-emission spectrum and to see how these parameters can be determined from the measurements, some preliminary calculations have been made (Figure 1, Table 1).

The radiative equilibrium temperature distribution for a simulated Martian atmosphere has been calculated, using technique described in Reference 1. Some cases are shown in which the temperature distributions require modification due to convective energy transport. Five individual cases were studied:

Case 1 corresponds to the estimated maximum conditions which could possibly occur near the subsolar point. The surface temperature was assumed to be 320°K, slightly above the maximum measured from the earth in the atmospheric window. The calculated temperature profile is shown in Figure 1.

Case 2 corresponds to the expected nominal condition in the late afternoon local Martian time and $\pm 45°$ latitude.

Cases 3 and 4 have been calculated for higher surface pressures.

Case 5 is representative of the coldest conditions expected during the Martian night.

All calculations were carried out for an N_2–CO_2 atmosphere with trace amounts of H_2O. Other gaseous constituents that may be detected (by techniques described later) may influence the equilibrium temperatures, and will have to be considered in addition to the CO_2 and the small amount of water vapor. Furthermore, these calculations assume only pressure broadening of the spectral lines. In the low-pressure conditions to be expected on Mars, Doppler broadening will be an important factor and must be considered in a more refined treatment.

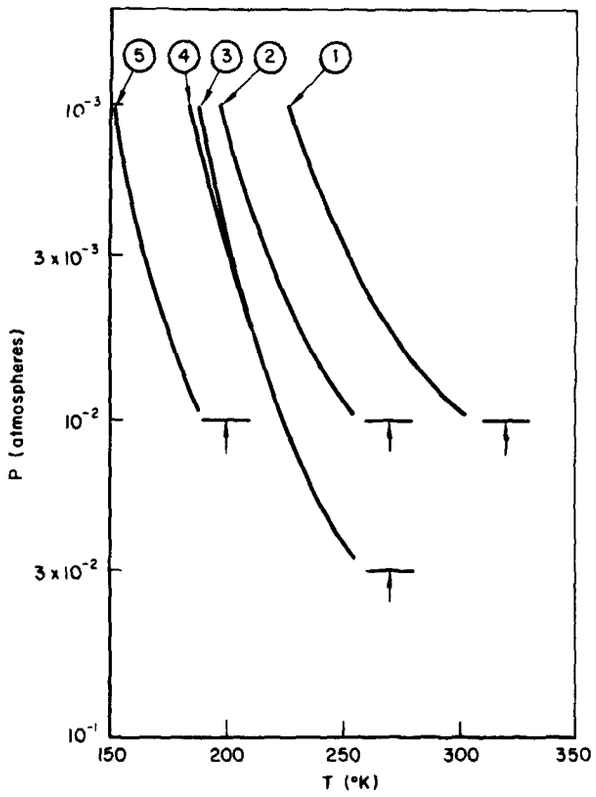

FIGURE 1.—Radiative equilibrium temperatures in a simulated N_2–CO_2 atmosphere with trace amounts of water.

TABLE 1.—*Summary of Assumptions Made in the Calculations of Temperatures for the Five Cases Shown in Figure 1.*

Case	1	2	3	4	5
Solar zenith angle	0°	60°	60°	60°	night
Surface temperature (degrees Kelvin)	320°	270°	270°	270°	200°
Surface pressure (atmospheres)	.01	.01	.03	.03	.01
CO_2 concentration	.25	.25	.10	.25	.25
H_2O concentration	$.4 \cdot 10^{-4}$	$.4 \cdot 10^{-4}$	$.4 \cdot 10^{-4}$	$.4 \cdot 10^{-4}$	$.4 \cdot 10^{-4}$
Surface emissivity	1	1	1	1	1
Surface reflection for near-infrared	.25	.25	.25	.25	.25

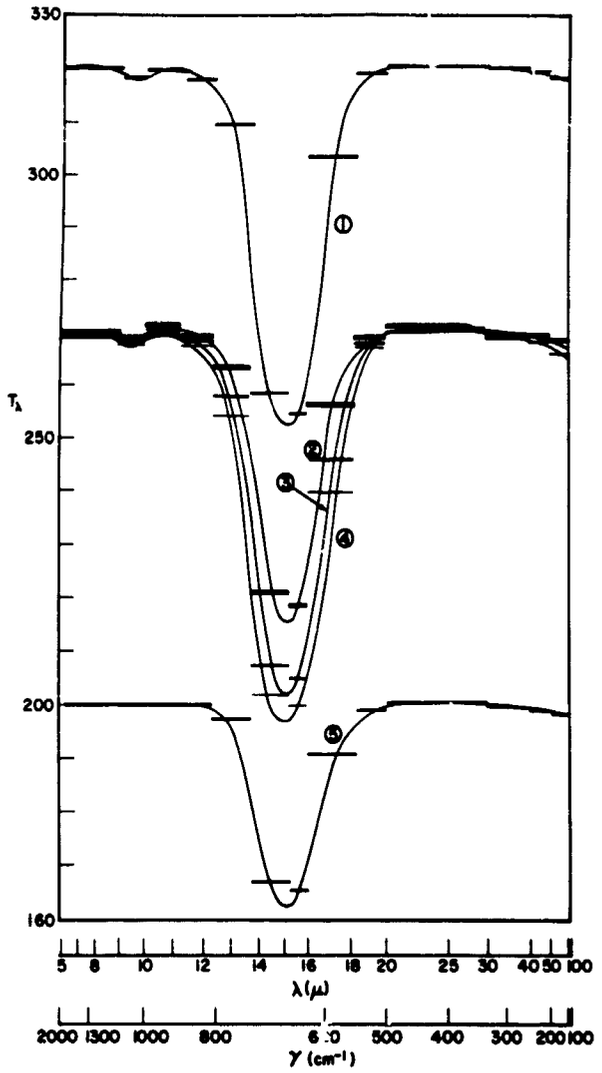

FIGURE 2.—Low-resolution thermal spectra calculated for temperature profiles shown in Figure 1.

Figure 2 shows the corresponding thermal spectra. The spectral resolution of the diagram is very low, varying between approximately 50 and 100 wavenumbers in the most interesting portions. The abscissa is proportional to the fraction of the energy available from a blackbody at 270°K. The wavenumber and the wavelength scales are nonlinear. The strong 15-micron CO_2 band dominates the central part in all spectra. Although the temperature profiles of Cases 3 and 4 are almost the same, the higher abundance of CO_2 in Case 4 causes lower temperatures in the 15-micron band. A comparision between Cases 2 and 4 clearly show the strong influence of the surface pressure, evidence that the surface pressure may be extracted from the emission spectrum.

2.2 Atmospheric Composition

Identification of gases known to be present in the Martian atmosphere (CO_2, H_2O) and estimates of their abundances are among the objectives of the IRIS experiment. But an even more important objective is the possible detection; as well as the establishment of better upper limits, of yet unidentified but suspected constituents (N_2O, NO, NO_2, CH_4, C_2H_4, C_2H_6, NH_3, O_3).

The identification of gases is based on the characteristic absorption spectrum of each gas. Gases in the atmosphere absorb thermal radiation from the surface and, according to Kirchhoff's law, re-emit blackbody radiation as determined by their own temperature. As most atmospheric temperatures will be somewhat lower than surface temperatures, the atmospheric spectra will appear as absorption spectra. However, this is not necessarily true under all conditions; for example, under the condition of a strong temperature inversion in the atmosphere, or in spectral regions where the surface emissivity is low, a reversal may take place and the spectrum of a gas may appear in emission. These complications do not exist in the interpretation of spectra in the visible or near-infrared (say below 2 microns) where thermal emission is negligible compared to reflected solar radiation.

The long-wave infrared spectra may be more difficult to interpret, and the theory of radiative transfer must be used extensively in a proper treatment of the long-wave spectra; but the thermal-emission spectra yield additional information, such as the temperature profile, which will be discussed later. Furthermore, many atmospheric constituents which might be of biological interest, such as CH_4, are relatively complex molecules which show strong vibrational and rotational bands in the middle and far infrared but very little detectable absorption phenomena in the visible part of the spectrum. For these reasons, the analysis of atmospheric contituents in the far infrared is extremely interesting in spite of the difficulties associated with their interpretation.

Figure 3 shows the spectra of constituents which may be expected in the atmosphere of Mars. The spectra are drawn schematically only, without the many details which can be recognized with a resolution of 5 wavenumbers. The abundance of the gases was taken according to the

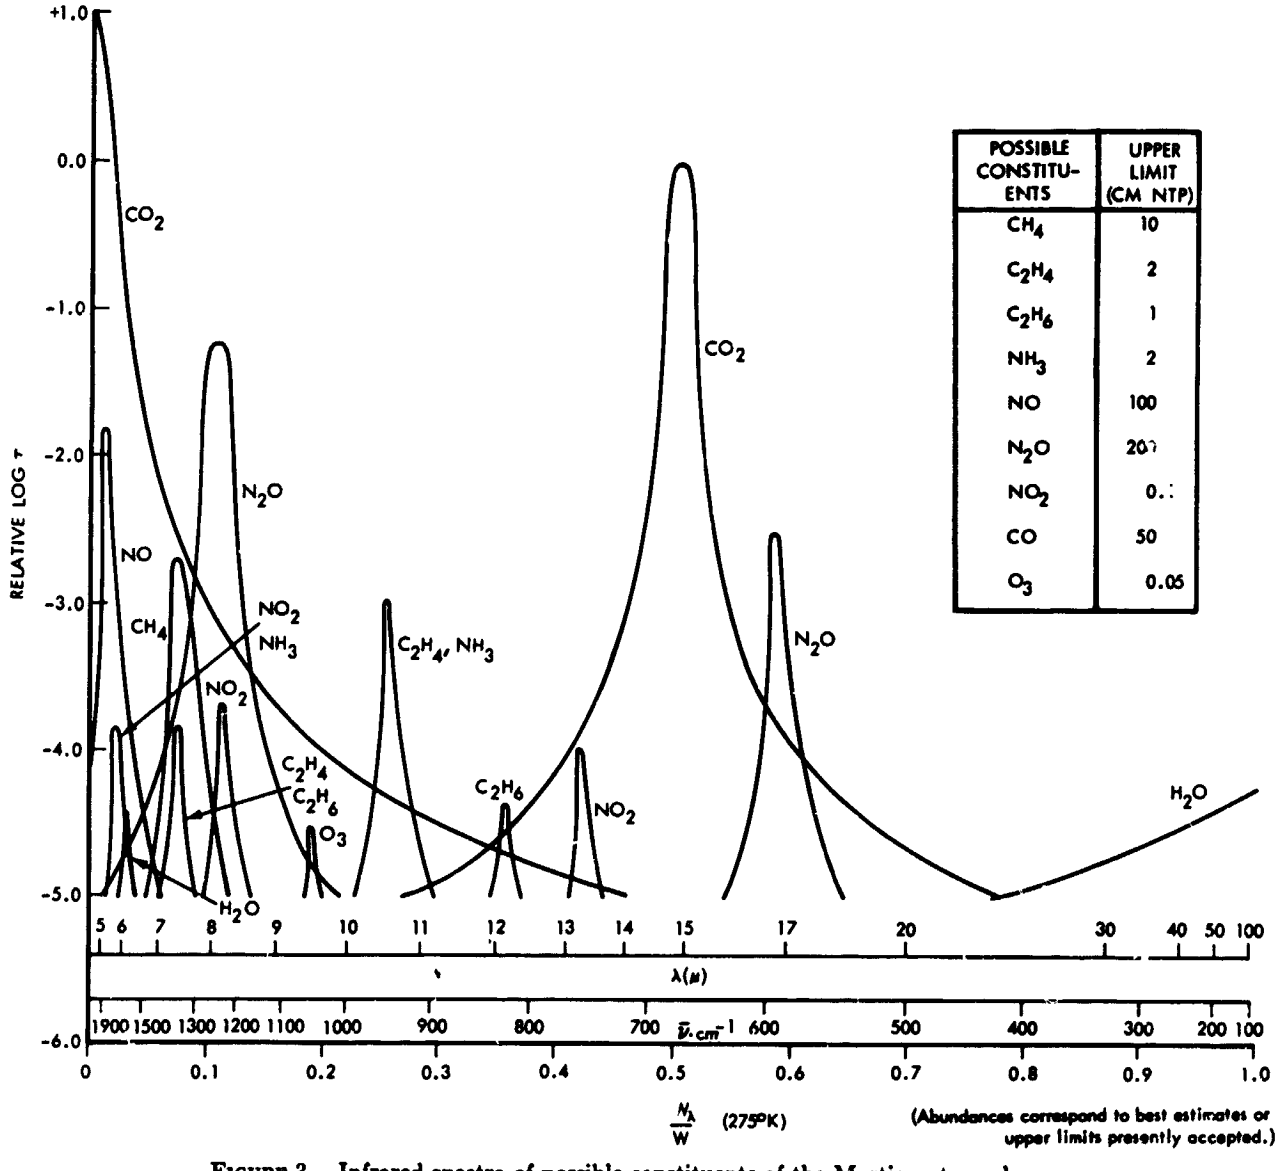

FIGURE 3.—Infrared spectra of possible constituents of the Martian atmosphere.

upper limits presently accepted (Kuiper, 1952; Sinton, 1961)*. The optical depth is shown on a relative scale.

The broad wings of the bands shown in Figure 3 correspond to the absorption continuum arising from the sum of the wings of all individual lines in the band. The situation for the Lorentz line shape is shown. This must be considered an upper limit for a number of reasons: First, as Benedict has shown, the Lorentz shape does not strictly apply far away from the line centers; second, and more important, Doppler broadening will be an important factor which causes a much faster decay of the line shape away from the line center and consequently gives rise to a much weaker continuum than that indicated. The 15-micron CO_2 band and the N_2O band near 8 microns, using the above upper limits and measured band intensities, are strong enough to be totally opaque. Methane (CH_4) and other hydrocarbons (C_2H_4) may also be detected. Water vapor, ozone, and others are more difficult to extract from the spectra But, because water vapor is extremely important both from an atmospheric-physics and from a biological viewpoint, a technique for the possible identification of this as well as other less abundant constituents will be described here.

*References 2 and 3.

Water vapor has strong vibration-rotation bands near 6.3 microns and the rotational band beyond 20 microns. If the spectral response of the instrument is restricted to 20 microns, then only the first bands are available for analysis. Figure 4 shows the transmission of a synthetic atmosphere consisting of the expected amount of CO_2 and water vapor, in the full detail to which the spectra can be generated by the interferometer. In addition, the figure shows spectral transmission of CH_4 and N_2O, both present in a quantity corresponding ot the presently accepted upper limit, and under the expected average atmospheric conditions. As can be seen, the atmosphere is nearly opaque between 600 and 750 wavenumbers (15-micron CO_2 band) and near 1300 (N_2O). Water vapor shows absorption phenomena between about 1300 and 2000 wavenumbers. Even in the strongest parts, the maximum absorption does not exceed a few percent. Consequently, it will be difficult to recognize the presence of water vapor in this band, and even more difficult to determine the abundance quantitatively. Fortunately, however, the water-vapor band spreads over almost 700 wavenumbers and shows considerable structure. This feature allows the use of statistical methods to obtain information about water vapor from almost 140 individual spectral data points derived from a single interferogram. The cross-correlation function of the received spectrum and the known spectrum of water vapor is obtained by

$$C_{(x)} = \int I_\nu W_{(\nu+x)} d\nu.$$

Even under conditions of severe noise, the cross-correlation function shows a maximum for $x = 0$. The correlation technique is a powerful tool for recognizing and estimating the amount of particular constituents in a complicated and possibly noisy spectrum. Figure 5 shows a sample of a cross-correlation function of the water-vapor spectrum with a combination of random noise and water vapor (signal-to-noise ratio equal to one). The same technique may also be employed to assess the amounts or upper limits for other atmospheric constituents.

2.3 Atmospheric Structure

Use of satellite-measured radiation values to determine the atmospheric temperature distribution of the earth's atmosphere has been discussed by Kaplan (1960), Wark (1961), Yamamoto (1961), King (1963), and Fleming, et al. (1964).*

Temperature distribution in the atmosphere is related to the absorption characteristics and the upward radiance through the radiative transfer equation expressed, for example, in terms of the pressure. In the spectral region of strongest

*References 4, 5, 6, 7, and 8.

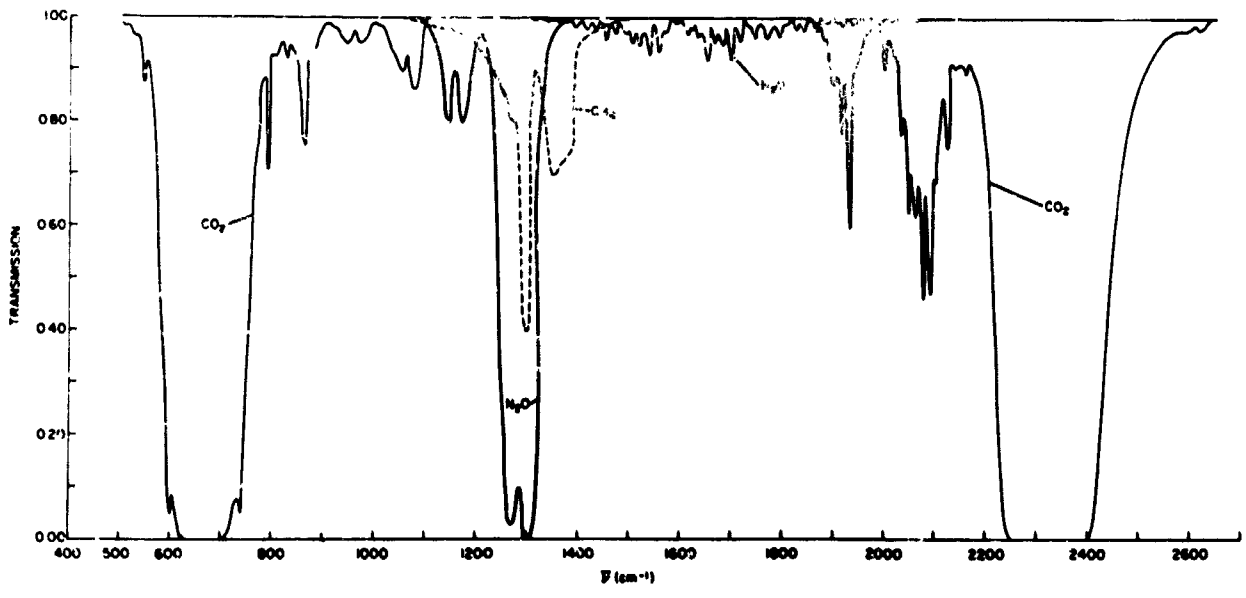

FIGURE 4.—Transmission of a synthetic atmosphere of the expected amount of CO_2 (55m atm) and water vapor (14 precipitable microns) and the upper limits of N_2O and CH_4.

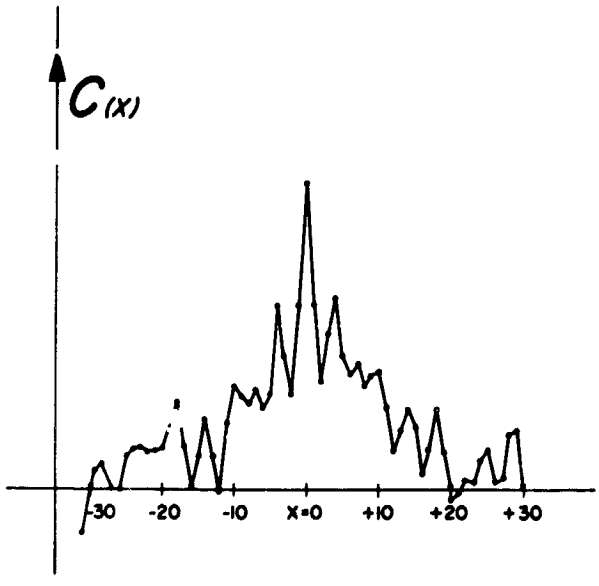

FIGURE 5.—Cross-correlation function of the spectrum of water vapor and a combination of water vapor plus random noise with a signal-to-noise ratio of unity.

absorption, the atmospheric emission arises from the upper portion of the atmosphere. Radiation in spectral regions of weaker absorption originates from lower layers in the atmosphere. Similar considerations can be applied to the extraction of the temperature distribution of the Martian atmosphere.

To illustrate, Figure 6 shows the transmission in selected spectral intervals within the 15μ carbon dioxide band. The transmission data were provided by Wark and Yamamoto. The transmission curves are based upon unpublished laboratory measurements (Yamamoto, Sasamori, Wark and Moore abstract in Publication IAMAP No. 13 on the XIIIth General Assembly of the IUGG, 1963) which assumed that the total amount of CO_2 was 5500 cm atmospheres, and the surface pressure 10 mb (Kuiper, 1964)* which corresponds approximately to the expected conditions on Mars.

Temperature corrections were made in the same manner as in the Meteorological Satellite Laboratory (USWB) reports #10 and #21, using a Mars model atmosphere to calculate effective temperatures T_e (surface temperature 270°K, adiabatic lapse rate to 6.5 mb, radiative equilibrium to 1 mb, extrapolation above.)

Figure 7 shows the atmospheric zones contributing to the outgoing radiance which can be

*Reference 9.

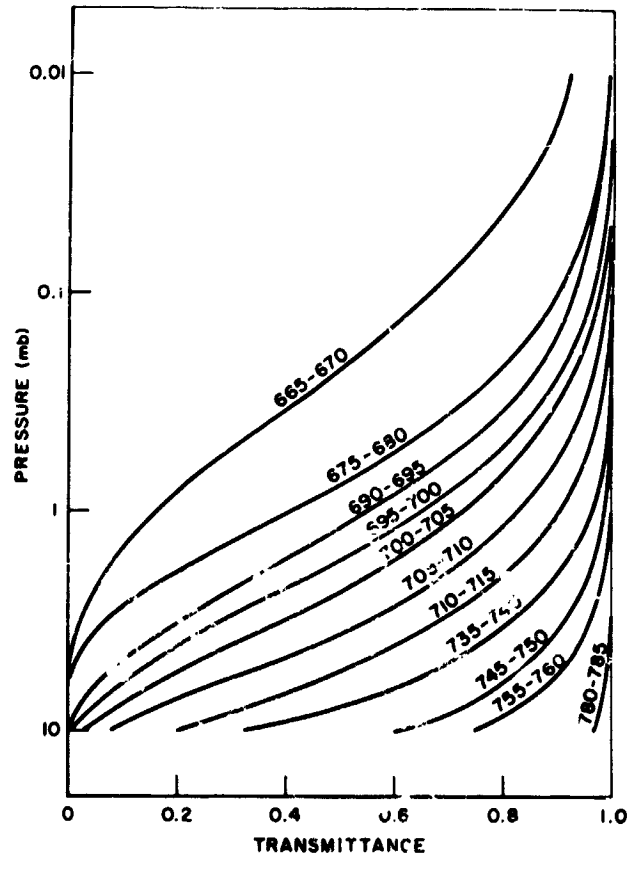

FIGURE 6.—Transmission function of CO_2 in selected spectral intervals in the 15μ band.

detected by the probe. Lorentz broadening only was taken into account; this approach is inaccurate, especially at the lower atmospheric pressures. In general, a somewhat greater absorption will be found than that shown, but the differences will be very small in all but the intervals of greatest absorption. Figure 7 demonstrates that the radiance values recovered by the interferometer allow a determination of the temperature profile. As the interferometer resolution is 5 cm^{-1} over the whole band, redundant measurements are available which increase the accuracy of the temperature determination.

2.4 Surface Studies

After the atmospheric constituents are identified, the effect of atmospheric absorption can be removed from the spectrum in those spectral ranges where the atmosphere is not opaque. The specific intensity emitted by the surface in the non-opaque regions is then obtained,

$$I_\nu(\text{surface}) = \epsilon_\nu B_\nu(T_{surface}).$$

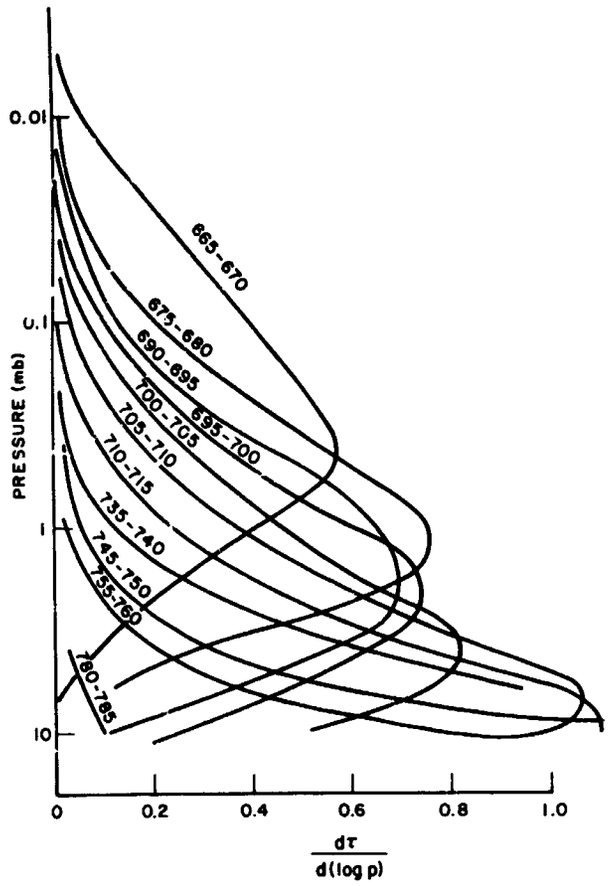

FIGURE 7.—Weighting functions indicating the pressure range from which thermal emission originates.

In the far infrared, most natural surfaces known on earth (rocks, gravel, plants, snow, etc.) have a high emissivity over large spectral ranges. However, the crystalline structure of minerals and the structure of complex molecules create stretching and bending resonances. For example, quartz exhibits strong stretching bands between 800 and 1100 cm^{-1} caused by the Si-O bond; other stretching groups (Si-Si) appear between 600 and 800 cm^{-1}. The same mineral has a bending mode (Si-O-Si) at 430 to 460 cm^{-1}. These resonances give a pronounced rise in the infrared reflectivity which can best be observed on polished samples. The increase in reflectivity is necessarily associated with a reduction in emissivity over the same spectral range.

The sharp rise in reflectivity has been well known since the early days of infrared studies. Rubens used the selective reflectivity of quartz plates to isolate narrow spectral bands in the far infrared. The reststrahlen phenomenon depends somewhat on the temperature of the sample and to a much higher degree on the surface roughness. Lyon (1963)* has studied the emission and reflection spectra of many minerals in great detail. The emissivity of several rocks in solid but unpolished form can be judged from Figure 8.

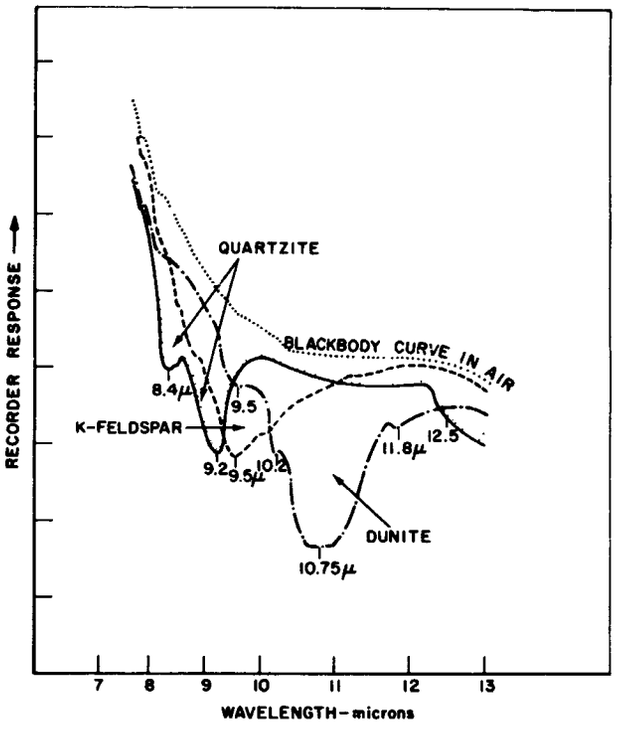

FIGURE 8.—Emissivity in the infrared of rock samples.

Polished samples show an even stronger reststrahlen effect. Grooves on a rough surface act as small cavities and increase the emissivity considerably. Similar phenomena can be recognized in the sandy or powdered form, as shown in Figure 9. Fine dust of a particle size below 1 micron loses the reststrahlen effect almost completely, and the surface emits almost with the characteristics of a graybody or possibly even a blackbody. Scattering effects also become important for these particle sizes. For a grain the size of fine sand, approximately 25 to 50 microns, the reststrahlen phenomenon is weak, but the identification of the material may still be possible, as has been demonstrated also by Bell and Eisner (1956).† Identification of the mineralogical com-

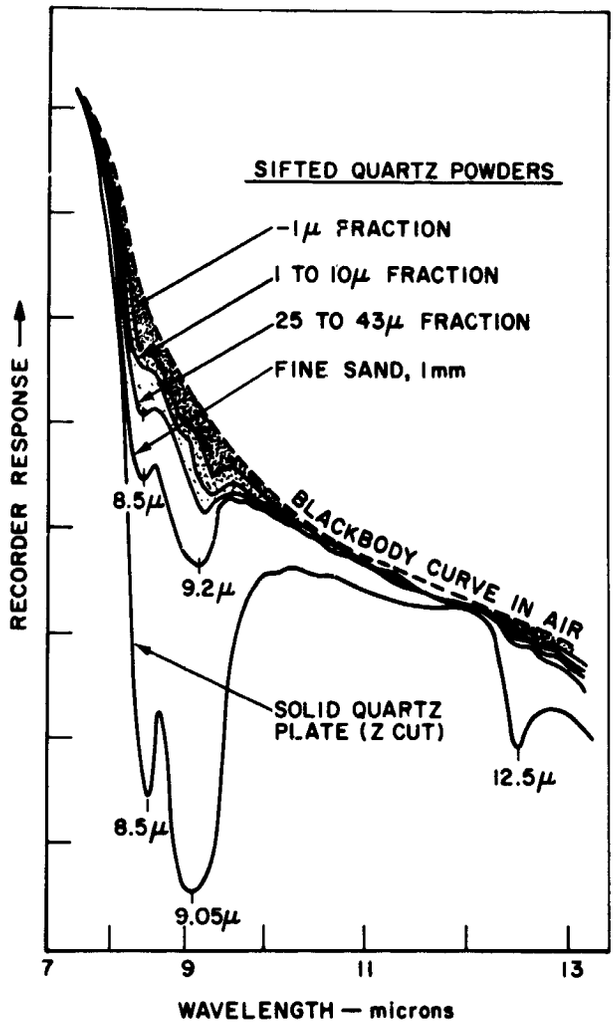

FIGURE 9.—Emissivity in the infrared of quartz and quartz sand of different grain size.

position of the Martian surface by the thermal-emission spectrum is, therefore, very promising, except for areas where fine dust may cover a large portion of the surface. Such areas may exist on Mars, but other areas may expose more solid rocks or gravel or coarse sand. Winds may sweep highlands clear of the finer particles and dust may accumulate in the valleys. The appearance of a pronounced reststrahlen effect would not only allow identification of a particular mineral, but would also be indicative of a coarse surface structure.

The surface emission spectrum may also yield important information on the existence of other chemical substances of inorganic, or possibly even organic, nature if they occur in a sufficiently high concentration. The Sinton bands near 3.5μ, although outside the spectral range of this experiment, are a typical example of unexpected (and so far unexplained) spectral features. The search for reflection or absorption phenomena is especially interesting if the spatial resolution allows measurements in predominantly bright and predominantly dark areas.

A broad program of laboratory and field measurements on earth is an indispensable requirement for proper interpretation of planetary emission spectra. The engineering model of the interferometer under construction will be used for experimental studies in this area.

2.5 Additional Investigations

In addition to the generally well defined tasks already mentioned, a number of inferences may be derived directly or indirectly from the spectra:

Chemistry of the Atmosphere and Surface

Chemical equilibrium between identified gases and others can be used to estimate the abundance of unidentified but suspected constituents; the photochemical equilibrium between CO_2, CO, O_2, and O_3 is one example. Furthermore, the atmospheric gases must be in chemical equilibrium with the surface materials.

Ultraviolet Radiation

Knowledge of the composition of the atmosphere, especially the CO_2 content and upper limits for O_3, allows calculations of the upper limits of the solar ultraviolet spectrum at the surface of the planet. The ultraviolet radiation at the surface is of biological significance.

Relative Humidity in the Atmosphere

The relative humidity near the surface is again of great biological interest. Low temperatures near the morning terminator may allow water vapor to condense in the form of dew or frost; condensation of this nature may be the only source of water available to vegetation if it is present. High temperatures near the subsolar point would cause the water to boil there. At 10 mb, water boils at +7°C. The relative humidity in the atmosphere also governs the condensation of clouds. Atmospheric regions where water or

ice clouds are possible, or likely, can therefore be determined. All these considerations will be greatly aided by theoretical studies of radiative and convective equilibrium conditions in the Martian atmosphere.

Meteorology

The temperature distribution in the atmosphere and the mode of energy transport are intimately connected. The measured temperature profile will give an indication of atmospheric stability. Lapse rates close to the adiabatic one may indicate a convective layer in the atmosphere (troposphere). Theories on the general circulation, or more concisely the Martian meteorology, are intimately related to the temperature profile.

The temperature-versus-pressure data will also be important in investigating the existence and occasional sudden disappearance of the blue haze. If this phenomenon is associated with condensing or sublimating material, the phase diagram of suggested materials must be consistent with the temperature structure derived by the experiment.

The planning of missions designed to land probes on the surface of Mars will benefit also from a better knowledge of the temperature profile, the atmospheric composition, and the surface pressure.

Spectral Emissivity and Surface Temperature

Determination of the spectral emissivity allows a more accurate determination of the true surface temperature. Most materials which show residual ray phenomena in certain parts of the spectrum radiate as nearly blackbodies elsewhere. Therefore, the maximum equivalent blackbody temperature determined over a wide spectral range will be closer to the true temperature of the surface than measurements obtained by radiometers covering a wide or narrow spectral interval. A better interpretation will be possible of radiometric data obtained in the atmospheric window from the earth, or of radiometric measurements performed from fly-by spacecraft. However, special care must be taken in interpreting surface temperatures if the surface is covered with very fine powdery material; this situation will require application of the scattering theory of small particles densely packed, which is quite complicated and not well understood today.

Thermal Inertia of Surface Material

The surface temperature as a function of solar zenith angle, especially near the morning terminator, provides data about the thermal inertia of the surface material. Calculations similar to those performed for the lunar surface can be applied. The great difference in thermal inertias of loose sand and solid rock provides a tool for distinguishing among various surface conditions.

3. THE INTERFEROMETER SPECTROMETER

The instrument, basically a Twyman-Green modification of the Michelson interferometer (Figure 10), departs from the classical laboratory designs in several areas:

The drive mirror is suspended by a parallel leaf-spring system.

The mirror assembly is driven by a moving coil in a strong magnetic field; nearly critical damping is provided by electronic means.

The mirror motion is monitored by an auxiliary interferometer to assure proper sampling times and uniformity in the mirror speed by closed-loop feedback control.

The compensating plate is moved to a position adjacent to the beam-splitter.

The particular configuration of the interferometer (Figure 11) was chosen because of its inherent compactness, large light-gathering power, and design simplicity.

Radiation arriving within the field of view is divided by the beam-splitter into two components which recombine and interfere after reflections on the fixed and moving mirrors respectively. The recombined beam, focused on the detector, is modulated by the motion of the scan mirror proportional to the speed of the mirror and the wavenumber of the incident radiation. The output signal from the detector, called the interferogram, is the Fourier transformation of the spectrum of the incident radiation. The signal is amplified, digitized, and transmitted over the spacecraft telemetering system. On the ground, the spectrum is reconstructed by applying the inverse transformation. The original spectrum can be precisely reconstructed only within certain limits of accuracy of spectral range and of spectral resolution.

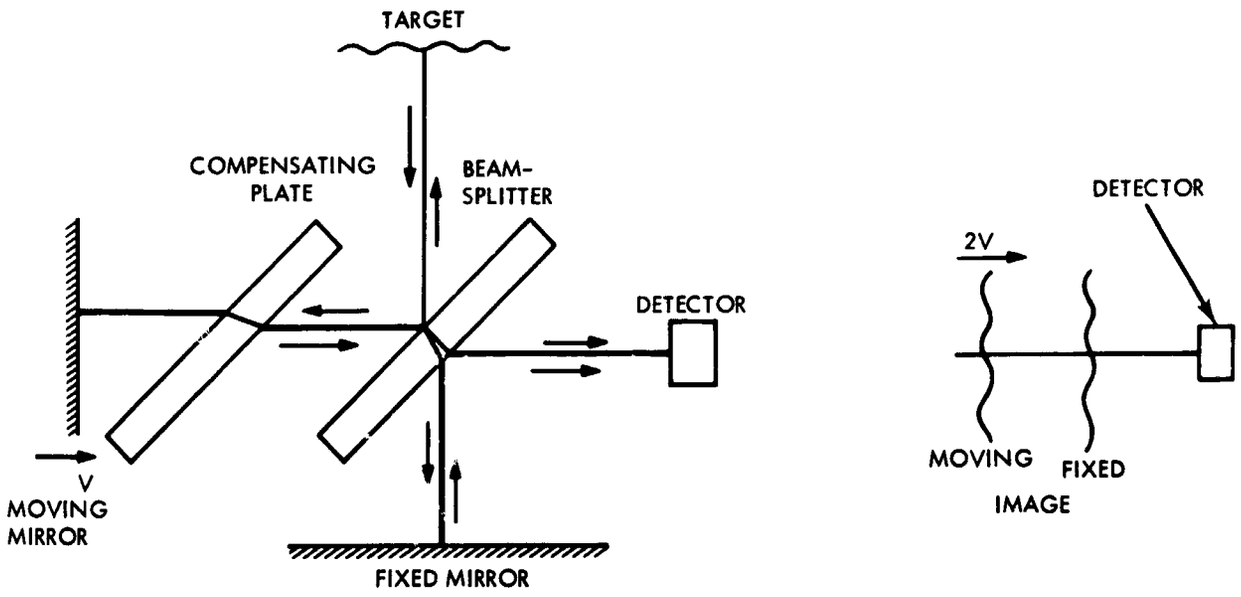

FIGURE 10.—Schematic operation of Michelson interferometer.

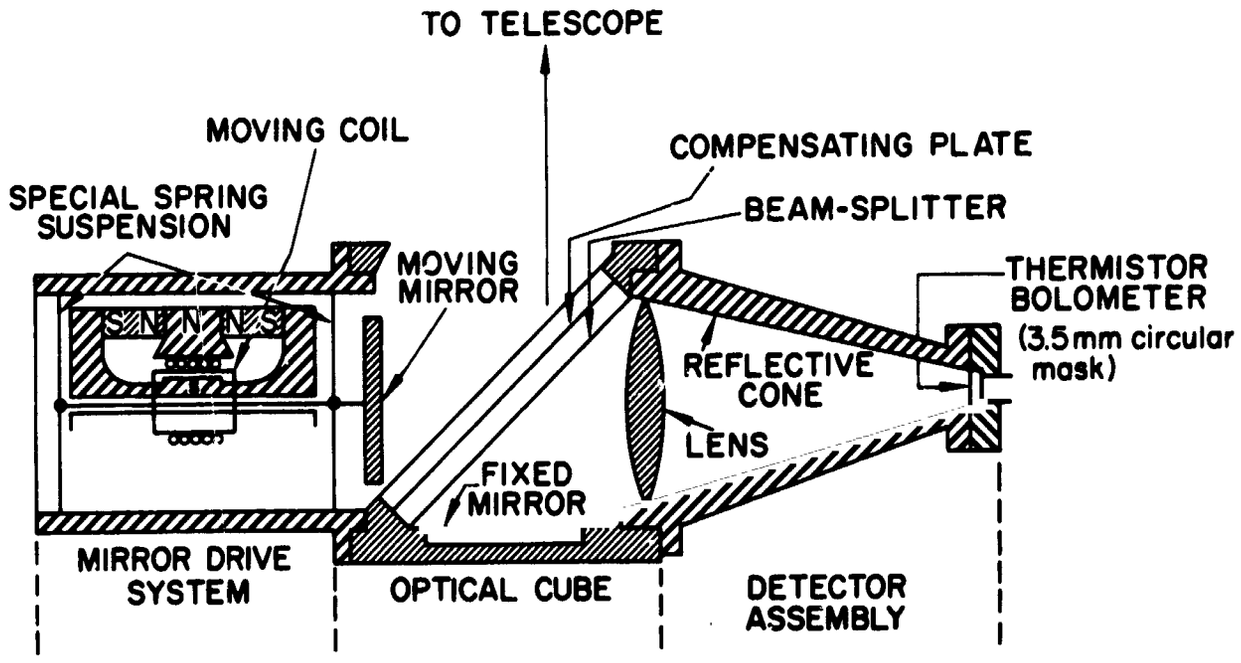

FIGURE 11.—Schematic diagram of interferometer cube, mirror drive system, and detector assembly.

3.1 Theory of Fournier Spectroscopy

Interference spectroscopy, first suggested by Michelson after the development of his original interferometer, was not pursued because of extreme computational difficulties, and further development was forced to wait upon the advent of electronics and high-speed digital computers. In the last decade, interference spectroscopy has made great advances; work has been reported by Fellgett (1958), Gebbie (1959), Mertz 1956), Connes (1961), Strong and Vanesse (1958–59), Loewenstein (1963),* and many others. Excellent summaries may be found in articles by Jacquinot (1960) and by Connes (1961).†

*References 12, 13, 14, 15, 16, 17, and 18.
†References 19 and 20.

The interferometer is shown schematically in Figure 10; the source of radiation will be an extended source which completely fills the field-of-view with radiation passing through the instrument without collimation. The output fringe pattern of the interferometer is focused on the detector, which is masked to eliminate all but the central fringe. The output of the detector is amplified and recorded as a function of path difference, d, between the fixed and movable mirror.

The relationship between the effective path difference, the order of interference, and the radiation wavelength is

$$m\lambda = 2d \cos \theta$$

where

d is the path difference between the two interferometer paths (cm)

m is the order of interference

λ is the wavelength (cm)

θ is the angle of an oblique ray through the interferometer.

This expression shows that, for a given monochromatic signal of wavelength λ, the circular fringe corresponding to a given order m expands away from the center of the pattern as the separation of the mirrors is increased. The detector is mounted behind the mask so that only the central fringe is detected; each spectral element is thereby modulated sinusoidally at a rate inversely proportional to its wavelength. As the source has an appreciable range of spectral elements, the signal detected will be the superposition of many modulated intensities multiplied by a parameter which is the "responsivity" of the system; i.e.,

$$\phi_x = \frac{1}{2}\int_0^\infty K_\nu N_\nu d\nu + \frac{1}{2}\int_0^\infty K_\nu N_\nu \cos 2\pi\nu x \, d\nu$$

where N_ν is the spectral radiance of the source (assumed to be the same at all parts of the field-of-view)

ν is the wavenumber, $\text{cm}^{-1}\left(\nu = \frac{1}{\lambda}\right)$

x is the instantaneous value of the effective path difference of the two beams of the interferometer (cm)

K_ν is a parameter which expresses the effective spectral responsivity of the interferometer, including the characteristics of the optics, the detector, and the electronic amplifiers

The interferogram is then taken to be

$$I_x = 2\left[\Phi_x - \frac{1}{2}\Phi(0)\right]$$

$$= \int_0^\infty K_\nu N_\nu \cos 2\pi\nu x \, d\nu,$$

which is the Fourier cosine transform of $K_\nu \cdot N_\nu$. The product $K_\nu \cdot N_\nu$ can be obtained uniquely from the measured interferogram, taking the inverse transform by digital computation. The relationship between N_ν and the product $K_\nu \cdot N_\nu$ will be established by laboratory calibrations; the validity of the laboratory calibrations is established by in-flight calibrations.

The true spectral distribution $K_\nu \cdot N_\nu$ is found only when the interferogram is recorded for an infinite range of x. For a finite range of x, each spectral component is spread out into a shape known as the instrumental profile. This profile also depends on the obliquity of rays through the interferometer, and thus on the solid angle of the field-of-view. The instrument profile may be modified as desired during computation of the transform; this process, called apodization, usually is done to remove secondary maxima at the expense of resolution. Including all these effects, the expression for the interferogram becomes

$$I_x = \int_0^\infty N\nu \cdot s(\nu, x) \cdot \cos\left[2\pi\nu x + \phi(\nu, x)\right] d\nu,$$

where

$$S(\nu, x) = s(\nu, x) \exp\left[i\phi(\nu, x)\right]$$

is the Fourier transform of the instrument profile (including the parameter K_ν mentioned previously).

The spectral distribution is again obtained by computing the Fourier transform of $I_{(x)}$. Reconstruction of the spectral distribution of the source

N_ν is obviously an approximation of the actual spectral distribution. This approximate solution (i.e., the transform of the interferogram) is the convolution of the actual spectral distribution with the instrument profile; therefore, it is mandatory to determine the form of the instrument profile. This can be done experimentally, because the instrument profile is the apparent spectral distribution given by a monochromatic source. This determination of the instrument profile is an important part of the laboratory calibrations.

Two factors which influence the instrument profile and reduce the quality of the data are the limitation arising from the finite path of the movable mirror, and the effect of oblique rays through the interferometer. The resolution limit imposed by the finite-path limitation is

$$R=\nu L \text{ or } \Delta\nu=\frac{1}{L},$$

(assuming linear apodization to remove secondary maxima in the instrument function). The resolution limit imposed by oblique-ray effects is

$$R\Omega=2\pi, \text{ or } \Delta\nu=\frac{\nu\Omega}{2\pi}.$$

In the above, R is the resolution $\nu/\Delta\nu$, L is the maximum path difference on either side of zero path difference, and Ω is the solid-angle field-of-view of the interferometer.

Advantages of the Interferometer

An analysis by Jacquinot indicates that, where a source whose spectrum is defined by a radiance N_ν, having M spectral elements of interest, is to be analyzed with a resolution R in a time T with an optical system which is detector-noise-limited (as presently in the infrared), then the signal-to-noise ratio is increased by maximizing the time t of observation of each spectral element, the admissible solid angle Ω, and the transmission factor ϵ_ν (the optical efficiency).

An interferometer fulfills these requirements to a high degree. The time of observation is $t=T(m/M)$, where m is the number of spectral elements studied simultaneously. For an interferometer, m equals M, and m/M has the maximum value 1. The luminous energy received by the detector is $N_\nu \cdot A \cdot \Omega$. The quantities A and Ω can both be made large for an interferometer, as long as the resolution limitation $R\Omega=2\pi$ is not exceeded (for comparison, the same resolution limit for a grating spectrometer is $R\Omega<0.1$). The transmission factor ϵ is the only area where the superiority of the interferometer, may be questioned for a given application. The reflectivity and transmissivity of the beam-splitter is of primary importance and it may be difficult to obtain high efficiency from mechanically suitable materials in certain portions of the infrared spectrum.

3.2 Mechanical and Electromechanical Design

The instrument for the IRIS experiment consists of:

- interferometer (cube, detector, mirror drive system, preamplifiers)
- two auxiliary detectors, one for reflected solar radiation, the other for total thermal radiation
- telescope with calibration target (blackbody)
- electronics compartment, containing all electronic circuits except for the preamplifiers in the cube
- mechanical structure to receive the interferometer, the auxiliary detectors, the telescope, and the calibration target, and to provide mechanical strength and thermal protection

The electronics compartment, located separately, is connected to the interferometer and to the auxiliary detectors by a cable.

The mechanical design of the interferometer is modular. The drive unit, the fixed mirror assembly, the detector assembly, and the monochromatic reference source-detector combination are integral components attached to the optical cube, which houses the beam-splitter and provides mechanical strength and thermal conduction to all components.

The scan mirror is one of the most critical items in the design because it must be moved through a distance of 2 mm with a total angular rotation of less than 2 seconds of arc.

The use of parallel leaf springs to support the mirror was chosen in preference to slides on ways, or pivot-point mounts, since it avoids

frictional surfaces undesirable in space applications. The driving force is generated by an electrical current in a moving coil in a strong magnetic field. As Figure 11 shows, the magnetic gap is inside the dual-magnet design, thus minimizing residual magnetic fields on the outside.

Lack of uniformity in drive-mirror speed normally produces catastrophic effects on the wavenumber calibration of interferometers. A resolving power of 400 would require a drive-speed constancy of better than 1 part in 400. Two methods used to eliminate virtually all errors and uncertainties in the mirror motion, and in the subsequent wavelength calibration, are both based on the use of an auxiliary interferometer:

- A monochromatic source (0.5852 micron) feeds the interferometer and generates a sine wave at an auxiliary detector. The frequency of the sine wave is directly proportional to the speed of the mirror. An error signal, derived by a digital comparison of this frequency to a reference frequency generated by a clock, provides fine adjustment of the mirror-drive system. The speed of the drive mirror is therefore feedback-controlled.
- Sampling times of the interferogram are also derived from the reference frequency.

Actually, either of the aforementioned methods would suffice.

3.3 Optical Design

The optical design of the interferometer is conventional. The flat mirrors and the detector determine the limiting apertures. The condition of optimum solid angle $R\Omega = 2\pi$ is fulfilled at the highest wavenumber to be analyzed (2000 cm^{-1}, 5μ). The optimum angle is then 8 degrees (± 4 degrees) for a resolving power of 400 (5 cm^{-1} at 2000 cm^{-1}).

The fixed mirror and the scan mirror are made of gold-coated quartz polished to a flatness better than 0.1μ. Gold was selected because of its stability and its high reflectivity in the infrared. The two-axis mirror mount is machined from a single piece of metal. A differential screw which produces the fine adjustment required also anchors each adjustment plane at three points.

The condensing optic consists of a KRS–5 lens, combined with a gold-coated reflective cone which increases the effective detector area. Dimensions are chosen to provide the 8-degree optimum acceptable angle. This particular optic has sensitivity to almost 40μ, which will be important for the future development of the instrument in extending the long wavelength limit. The f-number of this system will approach the ideal limit of 0.5.

The bolometer in this design is essentially an integral part of the condensing optic. The detector is a 3.5-mm square masked to a circle of 3.5-mm diameter, having a time constant of 1 millisecond.

The beam-splitter is the most critical item in the optical train. All the rays make two passes through the beam-splitter; hence, all the losses arising in this unit are doubled. Although metallic beam-splitters are preferable from the standpoint of uniformity with wavelength, they have the serious disadvantage that an absorption loss from 25 to 35 percent occurs, depending on the metal used. Dielectric beam-splitters cannot be made uniform with wavelength, but over the wavelength span of interest the efficiency will be at least equal to that of a metallic splitter. The dielectric material selected is germanium, which has the additional advantage of being highly reflective for wavelengths shorter than 2μ so that most of the reflected visible radiation will not be collected.

The substrate material selected for the beam-splitter and the compensating plate is IRTRAN–4, basically a glass, which can be optically worked in the same fashion as any optical glass. This is a great advantage, because the beam-splitter must be flat to 1/10 wavelength of the shortest wavelength of interest. The principal disadvantage of IRTRAN–4 is its long wavelength cutoff at 20μ.

Other materials investigated for their suitability as beam-splitters (including KBr, KRS–5, CsI, and plastic pellicles) have higher transmission to long wavelengths, but are less suitable in other respects. Further investigations are in process.

The radiation source for the monochromatic reference signal will be the 0.5852μ neon line, which is quite strong; in conjunction with a suitable interference filter, the signal is suitably monochromatic. Neon was selected because lamps are available in small sizes and very little power is required. The focusing and condensing

optics are all glass of conventional and straightforward design. A silicon photovoltaic cell serves as a detector.

The telescope is designed to accept a beam of parallel radiation with an angular aperture of 2.8 degrees and to fill completely the 8-degree field-of-view of the interferometer. The primary and secondary mirror are electroformed for lightweight construction and then gold-coated.

3.4 Electronic Design

The electronic circuitry for the interferometer package is designed to operate as independently of the spacecraft as possible. The spacecraft supplies the power and command signals necessary to operate the experiment; the electronics subsystem of the experiment processes the interferometer data and presents them to the spacecraft in a digital format. The spacecraft supplies a single command at the beginning of each interferometer frame, but the necessary sequence of events to complete the data frame is generated by means of the interferometer system.

Functions of the interferometer electronics (Figure 12) are:

- To convert the 2400-cps 100v *p-p* spacecraft power into the voltages required to operate the interferometer instrument
- To provide the necessary power and control to drive the mirror
- To amplify the thermistor bolometer output signal
- To sample the bolometer signal, and to present it in digital form to the spacecraft

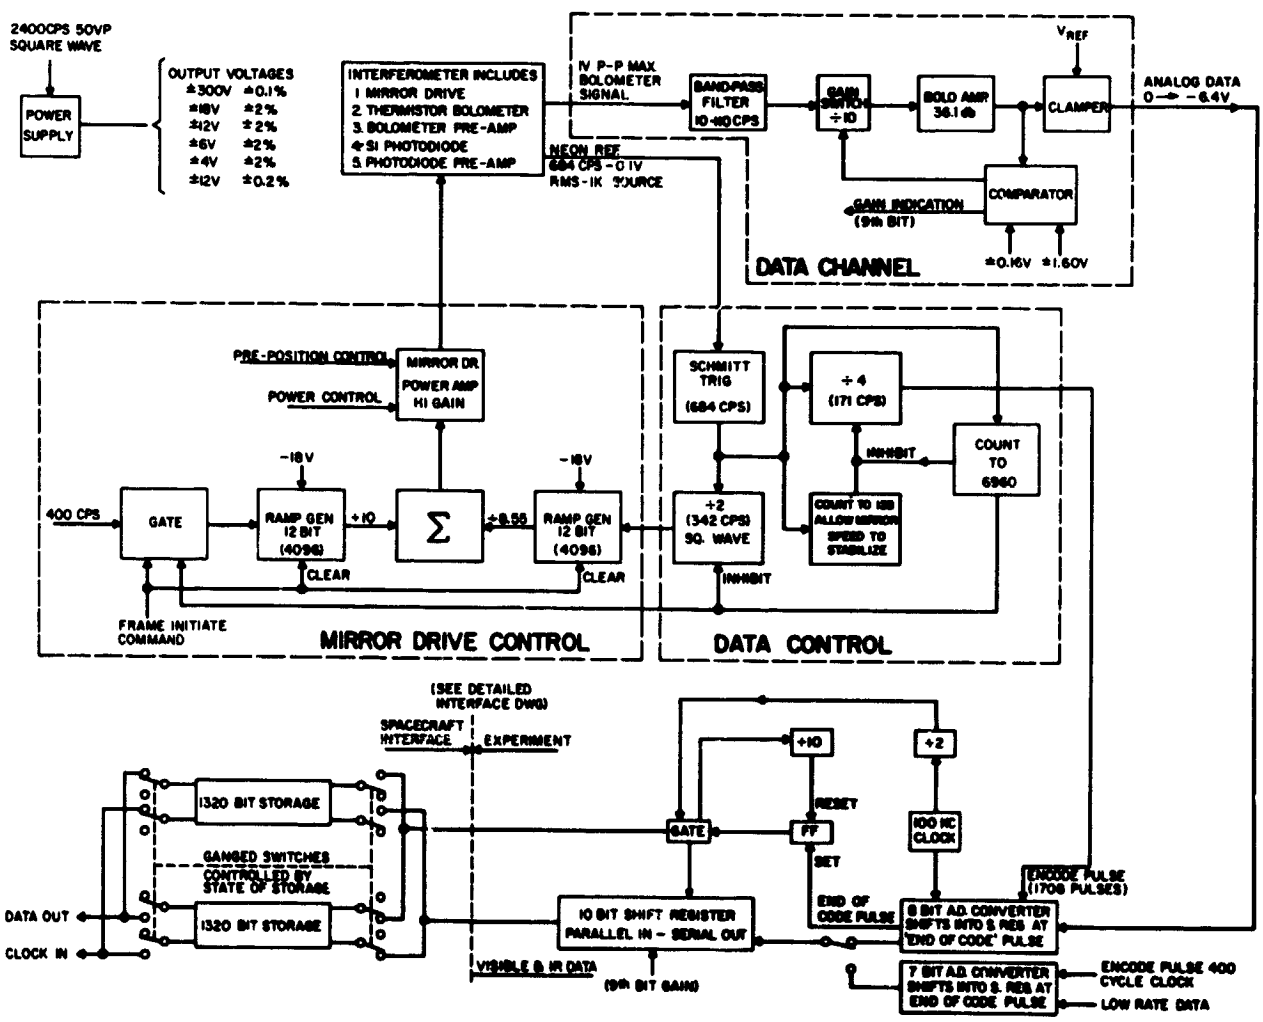

FIGURE 12.—Interferometer electronics, block diagram.

The power supply converts the 2400-cps 100v *p-p* spacecraft power to the voltage levels necessary for operating the interferometer. The power supply includes the necessary regulation (±5 percent) to maintain the voltage to the required accuracy. Three telemetry points are included to monitor:

- Spacecraft input voltage
- 300v ±0.1 percent bolometer bias supply
- 12v ±0.2 percent reference for mirror drive

The power supply is regulated to 1 percent by feedback to the primary of the power transformer; the 300-volt supply has an additional control that maintains 0.1 percent regulation.

The data channel receives the signal from the thermistor bolometer preamplifier. The signal is band-limited between 10 cps and 110 cps in an electrical filter network. This band-limited signal is then coupled to a switched attenuator and amplified.

The attenuator has two positions, controlled by the level of the preamplifier output voltage: 0–db attenuation and 20–db attenuation. The preamplifier output fed into a comparator generates an output to switch in the 20–db attenuator when the preamplifier output exceeds ±3.2 volts, and to switch out the attenuator when the signal falls below ±0.32 volts. The gain change is necessary to accommodate the extremely large dynamic range (2000:1) of the input signal from the bolometer preamplifier. The output of the bolometer preamplifier is maintained between 0 and 6.4 volts, a value which is compatible with the analog-to-digital converter.

The function of the data control channel is to:

- Provide the necessary encode pulses to the analog-to-digital converter at proper mirror positions
- Ensure that data points are not transmitted until the mirror velocity has stabilized
- Allow precisely 1708 data points for each data frame

The count-to-128 inhibits the encode pulse for a sufficient time to allow the mirror velocity to stabilize at 0.2 mm/sec. After 128 counts, the 171-cps squarewave is coupled to the analog-to-digital converter as encode pulses. The count-to-1708 circuit counts the number of encode pulses that have been applied to the analog-to-digital converter. After 1708 samples, the mirror drive circuit is de-energized and reset to zero, preparing the experiment for the next frame-initiate command from the spacecraft.

The analog-to-digital converter generates an 8-bit binary word from the bolometer amplifier output. The encode pulse from the data-control channel initiates the digital-to-analog voltage ramp that is compared with the analog voltage from the data channel. When the reference analog voltage matches the data voltage, the digital-to-analog circuit is stopped and the digital word transferred in parallel into the 10-bit shift register as the 8 least significant bits. The ninth bit is generated by comparator in the data channel designating the amplifier gain; the tenth bit is word synchronization.

At the end-of-code pulse, a gate is opened that allows the 50-kc clock to shift the 10-bit word serially into the spacecraft buffer storage. After 10 counts, the gate between the 50-kc clock and the 10-bit shift register is closed. The tenth bit in the shift register is used for synchronizing the data words in the ground stations.

An additional 7-bit analog-to-digital converter and a set of analog gates are included to sample the low data-rate channels. The analog-to-digital converters are sequentially switched into the spacecraft buffer storage system. The frame-initiate command switches the high data-rate channel into the spacecraft storage, and the end-of-frame pulse switches in the low data-rate channel.

The 400-cps spacecraft clock is coupled to the low data-rate commutator and the 7-bit analog-to-digital converter to serve as switching pulses and encode pulses.

The low data-rate channel contains the housekeeping telemetry and auxiliary measurements of the integrated visible and thermal radiation from the planet; these measurements are transmitted in real time as well as in the low data rate.

The function of the mirror-drive servo-loop is to maintain the mirror velocity constant at 0.2 mm/sec for the 10-second duration of the interferometer data frame. The control system consists of two digital-to-analog voltage ramp generators fed into a summing circuit that drives the mirror drive-power amplifier. The first ramp is a positive-going voltage generated from the 400-cps

spacecraft clock; the second ramp is a negative-going voltage generated from the 342-cps neon signal from the interferometer. The output voltages from the two digital-to-analog circuits are weighted so that no signal is applied to the mirror power amplifier when the mirror velocity is constant at 0.2 mm/sec. The loop characteristics of the servo stabilize the mirror velocity at 0.2 mm/sec ±1 percent within a fraction of a second after the frame-initiate pulse is received from the spacecraft. After the 1708 data points have been sampled, a pulse from the data-control circuit closes the gate between the 400-cps clock and the digital-to-analog circuits, and resets the counters in the digital-to-analog circuits to zero.

The electronics for the IRIS instrument are designed to perform the functions necessary to control the interferometer and process the data presentation to the spacecraft. The design consists primarily of digital electronics, because of the inherent reliability of digital systems. The digital circuits are constructed of Texas Instrument modules. This subsystem is a self-contained instrument requiring a minimum of external control for the operation of the experiment. A reliability survey will be conducted as one of the system evaluation parameters.

3.5 Signal-to-Noise Ratio

The peak signal falling on the detector (for zero path difference) is

$$P=\frac{1}{2}N\cdot A\cdot\Omega\cdot\epsilon,$$

where

P = radiant power (watts)

N = target radiance (watt cm^{-2} ster^{-1})

A = effective aperture (cm^2)

Ω = solid angle (ster)

ϵ = average optical efficiency

The factor ½ accounts for the 50-percent reflection losses inherent in this type of interferometer. The noise at the detector is given by the noise equivalent power (NEP) of a thermistor bolometer, which is approximately

$$NEP=1.6\cdot10^{-10}\sqrt{a}\sqrt{\frac{\Delta f}{\tau}},$$

where

a = area of detector (cm^2)

Δf = noise bandwidth (cps)

τ = detector time constant (sec)

Additional noise will be contributed by the compensating thermistor ($\sqrt{2}$), noise in the bias supply ($\sqrt{2}$), and preamplifier noise ($\sqrt{2}$). For operation at 260 or 270°K, the NEP is lower; however, this improvement will not be considered here.

The peak signal-to-noise ratio in the interferogram, for zero path displacement, is then

$$\frac{S}{N}=\frac{P}{NEP}\approx10^9NA\,\Omega\epsilon\sqrt{\frac{\tau}{2a\Delta f}}.$$

The signal power in the spectral interval $\Delta\nu$ will be approximately equal to the peak power P times the ratio $N_\nu\Delta\nu\epsilon_\nu/N\epsilon$. In addition, a signal-to-noise improvement factor proportional to $\sqrt{n/2}$ (n = number of samples per interferogram) is obtained; therefore,

$$\left(\frac{S}{N}\right)_{\Delta\nu}\approx10^9N_\nu\Delta\nu\epsilon_\nu A\cdot\Omega\sqrt{\frac{\tau n}{2a\Delta f}}.$$

Assuming reasonable numerical values for some parameters,

effective aperture $A=10$ cm^2

solid angle $\Omega=1.57\cdot10^{-2}(8°)$

optical efficiency $\epsilon\approx\epsilon_\nu=0.2$

detector time const. $\tau=1$ ms

detector area $a=.1225$ cm^2

number of samples $n=1708$

spectral element $\Delta\nu=5$ cm^{-1}

noise equivalent bandwidth $\Delta f\approx136$ cps

the peak signal-to-noise ratio becomes

$$\frac{S}{N}=2.5\cdot10^5N_\nu,$$

and for a spectral interval

$$\left(\frac{S}{N}\right)_{\Delta\nu}=3.6\cdot10^7N_\nu.$$

The instrument temperature (270°K) was chosen to give approximately equal signals for the maximum blackbody temperature to be measured (320°K), and for outer space (0°K), which is used as a check of calibration. The maximum radiance between 500 and 200 cm^{-1} is about $8 \cdot 10^{-3}$ watt cm^{-2} $ster^{-1}$ (320°K); therefore, the maximum signal-to-noise ratio is about 2000.

Within the spectral intervals, the signal-to-noise ratios depend largely on spectral radiance. A plot of the N_ν for various blackbody temperatures is shown in Figures 13 and 14; in both cases, the instrument is at 270°K. However, before the final signal-to-noise ratio can be discussed realistically, errors in the coding process must be taken into account.

The most efficient way to encode is to set one coding step equal to the rms value of the noise in the interferogram. Higher coding accuracy yields

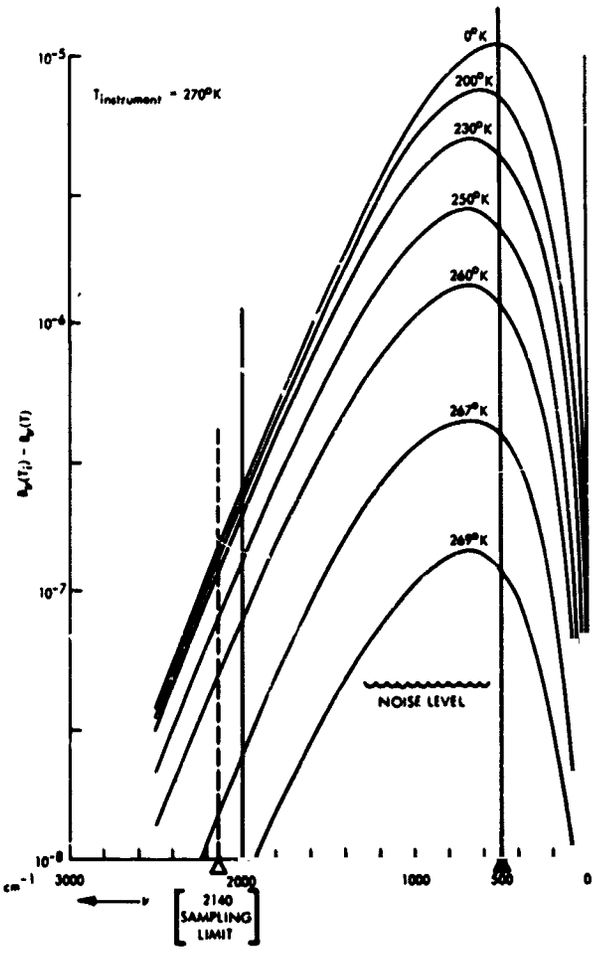

FIGURE 13. — Difference in spectral radiance of a target colder than the interferometer.

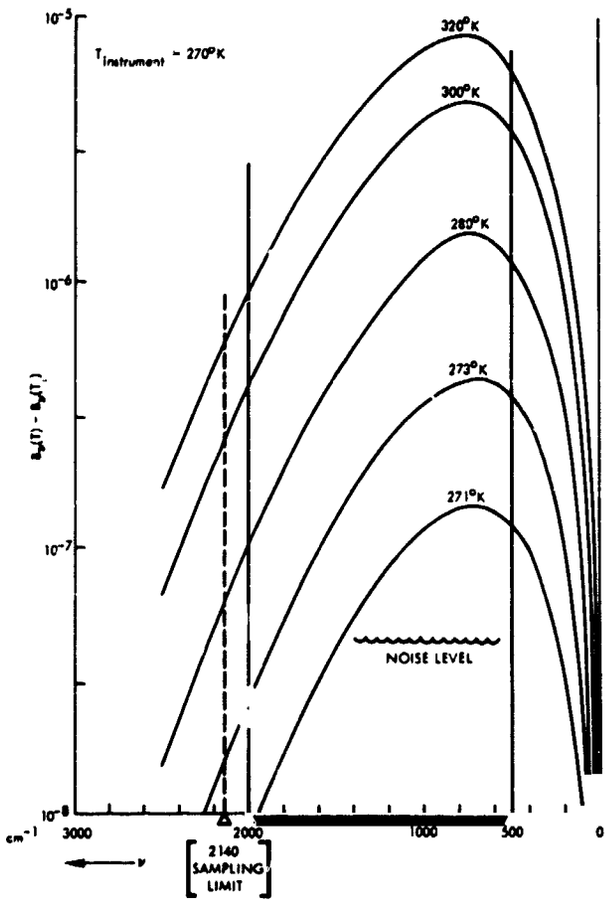

FIGURE 14. — Difference in spectral radiance of a target warmer than the interferometer.

insignificant improvement; lower coding accuracy is undesirable. If encoding is performed to 1 part in 2000 of the maximum possible amplitude in the interferogram, the uncertainties introduced by the coding process will equal errors caused by detector noise. The final signal-to-noise value, including the coding error, becomes

$$\frac{S}{N} = 1.7 \cdot 10^{3} N \text{ and } \left(\frac{S}{N}\right)_{\Delta\nu} = 2.5 \cdot 10^{7} N_\nu.$$

A $(S/N)_{\Delta\nu}$ equal to unity is obtained for $N_\nu = 4 \cdot 10^{-8}$. This value is indicated in Figures 13 and 14. A temperature difference of 1°K should therefore be detectable below 1400 cm^{-1} (above 7 microns); at 1800 cm^{-1} (5.5 microns), 3°K corresponds to the noise, and at 2000 (5 microns) only about 6°K.

These numbers were derived for 5 cm^{-1} resolution. Clearly, numerical smoothing techniques

can be applied and resolving power can be traded against accuracy. This operation is done on the ground after the interferogram has been received, so that considerations of this nature do not influence the design of the instrument.

It remains to be shown how a signal-to-noise ratio of 2000 can be obtained in the coding process. The large central peak in the middle of most interferograms is very pronounced; in most cases, the amplitudes in the rest of the interferogram are considerably smaller. An 8-bit word is used to encode on a scale of plus and minus 128 levels, or a total of 256. One level is equal to the rms value of the noise. Larger amplitudes are divided by 10 electronically and then encoded. The position of the divide-by-10 circuit is indicated by a ninth bit. This effective dynamic compression maintains full accuracy for most points in the interferogram, but only one-tenth of the full accuracy for all points exceeding a tenth of the maximum possible amplitude. However, the one-tenth value in amplitude is exceeded for only a very small number of data points, compared to the total of 1708 points. The slightly reduced accuracy of a few data points can be shown to have negligible influence on the reproducibility of the spectra.

3.6 Auxiliary Measurements

A number of auxiliary measurements will be performed to facilitate better interpretation of the interferograms and to validate the operation of the instrument.

Reflected Solar Radiation

Reflected solar radiation between 0.5 micron and about 1 micron will be measured by a small radiometer, bore-sighted with the optical axis of the interferometer and having the same field-of-view as the interferometer. The purpose of this measurement is to allow correlation of dark and bright areas on the planet with the interferograms. This instrument will use a silicon cell as a detector, with a time constant of about 10 seconds. A 2-percent relative accuracy and a 10-percent absolute accuracy are sufficient for this measurement.

Thermal Radiation

Also bore-sighted with the interferometer will be a thermopile having the same spectral response and the same field of view as the interferometer. The purpose of this instrument is to furnish additional calibration of the interferometer during planetary encounter. The time constant of this instrument will also be 10 seconds. A 2-percent relative accuracy are likewise sufficient for this measurement.

Temperature Sensors

Various temperatures will be measured in the optical cube (the temperature of the bolometer mounting, the drive mirror, the beam-splitter mounting, and a point near the entrance aperture) with an accuracy of 0.5°C. These temperature measurements will aid in the proper interpretation of the interferograms. In addition, the temperature of the primary and secondary mirror will be monitored (±5.0°C). The blackbody used for calibration purposes before and after planetary encounter will be monitored by two lead thermistors to provide redundancy in this measurement. Twelve temperature sensors are provided, including the two temperature sensors in the auxiliary radiometers and the two sensors located in the electronics compartment.

Voltage Measurements

A number of important voltages and execution commands will be monitored to certify proper operation of the instrument. The measured voltages include the bolometer bias voltage, the main power in the optical cube (−12 and −18 volts), and other strategically important voltages in the electronics compartment. A total of 25 auxiliary measurements will be performed.

4. DATA REDUCTION

Computational efforts concerned with the IRIS experiment fall into two major categories: computer simulation of the interferogram, and subsequent analysis to retrieve the optimum amount of information from the received data. The artificially synthesized interferograms will serve as aids for signal-to-noise requirements and in verifying the encoding and digitizing techniques to be applied, as well as in furnishing the basis for the early development of the data analysis techniques to be used. The synthesis of the interferograms has been divided into two phases and the analysis of the data into three phases.

4.1 Synthesis

The purpose of this portion of the study is to simulate the interferogram in order to study the effects of various levels of detector noise, to analyze the possible methods of digital encoding, and to determine the total effect on the ability to recover the underlying frequencies of interest.

The objective of the first phase of the study is a computer program which generates (for specified wavenumbers, instrument and target temperatures, time duration, and sampling rates) the amplitudes of a Fourier series (interferogram) according to the basic instrument characteristics. All computer outputs are formatted, if desired, for plotting offline on an x-y plotter. This part of the program has been completed, and artificial interferograms which were constructed have played an important role in the initial design of the digitization scheme for the instrument.

The first step of the second phase of the interferogram synthesis program is to include the instrument function. The second step is to generate and apply any desired level of detector noise to the signal. The third step is to apply several scaling techniques to find the best one, which will then be used for the actual instrument. Finally, the digitized version of the interferogram will be formatted to become identical to the output of the physical instrument. The result—the final, simulated interferogram—is again formatted for offline plotting.

4.2 Analysis

The analysis program is being developed concurrently with the synthesis program, because it is essential that the actual interferogram provide the best possible analysis of the data, and of the information extracted. In order to accomplish this, the synthesis and analysis process must be a "closed-loop" learning and improvement system. The resulting analysis program should, therefore, be one which is best fitted to analyze the data from the actual instrument.

The purpose of the first phase of the analysis program is to apply the inverse of the "second-order" effects of the synthesis program; that is, given an interferogram in digital form, the inverse operations of scaling digitizing must be applied, and an apodization function applied, before the frequency analysis is begun.

The second phase of the analysis consists of performing a general Fourier analysis to determine the individual frequency components contributing to the overall composite signal. The Fourier analysis is carried out using both cosine and sine terms.

As a third phase, refinements in the analysis are comtemplated. A spectral analysis typically consists of resolving ambiguities and questions that usually cannot be answered by a single analytical technique. The third phase is devoted to the study and development of techniques to be used instead of (or in addition to) the classical, generalized Fourier analysis mentioned above. Techniques to be investigated include auto-regressive analysis—to be used in conjunction with stepwise Fourier analysis—and digital bandpass filters, based on the Laplace transform.

5. INSTRUMENT CALIBRATION

To verify the proper operation of the instrument and to assure accuracy in the received data, an in-flight calibration technique will be used. Following is a summary of the final calibrations to be performed on earth, prelaunch check-of-calibration procedures, and in-flight calibration requirements.

5.1 Primary Calibration

The primary calibration and check of performance of the instrument will be carried out in a vacuum chamber with cryogenic walls at liquid N_2 temperature. The thermostat of the instrument will maintain the proper operating temperature of about 270°K in the optical cube. A blackbody will be placed in the field-of-view whose temperature can be adjusted between +80°K and +320°K. Interferograms will be taken at 10°K increments. Adjustments of gains, thresholds, etc., will be set at this time. Calibration with the instrument's own reference blackbody will also be checked at this time.

Spectral calibration and resolution will be checked by two methods: First, a polyethylene sheet will be inserted in front of the blackbody in vacuum. Polyethylene has numerous absorption bands of precisely known wavelengths. Second, while in air (or in a chamber with walls and instrument at room temperature), a blackbody at a distance of about 10m (1 m in the CO_2 chamber) will be kept 10 to 20 degrees above the instrument

temperature. The strong Q branch of the 15μ CO_2 band, which should be clearly observable in absorption, serves as a wavelength standard. As the mirror speed is derived from the 0.5852-micron neon reference line, this test will verify only proper scan speed. Adjustments will not be necessary.

The field-of-view of the instrument with respect to the mounting interface will be measured on an optical bench. The interferometer will not be operated in the conventional sense for this measurement; the output of the thermistor bolometer will be monitored while a chopped, high-intensity source is moved at a fixed distance. The response will be mapped as a function of the angular position of the source.

5.2 Calibration Checks During Environmental Tests

Before and after vibration, during vacuum thermal tests, etc., check of calibration are performed by exposure to blackbodies. In air, blackbodies above room temperature are used; in vacuum tests, blackbodies above and below operating temperatures (+80°K to 320°K). Also, exposure to the electrically-heated reference blackbody which is part of the instrument is performed regularly.

The spectral response is checked by placement of filters (polyethylene or mylar) in front of a blackbody.

The field-of-view is checked in air only, by exposure to a small hot source placed in front of a room temperature background. Readout takes place in the normal operation mode of the interferometer.

5.3 Check of Calibration in the Launch Area and on Launch Pad

Exposure to the electrically heated, thermostatically controlled reference blackbody will serve as the check of calibration.

5.4 Check of Calibration During Interplanetary Flight

Two complete interferometer frames will be required for each check of calibration. During the first frame, the reference blackbody will be placed within the field-of-view; this is the normal position of the reference blackbody during flight. The second calibration frame will be taken without the blackbody, with the interferometer viewing outer space. After this, the blackbody will be returned into its normal stowed position. In-flight calibration is required at regular intervals of 15 or 30 days, except during the first week, when one calibration every other day is required.

5.5 Calibration at Planetary Encounter

Shortly before and shortly after planetary encounter, a sequence of two calibration frames is required. The pre-encounter calibration should be as close as possible before encounter but definitely not earlier than 1 hour before. Both pre-encounter calibration frames and post-encounter frames should be stored and transmitted together with the data frames. After encounter, the sequence of the calibration frames will be reversed: first, the sky background will be measured as the planet moves out of the field-of-view of the instrument; then the reference blackbody will be brought in, and the final calibration frame will be taken. Thereafter no further data will be required from the interferometer.

6. MISSION PROFILE

6.1 Planetary Transfer

If possible, the instrument will be launched and stowed in the "power on" position. All circuits will be energized and the scan mirror placed in the midrange neutral position. The calibration target (blackbody) will be in front of the telescope so that it seals the instrument thermally; in this position, the blackbody will protect the optical elements during launch and will minimize the heater power necessary to maintain the proper operating temperatures of the instrument (270°K) and the blackbody (285°K). Total electrical power required during this time will not exceed the power required during the data-gathering period (approximately 7 watts). Check of calibration is performed at regular intervals as discussed in 5.4.

The following command and readout sequence constitutes the in-flight calibration:

- Frame-initiate command to obtain one interferogram of the reference target
- Command to move the blackbody out of the field-of-view of the telescope

- Frame command to obtain an interferogram of outer space
- Command to return the blackbody to the normal position in front of the telescope

6.2 Planetary Encounter Mode

The planetary encounter mode consists of calibration before and after encounter, as discussed in 5.5, with an intervening data-gathering period. The following sequence of commands and events constitutes the encounter mode:

- Frame-initiate command to obtain one interferogram of the reference target
- Command to move the blackbody to a position which will clear the field-of-view of the telescope
- Frame command to obtain an interferogram of outer space
- Frame command at least every 30 seconds (or, if possible, every 15 seconds) during planetary encounter
- Frame command after the planet has left the field-of-view
- Command to return the blackbody to the normal position in front of the telescope
- Frame-initiate command to obtain interferogram of reference target

After the encounter mode, the data-gathering part of the experiment will be completed and electrical power may be removed from the instrument.

6.3 Other Experiment Considerations

- Trajectory—No special requirements
- Fly-by distances—A fly-by distance of 2000 km (closest approach to surface) would be most desirable; at this distance, the interferometer can be used without a telescope. Presently the telescope is designed to cover the range between 5000 and 10,000 km. An approach distance between 10,000 and 20,000 km would also be acceptable, but would require a new (larger) design of the telescope.
- Fly-by velocity—Low fly-by relative velocity is desirable primarily to minimize the spatial smear during the 10-second time required for each interferogram.
- Aiming point—The aiming point should be chosen to fulfill the following conditions, listed in sequence of importance:
  (1) Equal chance to observe "dark" and "bright" areas of Mars
  (2) View of the subsolar point and equatorial regions
  (3) Scan across the terminator (morning terminator preferred)
  (4) Observe primarily the illuminated portion of Mars, but to have a chance to see part of the dark side also
- Magnetic cleanliness—No special requirements
- Electrical noise—Only the output circuit of the bolometer and the input to the preamplifier would be sensitive to stray electrical fields. Care will be taken to have proper shielding. The rest of the circuit, which is digital, should be insensitive to stray electrical fields. The noise level which can be tolerated at the electrical interface will be small, but numerical values cannot be specified at this time.
- Acoustical and structural noise—During the 10-second periods of data collection or calibration, the platform should not be exercised. The normal motion of adjustment (hunting) of the spacecraft's control system should not provide problems. The effect of structural noise is not fully known at this time, and specifications of the vibrational environment to which the instrument will be exposed on the spacecraft are urgently needed.
- Interaction and coordination with other experiments—It is strongly suggested that all radiometric experiments be bore-sighted to allow cross-correlation among the data obtained. Simultaneous ground-based observations should be encouraged.
- Spacecraft engineering measurements—No engineering measurements are required from the spacecraft. All auxiliary measurements are part of the interferometer experiment.

7. EXPERIMENT-SPACECRAFT INTERFACE

The interface between the experiment and the spacecraft (Figure 15) consists of power input, commands, clock pulses and data signals.

The frame-initiate commands supplied by the spacecraft consist of pulses occurring every 30 or 15 seconds after planet acquisition. The pulse should be about 2 milliseconds in duration and +2 volts in amplitude, with a risetime of about 10 microseconds from a source impedance of about 100 ohms.

The end-of-frame command supplied by the experiment and coupled into the spacecraft is a pulse with an amplitude of 2.5 volts, and a risetime of less than 5 microseconds from a source impedance of about 5K ohms.

The 400-cps clock consists of pulses of a 4-volt amplitude with a 0.3-microsecond risetime and a source impedance of about 100 ohms.

The 50-kc clock coupled from the experiment to the spacecraft will have a source impedance of about 100 ohms and an amplitude of 2.5 volts. The risetime will be on the order of 1 microsecond.

Data output from the experiment will consist of a series of 10-bit digital words, a "one" corresponding to +2.5 volts and a "zero" corresponding to 0 volts. The source impedance in the data channel is 5K ohms.

The real-time data from the thermal and visible channel will consist of · pulse-width about 10 microseconds in duration, with an amplitude of +2.5 volts and a 1-ms risetime.

Design Parameters for Infrared Interferometer

Spectral range	2000–500 cm^{-1} (5–20μ) (possible extension to 300 cm^{-1} (33μ)
Spectral resolution	5 cm^{-1} over total range
Travel of drive mirror	0.2 cm
Diameter of effective aperture	3.6 cm
Dectector	Thermistor bolometer in conical light pipe
Detector time constant	1–2 ms
Duration of interferogram	10 sec
Electrical frequencies at detector	20–80 cps
Sampling	Every fourth fringe of monochromatic source 5852.5 Å
Sampling rate	171 samples sec^{-1}
Samples per interferogram	1708

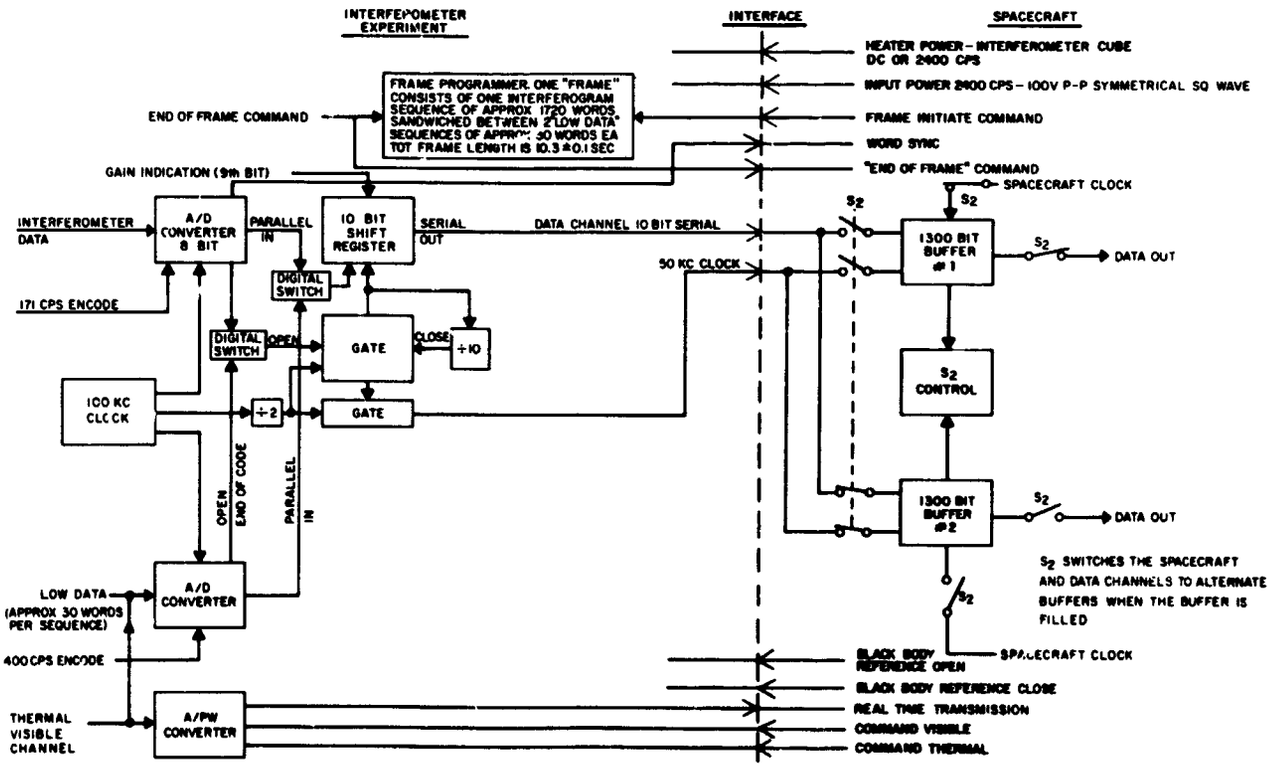

FIGURE 15.—Spacecraft-experiment interface.

Housekeeping information	25 samples per interferogram
Samples per frame	1733 samples
Frame synchronization	3 words
Words per frame	1736
Bits per word	10
Bits per frame	17360
Calibration frames in vincinity of planet	4
Minimum number of data frames for minimum fly-by speed	40 (every 30 sec) 80 (every 15 sec)
Total number of frames	44 (for 30-sec interval) 84 (for 15-sec interval)
Total number of bits to be stored	$.765\times10^6$ (for 30-sec interval) 1.46×10^6 (for 15-sec interval)
Field-of-view of interferometer	1.57×10^{-2} ster ($\sim8°$)
Field-of-view with telescope	2×10^{-3} ($\sim2.8°$) (approx. circle of 250 km diameter at 5000 km)
Calibration during interplanetary flight before and after planetary encounter	
a. space	
n. blackbody	
Monochromatic source	Neon lamp plus interference filter
Monochromatic wavelength	5852.5 Å
Detector for monochromatic light	Silicon junction
Frequency of reference signal	684 cps

RADIATIVE EQUILIBRIUM IN PLANETARY ATMOSPHERES. I. APPLICATION OF THE STRONG LINE ABSORPTION LAW TO THE ATMOSPHERE OF VENUS*

RUDOLF A. HANEL AND FRANK BARTKO

The interpretation of the data obtained for Venus in the $8-12\mu$ atmospheric window clearly requires some knowledge of the temperature distribution in the planet's upper atmosphere. For this purpose temperatures, net fluxes, and specific intensities were calculated for a CO_2-N_2 atmosphere in radiative equilibrium. The wavelength, temperature, and pressure dependence of the CO_2 absorption, including the excited bands, was considered. Solar radiation absorbed in the clear atmosphere influences the temperature profile distinctly. The effects of various CO_2 concentrations, cloud top pressure levels, and cloud reflectivities on the equilibrium temperatures are also discussed.

LIST OF SYMBOLS

$\bar{A}_i$	Fractional absorptance in the wavelength interval i.
$B_\nu(T)$	Planck function at temperature T (watts cm^{-2} $ster^{-1}$ wave $number^{-1}$).
c	Subscript denoting cloud surface.
$E_n(\tau)$	Exponential integral of order n.
$\pi F_\nu(\tau_\nu)$	Spectral total flux at τ_ν (watts cm^{-2} wave $number^{-1}$).
H	Pressure scale height (H_0=value at 273°K).
i	Index denoting wave number interval.
$I_\nu(\mu, \tau_\nu)$	Specific intensity (watts cm^{-2} $ster^{-1}$ wave $number^{-1}$).
j	Index denoting vertical coordinate.
$J_\nu(\tau_\nu)$	Spectral mean intensity at optical depth τ_ν (watts cm^{-2} wave $number^{-1}$ $ster^{-1}$).
l_ν	Generalized absorption coefficient, $l=m^n$ (cm^{-1} NTP).
m	Parameter defined in Equation 19.
n	Exponent defined in Equations 2 and 19.
P	Pressure (P_0=1 atm).
q	CO_2 volume concentration.
r_{ic}	Cloud reflectivity in wave number interval i.
s	Geometric path length (cm).
S_ν	Solar constant in wave number interval 18 (watts cm^{-2}).
t	Integration variable.
T	Atmospheric temperature (T_0=273°K).
u	Path length of active gas at NTP (cm).
u*	Modified pressure- and temperature-reduced path length (cm). See Equation 16.
X	Parameter proportional to the product of the spectral line intensity and the ratio of path length to line half width.
α	Flux convergence criterion (Equation 40).
β	Parameter proportional to the ratio of the spectral line half-width to the average line spacing.

*Published as *NASA Technical Note* D-2397, August 1964; also presented at the Conference on Atmospheric Radiation, Eppley Laboratories, Newport, R. I.

γ Exponent describing the temperature dependence of excited bands (Equation 13).

$\epsilon_{\nu 0}$ Spectral emissivity of cloud surface.

ζ Cosine of the solar zenith angle.

μ Direction cosine ($\mu = \cos\theta$).

ν Wave number (cm^{-1}).

ρ Atmospheric density.

$\tau_{\mu\nu}$ Optical thickness in direction μ at wave number ν.

ω Solid angle (ster).

INTRODUCTION

The structure of a planet's atmosphere is governed primarily by convective and radiative energy transport. On the earth, convective processes preponderate in the troposhpere and radiative processes in the stratosphere. Similarly, the atmospheres of Mars and Venus should exhibit zones of convective and radiative transfer. Convection probably characterizes the Venus atmosphere below the cloud level, especially if the clouds consist of dust particles, whereas the region above the cloud layer is probably dominated by radiative transfer. The interpretation of infrared measurements of the atmospheres of the terrestrial planets must, therefore, be based on the theory of radiative transfer and appropriately modified for convection where necessary. The objectives of the program discussed in this paper were to establish an analytical tool for the study of planetary atmospheres based on the radiative transfer theory. An initial version of this program has been applied to the atmosphere of Venus. This application must be used with relatively inaccurate estimates of physical parameters which influence the solution of the transfer equation. However, the program permits a parametric study where the number of possible solutions is ultimately restricted by observational constraints.

The equilibrium temperature distribution of an N_2–CO_2 atmosphere was calculated for several volume concentrations of CO_2. The wavelength, temperature, and pressure dependence of the absorption coefficients was taken into account. The effect of direct and diffusely reflected solar radiation absorbed by the atmosphere was also included. An effective surface emissivity was introduced as an additional parameter and permitted a deviation from the usual assumption that the surface radiates like a blackbody in the infrared. In addition to the radiative equilibrium temperatures, the specific intensities were calculated. Net fluxes were obtained by angular integration, taking into account fully the dependence of the intensity on direction. The simplifying procedure of converting parallel beam radiation to an equivalent diffuse radiation field was avoided (References 1–3).

The net flux of a planet can be determined independently from the heat budget by considering the observed albedo and the appropriate value of the solar constant. This restricts the number of theoretically possible solutions, since only those which yield total flux values consistent with the albedo can be admitted. The number of solutions can be restricted further by a comparison of calculated and measured values of the specific intensity at several wavelength intervals and zenith angles.

In the discussion below, the assumptions and limitations of the calculations are stated and the mathematical formulation is presented. An illustration of the effects of the various parameters on the temperature profiles follows, but further conclusions will be discussed elsewhere.

SOLUTION OF THE RADIATIVE TRANSFER EQUATION

In order to calculate the equilibrium temperatures in a finite, nongrey, optically thick atmosphere, the equation of radiative transfer must be solved, subject to appropriate boundary conditions (Reference 4, for example). The assumption of radiative equilibrium holds as long as the atmosphere is stable against convection (Reference 5, for example). Stability, in turn, is maintained as long as the temperature gradient is everywhere less than the adiabatic gradiet.

For the particular application considered here, the surface is taken to be the cloud tops and is assumed to be the demarcation between regions of energy transport dominated by radiation and convection. It is realized that the assumption of a solid surface for the clouds is a severe simplification. A more rigorous treatment would apply

the theory of radiative transfer for a scattering medium (Reference 6, for example).

For an atmosphere in local thermodynamic equilibrium the equation of transfer is

$$\frac{dI_\nu(\mu, \tau_{\mu\nu})}{d\tau_{\mu\nu}} = I_\nu(\mu, \tau_{\mu\nu}) - B_\nu(T) , \quad (1)$$

where $B_\nu(T)$ is the Planck function and $I_\nu(\mu, \tau_{\mu\nu})$ the specific intensity of the radiation field. For radiative transfer calculations dealing with strong molecular band absorption, the optical thickness $\tau_{\mu\nu}$ can be expressed

$$\tau_{\mu\nu}(l_\nu, u^*, \mu) = l_\nu \left(\frac{u^*}{\mu}\right)^n = \frac{\tau_\nu(l_\nu, u^*)}{\mu^n} , \quad (2)$$

where l_ν is a generalized absorption coefficient and u^*/μ a pressure- and temperature-reduced path length. It is convenient to use the optical path in the vertical direction, τ_ν, and the direction cosine μ, instead of the optical path, $\tau_{\mu\nu}$, in an arbitrary direction. The appearance of μ under the exponent n has a significant influence on the transfer problem. The value of n is unity for weak line or grey absorption and one-half or less for the square root or strong line absorption law (Reference 7). In contrast to weak line or grey absorption, the strong line absorption law reduces the thermal coupling between adjacent atmospheric layers and permits a more effective exchange of radiative energy over greater optical distances.

Very general boundary conditions have been selected. At some optical depth, $\tau_{\nu c}$, the atmosphere is assumed to be bounded by a perfectly diffuse reflector of effective emissivity $\epsilon_{\nu c}$, related to the surface reflectivity by

$$\epsilon_{\nu c} = 1 - r_{\nu c} . \quad (3)$$

For positive values of μ this assumption requires the solution of Equation 1 at the boundary $\tau_{\nu c}$ to be

$$I_\nu^+(\tau_\nu = \tau_{\nu c}) = \epsilon_{\nu c} B_\nu(T_c) + r_{\nu c} F_\nu^-(\tau_{\nu c}) + \frac{S_\nu}{\pi} \zeta r_{\nu c} e^{-\frac{\tau_{\nu c}}{\zeta^n}} . \quad (4)$$

The first term on the right represents the thermal emission by the surface of temperature T_c. The second term arises from the nonblack characteristic of the surface; the downward flux incident on the surface is partially reflected back into the atmosphere. The third term describes the reflected solar component.

At the top of the atmosphere where $\tau_\nu > 0$ only solar radiation is assumed incident. For thermal radiation outer space is considered a perfect sink. Hence the upper boundary condition is

$$I_\nu^-(\zeta, \tau_\nu = 0) = \frac{S_\nu}{\pi} \zeta . \quad (5)$$

The solution of the transfer equation subject to the boundary conditions and the absorption law for τ_ν may be verified to be

$$I_\nu^+(\mu, \tau_\nu) = \epsilon_{\nu c} B_\nu(T_c) e^{-\frac{\tau_{\nu c} - \tau_\nu}{\mu^n}} + \int_{\tau_\nu}^{\tau_{\nu c}} B_\nu(t) e^{-\frac{t - \tau_\nu}{\mu^n}} \frac{dt}{\mu^n}$$

$$+ r_{\nu c} e^{-\frac{\tau_{\nu c} - \tau_\nu}{\mu^n}} \frac{2}{n} \int_0^{\tau_{\nu c}} B_\nu(t) E_{\frac{2}{n}}(\tau_{\nu c} - t) dt + \frac{S_\nu}{\pi} r_{\nu c} \zeta e^{-\frac{\tau_{\nu c}}{\zeta^n}} e^{-\frac{\tau_{\nu c} - \tau_\nu}{\mu^n}} , \quad (6)$$

and

$$I_\nu^-(\mu, \tau_\nu) = \int_0^{\tau_\nu} B_\nu(t) e^{-\frac{\tau_\nu - t}{\mu^n}} \frac{dt}{\mu^n} + \frac{S_\nu}{\pi} \zeta e^{-\frac{\tau_\nu}{\zeta^n}} . \quad (7)$$

In Equation 6 $I_\nu^+(\mu, \tau_\nu)$ is the upward intensity whose respective components arise from the surface emission, the atmospheric emission by all layers at optical depths greater than τ_ν, and the downward fluxes diffusely reflected upwards. $I_\nu^-(\mu, \tau_\nu)$ is the downward intensity consisting of the atmospheric emission arising from all layers with optical depths less than τ_ν and the incident solar radiation.

The temperature distribution is obtained from a solution of the equation of radiative equilibrium which equates the total emitted and absorbed radiation for each volume element. For a stratified atmosphere each layer must satisfy the energy balance condition

$$\int_\nu \int_\omega \int_V l_\nu \, e^{-\frac{\Delta\tau}{\mu^n}} B_\nu \, dV \, d\omega \, d\nu = \int_\nu \int_\omega \int_V l_\nu \, e^{-\frac{\Delta\tau}{\mu^n}} I_\nu \, dV \, d\omega \, d\nu \, . \qquad (8)$$

The exponential term represents the attenuation losses due to self-absorption in the layer of finite optical thickness. Integration over all directions is required since I_ν as well as $e^{-\Delta\tau/\mu^n}$ is a function of μ. Furthermore, since absorption and emission may occur in different parts of the spectrum the equality holds only if the integration is taken over all frequencies. This general form of the condition of radiative equilibrium applies to any volume element as well as to different forms of absorption laws. If $\Delta\tau$ is very small in all directions, the familiar form (References 8 and 9) of the radiative equilibrium equation results:

$$\int_\nu l_\nu \, B_\nu \, d\nu = \int_\nu l_\nu \, J_\nu \, d\nu \, . \qquad (9)$$

Substitution of the intensities obtained (Equations 6 and 7) into the equation of radiative equilibrium leads to a Milne-type integral equation in $B_\nu(\tau)$, whose solution is required in obtaining the temperature distribution. The solution is obtained by iteration beginning from an assumed temperature distribution. The net flux is computed after each iteration. When the distribution of the net flux is constant within specified limits, radiative equilibrium is achieved and the calculation proceeds to the final step, the computation of limb darkening.

The components of the upward and downward intensities, the net flux, and the condition of radiative equilibrium will be examined in more detail in the manner required for computer solution. Hence a brief description of the coordinate system and the calculation of τ_ν follows.

COORDINATE SYSTEM

A plane parallel atmosphere is assumed and the computations are carried out in a 33 layer coordinate system (Figure 1). The interface between

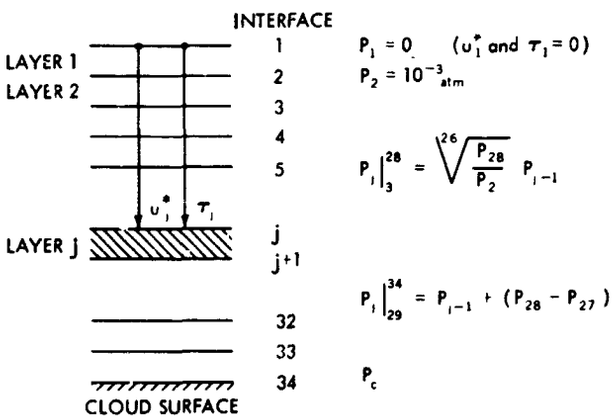

FIGURE 1.—Coordinate system.

layer j–1 and j is called interface j and the quantities u_j^* and τ_j are computed from the top of the atmosphere (interface one, zero pressure) to interface j and the corresponding pressure P_j. In all computations the pressure at interface j=2 was taken equal to 10^{-3} atm. Layer one above this level is included for the sake of completeness. The computed temperature is only an average value and it should not be interpreted that layer one is isothermal. For this region of the atmosphere, local thermodynamic equilibrium may not exist (Reference 10, for eaxmple) and the absorption lay adopted may not strictly apply (Reference 11). In addition, photochemical and other atmospheric processes will have a strong effect on

the temperature in this region. For layers between j = 2 and 28, pressures are calculated according to the recursion formula

$$P_j = \sqrt[26]{\frac{P_{28}}{P_2}}\, P_{j-1} \quad . \tag{10}$$

This mode of pressure slicing yields layers of approximately the same geometrical height but of increasing optical thickness. To avoid a very thick layer adjacent to the cloud boundary, a linear pressure slicing was applied between j = 28 and the surface (j = 34).

ABSORPTION COEFFICIENTS

The calculation of the optical thickness requires a value of the absorption coefficient, which varies with pressure and temperature, and a value for the mass of the absorbing gas. For pressures greater than 10^{-3} atm the individual line shape is determined primarily by collision broadening. The effect of this factor on atmospheric structure has been studied by several authors (Reference 12, for example). For band absorption the concept of optical thickness defined for a single frequency is still very useful, but τ becomes, in general, a complicated function of u*. For all cases studied in this paper, an analytical expression can be derived for this function, based on the so-called strong line absorption law (Reference 7). This approximation applies to CO_2 within the pressure ranges of interest, namely from 10^{-3} to 1 atm for CO_2 concentrations exceeding 0.01 part per volume.

The mass of active gas is usually expressed in terms of a path length. An element of the path length is defined by the product of the geometric path length ds and the normalized density of the active gas

$$du = q\frac{\rho}{\rho_0}\, ds \quad . \tag{11}$$

Since $\rho = MP/RT$,

$$du = q\,\frac{P}{P_0}\,\frac{T_0}{T}\, ds \quad . \tag{12}$$

In the domain of collision broadening, the pressure and temperature dependences of the half-width of absorption lines are usually considered by defining a reduced path length equal to the product of du, the pressure, and the inverse square root of the temperature. The temperature dependence of the excited bands may be included by an exponential term which represents the increase of the population of the lower vibrational energy state with temperature (References 13, for example). An additional temperature dependence of the rotational levels, within each vibrational state, has the effect of altering the band shape. However, this effect is much smaller than that due to changes in the population of the vibrational state. The reduced path length, with these effects, is then

$$du^* = q\left(\frac{P}{P_0}\right)^2 \left(\frac{T_0}{T}\right)^{3/2} e^{\gamma\left(\sqrt{250} - \sqrt{T}\right)}\, ds \quad . \tag{13}$$

The numerical value of γ was computed from Reference 14 for each spectral region, and the adopted values are listed in Table 1. The value

Table 1

μds equals the vertical path element dh. Thus, by using the hydrostatic equation

$$\frac{dh}{H} = -\frac{dP}{P} \quad . \tag{14}$$

the reduced path length in a direction μ can be expressed by

$$du^*(\mu) = -\frac{1}{\mu} qH_0 \left(\frac{T_0}{T}\right)^{1/2} e^{\gamma\left(\frac{1}{250} - \frac{1}{T}\right)} \frac{P\,dP}{P_0^2} \quad (15)$$

For the remainder of this paper, only the reduced path length in the vertical direction, $u^*(\mu=1)$, is used. The reduced path length from a level P to outer space is a function of the wavelength as well as the temperature profile,

$$u_\nu^* = qH_0 \int_0^P \left[\frac{T_0}{T(P)}\right]^{1/2} e^{\gamma_\nu \left(\frac{1}{250} - \frac{1}{T(P)}\right)} \frac{P\,dP}{P_0^2} \quad (16)$$

For the numerical computations Equation 16 was reformulated in terms of the adopted coordinate system,

$$u_{i,j}^* = u_{i,j-1}^* + qH_0 \left(\frac{T_0}{T_{j-1}}\right)^{1/2} e^{\gamma_i \left(\frac{1}{250} - \frac{1}{T_{j-1}}\right)} \frac{P_j^2 - P_{j-1}^2}{2P_0^2} \quad (17)$$

A constant temperature within each layer is assumed. The scale height H_0 for standard temperature is a function of the molecular weight and, therefore, of the fractional concentration of each gas; adopted values are given in Table 2.

Table 2

Pressure Scale Height in the Atmosphere of Venus as a Function of the CO_2 Concentration.

q(CO_2 per volume)	H_0 (cm)	q H_0 (cm)
1.0	5.901×10^5	5.901×10^5
0.75	6.491×10^5	4.865×10^5

0.05	9.015×10^5	4.508×10^4
0.01	9.210×10^5	9.210×10^3

Since CO_2 is the primary absorbing constituent, an accurate representation of its absorption spectrum as a function of pressure, temperature, and path length is required. The absorption spectrum of CO_2 can be separated into three important regions. The near infrared region from 1 to about 6μ is most important in regard to the absorption of solar radiation but less significant in regard to the thermal emission spectrum of the clouds (Reference 15). The 9.4 and 10.4μ excited bands of CO_2 are within the second region considered in this calculation. They lie in a spectral region for which planetary observations exist (References 16–18), although they play only a minor role in the determination of the atmospheric structure. Any realistic interpretation of the data from References 16–18 must necessarily represent this part of the spectrum adequately. The strong bands near 15μ determine the atmospheric structure in the radiative regime; the interval of 12–20μ is the third region considered.

The spectrum should be divided into many intervals for accurate representation, but the number of intervals must be limited to avoid unreasonably long computing times. As a compromise, the 18 intervals listed in Table 1 were selected.

For the pressure and temperature ranges considered, the individual line shapes are controlled primarily by collision broadening. For high concentrations of CO_2 ($q \geq 0.01$) the distribution of the lines and their spacings in the major bands indicates appreciable overlapping. The square root law would overestimate the absorption in such intervals; but the strong line approximation is a generalization of this law which is valid even when overlapping occurs. This approximation is expressed in terms of a single variable u^* and is well suited to extrapolation of the absorption to large path lengths and low pressures (Reference 7).

For each spectral interval, the fractional absorption was computed from the expression

$$\bar{A}_i = 1 - e^{-\tau_i} \quad (18)$$

where

$$\tau_i = (m_i u_i^*)^{n_i} \quad (19)$$

The m_i are similar to the generalized absorption coefficients and the n_i are constants determined by the degree of overlapping of the individual lines and the slope of the curve of growth.

Wherever possible, the spectral intervals were chosen to coincide with the intervals used by Burch et al (Reference 13). The coefficients m_i and n_i were determined graphically by a fit of the strong line curve with applicable data points taken from this source. Where experimental data were not available the calculated tables of CO_2 absorption compiled by Stull et al. (Reference 14) were used. A sample is shown in Figure 2 and the various values of m and n are listed in Table 1.

The application of the strong line approximation is valid whenever the central regions of the various lines become opaque. For each spectral interval a check of the validity of the strong line approximation for the conditions considered was carried out. A relatively weak absorbing region (720–810 cm^{-1}) of the 15μ CO_2 band may serve as an illustration. If the approximation holds for this spectral interval, then it will be valid for stronger absorbing regions. According to Plass (Reference 7) the strong line approximation applies for all values of β to an accuracy of 10 percent, if $X > 1.63$. For this interval

$$\left.\begin{aligned} \beta &= 0.023\ P\ , \\ X &= 0.01\ \frac{u}{P}\ . \end{aligned}\right\} \qquad (20)$$

According to Equations 12 and 14, u/P equals qH and defines the CO_2 concentration (see Table 2). As can be seen, the strong line approximation is valid within an accuracy of 10 percent for CO_2 concentrations in excess of 10^{-3} and more accurate for concentrations in excess of 10^{-2}, which is the range of interest for Venus.

SPECIFIC INTENSITY

The formulas derived in the section concerned with the solution of the radiative transfer equation must be expressed in terms of the adopted coordinate system. The specific intensity is a function of ν, τ, and μ and is conveniently expressed by

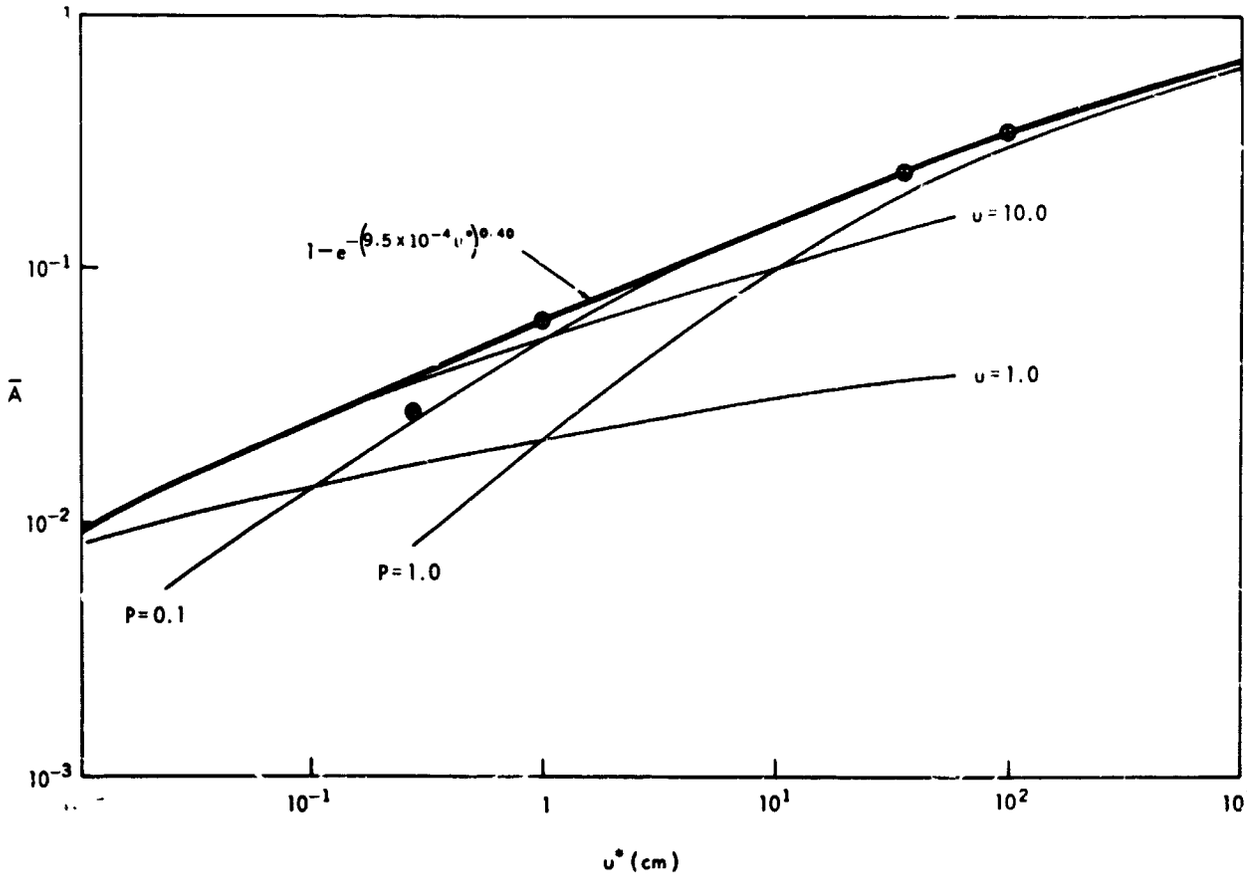

FIGURE 2.—Illustration of strong line approximation fit for the spectral interval 720–810 cm^{-1}, as derived from Stull et al. (Reference 14). Data points taken from Burch et al. (Reference 13) and slightly modified are included for comparison.

upward and downward vectors. As mentioned before, the solution of the transfer equation appropriate here requires four components for the upward intensity:

1. Thermal emission from the cloud surface
2. Direct thermal emission from the atmosphere below interface j
3. Downward thermal emission from the whole atmosphere, reflected upward by the clouds
4. Downward solar radiation reflected upward by the clouds.

The downward intensity includes values for:

5. Direct emission from the atmosphere above interface j
6. Direct solar radiation.

These six components are shown in Figure 3 and discussed below.

Surface Emission

For a frequency interval i and an interface j, the thermal radiation emitted, which is attenuated between the sufrace and the interface j, is given by

$$I_{ij} = \epsilon_{ic} B_{ic} e^{-\frac{\tau_{ic} - \tau_{ij}}{\mu^n}} . \qquad (21)$$

The designation of emissivity applies directly for a solid or liquid surface, but some qualifications regarding the interpretation of ϵ_{ic} are necessary for a scattering medium such as a cloud surface. At this level the gas and cloud particles have a

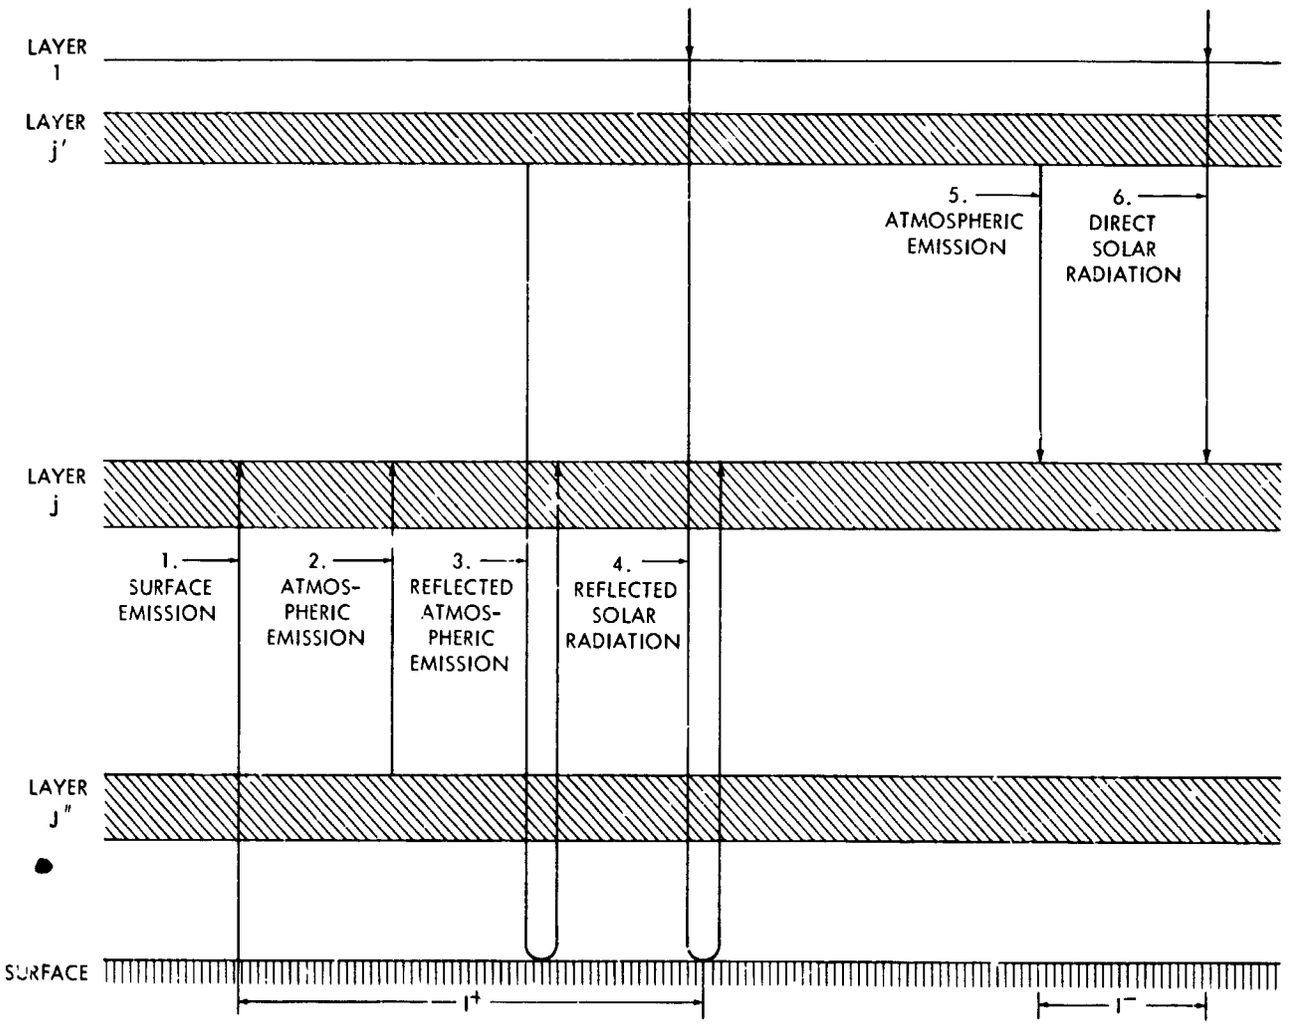

FIGURE 3.—Schematic diagram of the radiation components considered.

temperature T_c. For those spectral intervals where the atmospheric gas is opaque, the optical properties of the cloud particles are not important. In regions of the spectrum where the gas between particles is transparent the optical properties of the particles and their concentration become very important. For these intervals ϵ_c is defined as a boundary value, which indicates how much smaller the emerging radiation is compared with a blackbody at temperature T_c. The cloud emissivity was taken as unity in the strong absorption bands and set equal to a constant value in the transparent regions. In general, ϵ_{ic} may be a complicated function of wavelength and μ but this dependence is ignored.

Emission from the Atmosphere below Interface j

The contribution from each layer is proportional to the Planck function, an attentuation factor, and the optical thickness,

$$I_{ij} = \sum_{j'=j}^{33} B_{ij'} \, e^{-\frac{\tau_{ij'} - \tau_{ij}}{\mu^n}} \, \frac{\Delta\tau_{ij'}}{\mu^n} \quad . \tag{22}$$

Emission from the Atmosphere Reflected by the Clouds

This component is the product of the downward flux at the cloud surface, the reflectivity, and the attenuation factor of the atmosphere between the surface and τ_j. Since constant temperature is assumed within a layer, the flux integral (see below) can be integrated for each layer by using the recursion formula for exponential integrals,

$$E_n(\tau) \, d\tau = dE_{n+1}(\tau) \quad . \tag{23}$$

The reflected intensity becomes

$$I_{ij} = r_{ic} \, e^{-\frac{\tau_{ic} - \tau_{ij}}{\mu^n}} \, \frac{2}{n} \sum_{j'=1}^{33} B_{ij'} \left[E_{\frac{2}{n}+1}\left(\tau_{ic} - \tau_{i,\,j'+1}\right) - E_{\frac{2}{n}+1}\left(\tau_{ic} - \tau_{ij'}\right) \right] \quad . \tag{24}$$

Reflected Solar Radiation

Similarly, the reflected solar intensity is calculated from

$$I_{18,\,j} = \frac{S}{\pi} \, \zeta \, r_{18,\,c} \, e^{-\left(\frac{\tau_c}{\zeta^n} + \frac{\tau_c - \tau_j}{\mu^n}\right)} \quad . \tag{25}$$

Within the spectral range of 1.25 to 5.9μ the reflectivity of the clouds for solar radiation was taken equal to 0.6 which is consistent with recent observations (Reference 19). Again clouds were considered to be perfect diffusers.

Direct Emission from Atmospheric Layers above Interface j

This contribution is analogous to the emission from lower layers:

$$I_{ij} = \sum_{j'=1}^{j-1} B_{ij'} \, e^{-\frac{\tau_{ij} - \tau_{ij'}}{\mu^n}} \, \frac{\Delta\tau_{ij'}}{\mu^n} \quad . \tag{26}$$

Direct Solar Radiation

The direct solar radiation is given by the solar constant for 1.25 to 5.9μ appropriate for the distance of Venus (0.047 watt cm^{-2}):

$$I_{18,\,j} = \frac{S}{\pi} \, \zeta \, e^{-\frac{\tau_j}{\zeta^n}} \quad . \tag{27}$$

FLUX

The flux is derived conventionally by integration of the components of specific intensity over μ (Reference 9, for example):

$$\pi F = \int I \, \mu \, d\omega = 2\pi \int I \, \mu \, d\mu \quad . \tag{28}$$

Integration leads to exponential integrals of the form of

$$\int_0^1 e^{-\frac{\tau}{\mu^n}} \, \mu \, d\mu = \frac{1}{n} \, E_{\frac{2}{n}+1}(\tau) \quad , \tag{29}$$

$$\int_0^1 e^{-\frac{\tau}{\mu^n}} \, \frac{d\mu}{\mu^{n-1}} = \frac{1}{n} \, E_{\frac{2}{n}}(\tau) \quad . \tag{30}$$

The results are expressed by exponential integrals tabulated for integral order numbers (Reference 20). For all wavelength intervals concerned with thermal radiation (i = 1 to 17) n is close to 1/2; for integration, n was taken equal to 1/2, which leads to exponential integrals of the fifth and fourth orders respectively. For the interval concerned with solar radiation (i = 18) the exponent n is 0.27; for integration, n was taken equal to 1/4, which leads in this case to exponential integrals of the ninth and eighth orders respectively.

Analogous to the intensity, the upward flux consists of four components, and the downward flux consists of two.

The individual components of the upward flux F_{ij}^{+} are

1. $$4\epsilon_{ic} B_{ic} E_5(\tau_{ic} - \tau_{ij}) \quad , \tag{31}$$

2. $$4 \sum_{j'=j}^{33} B_{ij'} \left[E_5(\tau_{ij'} - \tau_{ij}) - E_5(\tau_{i,j'+1} - \tau_{ij}) \right] \quad , \tag{32}$$

3. $$16 r_{ic} E_5(\tau_{ic} - \tau_{ij}) \sum_{j'=1}^{33} B_{ij'} \left[E_5(\tau_{ic} - \tau_{i,j'+1}) - E_5(\tau_{ic} - \tau_{ij'}) \right] \quad , \tag{33}$$

4. $$8 \frac{S}{\pi} r_{18,c} \zeta e^{-\frac{\tau_c}{\zeta^n}} E_9(\tau_c - \tau_j) \quad . \tag{34}$$

The components for the downward flux F_{ij}^{-} are

5. $$4 \sum_{j'=1}^{j-1} B_{ij'} \left[E_5(\tau_{ij} - \tau_{i,j'+1}) - E_5(\tau_{ij} - \tau_{ij'}) \right] \quad , \tag{35}$$

6. $$\frac{S}{\pi} \zeta e^{-\frac{\tau_j}{\zeta^n}} \quad . \tag{36}$$

The net flux ($\pi F_\nu = \pi F_\nu^{+} - \pi F_\nu^{-}$) is calculated for each layer j, for each wavelength interval i, and for the sum over all spectral intervals.

CONDITION OF RADIATIVE EQUILIBRIUM

The general condition of radiative equilibrium (Equation 8) will now be applied to an atmosphere consisting of many layers of finite optical thickness. For an element of area dA in a layer of optical thickness $\Delta\tau_\nu$, the element of reduced volume is

$$dV = \mu \, dA \left(\frac{\Delta u^*}{\mu} \right)^n \quad . \tag{37}$$

In this expression μdA represents the projection of the element of area in a direction μ, and $(\Delta u^*/\mu)$ is the effective element of the radiating gas. For convenience and consistency with the equation for τ (Equation 2), l_ν in Equation 8 may be included with Δu^*. Upon inserting Equation 37 into Equation 8, the factor $(m\Delta u^*/\mu)^n e^{-\Delta\tau/\mu^n}$ becomes just the increment of absorptance of the layer. Upon integration from 0 to $\Delta\tau$ the radiative equilibrium condition becomes

$$\int_\nu \int_\mu I_\nu(\mu) \left(1 - e^{-\frac{\Delta\tau}{\mu^n}} \right) \mu \, d\mu \, d\nu = \int_\nu B_\nu \int_\mu \left(1 - e^{-\frac{\Delta\tau}{\mu^n}} \right) \mu \, d\mu \, d\nu \quad . \tag{38}$$

The computed intensities were inserted into Equation 38 and integration over μ was carried out analytically. In terms of the adopted coordinate system, the radiative equilibrium condition is

$$
\begin{aligned}
&4\sum_{i=1}^{17} \epsilon_{ic} B_{ic} \left[E_5(\tau_{ic} - \tau_{i,j+1}) - E_5(\tau_{ic} - \tau_{ij})\right] \\
&+4\sum_{i=1}^{17}\sum_{\substack{j'=1 \\ j'\neq j}}^{33} B_{ij'} \left[E_5\left(|\tau_{ij} - \tau_{i,j'+1}|\right) - E_5\left(|\tau_{i,j+1} - \tau_{i,j'+1}|\right) + E_5\left(|\tau_{i,j+1} - \tau_{ij'}|\right) - E_5\left(|\tau_{ij} - \tau_{ij'}|\right)\right] \\
&+16\sum_{i=1}^{17} r_{ic} \left[E_5(\tau_{ic} - \tau_{i,j+1}) - E_5(\tau_{ic} - \tau_{ij})\right] \sum_{j'=1}^{33} B_{ij'} \left[E_5(\tau_{ic} - \tau_{i,j'+1}) - E_5(\tau_{ic} - \tau_{ij'})\right] \\
&+\frac{S}{\pi}\zeta\left\{e^{-\frac{\tau_{18,j}}{\zeta^{1/4}}}\left(1 - e^{-\frac{\Delta\tau_{18,j}}{\zeta^{1/4}}}\right) + 8e^{-\frac{\tau_{18,c}}{\zeta^{1/4}}} r_{18,c}\left[E_9(\tau_{18,c} - \tau_{18,j+1}) - E_9(\tau_{18,c} - \tau_{18,j})\right]\right\} \\
&= 2\sum_{i=1}^{17} B_{ij}\left[1 - 4E_5(\Delta\tau_{ij})\right] \quad .
\end{aligned}
\tag{39}
$$

The terms on the left side are arranged in the adopted sequence; the contribution from the surface, then the contribution from the atmosphere (direct and reflected), and finally solar radiation, (direct and reflected).

Radiation from the atmospheric layers above and below layer j is combined into one expression by the use of absolute value signs in the arguments of the exponential integrals. The right side represents the emission from layer j and the left side represents radiation absorbed by layer j.

The numerical solution of Equation 39 was carried out on an IBM 7094 computer. For each layer j and temperature T (between 100 and 350°K) the i wave number intervals of the right side of Equation 39 were summed by using the appropriate value of $\Delta\tau_{ij}$. A functional relationship between the total thermal emission E_j from a layer at temperature T_j was tabulated. The thermal emission from a layer depends on the Planck function and the optical thickness; both are functions of the temperature. The optical thickness depends on temperature through u^* (Equation 16). With this set of E vs. T tables for each layer, the calculation of the temperature profile continued as follows.

First the energy absorbed by a layer j (left side of Equation 39) was computed from an estimate of the temperature profile. After the absorbed energy was obtained, the computer searched the previously computed table for a temperature for layer j which balanced Equation 39. In other words, it determined the temperature at which layer j could reradiate the absorbed energy. This was repeated for each layer and the resulting temperature distribution was checked for constancy of the net flux. If the flux criterion was not satisfied, the computed temperature distribution was re-inserted and the iteration procedure continued.

The convergence criterion used in terminating the calculation was

$$
\left|\frac{F_{(\text{layer } 10)} - F_{(\text{layer } j)}}{F_{(\text{layer } 10)}}\right| \leq \alpha \quad . \tag{40}
$$

where α was chosen according to the desired accuracy. In general α was taken equal to 0.005. Obviously, higher accuracy would require more iterations. Once the convergence criterion was satisfied, the limb function was calculated in the final step,

$$\frac{I_i^{\uparrow}(j = 1, \mu)}{I_i^{\uparrow}(j = 1, \mu = 1)} \quad (41)$$

The limb function was computed for each spectral interval i and for a range of specified μ, by using the computed equilibrium temperature distribution. This expression (41) includes all upward components of the specific intensity.

The iteration process converges rapidly for low surface pressures, where, for a praticular layer, radiation from the surface dominates radiation from other atmospheric layers. For optically dense atmospheres the convergence process takes much longer. These effects are demonstrated in Figures 4 and 5 where samples of the iteration process for low and high surface pressures and for low and high initial temperature estimates are shown. More general studies of the convergence of iterative processes are available (Reference 21, for example).

RESULTS

As stated earlier, a portion of the atmosphere of Venus was selected for analysis with the formulated program. Several sets of good observational material presently exist which can serve as a basis for comparison with the computed results.

The atmosphere of Venus above the clouds is more amenable to analysis and consequently is better understood than the region between the surface and the upper cloud layer (References 22–27). However, starting from essentially the same set of observational data, various students of Venus have reached different conclusions. Estimates of the cloud top pressure range from 0.007 to 1 atm (References 23 and 28–30). Large discrepancies exist in estimates of the water vapor content (References 31–33), and the abundance of

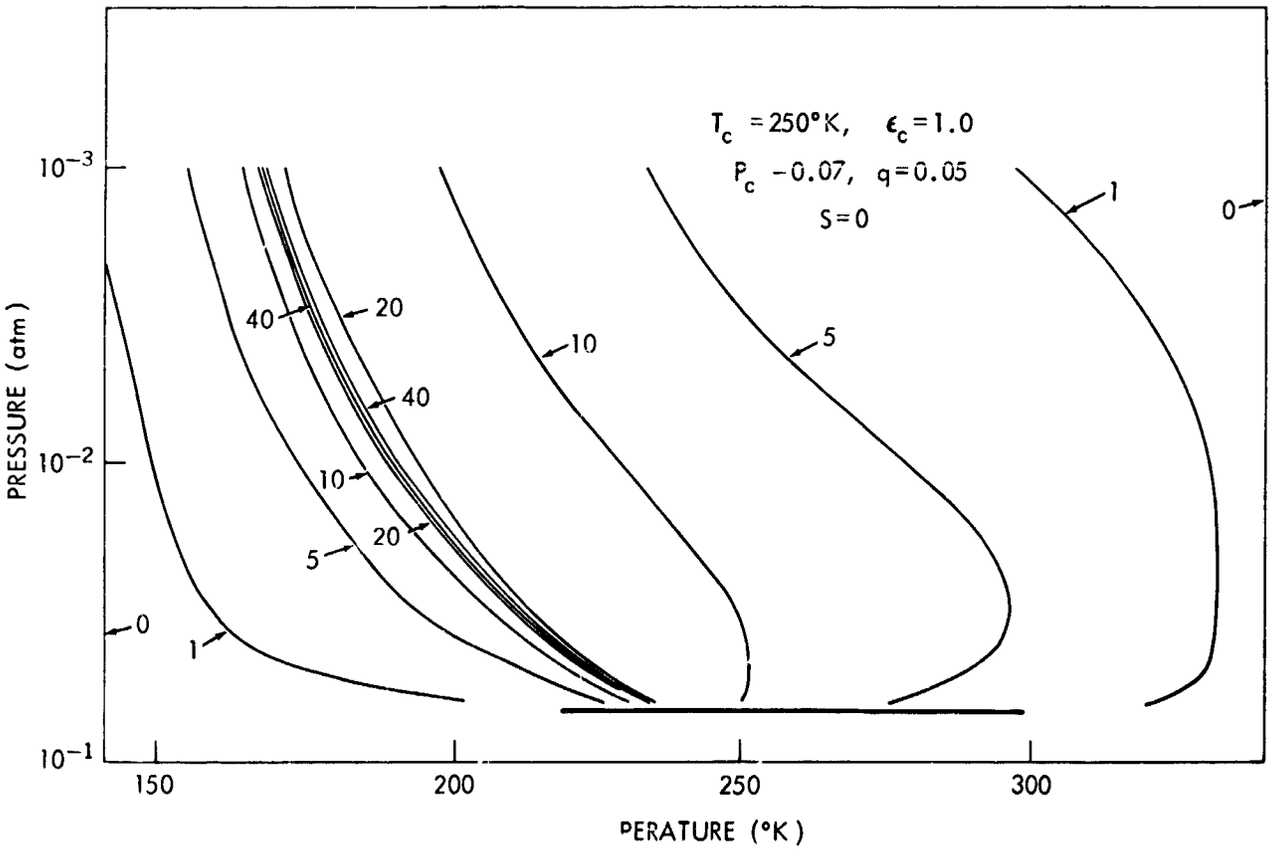

FIGURE 4.—Sample of the convergence of the iteration pr r an optically thin atmosphere. The numerals adjacent to each curve in the figure indicate the iteration numbe corresponding to each temperature distribution sl n.

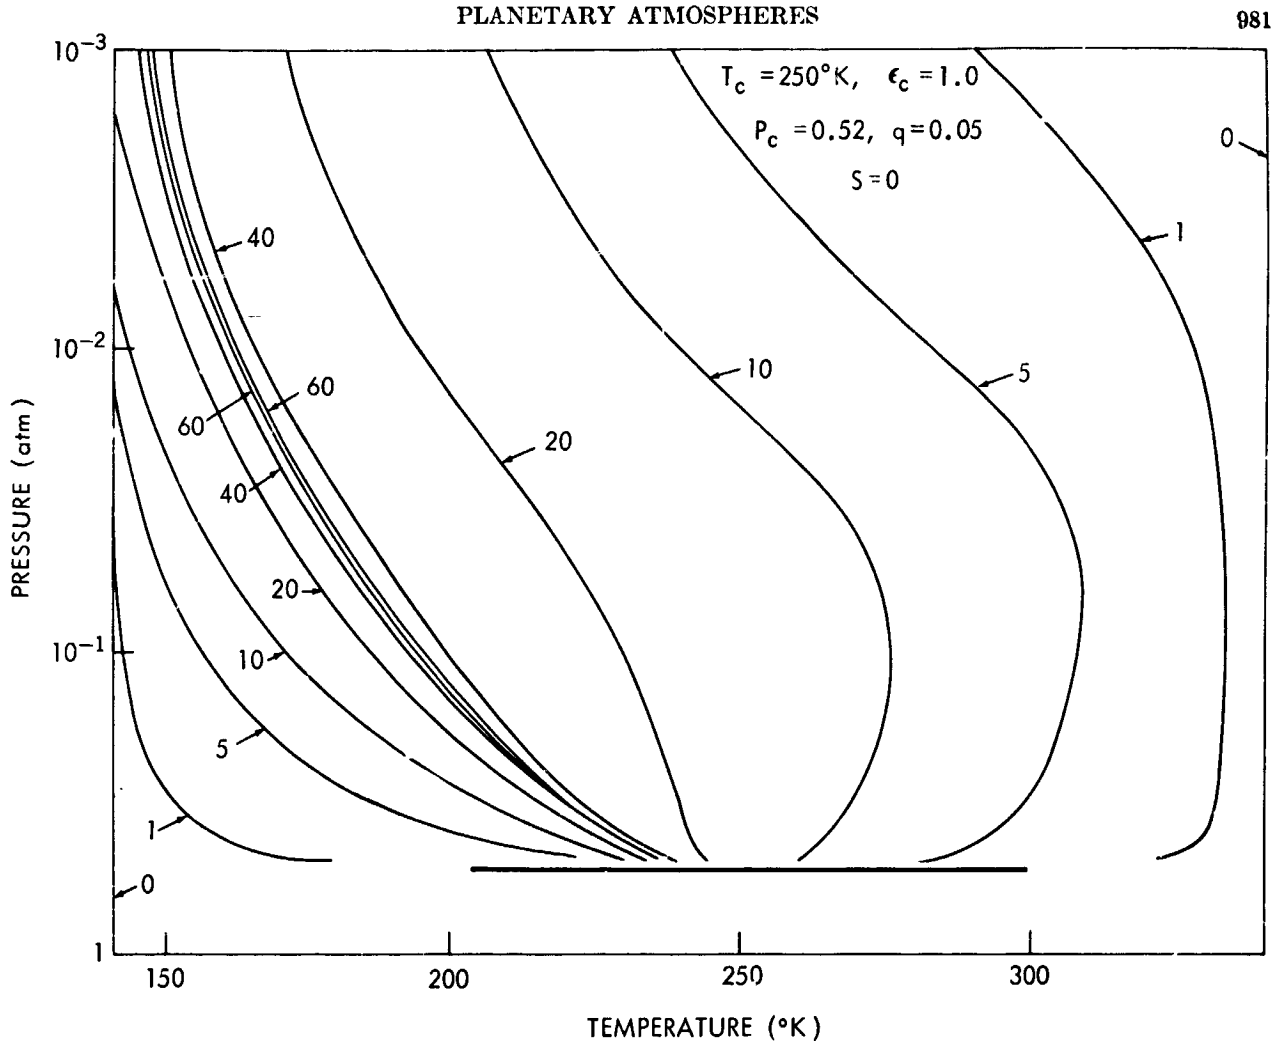

FIGURE 5.—Sample of the convergence of the iteration process for a more optically dense atmosphere than that considered in Figure 4. The numerals adjacent to each curve in the figure indicate the iteration number corresponding to each temperature distribution shown.

CO_2 (References 34–36) is still subject to discussion. The reasons for the discrepancies are manyfold, but the solution to the problem will depend on better observations and more refined interpretation of existing data.

The interpretation of the intensities measured within the atmospheric window by Sinton and Strong (Reference 16), Murray, Wildey and Westphal (Reference 17), and by Chase, Kaplan, and Neugebauer (Reference 18) clearly requires some knowledge of the temperature profile in the upper atmosphere of Venus. So far, only the black-transparent model used by Mintz (Reference 37) and the grey model used by Rasool (Reference 38) and Ostriker (Reference 39) have been applied. None of these calculations consider the strong temperature dependence of the 9.4 and 10.4μ CO_2 excited bands or the solar heating in the clear atmosphere.

It is instructive to note that early application of the grey atmospheric model to the earth's atmosphere by Humphreys (Reference 40), Gold (Reference 41), and Emden (Reference 42) yielded only crude agreement between calculations and reality. Subsequent treatments (References 5 and 43–47, for example) which included the wavelength dependence of the H_2O, CO_2, and O^3 absorption were necessary for satisfactory temperature profiles. Similarly, a more exact and detailed study of the atmosphere of Venus should give better results.

Highly developed nongrey atmospheric models (Reference 48, for example) used to describe the earth's stratosphere exist but have not been

applied to Venus. However, recent work by Arking (Reference 49) and Ohring (Reference 46) with nongrey models have been applied to the atmosphere of Mars. For Venus, the discrepancies in estimates of composition, cloud top pressure, and other parameters necessary for accurate calculations have probably discouraged the application of these models. Furthermore, CO_2 absorption coefficients for relatively large concentrations have become available only recently (References 13, 14, and 50). However, it is felt that a parametric study with a variety of values for cloud top pressure and temperature and for CO_2 concentration should improve our understanding of the physical conditions in the atmosphere of Venus. Results of the calculations can be compared with existing and forthcoming measurements, and the range of values for importar parameters then, hopefully, can be narrowed.

The effect of solar heating, carbon dioxide concentration, and assumed cloud top pressure, temperature, and emissivity, on the atmospheric temperature above the clouds can now be discussed. A number of conclusions can be drawn from this parametric study. However, the attempt to match, in detail, the calculated intensities, fluxes, and limb functions with the observations is still underway.

The pronounced effect of solar heating in the clear atmosphere is apparent in Figure 6. A realistic interpretation of planetary observations of a partially illuminated disk requires further averaging over zenith angles. The temperature maximum disappears for larger zenith angles and the temperature distribution approaches the

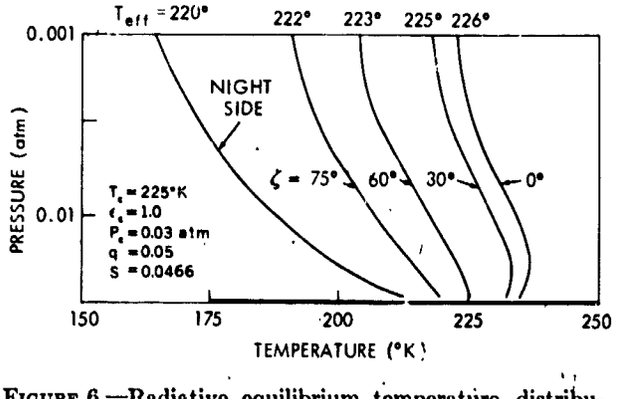

FIGURE 6.—Radiative equilibrium temperature distribution in the Venus atmosphere, illustrating the effects of solar heating for various solar zenith angles.

equilibrium condition on the dark side. Three factors make the large amount of solar heating understandable. Relative to the earth, the solar constant is nearly double; secondly, the high reflectivity of the clouds gives rise to strong reflected radiation and consequently to an additional heat source; and finally, the CO_2 concentration is much higher. The high CO_2 concentration increases the ability of the layers to cool very effectively, but at long wavelengths many spectral regions are already saturated. This atmospheric greenhouse effect is very pronounced. The near infrared absorption region considered in this discussion, spectral interval number 18 (1.25–5.9μ), would saturate at much higher pressures (between 3 and 10 atmospheres). Observations at the 8–12μ window and at 3.75μ (Reference 51) indicate essentially the same brightness temperatures in the sunlit and dark hemispheres. This is not in contradiction to the calculated large temperature differences in the clear atmosphere since the observations exist only for relatively transparent spectral regions. Larger differences are expected in moderately strong absorption regions, but unfortunately data are not available there.

The equilibrium temperatures with and without solar heating for various cloud top pressures are illustrated in Figure 7. For low cloud top pressures and consequently low optical thicknesses, the surface can be observed more readily and hence the effective temperature approaches the cloud top temperature. The discontinuity in the temperature profile near the lower boundary is characteristic of radiative equilibrium considerations in a bounded, finite atmosphere and has been discussed by several authors (References 5 and 52, for example). A more realistic representation of the cloud top which does not assume a "solid surface" will remove the discontinuity and limit the gradient to an adiabatic one. If necessary, allowance for convective as well as radiative transport of energy must be made. It can also be seen from Figure 7 that some of the calculated gradients approach and even exceed the adiabatic one near the cloud top surface. Convection would be induced and an upward transport of cloud particles would occur.

A curve which indicates saturation temperatures for CO_2 is included in Figure 7. For the conditions considered, condensation and possible

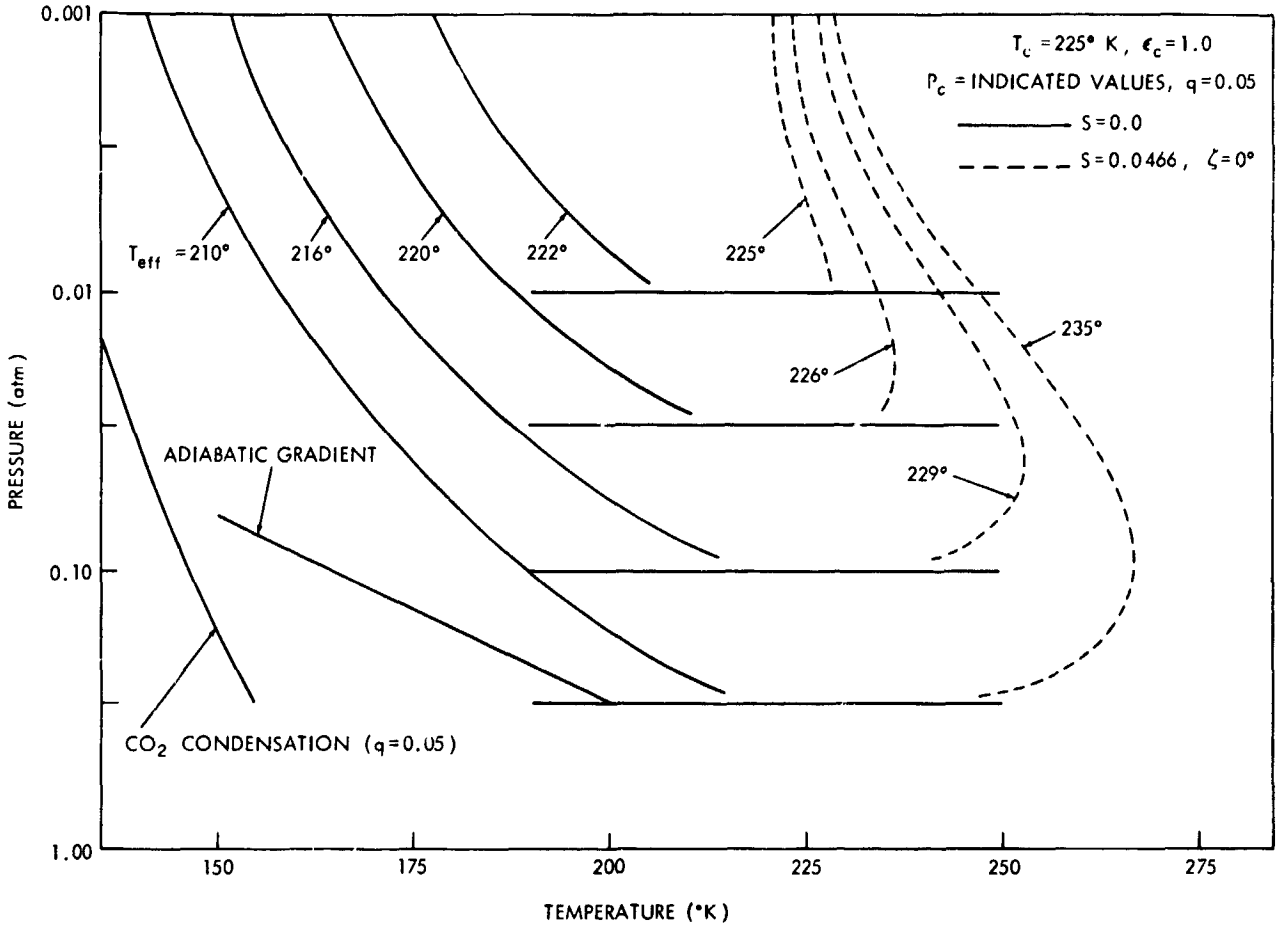

FIGURE 7.—Radiative equilibrium temperature distributions as a function of cloud top pressure level, for the dark and sunlit hemispheres.

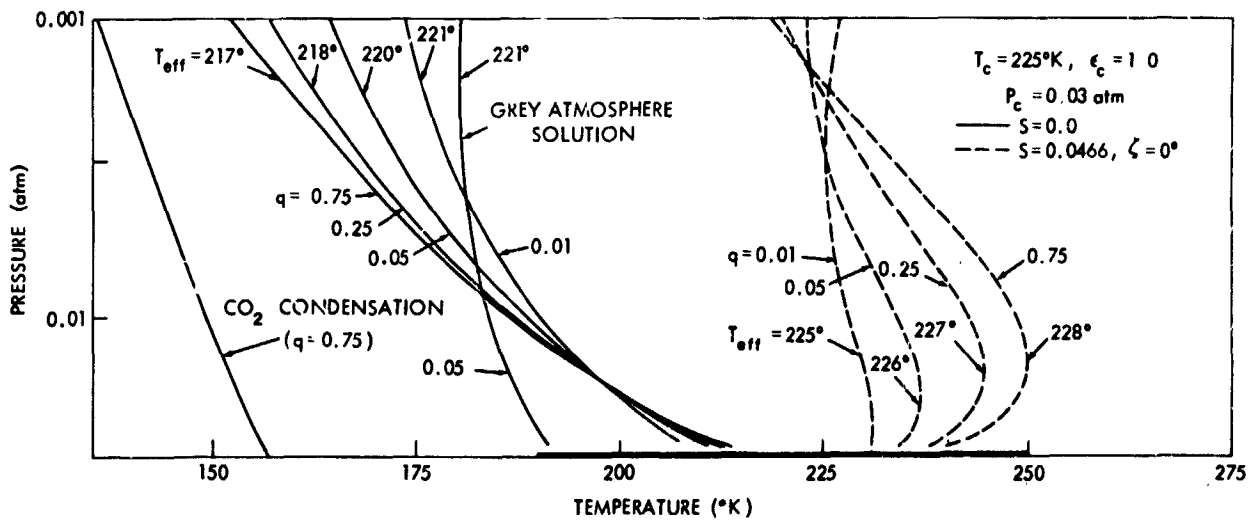

FIGURE 8.—Radiative equilibrium temperature distributions showing the effects of various CO_2 concentrations, for the dark and sunlit hemispheres.

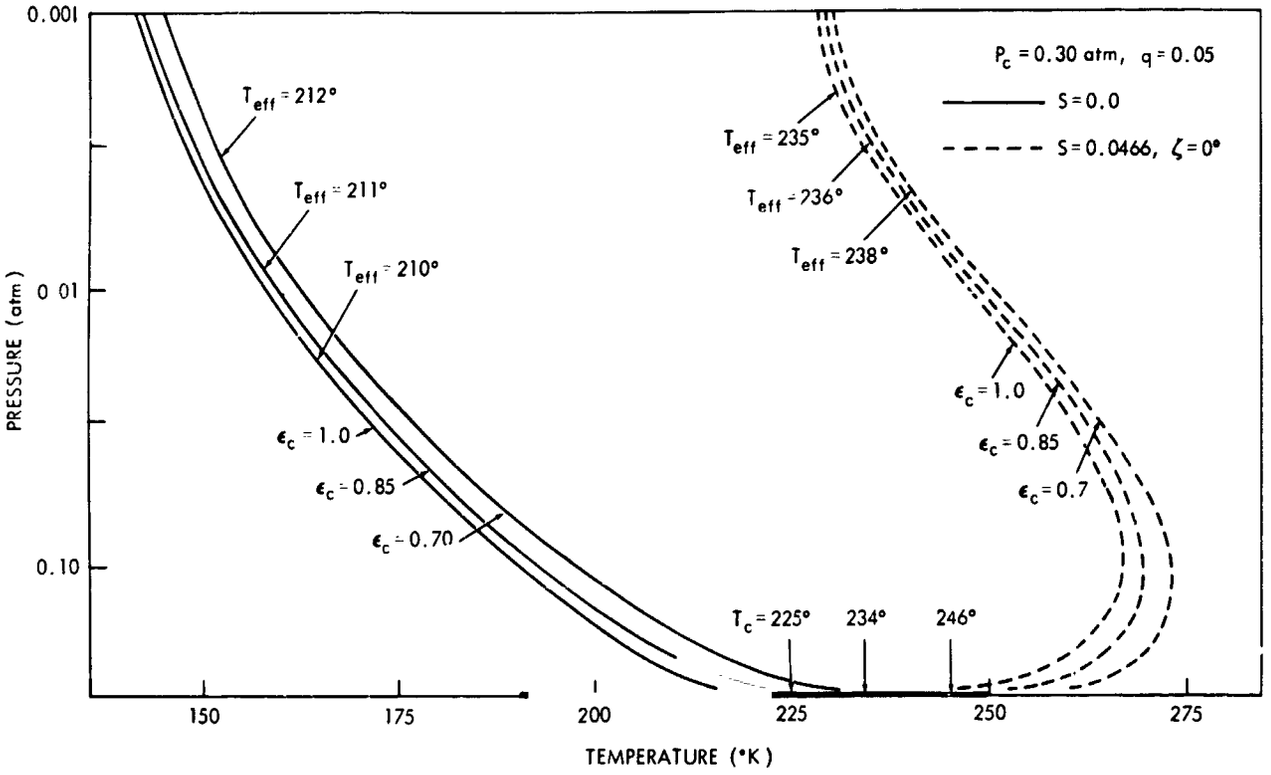

FIGURE 9.—Radiative equilibrium temperature distributions illustrating the effect of cloud top emissivity and temperature, for an almost constant net flux, for the dark and sunlit hemispheres.

formation of CO_2 clouds is unlikely. The wide spread and the slope of temperature profiles shown in Figure 7 make it difficult to extrapolate the temperatures, in detail, to much lower pressures. Caution must be exercised, especially in extrapolations to the low pressures for the occultation measurements $\approx 2.6 \times 10^{-6}$ atm (Reference 53).

The effects of CO_2 concentration on the temperature distribution (Figure 8) are different for the dark and sunlit hemispheres of the planet. On the dark side, the temperatures depend very little on the CO_2 concentration, with the exception of very high layers which can cool more effectively for the higher concentrations. The effects of solar heating have already been discussed.

The temperature distribution of a grey atmospheric model is included for comparison and clearly illustrates the difference between the isothermal character of the grey model and the larger gradients obtained by applying nongrey absorption.

The final illustration (Figure 9) demonstrates the effect of nonblackness for the cloud top surface. The total net flux is kept approximately the same for all cases by adjusting the surface temperature upwards as the emissivity is lowered. As discussed before, the value of ϵ was set equal to unity for the intervals i = 7, 8 and 16, where CO_2 absorption is strongest. In all other intervals ϵ was set equal to the value designated in the figure. The effect on the resulting temperature distribution is small.

In summary then, radiative transfer calculations, which include pressure, temperature, and wavelength dependence of molecular absorption, are a strong analytical tool for the exploration of planetary atmospheres. The full capability of this tool has by far not been exhausted. Further analysis of the spectral and angular dependence of the emitted energy is required for more specific conclusions.

ACKNOWLEDGMENTS

The authors would like to express their gratitude to the following people for their contributions to the effort presented here: Mr. A. F. Simmons, for an expertly written computer program, Mr. T. Mahuron and Miss L. Coury for numerous calculations, and Mr. W. R. Bandeen and Dr. F. Möller for helpful criticism and discussion.

MIDDLE ULTRAVIOLET DAY RADIANCE OF THE ATMOSPHERE*

J. P. HENNES, W. B. FOWLER AND L. DUNKELMAN

The day radiance of the atmosphere has been measured, photoelectrically, at two middle ultraviolet wavelengths by rocket-borne photometers. Filters and collimators provided an effective field of view of 1.4×10^{-2} steradians, and bandpasses of approximately 100A at 2600A and 230A and 2200A. At a height of 146 km, nadir radiance values of about 0.5 ergs/sec cm² ster 100A were obtained at both wavelengths. There is good agreement between the radiance values measured and those which have been calculated on the basis of single Rayleigh scattering in the presence of ozone. From the radiance data an atmospheric diffuse reflectivity of about 8×10^{-4} at 2600A has been calculated. This may be contrasted with 1957 rocket observations of Mars and Jupiter which yielded albedos at 2700A of 0.94 and 0.26 respectively.

I. INTRODUCTION

If the earth's sunlit side is viewed from space it exhibits a bright appearance in the visible portion of the spectrum. In contrast, the appearance of the sunlit earth in the ultraviolet wavelength region below about 3100A may be expected to be rather dim and relatively uniform. In the visible region the upward flux out of the atmosphere is made up of Rayleigh scattered sunlight, sunlight reflected directly from clouds or from the earth's surface, light scattered from atmospheric dust, and a relatively small amount of resonant and fluorescent scattered sunlight or day airglow. In the middle ultraviolet region from 2100–3000A, however, because of the totally absorbing ozone region located from approximately 10 to 40 km, the day radiance will be produced only by Rayleigh scattering of sunlight in the thin upper atmosphere above the ozone region and by fluorescent scattered sunlight or ultraviolet dayglow. The combination of a thin atmosphere and strong ozone absorption produces a correspondingly low albedo. The absence of contributions from reflections by clouds and surface features and the strong wavelength dependence of Rayleigh scattering will produce a relatively uniform appearance.

The spherical albedo of a planet is the ratio of the total flux emitted in all directions by the planet to the total flux incident on the planet from the sun. Both quantities are being measured over the same wavelength interval. The earth's visual, spherical albedo has been experimentally determined, by studies of earth light on the moon, to range from 0.29–0.56 depending on the season and on which side of the earth is facing the moon. The average value of these visual albedos is given as 0.39–0.40 (Danjon, 1954; Dzhasybekova, Kazachevskii, and Kharitonov, 1960). The major part of the earth's visual albedo comes from contributions by reflection from clouds. If atmospheric scattering is considered separately, assuming no clouds, calculations (Kano, 1958) show the spectral albedos due to Rayleigh scattering to be: infrared region—.0075; visible region—0.096; and near ultraviolet region—0.23. The weighted sum of these various spectral albedos for a Rayleigh atmosphere is given as 0.066 by Kano (1958) for the entire spectral region $\lambda>2900$A, and has been independently calculated by Coulson (1959) to be p. 069. The contribution in these spectral regions from airglow is negligible except over narrow wavelength intervals near the more pronounced dayglow emission lines. The uses and difficulties of dayglow measurements have been summarized recently by Chamberlain (1963).

*Published as *Goddard Space Flight Center Document* X-613-64-70, April 1964; also published in the *Journal of Geophysical Research*, 69(13):2835–2840, July 1, 1964.

The calculations which have been made for scattered solar radiation in the near ultraviolet have included multiple scatterings, ozone distributions, and upward and downward fluxes (Sekera and Dave, 1961a, and Larsen, 1959).

In the middle ultraviolet region calculations have assumed single Rayleigh scattering with ozone absorption (Ban, 1962; Hubbard, 1963; Green, 1964; and Hrasky and McKee, 1964). Multiple scattering or fluorescence has not been included. The middle ultraviolet day radiance must originate in scattering above the ozone region. This insures a relatively small flux since even the high altitude ozone distribution is strongly absorbing in this spectral region. Dalgarno (1962, 1963) and Chamberlain and Sobouti (1962) have derived equations to show the effect of non-Rayleigh resonant and fluorescent scattering near atomic and molecular resonance lines, and point out that this effect could be significant in the ultraviolet where small Rayleigh scattered fluxes are expected.

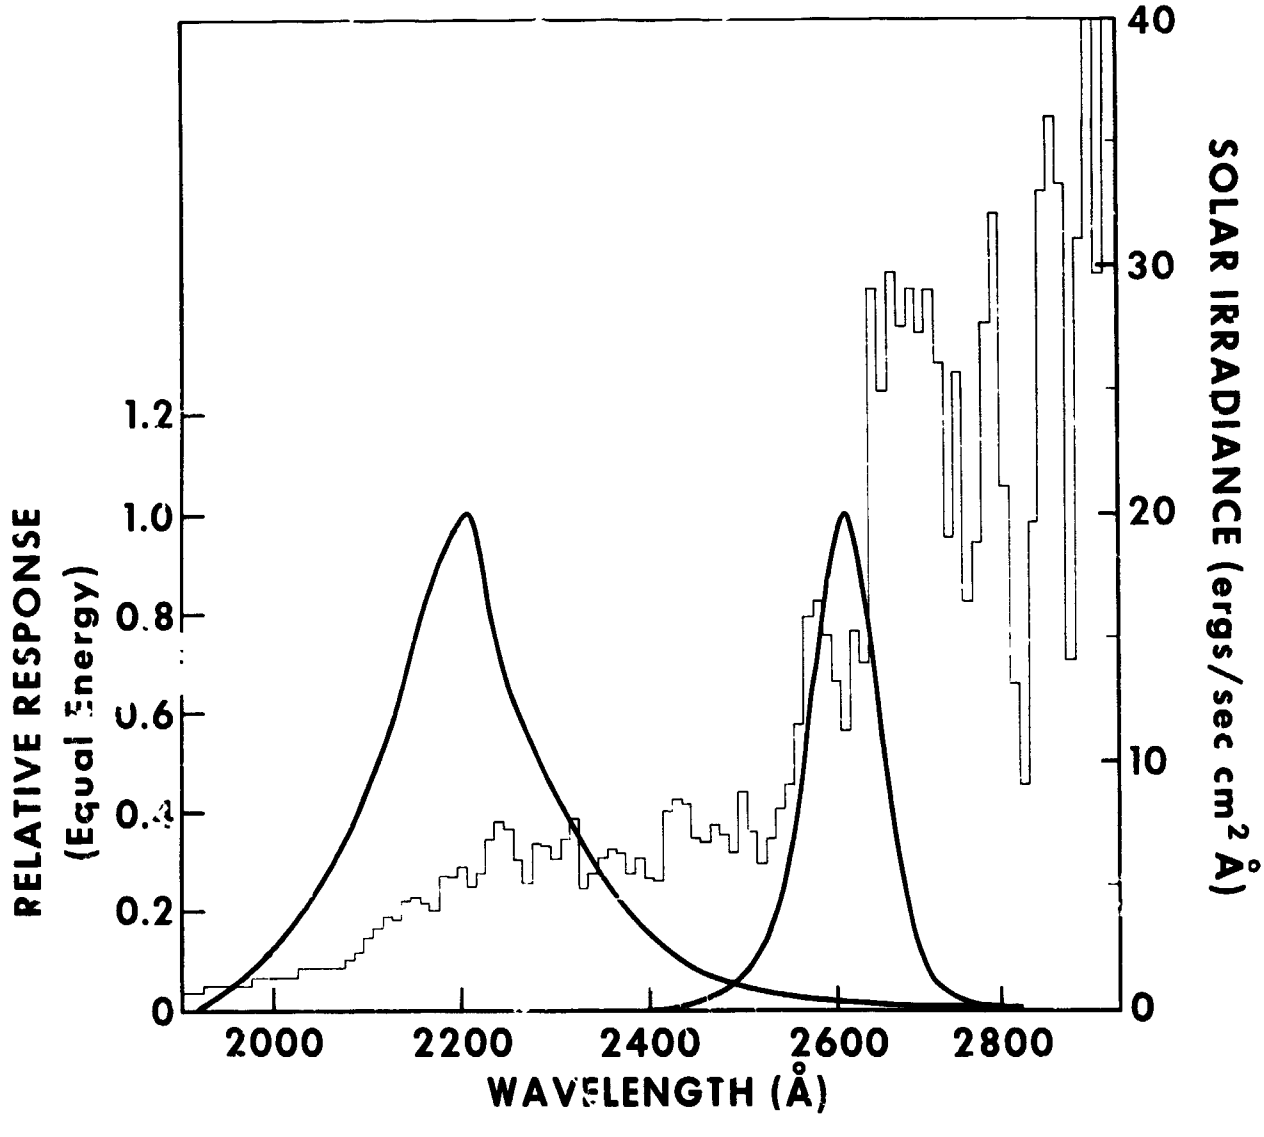

FIGURE 1.—Photometer response curves. Relative response of both photometers is shown on an equal energy basis. The solar spectrum, averaged over 10A intervals, is also shown. (Wilson et al., 1954; Malitson et al., 1960). The 2200A photometer response is provided by a combination of an interference filter and 4 mm $NiSO_4(H_2O)_6$, crystal. The 2600A photometer combines an interference filter, Corning 7-54, 4 mm $NiSO_4(H_2)_6$, Cation-X, and 2 mm Pb doped KCl:KBr crystal (Childs. 1961).

II. THE EXPERIMENT

At 1155 EST (1655 UT) on 8 August 1962 two middle ultraviolet photometers were included in an Aerobee rocket (NASA 4.60) launched from Wallops Island, Virginia. Measurements of the ultraviolet day radiance were taken continuously as the rocket climbed to a peak altitude of 150 km. Each photometer consisted of a mechanical collimator, a filter, and a photomultiplier sensitive only to ultraviolet radiation. The collimator produced an effective field of 1.4×10^{-2} ster (about a 7 degree square field). The filters were of the type described by Childs (1961). The phototubes were type EMR 541F–05 photomultipliers with sapphire windows and cesium-tellurium cathodes (Dunkelman, Fowler, and Hennes, 1962).

The relative spectral response of these photometers is given in Figure 1 on an equal energy basis (amps/watt). Also included in Figure 1 is the solar spectrum, averaged over 10A intervals, taken from data reported by Wilson, et al., (1954) and Malitson, et al., (1960). The effective wavelengths of the photometers were at 2217A and 2610A with effective bandwidths of 230A and 100A respectively. The contribution from the long wavelength region beyond 2800A has been examined and found to be much less than the magnitudes of the radiance measurements made.

During the flight the rocket pitched through a wide range of zenith angles. Its motion, however, was confined by an attitude control system to a single plane having an azimuth of 175° passing through the zenith and the sun. The sun was at a zenith angle of 22°. The photometers, which were pointed out the side of the rocket approximately in the pitch plane and at an angle of 122° with the rocket axis, swept from the nadir up to a zenith angle of about 80° in both the north and south sky at various times.

III. RESULTS

The data are shown in Figure 2 which give (curve a) the zenith angle of the photometers as a function of both flight time and altitude. The aspect data was obtained from solar sensing aspect cells, magnetometers, and the attitude control system error signals and pitch-rate signals. During the flight the rocket's attitude control system malfunctioned to the extent that, although controlled in two axis, the vehicle pitched through much larger angles than those for which the aspect instruments had been designed. Pitch rate signals were integrated to find approximate zenith angles outside of the region of aspect sensor operation. These calculations could be checked by fitting with the aspect signals as the rocket periodically moved back throu the sensor region. The photometer data, reduced from the original telemetry record at one second intervals, are shown in curves (b) and (c). Relative intensity is plotted, with the data normalized to unity for nadir (180°) values. The scatter in the relative intensity values is produced by photometer noise introduced because the signal level was near the bottom of a three-decade logarithmic scale. The photometer sensitivity in this exploratory measurement had been set low to avoid the possibility of saturation due to either unexpectedly large reflectivities or unusually intense dayglow or auroral emissions. Lines have been added to clarify the peaks beyond 260 seconds.

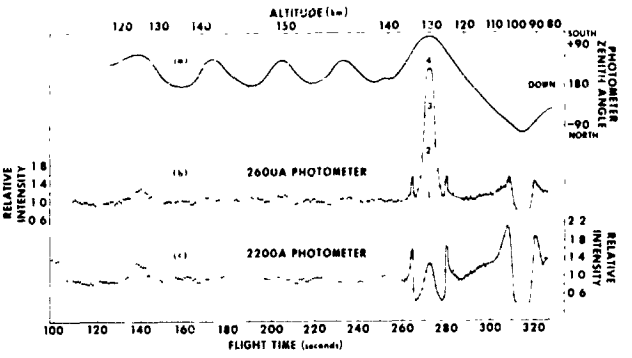

FIGURE 2.—Rocket flight data. Curve (a) is the zenith angle of the photometer direction as a function of time. Curves (b) and (c) are a sampling of the reduced telemetry data plotted in terms of the relative intensity received by the photometer. The points show scatter produced by photometer noise and a small amount of structure as a function of zenith angle. The peaks after 260 seconds correspond to the horizon limb brightening. The large peak at 273 seconds, which is extraneous, is produced by sunlight reflected off the photometer entrance with the photometers pointed above the horizon in the south. Without this sunlight effect the record would appear as it does at 310–320 seconds with the photometers pointed above the horizon in the north.

In Figure 3 the data are replotted as a function of zenith angle. Data are shown only for 10 degree intervals of zenith angle. Part of the spread in the points is due to photometer noise,

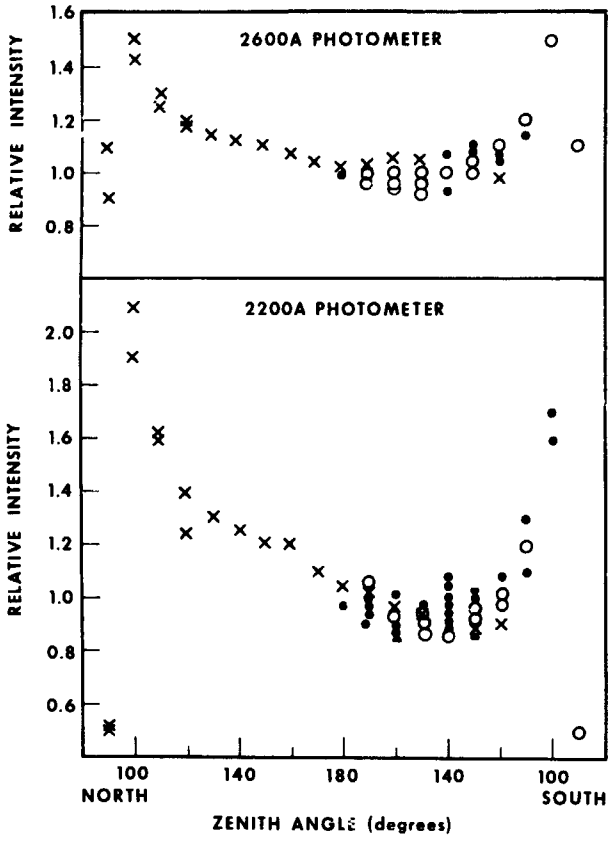

FIGURE 3.—Ultraviolet day radiance as a function of zenith angle. The data in Figure 2 are replotted here as a sampling of telemetry data taken at 10 degree intervals. The crosses indicate data taken at altitudes less than 120 km. Circles indicate data taken at altitudes above 120 km. Solid circles are single points, open circles represent several data points (2–5) occupying the same position. The limb brightening is evident.

part is due to combining data taken at the same zenith angles but from different altitudes.

The values of day radiance measured during this flight are notable for the lack of features seen over a large range of zenith angles. Even the horizon brightening is only a factor of two times the nadir radiance. The photometer field of 1.4 $\times 10^{-2}$ steradians would, of course, diminish the effect of any increased radiance that extended over only a relatively narrow field.

The peaks at about 272 seconds in Figures 2 represent direct sunlight reflected off the photometer entrance. The photometer was pointed up in the southern sky at that point at a zenith angle of about 70 degrees. The magnitude of the reflected solar signal under those conditions was determined by laboratory measurements to be about 10^{-5} that of direct sunlight. Note that this scattered light signal is still larger than the earth radiance signal. The problem of making measurements in the presence of direct sunlight is emphasized by this result.

The magnitude of the radiances detected by the photometers is expressed in Table 1. The nominal effective wavelength and the effective band width are given. The third column gives the earth's radiance, at the nadir, with the sun at 22° zenith angle, assuming a uniform and equal distribution across the wavelength region described by the effective bandwidth. The equivalent photon emission rate in kilo-rayleighs per 100A is also given. The day radiance values determined by these measurements have uncertainties of about 10–15 percent arising from noise in the photometer signal and uncertainties in ultraviolet radiometric standards.

The last column gives the diffuse spectral reflectivity of the earth's sunlit atmosphere averaged over each of the wavelength intervals. This number is arrived at by assuming the scattered sunlight has the same spectral distribution as the incident sunlight throughout each bandwidth (see Figure 1). The values of solar irradiance are taken from the sources cited. The uncertainties in the calculated reflectivities are greater than

TABLE 1.—*Ultraviolet Day Radiance Measurements of the Earth Taken 8 August 1962, at 146 km, with Photometers Pointed at the Nadir; Solar Zenith Angle 22°.*

Nominal Wavelength (A)	Effective Bandwidth (A)	Radiance (ergs/sec cm² ster 100A)	Emission (kilorayleigh/100A) Rate	Diffuse Reflectivity
2600	100	0.5	8×10^{2}	8×10^{-4}
2200	230	0.5	7×10^{2}	3×10^{-3}

those for our observed radiance values by the amount of uncertainty in published absolute spectral solar intensities. If we make the further assumption that the entire earth is a diffuse Lambert reflector, then the diffuse reflectivity of about 8×10^{-4} at 2600A becomes the earth's spherical albedo. This number can be contrasted with the earth's total observable spherical albedo of 0.39–0.40, and with the calculated Rayleigh scattered albedo contribution in the near ultraviolet of 0.23 as given in the introduction.

Of interest also is a comparison of the earth's low middle ultraviolet effective albedo with measurements of the relatively high effective albedos of Mars and Jupiter made in 1957 with a photometer of about 300A bandwidth centered at 2700A (Boggess and Dunkelman, 1959). They obtained values of about 0.24 for Mars and 0.26 for Jupiter.

One other known experimental observation has been made of the middle ultraviolet day radiance. Friedman, Rawcliffe, and Meloy (1963) have reported a satellite borne photometer measurement of the day radiance with a spectral pass band of 140A centered at 2550A. Their result, with the sun at a zenith angle of 49° and the detector pointed at the nadir with a field of 1.2×10^{-4} steradian, showed an atmospheric radiance of 2.0 ± 0.3 ergs/sec cm^2 ster 100A.

Table 2 gives the various measured and calculated middle ultraviolet day radiance values. The calculated values tend to support our results rather well. It should be borne in mind that the data were all taken or calculated using different parameters of altitude, solar zenith angle, ozone distribution, season, etc. so that the results cannot be compared too directly. The relatively large factor of four between the experimental results of Friedman, Rawcliffe and Meloy and ourselves is possibly explained by either a large change in the high altitude ozone distribution between the time of the two measurements or the difficulties in maintaining calibration during the preparations for and launching of a satellite. The similarity of the various calculations and our measurements indicate that the simple approach to ultraviolet atmospheric radiance calculations, involving use of ozone distributions and single scattering with plane atmospheres (Ban, 1962; Hubbard, 1963; and Green, 1964) or spherical atmospheres (Hrasky and McKee, 1964) is adequate for broadband measurements. If higher spectral resolution were to be considered the agreement might be strongly affected by resonant or fluorescent scattering.

The calculated results depend very strongly on ozone distribution, especially in the region around

TABLE 2.—*Comparison of Measured and Calculated Nadir Ultraviolet Day Radiance Values. Radiance in ergs/sec cm² ster 100A.*

Source	2600A Region		2200A Region		Solar Zenith Angle

(a) Values estimated or rounded off from data published by the referenced authors.
(b) Measured values.
(c) Calculated values.
(d) A range of 0.05—0.8 is estimated depending on the ozone distribution chosen. The radiance listed is taken from Figure 14 representing a "standard" ozone curve.
(e) A range of 0.15—0.6 is estimated depending on the ozone distribution chosen. The radiance listed is taken from Figure 6 representing an analytical fit to the same "standard" ozone curve as used by Hubbard.

the peak of the ozone absorption curve at 2600A where the very high altitude ozone has a dominant role. The ozone distribution at higher altitudes is relatively unknown, however, so that appreciable uncertainties may be introduced into the calculated values. At the shorter wavelength region around 2200A and at longer wavelengths beyond 2800A the ozone is much less absorbing and incident solar radiation will penetrate more deeply into the atmosphere, thus permitting more scattering and producing higher albedos. By use of satellite-borne photometers with narrow spectral bandpasses, well removed from strong dayglow emission lines, and situated at various middle ultraviolet wavelengths from 2100 and 3000A, a profile of high altitude ozone distribution should be obtainable. Such an idea was proposed in 1957 by Singer and Wentworth (1957), who considered only wavelengths at 2800 and 3000A. Twomey (1961) carried out further calculations in this same wavelength region. The calculations in the near ultraviolet above 3000A have been considered in detail by Sekera and Dave (1961b). The altitudes above 50 km would require, however, use of wavelengths below 2800A where analysis should be much easier. The seasonal and latitudinal variations in upper atmosphere ozone, so important to atmospheric heating processes, would thus be available.

ACKNOWLEDGEMENT

We wish to express our appreciation to William Russell, Jr. of this Center who graciously provided support and the space for this experiment on one of the rockets under his supervision.

LYMAN-α RESONANT SCATTERING USING RANDOM STOKES VECTORS*

S. O. KASTNER

N64-28742

The case of relatively few scatterings of Lyman-α resonance radiation in a uniform hydrogen gas is treated by using Stokes vectors as random variables in a Monte Carlo type of calculation. Doppler redistribution of frequencies and the doublet nature of the line are taken into account.

INTRODUCTION

In radiative transfer problems in which the number of scatterings is low, the nature of the individual scattering process becomes important, i.e. whether isotropic or anisotropic. Lyman-α resonance scattering is an example in which one line component scatters isotropically, the other anisotropically.

We describe here a use of random Stokes vectors in a Monte Carlo type of calculation, to obtain the fluxes of Lyman-α radiation at various levels in a uniform (density and temperature) atmosphere of hydrogen atoms. The method incorporates Doppler redistribution of frequencies, and takes account accordingly of the fact that a photon may be scattered by either of the components of the Lyman-α doublet in the course of its flight. The polarization at each level could also be obtained from the same calculation, if required, by adding up the Stokes vectors. A non-uniform atmosphere was initially attempted, but pointed up a problem in that the mean free path of a photon becomes anisotropic and the anisotropy varies with level.

The interest in this approach stemmed from the possibility of its application to upper atmosphere night glow and similar phenomena in which the intensities, frequencies and polarization of the radiation may be sampled directly by rocket instruments as a function of altitude.

DESCRIPTION OF GENERAL APPROACH

A convenient way to characterize a beam of photons is by the Stokes vector, whose four components describe its intensity and state of polarization completely. The scattering of a photon may then be described by a scattering matrix operating on its Stokes vector to produce a new Stokes vector. If the photon suffers a subsequent scattering, the process is repeated on the new stokes vector, after first taking account of the fact that the coordinate system has changed. McMaster[1] gives an example of this in double Compton scattering.

The scattering matrix for resonant scattering is given in a general form by Chandrasekhar.[2] This is specialized to the Lyman-α case by putting in the appropriate atomic constants. There are two scattering matrices involved in Lyman-α scattering, because two transitions are involved, one isotropic and the other anisotropic.

Successive scatterings of this kind are set up in the present calculation. An incident photon (specified Stokes vector) is injected into the plane parallel atmosphere of H atoms. Its frequency is randomly picked within an assumed Doppler profile, and its direction of incidence may be either randomly picked from an isotropic distribution or chosen at a fixed angle.

The photon encounters an H atom every mean free path λ, where

$$\lambda = \frac{1}{N\sigma},$$

N being hydrogen number density, σ the cross-section for resonant scattering. However, it is not actually scattered if its frequency relative to the H atom is not the same as either one of the two Lyman-α components. It continues on until it does encounter an H atom such that its relative

*Published as *Goddard Space Flight Center Document X-614-64-165.*

frequency lies within the natural width of either of the two Lyman-α components; its Stokes vector is then multiplied by the corresponding scattering matrix. The direction of the scattered photon is decided on the basis of the intensity distribution given by the first two components of the Stokes vector.

(The atom absorbing a photon at any frequency within the natural width is made to re-emit the photon at only the center frequency. This corresponds to an arbitrary kind of redistribution. Actually, when a given atom is illuminated by a line broader than its natural width, its scattering redistributes the radiation over the natural width Heitler.[3] The natural width is negligible compared to the line width here, however.)

This process is repeated for the scattered photon so that successive scatterings are undergone, and the photon describes a random walk in the medium. The medium is divided into 100 zones, and a count of positive and negative flux is kept for each zone.

When the photon escapes from the prescribed region, either forward or backward, a new photon is injected.

DETAILS OF CALCULATION

[a] Photon Path

The medium is taken to extend from $z=0$ to $z=1$ and is infinite in the x, y directions. Photons are injected at $z=0$. The i-th collision-free path of a given photon has the direction cosines (l_i, m_i, n_i). The first scattering results in a scattering direction (l_2, m_2, n_2) which makes an angle θ with the incident direction (l_1, m_1, n_1) and has azimuthal angle φ (Cashwell and Everitt,[4] Ch. VII): θ and φ are chosen as in section (c) below. In subsequent scatterings the scattering angle θ is obtained by the procedure of section (d).

[b] The Lyman-α Scattering Matrix

The general resonant scattering matrix is given by Chandrasekhar[2] as:

$$T=\begin{vmatrix} (\frac{3}{4}E_1\cos^2\theta+\frac{1}{2}E_2) & \frac{1}{2}E_2 & 0 & 0 \\ \frac{1}{2}E_2 & (\frac{3}{4}E_1+\frac{1}{2}E_2) & 0 & 0 \\ 0 & 0 & \frac{3}{2}E_1\cos\theta & 0 \\ 0 & 0 & 0 & \frac{3}{2}E_3\cos\theta \end{vmatrix}$$

in which θ is the scattering angle and the constants E_1, E_2, E_3 depend on the particular energy levels involved.

In the case of Lyman-α, the transitions involved in resonant scattering are $(1s^2S\frac{1}{2}-2P^2P\frac{1}{2})$ and $(1s^2S\frac{1}{2}-2p^2P\frac{3}{2})$. For the first, $j=0$, initial $j=\frac{1}{2}$, and for the second $j=+1$, initial $j=\frac{1}{2}$. The constants E_1, E_2, E_3 are therefore respectively (0, 1, $\frac{2}{3}$) and ($\frac{1}{2}$, $\frac{1}{2}$, $\frac{5}{6}$).

[c] The First Scattering

The incident Stokes vector, which is multiplied by the scattering matrix T, is:

$$S_0=\begin{vmatrix} I_l^0 \\ I_r^0 \\ U^0 \\ V^0 \end{vmatrix}$$

(The relation between this set of components and the alternative set used by McMaster is discussed by Van de Hulst.[5] The component V does not mix with the others in the scattering process so that we can work with the first three components only throughout the calculation. It will be seen that U does get mixed with I_l and I_r in successive scatterings, however.

The scattered photon has its Stokes vector given then by

$$S_1=TS_0$$

If S_0 is the Stokes vector for natural (unpolarized) light,

$$S_0=\begin{vmatrix} \frac{1}{2} \\ \frac{1}{2} \\ 0 \end{vmatrix}$$

the first scattering gives a Stokes vector S_1 which is a function only of the scattering angle θ:

$$S_1=\begin{vmatrix} \frac{3}{4}E_1\cos^2\theta+\frac{1}{2}E_2 \\ \frac{3}{4}E_1+\frac{1}{2}E_2 \\ 0 \end{vmatrix} \equiv \begin{vmatrix} I_l' \\ I_r' \\ U' \end{vmatrix}$$

The probability of the photon actually being scattered at an angle θ_1 is taken to be proportional to the intensity sum $I_l'+I_r'$; θ_i is chosen randomly within this probability distribution by the Von Neumann device described by Cashwell and

Everitt.[4] The azimuth angle φ of the scattered photon is chosen at random within the interval $(0-2\pi)$.

[d] Subsequent Scatterings

Because the plane of the second scattering is rotated in general by an angle χ about the direction of incident propagation with respect to the plane of the first scattering, the Stokes vector S_1 is transformed by a matrix $M(\chi)$, where

$$M(\chi)=\begin{vmatrix} \cos^2\chi & \sin^2\chi & \frac{1}{2}\sin 2\chi \\ \sin^2\chi & \cos^2\chi & -\frac{1}{2}\sin 2\chi \\ -\sin 2\chi & \sin 2\chi & \cos 2\chi \end{vmatrix}$$

into a vector:

$$S_1'=\begin{vmatrix} \cos^2\chi(\frac{3}{4}E_1\cos^2\theta+\frac{1}{2}E_2)+\sin^2\chi(\frac{3}{4}E_1+\frac{1}{2}E_2) \\ \sin^2\chi(\frac{3}{4}E_1\cos^2\theta+\frac{1}{2}E_2)+\cos^2\chi(\frac{3}{4}E_1+\frac{1}{2}E_2) \\ -\sin 2\chi(\frac{3}{4}E_1\cos^2\theta+\frac{1}{2}E_2)+\sin 2\chi(\frac{3}{4}E_1+\frac{1}{2}E_2) \end{vmatrix} \equiv \begin{vmatrix} S_1'(1) \\ S_1'(2) \\ S_1'(3) \end{vmatrix}$$

multiplying this by T gives the resultant scattered Stokes vector S_2:

$$S_2=\begin{vmatrix} (\frac{3}{2}E_1\cos^2\theta+\frac{1}{2}E_2)S_1'(1)+(\frac{1}{2}E_2)S_1'(2) \\ \frac{1}{2}E_2\,S_1'(1)+(\frac{3}{2}E_1+\frac{1}{2}E_2)S_1'(2) \\ (\frac{3}{2}E_1\cos\theta)S_1'(3) \end{vmatrix} \equiv \begin{vmatrix} S_2(1) \\ S_2(2) \\ S_2(3) \end{vmatrix}$$

photons. Fig. 1 is a simplified flow chart of the program.

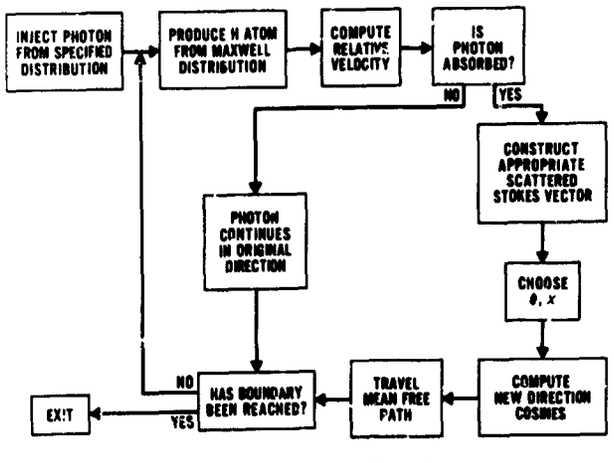

FIGURE 1.—Simplified flow chart.

To find an actual angle θ_2 resulting from the second scattering, the Von Neumann device is again used on the probability distribution

$$p^\theta=S_2(1)+S_2(2)$$

after first randomly choosing χ in the interval $(0-2\pi)$. (The assumption is thereby made that the plane of the second scattering is randomly related to that of the first).

[e] Computer Program

A computer program was written by C. Wade to carry out the calculation. It includes provision for injecting either a unidirectional beam at any specified angle, or isotropically incident

RESULTS AND DISCUSSION

A uniform plane-parallel atmosphere of hydrogen atoms at temperature 500°K, and of 500 km thickness, was taken as the medium on which to run the calculation. Two densities were successively assumed, 1.0×10^5/cc and 2.0×10^5/cc, and with each density two different isotropically incident radiation profiles were used, corresponding to Doppler temperatures T_D of 500°K and 5000°K. The curves of Fig. 2 were obtained for the four cases, each representing results for about 5000 photons. (A computer run for 5000 photons was about one half hour long). The ordinate represents the relative number of photons passing forward through a given plane in the atmosphere specified by the abscissa. Since all photons crossing a given plane are counted, the number corre-

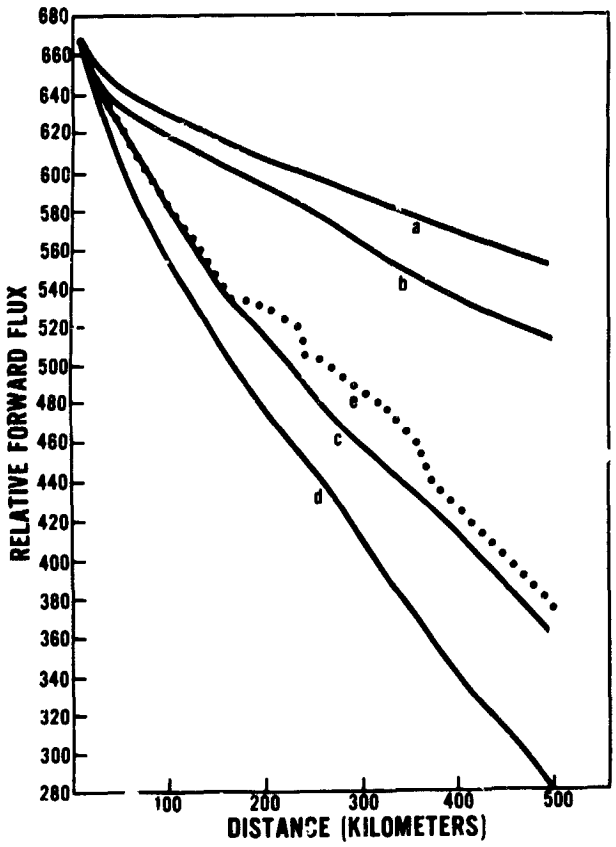

FIGURE 2.—Relative flux distributions.

sponds to the hemispheric flux πF of transfer theory, or to photometric radiancy.

The dotted curve represents the results of case (*c*) for a smaller sample of 1000 photons. The curve (*c*) for 5000 photons departs somewhat from the dotted curve, showing that "statistical equilibrium" has not yet been completely reached. Further runs were not made, however, because the models considered here are not of interest in themselves.

The average number of scatterings per photon in each case was: (*a*) 0.67, (*b*) 1.28, (*c*) 1.96, (*d*) 3.43. The reflection coefficients or albedos were: (*a*) 0.18, (*b*) 0.23, (*c*) 0.46, (*d*) 0.58. Broadening of the incident frequency profile gives greater transparency of the atmosphere to the radiation, as expected, while the two-fold increase in atmospheric density gives greater opacity.

An analytic treatment of the problem would involve the solution of a system of transport equations,[6] with a kernel which incorporates both the resonant scattering matrix and the Doppler redistribution in frequency.[7] The difficulty of this analysis precludes a complete check of the results, but at the same time is an argument for the convenience of the present method.

It may be that the use of a simpler scattering process, i.e. scattering by a single $1s-2p$ transition, would give essentially the same results.

SUMMARY

The use of Stokes vectors as random variables appears to be an effective way of handling some radiative transfer problems. We have applied the method here to Lyman-α scattering in a uniform gas of hydrogen atoms, of density low enough that few scatterings occur. It may be possible, with further work, to extend it to the case of a non-uniform atmosphere.

The same calculation can also, if required, give the frequency, profile and the polarization of the radiation at any level if the frequencies and Stokes vectors are recorded.

INFRASONIC WAVES FROM THE AURORAL ZONE*

KAICHI MAEDA AND TOMIYA WATANABE†

Pulsating aurorae are proposed as a source of the infrasonic waves associated with geomagnetic activity reported by Chrzanowski et al. One of the most plausible generation mechanisms of these long period pressure waves is the periodic heating of the air around 100 km, corresponding to the auroral coruscation reported by Campbell and Rees. In order to show the energetic relationship between source input and pressure change at sea level, some theoretical calculations are performed by using a simple model of auroral distribution in the isothermal atmosphere.

INTRODUCTION

The purpose of this paper is to interpret the origin of the strange traveling atmospheric waves observed at the ground during intervals of high geomagnetic activity (Reference 1). In particular, discussion centers on possible modes of atmospheric oscillations caused by the periodic bombardment of auroral particles in the polar mesosphere.

Trains of the waves are detected by a system of four microphones placed on each corner of a quadrant roughly 8 km square, located north of Washington, D. C. The presence of a traveling wave is established when the same wave forms can be found on all four records with certain time shifts between them. These time displacements are used to determine the direction of wave propagation and the horizontal phase velocity of the waves. The periods of these infrasonic waves are usually 20 to 80 sec, but occasionally 100 to 300 sec waves are recorded. The pressure amplitude ranges from about 1 to 10 dynes/cm^2.

One of the peculiar features of these waves is the change of arrival direction with time of day. The general trend is from the northeast in the evening, from the north about midnight, and from the northwest in the morning. The shift back to northeast is somewhat discontinuous. These waves occur less frequently in the daytime.

Since auroral activity predominates at about midnight local time, the time dependence of the appearance of infrasonic waves during intervals of high geomagnetic activity can be explained by assuming that the source of this kind of wave is located somewhere in the auroral region, as can be seen from Figure 1. The left side of this figure shows the diurnal variation of the arrival of sound waves during magnetic storms, reported by Chrzanowski et al. (Reference 1). This assumption is consistent with the finding that the enhancement of the wave intensity at Washington, D. C. is generally delayed several hours after the increase of geomagnetic activity, except in the case of very severe magnetic storms. During these storms the delay is less than 30 minutes, indicating southward spread of the source of these waves near Washington, D. C.

In attempting to understand these peculiar pressure waves, it is proposed that they originate from a certain domain of the ionospheric region in the auroral zone which is heated periodically by a severe bombardment of auroral particles. It is thought that this periodic precipitation of auroral particles occurs simultaneously with geomagnetic pulsations.

INTERRELATIONS BETWEEN GEOMAGNETIC FLUCTUATIONS, PULSATING AURORAE, AND INFRASONIC WAVES

The auroral luminosity often fluctuates with incoming auroral particles. The fluctuations of these particles, mostly electrons, can be explained by either a periodic change in the acceleration mechanism of incident particles or by the change of mirror heights of trapped particles in the earth's atmosphere, following the variations of the field intensity of the earth's magnetosphere. The variations of geomagnetic field intensity and of auroral brightness are therefore closely related. A clear example of the correspondence between

†University of British Columbia.

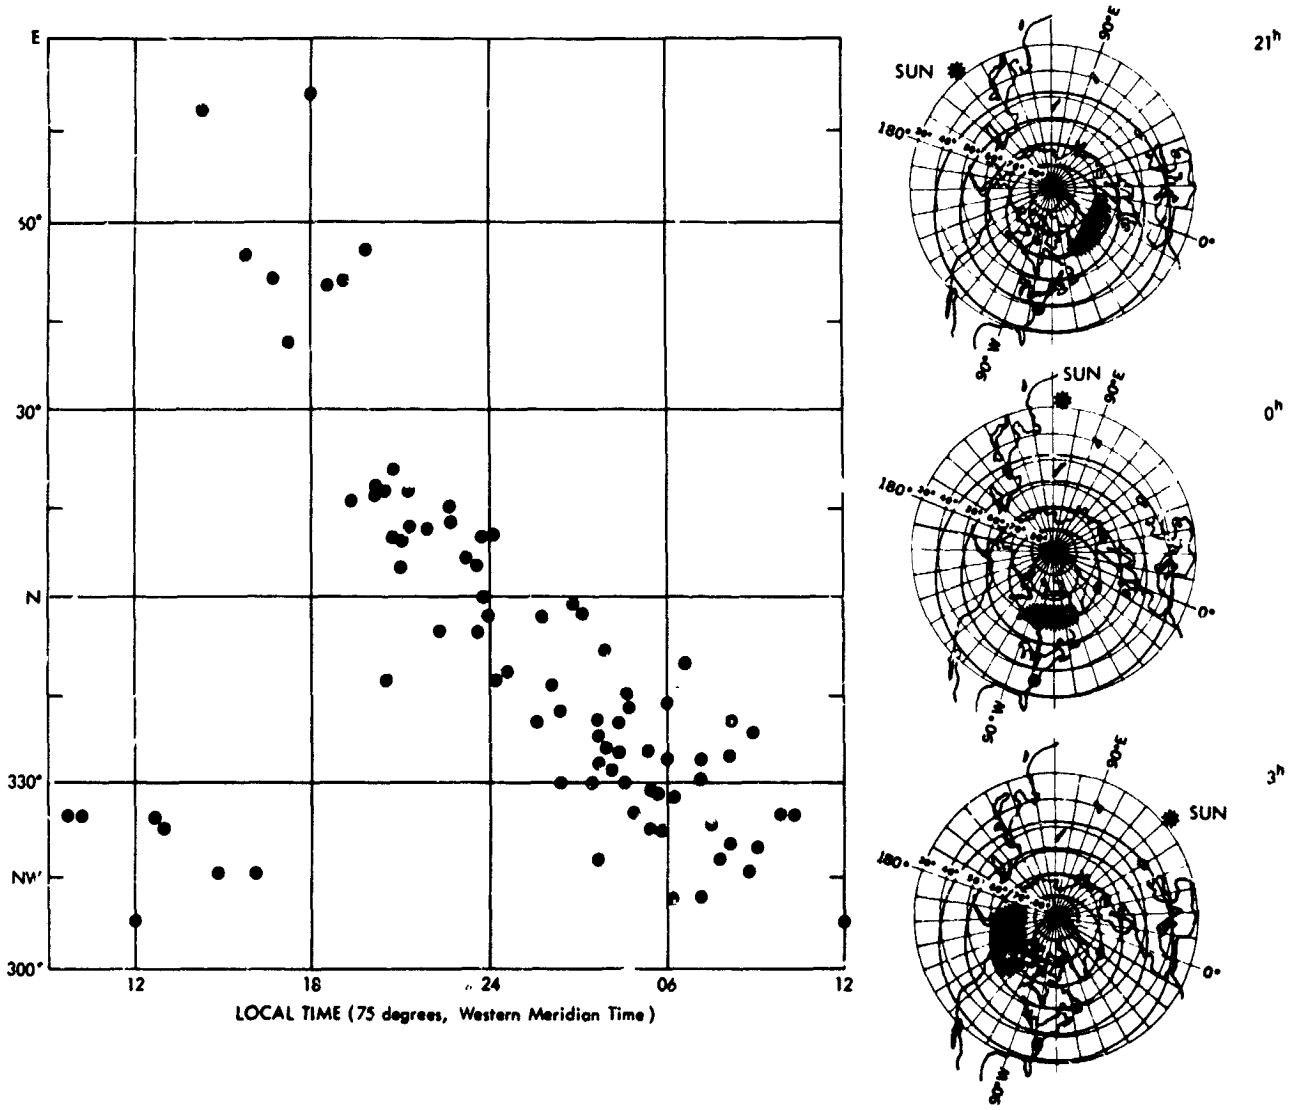

FIGURE 1.—Diurnal variation of the arrival direction of infrasonic waves during magnetic storms observed at the National Bureau of Standards, Washington, D.C. The three figures on the right indicate the shifts of the source of the pressure waves, corresponding to the movement of auroral activity.

the pulsating aurorae and the rapid variation of geomagnetic intensity observed at the ground has been given by Campbell (Reference 2).

According to the analysis of the space probe data given by Sonnet et al. (Reference 3), and that of Explorer X (1961 κ1) given by Heppner et al. (References 4 and 5), the region near the geomagnetic equator beyond about 10 earth radii is occasionally greatly disturbed. Such disturbances may be propagated along the magnetic lines of force as hydromagnetic waves, and are transformed into electromagnetic waves when they reach the conducting ionosphere (References 6–8). After penetrating the ionospheric region as electromagnetic waves, they are almost perfectly reflected at the earth's surface (Reference 9). This produces standing hydromagnetic waves along magnetic lines of force. The simplest mode of such standing waves is the fundamental mode, whose unique node is on the geomagnetic equatorial plane, with two loops of oscillation on the ends of the line of force on the earth, one in each hemisphere. This mode of oscillation has been investigated theoretically by Dungey (Reference 10), who called it the normal mode of torsional oscillations of the magnetic field in the earth's cavity. The eigen period of these oscillations increases rapidly with the latitude of the magnetic

line of force intersecting the earth's surface, varying from several tens of seconds in the subauroral region to about 10 minutes in the polar region (References 11–13).

In addition to the above mode, there is another mode of oscillation responsible for geomagnetic pulsations of shorter periods. As noted by Dessler (Reference 11), the velocity of Alfvèn waves decreases very rapidly with decreasing height in the exospheric region below around 2,000 km. Therefore, because of the continuity of energy flow Alfvèn waves of certain periods coming from the outer exosphere can be expected to be intensified. In this mode of oscillation, the layer of maximum Alfvèn velocity, approximately between 1500 and 3000 km, becomes the node of oscillation, and the loop of oscillation is near the earth's surface. This mode of hydromagnetic oscillation corresponds to the geomagnetic pulsations with periods from about 1 to several seconds, which appear more frequently in nighttime than in daytime (Reference 15).

In considering the above facts, it might be speculated that a possible mechanism for the production of infrasonic waves during auroral activity would be the penetration of Alfvèn waves, including modified Alfvèn waves and retarded sound waves (Reference 13), through the ionosphere. However, as will be shown later, these contributions are very small compared with the pressure disturbances produced by the periodic heating of the lower ionosphere caused by auroral bombardments.

As shown by Heppner (Reference 16) auroral activity predominates around midnight local time and the active region extends towards lower latitudes with increasing activity; pulsating aurorae appear at this phase of auroral activity. In other words, among several types of auroral displays pulsating aurorae appear with the largest disturbance in energy and they occur in fairly low latitudes.

According to Campbell and Ress (Reference 17) the peak of pulsating aurorae is around 100 km, the bottom is at 90 km, the effective thickness is of the order of 20 km, and the most frequent period is from 6 to 10 sec. From the direct measurement of auroral particles by means of rocket borne detectors, the energy flux of auroral particles, mostly electrons, is of the order of several tens of ergs/cm²–sec at weak aurora and increases by more than a factor of 50 at bright aurora (Reference 18). Thus, the energy flux in a strong pulsating aurora can be estimated to be of the order of 10^3 ergs/cm²–sec or more. This figure is consistent with the estimate given by Chamberlain (Reference 19), based on measurements of auroral luminosity.

On the other hand, the energy flux of hydromagnetic waves deduced from the magnetic pulsation data is less than 10 ergs/cm²–sec below 200 km. The energy flux of hydromagnetic waves increases with height. However, the contribution to pressure waves in the lower atmosphere decreases with the increasing height of the source, as will be shown later.

Another evidence for the present idea is the very good correspondence between the appearance of pulsating aurorae and that of infrasonic waves (Figure 2). The occurrence of pulsating aurorae shown on the right of Figure 2 is taken from the visoplot of auroral activity, reported by IGY

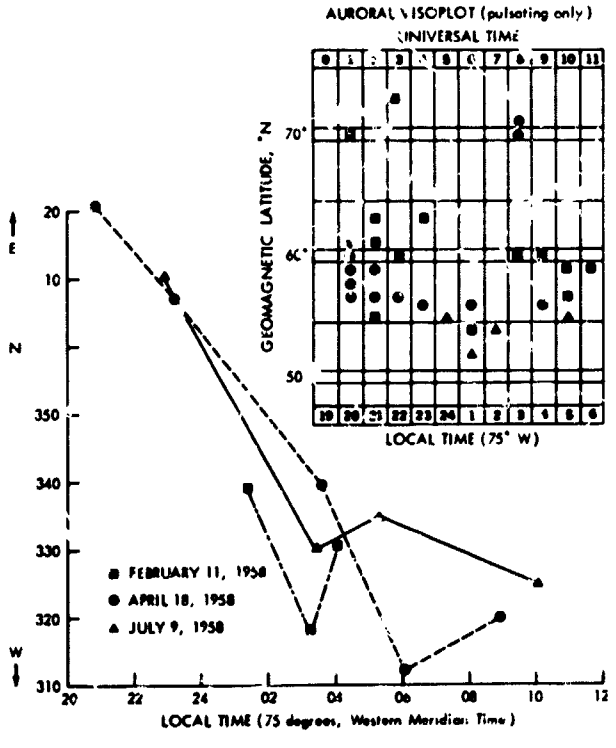

FIGURE 2.—Diurnal variation of the arrival direction of infrasonic waves during specific magnetic storms detected at the National Bureau of Standards, Washington, D. C. (Chrzanowski et al., 1960), and corresponding auroral activities observed in the northern hemisphere.

World Data Center A, on days which correspond to the events, reported by Chrzanowski et al. (Reference 1), shown on the left of this figure. Two occurrences of infrasonic waves in 1957 were reported, but since no visoplots of auroral activity are available before the IGY, they are omitted from this figure. The arrival direction of these waves might deviate from their true direction because of strong wind systems in high altitudes. Therefore, the appearances of pressure waves do not necessarily match the pulsating auroral events in detail. However, it is quite clear that there is a close correspondence between infrasonic waves and pulsating aurorae.

MATHEMATICAL TREATMENT

It is obvious that ray theory is not applicable in this problem, because the wavelength is of the order of an atmospheric depth or more for the infrasonic waves observed.

The excitation and propagation of long period pressure waves in the atmosphere have been investigated by several workers, mainly in two fields of geophysics, i.e., meteorology and ionospheric physics. The former consists of the study of atmospheric oscillations (References 20–24), and the study of micro-barometric disturbances (References 25–36). The latter is mostly concerned with the investigation of ionospheric disturbances and has been discussed by Martyn (Reference 37), Sen and White (Reference 38), White (References 39 and 40) and Hines (References 41 and 42).

Although the subjects considered in the noted references are quite different, the mathematical treatments are essentially the same. They are based on a differential equation of velocity divergence, which is derived from three fundamental equations, i.e., the equations of motion, continuity, and of first law of thermodynamics. The theoretical aspects of the problems in geophysics, including oceanography, are reviewed in References 43–46. Mathematical technique has been developed to solve these problems, introducing the so-called field variables instead of simple hydrodynamical variables.

In the present calculations, however, the classical method based on the equations of velocity divergence will be used, because of the convenience in comparing the results with observed data.

Notations and Fundamental Equations

Preliminary notation will now be given:

- c velocity of sound in the atmosphere in cm/sec, $c^2=\gamma gH$ where $H=RT/g$ is the scale height of the isothermal atmosphere,
- D/Dt Eulerian derivative, $\partial/\partial t+U\nabla$,
- $\mathbf{f}$ resultant of external forces except gravity, dynes/gm,
- $\mathbf{g}(0, -g)$ acceleration of gravity, $g=980$ cm/sec^2,
- k horizontal wave number corresponding to λ, in cm^{-1}, i.e., $2\pi/\lambda$,
- ℓ vertical wavelength of a pressure wave in cm,
- p, ρ, T small departures from static values of pressure, density, and temperature, functions of x, z, and t, in dynes/cm^2, gm/cm^3, and °K,
- p_0, ρ_0, T_0 static values of pressure, density, and temperature, functions of z only,
- p_s, ρ_s, T_s static values of pressure, density, and temperature of air at seal level.
- p_T, ρ_T, T_T total pressure, density, and temperature, i.e., p_0+p, $\rho_0+\rho$, and T_0+T,
- $q'(x, z)$ rate of net accession of heat, erg/gm–sec; $s(x, z)=(\gamma-1)q$ where $q=\rho_T q'$ in ergs/cm^3–sec,
- R gas constant of air, $B/M=2.87\times10^6$ ergs/gm–°C, where B is the universal gas constant, 8.314×10^7 ergs/mol–°K, and M is the molecular weight of air, approximately 28.97,
- $\mathbf{U}(u, w)$ velocity vector, where u is the horizontal (southward) and w is the upward component of air flow in cm/sec,
- x, z horizontal (southward) and vertical (upward) coordinates,
- γ ratio of the specific heats of air, $C_p/C_v\approx1.4$, where C_p and C_v are the specific heat of air at constant pressure and constant volume, respectively,
- η entropy of air in ergs/gm–°K,
- λ horizontal wavelength of a pressure wave in cm,
- σ frequency of the pressure wave corresponding to τ, i.e., $2\pi/\tau$,

τ period of pressure wave in sec,
$\chi(x, z)$ the divergence of velocity in sec^{-1}, i.e., $\chi = \partial u/\partial x + \partial w/\partial z$,
Ω Coriolis vector in rad/sec.

In Eulerian notation, the equation of motion is

$$\frac{D\mathbf{U}}{Dt} + \frac{1}{\rho}\nabla p + \mathbf{g} + \Omega \times \mathbf{U} = \mathbf{f} \quad . \tag{1}$$

and the equation of continuity is

$$\frac{D}{Dt}\left(\frac{1}{\rho}\right) - \frac{1}{\rho}\nabla \mathbf{U} = 0 \tag{2}$$

The variations of pressure due to thermal excitations can be derived from the first law of thermodynamics, which gives the change of entropy (References 43–45),

$$\frac{D\eta}{Dt} = \frac{q'}{T} \quad . \tag{3}$$

By making use of the perfect gas function for entropy (Reference 46) it can be shown that Equation 3 is equivalent to

$$\frac{Dp}{Dt} - c^2 \frac{D\rho}{Dt} = s(x, z, t) \quad . \tag{4}$$

where

$$s(x, z, t) = (\gamma - 1)\rho q'(x, z, t) = (\gamma - 1) q(x, z, t) \quad .$$

Since, in the present problem, the period of oscillation is less than a few minutes, the Coriolis force due to the earth's rotation is negligible, and all other external forces can be assumed to be zero. The equation of motion for the present problem is then simply

$$\frac{D\mathbf{U}}{Dt} + \frac{1}{\rho_0}\nabla p = \mathbf{g} \quad . \tag{6}$$

One-Dimensional Model

For the one-dimensional case atmospheric motion has only the z component of velocity, w; therefore, in its linear approximation form, the equation of motion (Equation 6) is

$$\rho_0 \frac{\partial w}{\partial z} = \frac{-\partial p}{\partial z} - \rho g \quad . \tag{7}$$

The equation of continuity in its linear approximation form is

$$\frac{\partial \rho}{\partial t} + \rho_0 \frac{\partial w}{\partial z} - \frac{\rho_0}{H} w = 0 \quad . \tag{8}$$

And the linear approximation form of the entropy equation (Equation 4) is:

$$\frac{\partial p}{\partial t} = -\rho_0 c^2 \frac{\partial w}{\partial z} + \rho_0 g w + (\gamma - 1) q \quad , \tag{9}$$

where $q = q(z, t)$ is the periodically changing heat source, which can be assumed to be

$$q(z, t) = \begin{cases} q(z)\, e^{i\sigma t} & \text{for } z \geq 0 \quad , \\ 0 & \text{for } -z_0 \leq z < 0 \quad , \end{cases} \tag{10}$$

where

$$q(z) = \frac{q_0 e^{-z/h}}{h} \quad ; \tag{11}$$

h is a constant and q_0 is the maximum rate of heat generation in an atmospheric column with unit cross section, in ergs/cm²-sec; $z = 0$ is taken as the height of the base of heating; and the value at the earth's surface is given by $z = -z_0$.

By eliminating p and ρ from the above equations, the following differential equation is obtained:

$$\frac{\partial^2 w}{\partial z^2} - \frac{1}{H}\frac{\partial w}{\partial z} - \frac{1}{c^2}\frac{\partial^2 w}{\partial t^2} = \frac{\gamma - 1}{\rho_0 c^2}\frac{\partial q}{\partial z} \quad . \tag{12}$$

In the region $z \geq 0$, where the heat source exists,

$$w = \frac{i}{k_2 - k_1} e^{ik_1 z}\left[\int_0^z e^{-ik_1 \xi} Q(\xi)\, d\xi + C\right] + \frac{i}{k_1 - k_2} e^{ik_2 z}\left[\int_0^z e^{-ik_2 \xi} Q(\xi)\, d\xi + D\right] \quad , \tag{13}$$

where k_1 and k_2 are given by

$$\left.\begin{aligned} k_1 &= \sqrt{\frac{1}{l^2} - \frac{1}{4H^2}} - i\,\frac{1}{2H} \\ k_2 &= -\sqrt{\frac{1}{l^2} - \frac{1}{4H^2}} - i\,\frac{1}{2H} \end{aligned}\right\} \quad (14)$$

and

$$\frac{1}{l} = \frac{\sigma}{c} ,$$

$$Q(\xi) = \frac{\gamma - 1}{\rho_0 c^2}\frac{dq(\xi)}{d\xi} . \quad (15)$$

C and D are integration constants, to be determined by the boundary conditions. The t[illegible] dependent factor, $e^{i\sigma t}$, is dropped in Equation 13 and will be always dropped hereafter.

For the region $-z_0 \leq z < 0$, where no heat source exists,

$$w = \frac{i}{k_2 - k_1} e^{ik_1 z} A + \frac{i}{k_1 - k_2} e^{ik_2 z} B ; \quad (16)$$

where A and B are constants. The condition that $w = 0$ at the earth's surface gives

$$B = e^{i(k_2 - k_1)z_0} A . \quad (17)$$

The vertical velocity w should be continuous at $z = 0$, and therefore

$$A - B = C - D . \quad (18)$$

The pressure p also should be continuous at $z = 0$, so that the following condition is to be satisfied:

$$\rho_c c^2 \left(\frac{dw}{dz}\right)_{z=0+\epsilon} - (\gamma - 1)\, q(0) = \rho_c c^2 \left(\frac{dw}{dz}\right)_{z=0-\epsilon} , \quad (19)$$

where $\epsilon \to 0$ and

$$\rho_c = (\rho_0)_{z=0} , \quad (20)$$

the atmospheric density at $z = 0$.

The above equations give

$$k_1 C - k_2 D - k_1 A + k_2 B = \frac{k_1 - k_2}{\rho_c c^2} (\gamma - 1)\, q(0) . \quad (21)$$

For $z \to \infty$, there should be no wave downward, thus from Equation 13

$$C = -\int_0^\infty e^{-ik_1 \xi} Q(\xi)\, d\xi . \quad (22)$$

From Equations 18 and 19,

$$A = C - \frac{\gamma - 1}{\rho_c c^2} q(0) . \quad (23)$$

To find the pressure variation at the earth's surface, we must obtain $(dw/dz)_{z=-z_0}$, which is given by using Equations 16 and 17;

$$\left(\frac{dw}{dz}\right)_{z=-z_0} = e^{-ik_1 z_0} A . \quad (24)$$

Then Equation 9 gives the pressure variation at the earth's surface,

$$p_{z=-z_0} = \frac{i}{\omega} \rho_s c^2 e^{-ik_1 z_0} A . \quad (25)$$

where ρ_s is the atmospheric density at the earth's surface. By substituting Equation 22 into Equation 23,

$$|A| = \frac{(\gamma - 1)\, q_0}{\rho_c\, c^2} \frac{1}{l} \left(1 - \frac{h}{H} + \frac{h^2}{l^2}\right)^{-1/2} , \quad (26)$$

provided that the angular wave frequency σ is larger than a critical frequency σ_A,

$$\sigma_A = \frac{\gamma g}{2c} . \quad (27)$$

By using Equations 14

$$\left|e^{-ik_1 z_0}\right| = e^{-z_0/2H} . \quad (28)$$

Thus the final expression of the amplitude of pressure variations at the ground, caused by the periodic disturbance in the upper atmosphere q(z, t), is

$$p_s = \frac{\gamma - 1}{c} q_0 \left(\frac{\rho_s}{\rho_c}\right)^{1/2} \left(1 - \frac{h}{H} + \frac{h^2}{l^2}\right)^{1/2} . \quad (29)$$

The values for p_s/q_0 which may be derived from this equation are plotted vs. h in Figure 3 for several values of angular frequency, σ. The full lines and dashed lines stand for the scale heights of 8 km and 6.8 km, respectively, for an isothermal atmosphere. The latter gives the proper ratio of $(\rho_c/\rho_s)^{1/2}$ as compared with the observed atmospheric densities. From this figure, it can be seen that periodic heating corresponding to a flux of the order of 100 ergs/cm²–sec produces pressure waves with amplitudes of the order of 1 dyne/cm² at the ground.

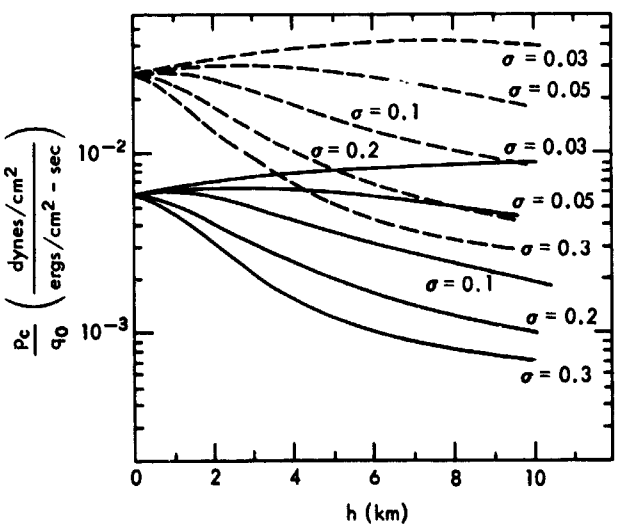

FIGURE 3.—Relative intensity of pressure waves on the ground, produced by periodic auroral heating, vs. the scale height of the heat source, for the one-dimensional model with an isothermal atmosphere.

Two-Dimensional Model

Equation of Velocity Divergence

From Equation 6 the equation of motion for the two-dimensional case is

$$\rho_0 \frac{\partial u}{\partial t} = -\frac{\partial p}{\partial x} , \quad (30)$$

$$\rho_0 \frac{\partial w}{\partial t} = -\frac{\partial p}{\partial z} - g\rho . \quad (31)$$

The equation of continuity (Equation 2) can be written in a first order approximation as

$$\frac{\partial p}{\partial t} + w \frac{\partial \rho_0}{\partial z} = -\rho_0 \chi , \quad (32)$$

where $\chi = \chi(x, z, t)$ is the velocity divergence. By using Equation 32, Equation 4 can be written as

$$\frac{\partial p}{\partial t} = \rho_0 gw - \rho_0 c^2 \chi + s . \quad (33)$$

Under the assumption that the time variations of u, w, p, ρ, and s are proportional to a factor $e^{i\sigma t}$, the following relations between u, w, and p are obtained from Equations 30–33:

$$-\sigma^2 u = \frac{\partial}{\partial x}\left(c^2 \chi - gw\right) - \frac{1}{\rho_0}\frac{\partial s}{\partial x} , \quad (34)$$

$$-\sigma^2 w = c^2 \frac{\partial \chi}{\partial z} - \gamma g \chi + g \frac{\partial u}{\partial x} - \frac{1}{\rho_0}\frac{\partial s}{\partial x} , \quad (35)$$

$$i\sigma p = \rho_0 gw - c^2 \rho_0 \chi + s . \quad (36)$$

By eliminating u, w, and p from these equations, the following differential equation for the velocity

divergence $\chi(x, z)$ is obtained:

$$\nabla^2 \chi + \frac{1}{c^2}\left(\frac{dc^2}{dz} - \gamma g\right)\frac{\partial \chi}{\partial z} - \frac{g}{c^2\sigma^2}\left[\frac{dc^2}{dz} + (\gamma - 1)g\right]\frac{\partial^2 \chi}{\partial x^2} + \frac{\sigma^2}{c^2}\chi$$

$$= -\frac{1}{c^2\sigma^2}\left[\frac{g}{\rho_0(z)c^2}\left(\frac{dc^2}{dz} + \gamma g\right)\frac{\partial^2 s}{\partial x^2} - \frac{\sigma^2}{\rho_0 c^2}\left(\frac{dc^2}{dz} + \gamma g\right)\frac{\partial s}{\partial z} - \frac{\sigma^2}{\rho_0}\nabla^2 s\right] \quad . \quad (37)$$

The derivation of this equation is given in Appendix A.

The Diagnostic Diagram

If there is no thermal excitation, the right side of Equation 37 is zero, and the solution of this homogenous differential equation corresponds to the free oscillation of the atmosphere on the nonrotating earth.

We will now consider pressure waves traveling horizontally in this flat atmosphere. If u, w, p, and ρ are proportional to a factor $e^{i(\sigma t - kx)}$, the following is the equation for the vertical change of $\chi(\sigma, z)$:

$$\frac{d^2\chi}{dz^2} + \frac{1}{c^2}\left(\frac{dc^2}{dz} - \gamma g\right)\frac{d\chi}{dz} + \left[\frac{\sigma^2}{c^2} - k^2 + \frac{gk^2}{\sigma^2 c^2}\left(\frac{dc^2}{dz} + \gamma g - g\right)\right]\chi = 0 \quad .$$

Since $c^2 = \gamma g H(z)$, this may be written

$$\frac{d^2\chi}{dz^2} + \frac{1}{H}(H' - 1)\frac{d\chi}{dz} + \left[\frac{\sigma^2}{\gamma g H} - k^2 + \frac{k^2 g}{\sigma^2 H}\left(H' + \frac{\gamma - 1}{\gamma}\right)\right]\chi = 0 \quad ,$$

where $H' = dH/dz$.

For simplicity, consider the case of an isothermal atmosphere, where $H' = 0$. Equation 39 becomes

$$\frac{d^2\chi}{dz^2} - 2N\frac{d\chi}{dz} + M^2\chi = 0 \quad , \quad (40)$$

where the constant $N = 1/2H$ and

$$M^2 = \frac{\sigma^2}{c^2} - k^2 + \frac{k^2 g^2}{c^2\sigma^2}(\gamma - 1) \quad . \quad (41)$$

This differential equation has the solution:

$$\chi(\sigma, z) = e^{Nz}\left(Ae^{-\mu z} + Be^{+\mu z}\right) \quad , \quad (42)$$

where A and B are constants,

$$\mu^2 = N^2 - M^2 \geq 0 \quad , \quad (43)$$

for the noncellular solution, and

$$\mu = i\eta \quad , \qquad \eta^2 = M^2 - N^2 > 0 \quad , \quad (44)$$

for the cellular solution. As was shown by Pekeris (Reference 27) for the noncellular solution in an isothermal atmosphere (Equation 42) the term with $e^{\mu z}$ must vanish, i.e, $B = 0$. Otherwise the kinetic energy of noncellular waves, which is proportional to $\rho_0(z)\chi^2$, would diverge. Furthermore, because of the condition that the vertical component of velocity must vanish at the ground, we get only two possible types of free oscillation, specified by the following characteristic relations:

Type I: $$k = \frac{\sigma}{c} \quad , \qquad V = U = c \quad , \quad \text{and} \quad \mu = \frac{g(2 - \gamma)}{2c^2} \quad , \quad (45)$$

Type II: $$k = \frac{\sigma^2}{g} \quad , \qquad V = \frac{g}{\sigma} \quad , \quad U = \frac{1}{2}V \quad , \quad \text{and} \quad \mu = \frac{\sigma^2}{g} - \frac{\gamma g}{2c^2} \quad . \quad (46)$$

where $V=\sigma/k$ and $U=d\sigma/dk$, the phase velocity and group velocity of noncellular horizontal waves. Type I corresponds to Lamb's wave (Reference 20), which exists at all frequencies; the waves of type II can be propagated only above a critical value σ_c,

$$\sigma_c = \frac{g}{c}\sqrt{\frac{\gamma}{2}} \qquad (47)$$

(the corresponding period is about 250 sec), and the wave is dispersive.

It should be noted that, because of the decrease of atmospheric density, the amplitude of the Lamb wave (pressure variation) decreases with altitude by a factor $\exp(-gz/c^2)$, preventing the propagation of waves in any except horizontal directions (Reference 46). On the other hand, for the cellular solution η stands for the wave number in the vertical direction and Equation 44 is equivalent to

$$\eta^2 c^2 = \frac{(\sigma^2-\sigma_A^2) + k^2c^2(\sigma_B^2-\sigma^2)}{\sigma^2} \qquad (48)$$

where

$$\sigma_A = \frac{g\gamma}{2c}$$

$$\sigma_B = \frac{g(\gamma-1)^{1/2}}{c} \qquad (49)$$

Brunt's frequency, σ_B, is the frequency of the vertical oscillation of a free air parcel in the atmosphere, changing adiabatically. This expression was also derived by Väisälä as a stability parameter of the atmosphere (Reference 46). The frequency σ_A can be called the atmospheric resonance sound frequency (Reference 47).

The curve for $\eta^2=0$ shown in Figure 4 (a plot of σ vs. k) consists of two branches, A and B. The curve A starts from the σ-axis at $\sigma=\sigma_A$ and is asymptotic to the line C, which corresponds to the solution of the noncellular Lamb wave, $\sigma=kc$. The other curve B passes through the origin and is asymptotic to the horizontal line $\sigma=\sigma_B$. Every point in the two regions where

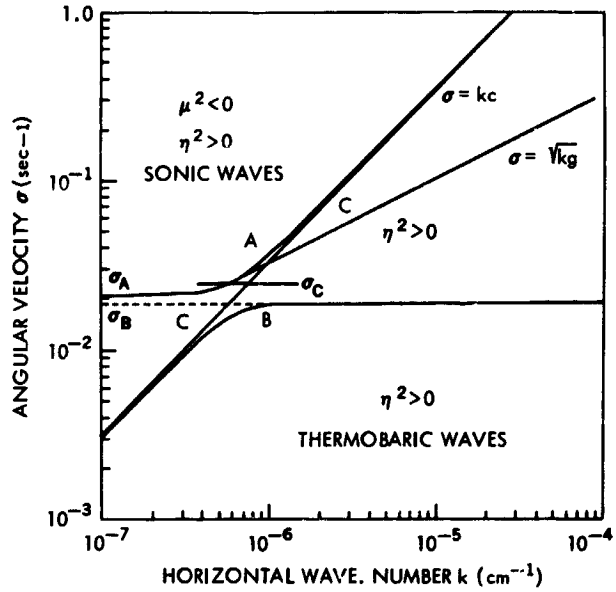

FIGURE 4.—Diagnostic diagram for an isothermal atmosphere with scale height H = 8 Km (T_0 = 273°K).

$\eta^2>0$, one surrounded by curve A and the other surrounded by curve B, leads to an eigen solution of Equation 39. In the third region (between the other two), where $\eta^2<0$, only the points on the line $\sigma=$ kc and $\sigma=\sqrt{kg}(\sigma>\sigma_c)$ lead to eigen solutions. Figure 4 is called the diagnostic diagram of the isothermal atmosphere, and the waves corresponding to the two domains in which $\eta^2>0$ are named Sonic (mode A) and Thermobaric (mode B), respectively (Reference 46). Sonic and thermobaric waves are called acoustic and internal gravity waves, respectively, by Hines (Reference 42).

Intensity of Pressure Waves at the Ground

Since the source of excitation s(x, z) is limited to a certain area inside the auroral zone, the right side of Equation 37 is not uniform with respect to x. Therefore, this differential equation is not in general separable with respect to the variables x and z, and the following assupmtions are made in solving the equation:

1. The atmosphere is isothermal, with scale height H, in km.
2. The distribution of the heat source is uniform along the y direction (this is assumed at the beginning to reduce the problem to two dimensions), but it is limited horizontally in the x direction within $\pm\lambda_0$ (i.e., $-\lambda_0 \le x < \lambda_0$) and is

extended vertically above a certain height z (i.e., $z \geq z_0$).

3. The time variation of the heat source is periodic with an angular frequency σ, and the same phase within the domain indicated in item 2 above.

The first assumption reduces Equation 37 to the following form:

$$\left(1 - \frac{\sigma_B^2}{\sigma^2}\right)\frac{\partial^2 \chi}{\partial x^2} + \frac{\partial^2 \chi}{\partial z^2} - \frac{1}{H}\frac{\partial \chi}{\partial z} + \frac{\sigma^2}{c^2}\chi = \frac{1}{\rho_0(z)c^2}\left[\left(1 - \frac{g}{\sigma^2 H}\right)\frac{\partial^2 s}{\partial x^2} + \frac{\partial^2 s}{\partial z^2} + \frac{1}{H}\frac{\partial s}{\partial z}\right] . \quad (50)$$

Assumptions 2 and 3 can be written as

$$s(x, z, t) = s(z)\, e^{i\sigma t}\, \theta(z - z_0)\left[\theta(x + \lambda_0) - \theta(x - \lambda_0)\right] , \quad (51)$$

where

$$s(z) = \frac{s_0}{h} e^{-(z - z_0)/h} = \frac{(\gamma - 1) q_0}{h} \exp\left[\frac{-(z - z_0)}{h}\right] , \quad (52)$$

and $\theta(\xi)$ is a unit step function of ξ,

$$\theta(\xi) = \begin{cases} 1 & \text{for } \xi \geq 0 , \\ 0 & \text{for } \xi < 0 . \end{cases} \quad (53)$$

It should be noted that q_0 is the maximum rate of heat release in the atmosphere in an air column of unit cross-section (in ergs/cm²-sec).

Since the atmosphere is assumed to be isothermal, the density of air in equilibrium at height z is

$$\rho_0(z) = \rho_s e^{-z/H} , \quad (54)$$

where ρ_s is the atmosphere density at the earth's surface and H is the scale height.

In order to solve Equation 50 under the conditions listed, the following Fourier transforms are applied with respect to x,

$$X(k, z) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{ikx} \chi(x, z)\, dx , \quad (55)$$

$$S(k, z) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{ikx} s(x, z)\, dx . \quad (56)$$

Since the heat source s(x, z) vanishes outside of the auroral zone, both s(x, z) and $\chi(x, z)$ must vanish at $x = \pm\infty$. Thus

$$\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \frac{\partial^2 \chi}{\partial x^2} e^{ikx}\, dx = -k^2 X(k, z) , \quad (57)$$

$$\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \frac{\partial^2 s}{\partial x^2} e^{ikx}\, dx = -k^2 S(k, z) . \quad (58)$$

With these transforms, Equation 50 is written

$$\frac{d^2 X}{dz^2} - 2N\frac{dX}{dz} + M^2 X = F(z, k) , \quad (59)$$

where

$$F(z, k) = \frac{1}{c^2 \rho_0(z)}\left[\frac{d^2 S}{dz^2} + \frac{1}{H}\frac{dS}{dz} - k^2\left(1 - \frac{g}{\sigma^2 H}\right)S\right] . \quad (60)$$

and N and M^2 are the same as in Equations 40 and 41. The solution of Equation 59 can be written:

$$X(k, z) = e^{n_1 z}\left[C_1 - \frac{1}{2\mu}\int_0^z F(z', k)\, e^{-n_1 z'}\, dz'\right] + e^{n_2 z}\left[C_2 + \frac{1}{2\mu}\int_0^z F(z', k)\, e^{-n_2 z'}\, dz'\right] , \quad (61)$$

where $F(z', k)$ is given by Equation 60 and n_1 and n_2 are the roots of the characteristic equation

$$n^2 - 2Nn + M^2 = 0 . \quad (62)$$

We assume

$$n_1 = N - \mu , \quad (63)$$

$$n_2 = N + \mu , \quad (64)$$

where

$$\left.\begin{aligned} \mu &= \sqrt{N^2 - M^2} \geq 0 \qquad \text{for } N^2 \geq M^2 , \\ \mu &= i\eta, \quad \eta^2 = M^2 - N^2 > 0 \qquad \text{for } N^2 < M^2 \end{aligned}\right\} . \quad (65)$$

The integration constants C_1 and C_2 are determined by the following two boundary conditions:

1. The vertical component of velocity vanishes at the ground,

$$w(x, z = 0) = 0 . \quad (66)$$

2. The kinetic energy of the waves at $z = \infty$ is either zero or remains finite. In the latter case, the vertical component of the disturbance should never be propagated downward at $z = \infty$.

The pressure change at the ground can be obtained from $\chi(x, z=0)$, which is given by the inverse Fourier transform of $X(k, z=0)$, i.e.,

$$\chi(x, 0) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} e^{-ikx}\, X(k, 0)\, dk , \quad (67)$$

where $X(k, 0)$ is the solution of Equation 59 at $z=0$ satisfying the above conditions. It is given by Equation B15 in Appendix B.

Since $w(x, 0)=0$, then $s(x, 0)=0$ and Equation 36 reduces to

$$p(x, 0) = -\frac{c^2 \rho_s}{i\sigma}\chi(x, 0) , \quad (68)$$

where $\chi(x, 0)$ is given by the inverse Fourier transform of $X(k, 0)$. The evaluations of $p(x, 0)$ are given in Appendix C and the results are shown in Figures 5–10. Various values are given in Tables 1 and 2. The symbols p_r and p_i signify the real and imaginary parts of the cellular mode, respectively.

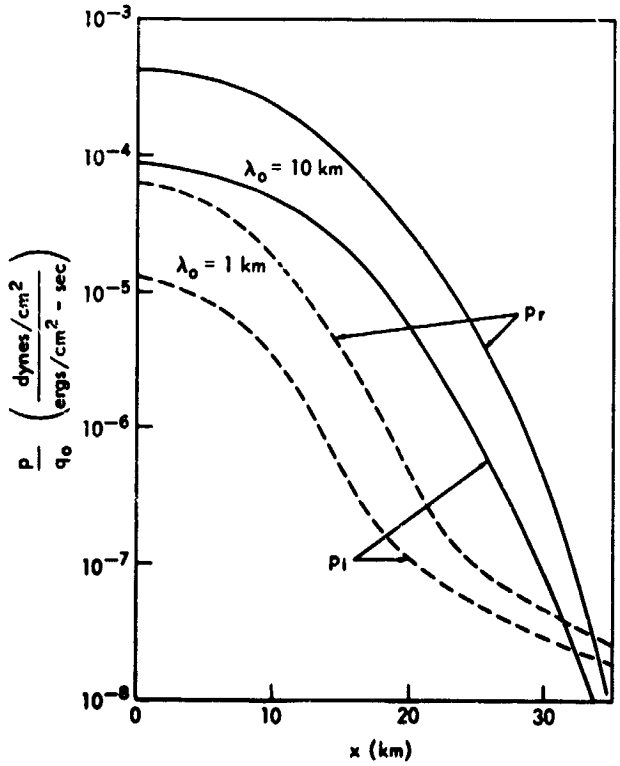

FIGURE 5.—A plot of the intensity of the cellular waves p_r and p_i on the ground, as a function of the input energy flux q_0 for $\tau = 30$ sec and $h = H$, vs. x, the horizontal distance from the center of the source. Full lines and dashed lines correspond to $\lambda_0 = 10$ km and $\lambda_0 = 1$ km, respectively.

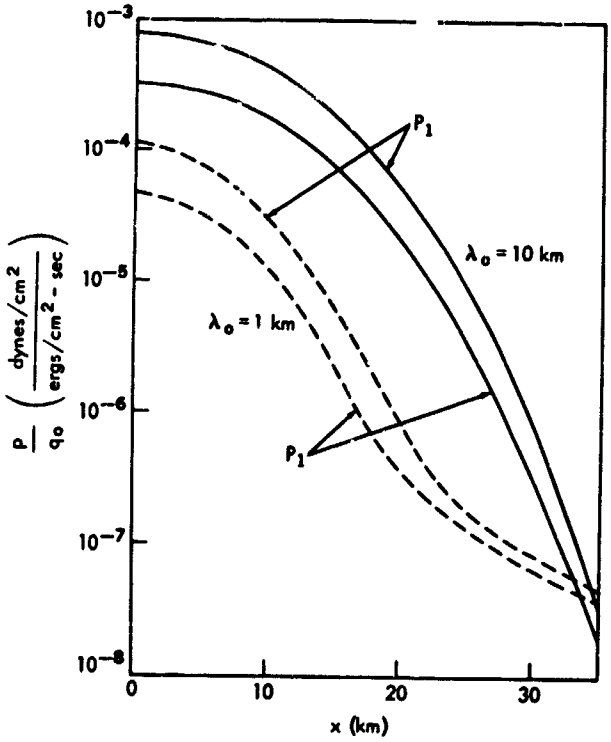

FIGURE 6.—The same plot as Figure 5 except that $h = \frac{1}{2}H$ instead of $h = H$.

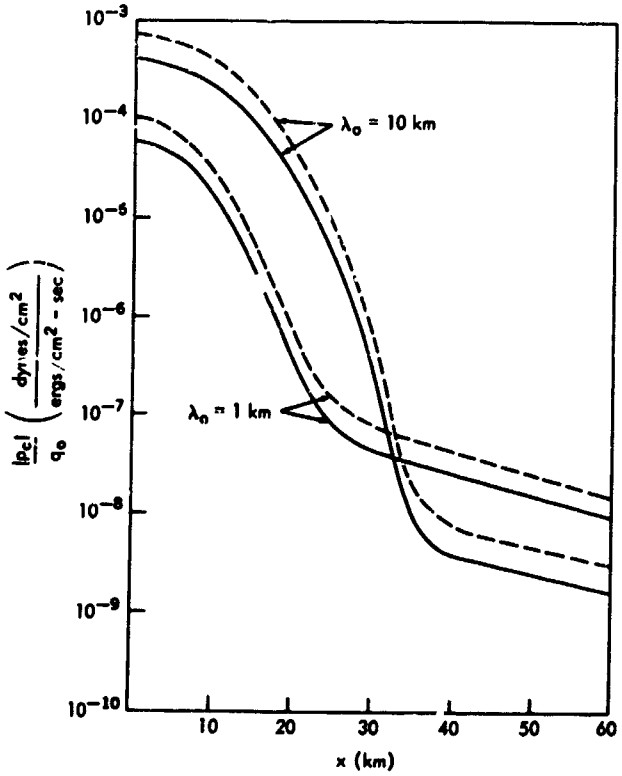

FIGURE 8.—The same plot as Figure 7 except that $\tau = 30$ sec.

ATTENUATION

Because of the viscosity and thermal conductivity of air, acoustic waves in the atmosphere attenuate. The attenuation coefficient $\alpha(\tau)$, in cm^{-1}, for a wave of period τ is given approximately by (Reference 48)

$$\alpha(\tau) = \frac{4\pi^2}{\tau^2}\frac{1}{c^3}\left(\frac{4}{3}\nu + \frac{\gamma-1}{\gamma}a^2\right), \quad (69)$$

where the coefficient of kinematic viscosity ν is approximately

$$\nu = \frac{1.7 \times 10^{-4}}{\rho(z)} \quad (70)$$

in cm^2/sec, and the coefficient of thermal conductivity a^2 is

$$a^2 = \frac{2.1 \times 10^{-5}}{\rho(z)}, \quad (71)$$

in cm^2/sec.

Since the air density ρ decreases exponentially with height, a^2 and ν increase exponentially with altitude. The so-called attenuation factor,

$$f_a(\tau, z) = \exp\left[-\int_0^z \alpha(\tau, z')\,dz'\right], \quad (72)$$

is shown in Figure 11 as a function of height, for $\tau = 10$ sec, 30 sec, and 100 sec.

It should be noted that the relative amplitude of the pressure wave grows as it propagates upward by a factor $e^{z/2H}$, where H is the scale height, whereas the absolute amplitude decreases by a factor $e^{-z/2H}$, because of the exponential decrease of air density (Reference 49). Therefore, if the amount of excitation energy is the same, the absolute intensity of the pressure wave at the ground increases with the base of the

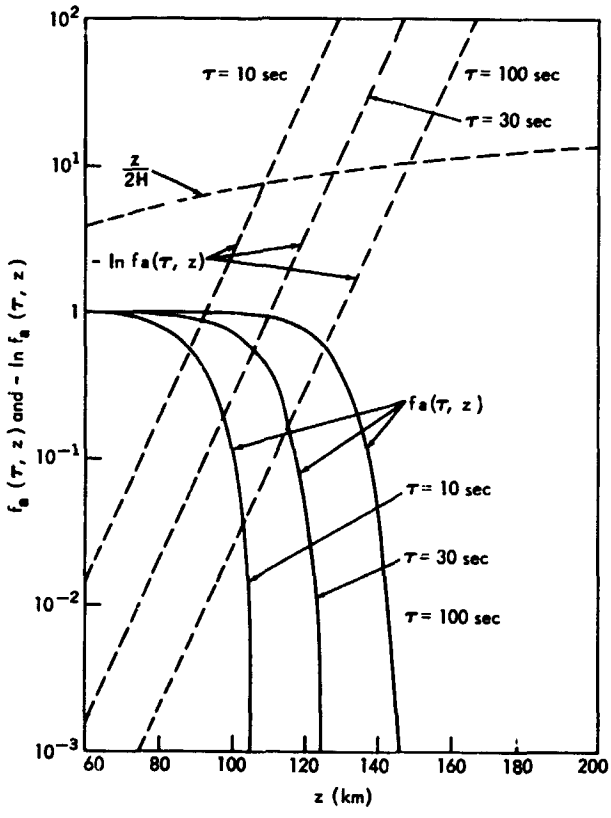

FIGURE 11.—Attenuation factor $f_a(\tau, z)$ vs. altitude of the source z in km and $-\ln f_a(\tau, z)$ vs. z:

$$-\ln f_a(\tau, z) = \int_0^z \alpha(\tau, z')\,dz',$$

a dashed line is also used to indicate the exponential amplification factor $\ln (\rho_z \rho_0)^{\frac{1}{2}} \approx z/2H$, where the scale height H is assumed to be 8 km.

excitation level. This is shown by Equation 29 and Equations C9 and C10 with a factor $e^{z_0/2H}$ for p_s, p_c ($z=0$), and $p_{nc}(z=0)$, and by a curved dash line in Figure 11.

However, because of the steep increase of the kinematic viscosity of air with altitude, the yield of pressure wave excitation drops sharply above a certain altitude for a given period (or frequency)

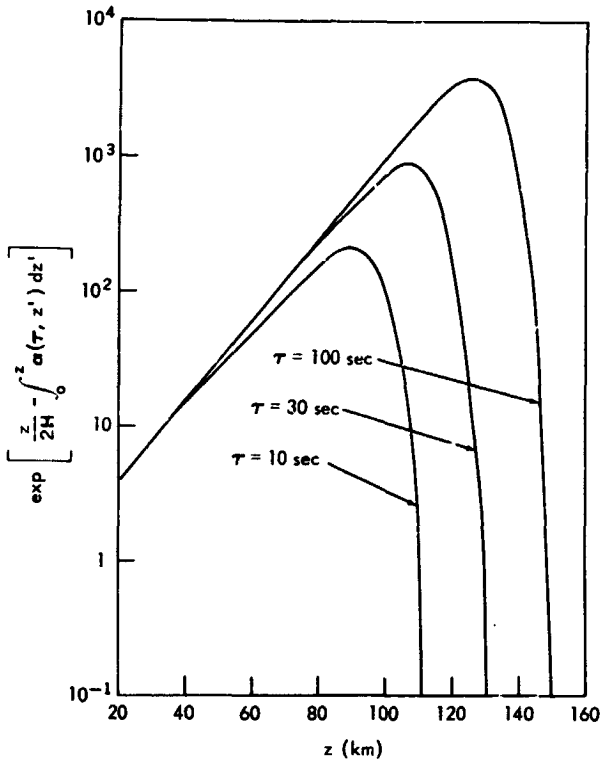

FIGURE 12. —Relative yield of the source to the infrasonic waves in the isothermal atmosphere

$$\sqrt{\frac{\rho(z)}{\rho_0}}\, f_a(\tau, z) \approx \exp\left[\frac{z}{2H} - \int_0^z \alpha(\tau, z')\,dz'\right]$$

vs. the altitude of the source z, where the scale height H is assumed to be 8 km.

of the wave. This is shown in Figure 12 for wave periods of $\tau = 10$, 30, and 100 sec. It can be seen that there is an effective height of excitation of atmospheric acoustic waves for a given period and that this height increases with the period.

As mentioned in the introduction, the excitation of pressure waves by hydromagnetic waves is only effective above the height of auroral activities. Figure 12 shows that waves produced at such a height are greatly attenuated before they reach the ground. Therefore, the contribution of hydromagnetic waves to the excitation of internal atmospheric waves is practically negligible. A more quantitative discussion will be given in the next section.

CONDITIONS FOR WAVE FORMATION

According to previous calculations, a pressure variation at the ground of the order of 1 dyne/cm² can be expected if the maximum rate of heat generation is of the order of 100 ergs/cm²-sec and the layer of periodic heating is around 100 km altitude, with a thickness less than 10 km. Electrons with an energy of the order of 100 kev will lose most of their energy within a layer of the order of 10 km thickness around the height of 100 km (Reference 19, p. 290). According to Chamberlain, the rate of heat generation is the order of 60 ergs/cm²-sec in a bright aurora. Therefore, if the rate of heat generation changes periodically with this order of amplitude, barometric oscillations of the order of 1 dyne/cm² at sea level can be expected from the sources in the upper atmosphere.

However, several other conditions must be satisfied in order that the energy brought into the upper air by auroral electrons can be converted efficiently to pressure waves in the atmosphere. At first, the time τ_1, in which an electron arrives at auroral height from outer space, should be smaller than the period, τ, of the waves concerned. If $\tau_1 \gg \tau$, the phase of the time variation of the source differs from place to place, and the resultant pressure wave originating from those different sources is weakened by superposition.

Since the auroral electrons, whose velocity is of the order of 10^9 cm/sec, lose their energy within a layer of 10 km thickness, $\tau_1 <$ approx. 10^{-4} sec. This is much smaller than the period of the acoustic waves considered here.

As discussed by Hanson and Johnson (Reference 50), electrons impinging into the upper atmosphere lose their energy mostly by inelastic collisions with neutral air particles until ≈ 2 ev, which is the lowest excitation energy of atomic oxygen (^{1}D state). The time τ_2 for ^{1}D excitation collisions with oxygen atoms is of the order of 10^{-3} sec at 100 km and of the order of 1 sec at 400 km.

Below 2 ev, the electrons lose energy in the upper atmosphere mainly by elastic collisions with ambient electrons. The time for those low energy electrons to equilibrate with ambient electrons, τ_3, is obtained from the expression for the rate of energy loss of a fast electron immersed in a thermalized plasma (Reference 50),

$$\tau_3 \approx \frac{5.7 \times 10^3\, E^{3/2}}{N_e}, \qquad (73)$$

where E is the electron energy, i.e., $E \approx 2$ ev, and

N_e is the electron concentration in cm^{-3}. The equilibration time, τ_3, given by this expression is about 10^{-1} sec at 100 km and of the order of 10^{-2} sec above 350 km. Thus $\tau_2+\tau^3$ is much smaller than the periods of the acoustic waves under discussion

It should be noted that elastic collisions with neutral particles dominate over those with ambient electrons below the F2 maximum (around 300 km). The time constant τ_4 for these elastic collisions consists of τ (O) and $\tau(N_2)$, the time constants for the loss of excess electron energy to atomic oxygen and to molecular nitrogen, respectively (Reference 50), and is given by

$$\tau_4 = \frac{2.08 \times 10^{11} E^{-1/2}}{n(O) + 2.36 n(N_2)} , \qquad (74)$$

where n(O) and $n(N_2)$ are the concentration per cm^3 of atomic oxygen and of molecular nitrogen, respectively. For E=2 ev, τ_4 is of the order of 0.1 sec at 100 km and increases with height. It is of the order of 100 sec at 350 km.

As shown in the previous section, the excitation of atmospheric pressure waves above 200 km is not important; the time constant τ_4 does not destroy the condition of wave formation. In other words, below 200 km $\tau_1+\tau_2+\tau_3+\tau_4 <$ approx. τ.

Another condition necessary for wave formation is that the time constant for cooling in a certain domain of auroral activity must be much longer than the period of oscillation. If the initial temperature T_0 is assumed to be horizontally uniform within the domain of the source, $-\lambda_0 \leq x \leq \lambda_0$, then the temperature at the center after t(sec) is

$$T(t) = (T_0 - T_a)\, \Phi\left(\frac{\lambda_0}{2\sqrt{a^2 t}}\right), \qquad (75)$$

where

$$\Phi(y) = \frac{2}{\sqrt{\pi}} \int_0^y e^{-x^2}\, dx , \qquad (76)$$

and a^2 is the thermal diffusivity (coefficient of thermal conduction) of air. T_a is the temperature outside the source.

The time, t_a, necessary to reduce the initial temperature difference between the inside and outside of the source region can be estimated from

$$\left.\begin{aligned} \Phi\left(\frac{\lambda_0}{2\sqrt{a^2 t_a}}\right) &= \frac{1}{2} , \\ t_a &\approx \frac{\lambda_0^2}{a^2} . \end{aligned}\right\} \qquad (77)$$

Since the thermal diffusivity of air a^2 at a height of 100 km is of the order of 10^6 cm^2/sec (see Equation 71), the minimum source width necessary to satisfy the condition for thermal oscillation is of the order of 30m for a period of 10 sec, and of the order of 100m for a period of 100 sec. The source width considered in the present calculation is significantly larger than these widths. In other words, the time constant for source cooling is sufficiently long for pressure wave production.

OTHER POSSIBLE MECHANISMS

Now the possibility of other suitable mechanisms for the generation of microbarometric oscillations during magnetic disturbances will be considered.

Periodic Heating Due to the Absorption of Hydromagnetic Waves

As stated in the introduction, hydromagnetic waves from the magnetosphere lose part of their energy in the lower exosphere and in the ionosphere. The remaining energy, which leaks through the ionosphere, is observed as fluctuations of the geomagnetic field intensity or geomagnetic pulsations.

The rate of energy dissipation of hydromagnetic waves in the ionosphere increases with increasing frequency (References 6, 51, and 52). According to Watanabe, the dissipation of the hydromagnetic wave energy in the ionosphere is negligible for waves with periods longer than 20 sec. In the auroral region, the amplitude of geomagnetic pulsations sometimes exceeds several tens of gammas (i.e., giant pulsations) and the periods are sometimes longer than several tens of seconds. The intensity of the incident wave is usually smaller for higher frequencies (Reference 15). As shown by the power density of the small scale fluctuations of magnetic field intensity observed

in the earth's magnetosphere between 5 and 15 earth radii (Reference 3), the frequency spectrum of hydromagnetic waves, which are regarded as the origins of geomagnetic pulsations observed at the earth's surface, is a decreasing function of frequency above the ionosphere. In any case, the upper limit of the incident wave amplitude may be taken as 100γ. The energy flux associated with these hydromagnetic waves is then of the order of several ergs/cm^2-sec^1, under the assumption that the Alfvèn wave velocity above the ionosphere is of the order of 10^8 cm/sec. The rate of heat generation by absorption of these hydromagnetic waves in the upper ionosphere has been estimated by several authors and their results are shown in Table 3.

The rate of heat generation is generally less than 1 erg/cm^2-sec, except when the period is 1 sec. Therefore the amount of heat generated by hydromagnetic waves penetrating the ionospheer is smaller than that due to the auroral particles. Table 3 also contains estimates of the thickness of the layer of heat generation. In every case the thickness is much larger for hydromagnetic waves than for auroral particles.

As shown in Figure 12, the effective height of pressure wave generation by periodic heating of the upper air is limited, and it is lower for the shorter period. Therefore, generation of acoustic waves by the attenuation of hydromagnetic waves is less efficient than generation by the periodic heating due to auroral particles, even if the energy flux of the incident wave is increased to be the same as the latter.

Pressure Waves Due to the Impacts of Auroral Particles

A particle coming into the atmosphere loses its energy by transferring its downward momentum to the air particles. A pressure wave can be generated if the flux of the particle changes periodically with time.

The upper limit of the pressure intensity, from this process, can be estimated by assuming that all the incoming particles would stop in a very short time within a very thin layer. By assuming the average energy of incident electrons is 6 kev and the maximum flux is of the order of 10^{10}cm^{-2}-sec^{-1}, the maximum pressure exerted upon the thin layer of virtual shock absorber is estimated to be of the order of 4.10^{-8} dynes/cm^2. The corresponding intensity at the earth's surface is of the order of 10^{-5} dyne/cm^2, if all electrons stop at an altitude of 100 km.

Penetration of Hydromagnetic Waves Through the Ionosphere

As mentioned above, most geomagnetic pulsations are due to hydromagnetic oscillations in the exosphere. These oscillations are related to electromagnetic oscillations in the space between the earth's surface and the lower boundary of the ionosphere. Any oscillation mode in which the compression of atmospheric matter is involved gives rise to a variation in the density, and consequently a pressure variation. Therefore, it may be possible that geomagnetic pulsations and microbarometric oscillations have the same origin,

Table 3

Rate of Heat Generation Due to Attenuation of Hydromagnetic Waves with a 100γ Incident Amplitude.

Source	Period of HM waves (sec)	Rate of Heat Generation in an Air Column of unit cross section (erg/cm^2-sec)	Thickness of Heating Layer (km)	Altitude of the Center of the Heat Generating Layer (km)
Dessler (Reference 53)	1	1.3	100	170
Francis and Karplus (Reference 51)	6.3 0.3	0.7 1.6	50 100	125 180
Akasofu (Reference 52)	1 10 100	9.7 0.17 0.028	100 200 300	225 240 250

i.e., hydromagnetic oscillations of the earth's exosphere.

A simple situation can be found at the geomagnetic equator, where geomagnetic pulsations appear sometimes in the N–S component of the geomagnetic field, with amplitudes of the order of several tens of gammas and periods of several minutes (Reference 54). The origins of this kind of pulsation presumably exist in the outer boundary of earth's magnetosphere near the geomagnetic equatorial plane, and it may be propagated as a modified Alfvèn wave. A modified Alfvèn wave is a transverse wave with respect to changes in the electric and magnetic fields. On the other hand, it is a longitudinal wave when viewed as fluid motion (Reference 55). An electromagnetic wave as well as a pressure wave should be in the space between the earth's surface and the lower boundary of the ionosphere. The energy flux associated with an incident modified Alfvèn wave is roughly $(B^2/8\pi)\ V_A$, where V_A is the group velocity of the modified Alfvèn waves and can be taken as the Alfvèn wave velocity at a higher portion of the ionosphere. B is the amplitude of the wave, i.e., the intensity of magnetic fluctuation above the ionosphere.

By assuming conservation of energy flux, the upper limit of the amplitude of the pressure wave at the earth's surface, p_e, can be estimated as follows:

$$\frac{1}{2}\frac{p_e^2}{c_s \rho_s} = \frac{B^2}{8\pi} V_A ,$$

where c_s is the sound wave velocity at the earth's surface, and ρ_s is the air density at the earth's surface. By taking $V_A = 3.10^7$ cm/sec (corresponding to daytime at the sunspot maximum activity) $B = 30\gamma$, $c_s = 3.10^4$ cm/sec, and $\rho_s = 1.25 \times 10^{-3}$ gm/cm^3, we find $p_e \approx 3$ dynes/cm^2. In this estimate the conversion factor between the energy of incident Alfvèn waves and that of secondary pressure waves is assumed to be unity. This factor must actually be very small because of reflections and energy dissipations of incident waves at the upper part of the ionosphere. If it is not small, infrasonic waves could appear in the equatorial region during strong magnetic disturbances. Since the occurrence of aurorae in these regions is negligible, this might provide a method of direct detection of modified Alfvèn waves coming into the earth's atmosphere from the magnetosphere.

CONCLUSIONS

We have shown that one of the most plausible mechanisms for pressure wave generation during geomagnetic disturbances is the periodic heating of the polar ionosphere by auroral particles, observed as pulsating aurorae. As emphasized by Campbell (Reference 56) the main energy source for this type of auroral activity is not necessarily incident auroral particles, but a flow of secondary electrons called the electro-jet. In this respect periodic heating by these intermittent electric currents is essentially the same as the so-called Joule heating discussed by Cole (References 57 and 58).

The following conclusions can be drawn from the present calculation:

1. From Figures 3, 5–9, and 13 it can be seen than an incident energy flux of more than 100 ergs/cm^2-sec will produce acoustic waves observable at the ground, provided the periods are longer than about 10 seconds.
2. The relative intensity of the pressure wave at the ground is higher when the heating is concentrated within a thin layer than when it is distributed over a wide range of altitudes (Figures 3, 5, and 6).
3. The intensity ratio between the inside of the source region and the outside is smaller for long periods than for short periods, as expected.
4. The gradient of intensity around the boundary of the source is steeper when the width of the source is wide.
5. Inside the source the ratio of noncellular to cellular wave intensity is of the order of 10^{-5} for $\tau = 10$ sec and 10^{-3} for $\tau = 100$ sec. Although the noncellular intensity exceeds the cellular at large distances from the source, the contribution of the noncellular wave to the observed intensity is negligible, because both waves attenuate in long distance propagation.
6. According to the present calculations, which are based on an isothermal atmosphere, the intensity of acoustic waves more than several hundred km from the region of

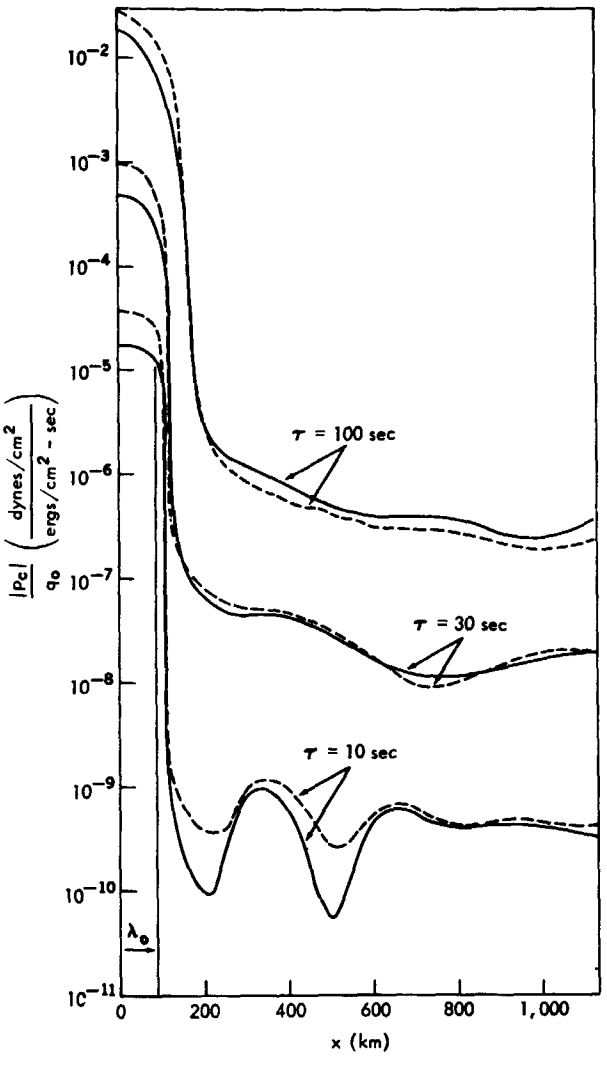

FIGURE 13.—Intensities of cellular waves on the ground in the units of q_0 vs. the horizontal distance x from the center of the source, of which the width λ_0 is 100 km, for τ=10 sec, 30 sec and 100 sec. Full lines and dashed lines stand for h=H and h=½H, respectively.

auroral activity is negligible. For the real atmosphere, therefore, the horizontal propagation of acoustic waves through the ducts around the mesopause and the stratopause is rather important in explaining the diurnal variation of the arrival direction of these waves during the period of high geomagnetic activity, as shown in Figure 1.

7. It should be noted that auroral activities are not necessarily within the auroral zone but, rather, extend toward lower latitudes (nearly to 50°N), when these sonic waves are observed during the periods of magnetic disturbances (as can be seen from the auroral visoplot shown in Figure 2).

To show the position and structure of sonic ducts as well as attenuation of the waves requires the actual atmospheric temperature distributions. This is discussed elsewhere (Reference 59).

Finally, it should be noted that the energy flux of acoustic waves at the ground S in ergs/cm²-sec is

$$S = Ec \quad , \tag{78}$$

where

$$E = \frac{p_s^2}{2\rho_s c^2} \quad ; \tag{79}$$

p_s and ρ_s are the maximum aplitude of pressure change in dynes/cm² and the static density of air atat sea level, and c is the sound velocity in cm/sec.

Since ρ_s is of the order of 1.25×10^{-3} gm/cm³, the energy flux corresponding to $p_s=1$ dyne/cm² is approximately 1.4×10^{-2} erg/cm²-sec. To show the energy relation between the input power and the observed output intensity, as given in Figures 3, 5–10, and 13, the above relation must be used.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Dr. J. M. Young and his co-workers at the National Bureau of Standards in Washington, D. C., who gave detailed information on their observations of infrasonic waves during magnetic disturbances. Thanks are also due to Dr. G. D. Mead for his comments, and Mr. E. Monasterski for his help on the computer calculations.

DERIVATION OF DIFFERENTIAL EQUATION 37

By differentiating Equations 30 and 31 with respect to t and using Equation 33

$$\frac{\partial^2 u}{\partial t^2} = \frac{\partial}{\partial x}\left(c^2 \chi - gw\right) - \frac{1}{\rho_0}\frac{\partial s}{\partial x} \quad . \tag{A1}$$

$$\frac{\partial^2 w}{\partial t^2} = \frac{\partial}{\partial z}\left(c^2 \chi - gw\right) - \left[(\gamma - 1)\, g + \frac{dc^2}{dz}\right]\chi - \frac{1}{\rho_0}\frac{\partial s}{\partial z} \quad . \tag{A2}$$

When the time dependences of u, w, p, ρ, and s are proportional to a common factor $e^{i\delta t}$, a straightforward calculation leads to Equations 34, 35, and 36 from Equations A1, A2, and 33, respectively.

Differentiating Equations A1 and A2 with respect to x and z, respectively, and adding them gives

$$\frac{\partial^2 \chi}{\partial t^2} = c^2 \nabla^2 \chi - g\frac{\partial \zeta}{\partial x} + \left(\frac{dc^2}{dz} - \gamma g\right)\frac{\partial \chi}{\partial z} - \left(\frac{dc^2}{dz} + \gamma g\right)\frac{1}{\rho_0 c^2}\frac{\partial s}{\partial x} - \frac{1}{\rho_0}\nabla^2 s \quad . \tag{A3}$$

where

$$\zeta = \frac{\partial w}{\partial x} - \frac{\partial u}{\partial z} \quad . \tag{A4}$$

Similarly, by differentiating Equations A1 and A2 with respect to z and x, respectively, and subtracting the former from the latter,

$$\frac{\partial^2 \zeta}{\partial t^2} = -\left[\frac{dc^2}{dz} + (\gamma - 1)\, g\right]\frac{\partial \chi}{\partial x} + \frac{1}{\rho_0 c^2}\left(\frac{dc^2}{dz} + \gamma g\right)\frac{\partial s}{\partial x} \quad . \tag{A5}$$

The elimination of ζ from Equations A3 and A5 results in

$$\frac{\partial^4 \chi}{\partial t^4} = c^2 \nabla^2 \frac{\partial^2 \chi}{\partial t^2} + g\left(\frac{dc^2}{dz} + (\gamma - 1)\, g\right)\frac{\partial^2 \chi}{\partial x^2} - g\frac{\partial}{\partial x}\left[\frac{1}{\rho_0 c^2}\left(\frac{dc^2}{dz} + \gamma g\right)\frac{\partial s}{\partial x}\right]$$

$$+ \left(\frac{dc^2}{dz} - \gamma g\right)\frac{\partial}{\partial z}\left(\frac{\partial^2 \chi}{\partial t^2}\right) - \left(\frac{dc^2}{dz} + \gamma g\right)\frac{1}{\rho_0 c^2}\frac{\partial}{\partial z}\left(\frac{\partial^2 s}{\partial t^2}\right) - \frac{1}{\rho_0}\nabla^2\left(\frac{\partial^2 s}{\partial t^2}\right) \quad . \tag{A6}$$

Since it is assumed that u, w, p, ρ, and s are proportional to $e^{i\delta t}$, the elimination of the time derivative from Equation A6 gives Equation 37.

Appendix B

SOLUTION OF EQUATION 59 AT z=0

Applying the Fourier transform to Equations 34 and 35 gives

$$-\sigma^2 U = ikc^2 X - ikgW - \frac{ik}{\rho_0} S \quad , \tag{B1}$$

$$-\sigma^2 W = c^2 \frac{dX}{dz} - \gamma g X + ikgU - \frac{ik}{\rho_0} \frac{dS}{dz} \quad . \tag{B2}$$

where U and W are the Fourier transforms of u and w. Solving these bilateral equations with respect to U and W yields

$$\left(\sigma^4 - k^2 g^2\right) U = -ikgc^2 \frac{dX}{dz} + ik\left(\gamma g^2 - \sigma^2 c^2\right) X + \frac{ik\sigma^2}{\rho_0(z)} S + \frac{kg}{\rho_0(z)} \frac{dS}{dz} \quad , \tag{B3}$$

$$\left(\sigma^4 - k^2 g^2\right) W = -c^2\sigma^2 \frac{dX}{dz} + g\left(\gamma\sigma^2 - k^2 c^2\right) X + \frac{k^2 g}{\rho_0(z)} S + \frac{\sigma^2}{\rho_0(z)} \frac{dS}{dz} \quad . \tag{B4}$$

Since $W(z=0)=0$ and $dS/dz|_{z=0}=S(z=0)=0$, from the above equations

$$\left.\frac{dX}{dz}\right|_{z=0} = m(\sigma) X(0) \quad , \tag{B5}$$

where

$$m(\sigma) = g\left(\frac{\gamma}{c^2} - \frac{k^2}{\sigma^2}\right) \quad . \tag{B6}$$

Similarly, the Fourier transform of Equation 33 is

$$i\sigma P(k, z) = g\rho_0(z) W - c^2 \rho_0(z) X(k, z) + S(k, z) \quad , \tag{B7}$$

where

$$P(k, z) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{ikx} p(x, z)\, dx \quad .$$

SOLUTION FOR X[z=0], DIRECT CALCULATION

From Equation 61

$$\frac{dX}{dz} = n_1 e^{n_1 z}\left[C_1 - \frac{1}{2\mu} \int_0^z F(z') e^{-n_1 z'} dz'\right] + n_2 e^{n_2 z}\left[C_2 + \frac{1}{2\mu} \int_0^z F(z') e^{-n_2 z'} dz'\right] \quad . \tag{B8}$$

Using Equation B5, from Equation B8 we get

$$C_1 = -\frac{n_2 - m(\sigma)}{n_1 - m(\sigma)} C_2 \quad . \tag{B9}$$

If we write

$$A_1 = C_1 - \frac{1}{2\mu} \int_0^z F(z') e^{-n_1 z'} dz'$$

and

$$A_2 = C_2 + \frac{1}{2\mu} \int_0^z F(z') e^{-n_2 z'} dz'$$

then from Equations B8 and B9, by assuming $h<2H$,

$$A_1 e^{-\mu z} = \begin{cases} C_1 e^{-\mu z} & \text{for } 0 \le z \le z_0 \ , \\ \left[C_1 + Q_0 \frac{\sigma^4 - k^2 g^2}{2\mu c^2 \sigma^2} \frac{1}{n_1 + \beta} C^{-(n_1+\beta)z_0} \right] e^{-\mu z} + Q_0 \frac{\frac{\beta}{h} + \frac{k^2 g}{\sigma^2 H} - k^2}{2\mu\, n_1 + \beta} C^{-\left[(1/h)-(1/2H)\right]z} & \text{for } z_0 \le z < \infty \ , \end{cases} \quad \text{(B10)}$$

and

$$A_2 e^{+\mu z} = \begin{cases} C_2 e^{\mu z} & \text{for } 0 \le z \le z_0 \ , \\ \left[C_2 - Q_0 \frac{\sigma^4 - k^2 g^2}{2\mu c^2 \sigma^2} \frac{1}{n_2 + \beta} e^{-(n_2+\beta)z_0} \right] e^{\mu z} - Q_0 \frac{\frac{\beta}{h} + \frac{k^2 g}{\sigma^2 H} - k^2}{2\mu\, n_2 + \beta} e^{-\left[(1/h)-(1/2H)\right]z} & \text{for } z_0 \le z < \infty \ , \end{cases} \quad \text{(B11)}$$

where

$$Q_0 = \sqrt{\frac{2}{\pi}} \frac{\sin \lambda_0 k}{k} \frac{(\gamma - 1) q_0}{\rho_s h c^2} e^{z_0/h} \ . \quad \text{(B12)}$$

and

$$\beta = \frac{1}{h} - \frac{1}{H} \ . \quad \text{(B13)}$$

The term including $e^{\mu z}$ represents the waves whose amplitudes increase with height. The corresponding kinetic energies diverge to infinity provided that $N^2 > M^2$. On the other hand, if $N^2 < M^2$ this term represents inward-going waves.

Because of the boundary conditions listed in the section "Mathematical Treatment," the terms including $e^{\mu z}$ must vanish. Therefore

$$C_2 = C_1 \frac{\sigma^4 - k^2 g^2}{2\mu c^2 \sigma^2} \frac{1}{n_2 + \beta} e^{-(n_2+\beta)z_0} \ . \quad \text{(B14)}$$

Putting this constant into Equation 61, for $z=0$, gives

$$X(k, 0) = \sqrt{\frac{2}{\pi}} \frac{(\gamma - 1) q_0}{h \sigma^4 c^2 \rho_0} e^{(z_0/2H) - \mu z_0} \frac{\sin \lambda_0 k}{k} \frac{\sigma^4 - k^2 g^2}{(n_1 - m)(n_2 + \beta)} \ . \quad \text{(B15)}$$

The continuity of $W(k, z)$ and $P(k, z)$ at $z = z_0$ is satisfied by the above choice of constants, i.e., it can be shown that

$$\lim_{\epsilon \to 0} W(z_0 - \epsilon) = \lim_{\epsilon' \to 0} W(z_0 + \epsilon') \ .$$

$$\lim_{\epsilon \to 0} P(z_0 - \epsilon) = \lim_{\epsilon' \to 0} P(z_0 + \epsilon') \ .$$

SOLUTION FOR X[k,0] BY MEANS OF THE LAPLACE TRANSFORM

By applying the Laplace transform with respect to z,

$$\tilde{X}(k, s) = \int_0^\infty e^{-sz} X(k, z)\, dz \tag{B16}$$

Equation 59 becomes

$$\left(s^2 - 2Ns + M^2\right) \tilde{X} - (s - 2N) X(0) - \left.\frac{dX}{dz}\right|_{z=0} = Q_0 \frac{e^{-(s+\beta)z_0}}{s+\beta} \left[s^2 - 2Ns - k^2\left(1 - \frac{g}{\sigma^2 H}\right)\right].$$

By making use of the relation shown by Equation B5, this is

$$\tilde{X}(k, s) = \frac{(s - 2N - m)}{(s - n_1)(s - n_2)} X(0) + \frac{Q_0 e^{-(s+\beta)z_0}}{\beta + s} \left[1 - \frac{\sigma^4 - k^2 g^2}{(s - n_1)(s - n_2) c^2 \sigma^2}\right] \tag{B17}$$

where n_1 and n_2 are given [illegible] and 64; $m = m(\sigma)$ and Q_0 are given by Equations B6 and B12.

By making use of the inverse [illegible] of Equation B16 the solution to Equation 59 is

$$X(k, z) = \left(\frac{2N - m - n_1}{2\mu} e^{n_1 z} - \frac{2N - m - n_2}{2\mu} e^{n_2 z}\right) X(0) + Q_0 e^{-\beta z} \theta(z - z_0)$$

$$- Q_0 \frac{\sigma^4 - k^2 g^2}{2\mu c^2 \sigma^2} e^{-\beta z_0} \left[\frac{e^{n_2(z - z_0)}}{\beta + n_2} - \frac{e^{n_1(z - z_0)}}{\beta + n_1} + \frac{e^{-\beta(z - z_0)}}{(\beta + n_1)(\beta + n_2)}\right] \theta(z - z_0) . \tag{B18}$$

Because of the boundary conditions at $z = \infty$, the term proportional to e^{nz} must vanish, i.e., from Equation B18

$$- \frac{2N - m - n_2}{2\mu} X(0) - Q_0 \frac{\sigma^4 - k^2 g^2}{c^2 \sigma^2} \frac{e^{-(\beta + n_2) z_0}}{2\mu(\beta + n_2)} = 0 . \tag{B19}$$

This gives the same solution as Equation B15. It should be noted that the above solution satisfies the conditions of continuity of w(x, z) and p(x, z) at $z = z_0$, although u(x, z) and s(x, z) are not continuous at $z = z_0$.

Appendix C

EVALUATION OF p[x, 0]

As can be seen from Equation B15 X(k, 0) is an even function of k. Therefore, the substitution of Equation B15 into Equation 67 gives

$$\chi(x, 0) = \frac{2}{\pi} \frac{(\gamma - 1) q_0 \sigma^2}{h k_g^2 \rho_s c^4} e^{z_0/2H} \int_0^\infty e^{-\mu z_c} \frac{\cos xk \sin \lambda_0 k}{k} \frac{k_g^2 - k^2}{(n_1 - m)(n_2 + \beta)} dk \qquad (C1)$$

where

$$k_g = \frac{\sigma^2}{g} . \qquad (C2)$$

Since μ is a real function of k for $k \geq k_c$ and complex for $0 \leq k < k_c$, where

$$k_c = \frac{\sigma}{c} \sqrt{\frac{\sigma^2 - \sigma_A^2}{\sigma^2 - \sigma_B^2}} . \qquad (C3)$$

Equation C1 can be written

$$\chi(x, 0) = \chi_c(x, 0) + \chi_{nc}(x, 0) , \qquad (C4)$$

where

$$\chi_c(x, 0) = \frac{2}{\pi} \frac{(\gamma - 1) q_0 \sigma^2}{h k_2^2 \rho_s c^4} e^{z_0/2H} \int_0^{k_c} e^{-i\eta z_0} \frac{\cos xk \sin \lambda_0 k}{k} \frac{k_g^2 - k^2}{(n_1 - m)(n_2 + \beta)} dk , \qquad (C5)$$

and

$$\chi_{nc}(x, 0) = \frac{2}{\pi} \frac{(\gamma - 1) q_0 \sigma^2}{h k_2^2 \rho_s c^4} e^{z_0/2H} \int_{k_c}^\infty e^{-\mu z_0} \frac{\cos xk \sin \lambda_0 k}{k} \frac{k_g^2 - k^2}{(n_1 - m)(n_2 + \beta)} dk . \qquad (C6)$$

The integrand of $\chi_{nc}(\chi, 0)$ has two singular points σ/c and σ^2/g, corresponding to the two types of free oscillations of the noncellular mode which were pointed out by Pekeris* and have been discussed earlier. Because of a steep exponential term $e^{-\mu z_0}$, however, contributions of these singularities to the integral is not as important as the contribution from the narrow band near $k \geq k_c$, where the exponential term is nearly unity.

The integrand of x_c has no singularities but oscillates by the term $e^{-i\eta z_0}$. The main contribution arises from a narrow domain near $k \leq$ approx. k_c. Equation 68 can be written

$$p(x, 0) = p_c(x, 0) + p_{nc}(x, 0) , \qquad (C7)$$

where

$$p_c(x, 0) = p_r + ip_i , \qquad (C8)$$

*Pekeris, C. L., "The Propagation of a Pulse in the Atmosphere. II," *Phys. Rev.* 73:145–154, January 15, 1948.

$$\left|p_c(x,0)\right| = \frac{2}{\pi}\frac{(\gamma-1)q_0\sigma}{hk_g^2c^2}e^{z_0/2H}\left|\int_0^{k_c} e^{-i\eta z_0}\frac{\cos xk\sin\lambda_0 k}{k}\frac{k_g^2-k^2}{(n_1-m)(n_2+\beta)}\,dk\right| = \sqrt{p_r^2+p_i^2}\,; \quad \text{(C9)}$$

and

$$p_{nc}(x,0) \approx \frac{2}{\pi}\frac{(\gamma-1)q_0\sigma}{hk_g^2c^2}e^{z_0/2H}\int_{k_c}^{k_g} e^{-\mu z_0}\frac{\cos xk\sin\lambda_0 k}{k}\frac{k_g^2-k^2}{(n_1-m)(n_2+\beta)}\,dk\,. \quad \text{(C10)}$$

N66 37966

ATMOSPHERIC DENSITIES FROM EXPLORER 17 DENSITY GAUGES AND A COMPARISON WITH SATELLITE DRAG DATA*

GEORGE NEWTON, RICHARD HOROWITZ AND WOLFGANG PRIESTER†

The purpose of this letter is to present the initial atmospheric densities directly measured by the ionization gages on the Explorer 17 satellite. The satellite has been described [*Horowitz*, 1963] and the gauges and their response to the atmosphere have also been reported [*Newton et al.*, 1963]. The data presented in this letter were obtained with two types of ionization vacuum gauges, the hot-filament thermionic type (Bayard-Alpert) and the magnetron type (Redhead). The absolute accuracy of these data is believed to be ±35 percent and the repeatability is ±20 percent. A more complete discussion of the experiment will be included in a paper now in preparation [*Newton et al.*, 1964].

The density data from 47 operations of the satellite in the altitude range 255 to 330 km for local times between 0700 and 2100 hours are plotted as a function of altitude in Figure 1. These data were recorded by the five northern midlatitude minitrack stations:

Blossom Point, Md.
Grand Forks, Minn.
Mojave, Calif.
St. Johns, Newfoundland
Winkfield, England

At the times the measurements were made, the daily planetary geomagnetic index (A_p) was between 0 and 50, and the 10.7-cm solar index ($F_{10.7}$) was between 70 and 100×10^{-22} w/m^2 cps. It is seen from Figure 1 that there is considerable variation in the atmospheric density at a given altitude (that is, greater than a factor of 3 at the altitude of 280 km) which is due in part to local time, geomagnetic activity, and solar activity effects.

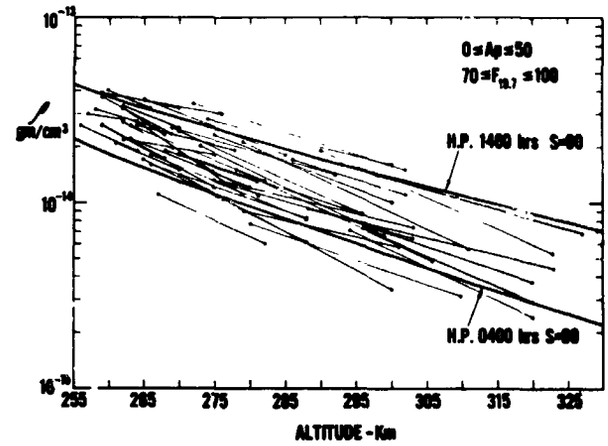

FIGURE 1.—Atmospheric density versus altitude measured by the Explorer 17 density gauges during 47 operations of the satellite. The densities were measured for times between 0700 and 2100 hours, with A_p varying between 0 and 50 and with $F_{10.7}$ varying between 70 and 100×10^{-22} w/m^2 cps.

To compare the directly measured densities with densities inferred from satellite drag, it is desirable to reduce the data to geomagnetically quiet conditions. In this regard, consider Figure 2, which shows $\Delta \log \rho$, the logarithm to the base 10 of the ratio of the measured density to the Harris and Priester model density selected for the appropriate time and altitude, plotted versus the daily geomagnetic index (A_p). These points represent 120 density-altitude profiles for altitudes between 255 and 600 km and most local times; the data were recorded over the same five minitrack stations as were the data in Figure 1. The darkened symbols represent an average of two or more

*Published in the *Journal of Geophysical Research*, 69(21):4690–4692, November 1, 1964.

†Goddard Space Flight Center; on leave from Bonn University.

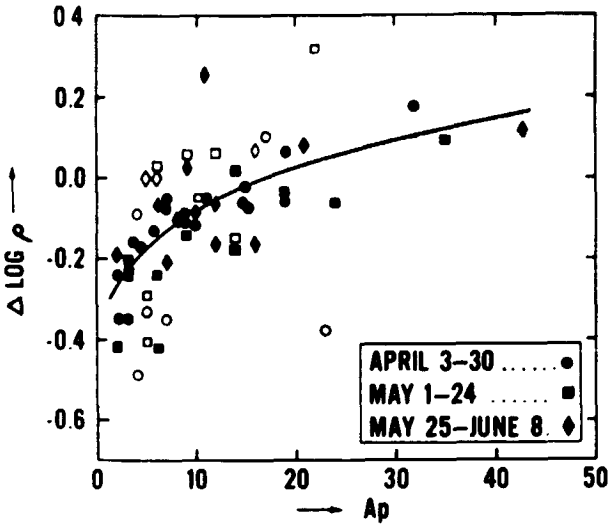

FIGURE 2.—Daily average of the logarithms of the ratios of the gauge measured density to the Harris and Priester model density, plotted against daily geomagnetic A_p index. Solid symbols represent averages of measurements obtained from two or more passes of the satellite over the telemetry stations. Open symbols represent single passes. The data have been adjusted to correspond to $F_{10.7}=83$. The semiannual variation of the atmospheric density has been accounted for in an approximate way by decreasing the model densities by 18% for May and June 1963.

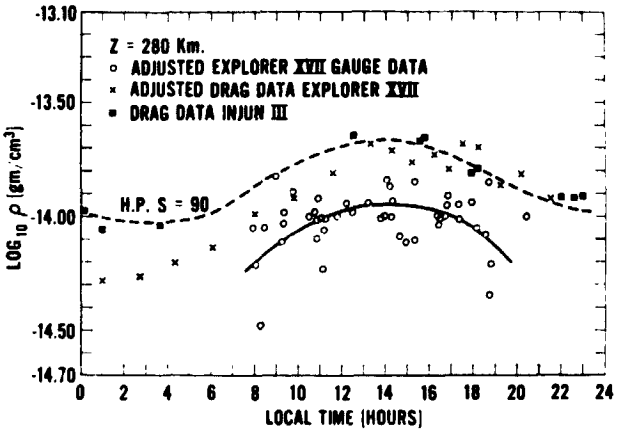

FIGURE 3.—Logarithms of densities normalized to an altitude of 280 km versus local time. Injun 3 data are selected for geomagnetically quiet conditions. Explorer 17 data are adjusted to $A_p=2$ using relation shown in Figure 2 and for an $F_{10.7}$ corresponding to 83.

passes within one day and the light symbols represent one pass. The passes have been individually corrected to an $F_{10.7}$ of 83 using *Roemer's* [1963] formula. The semiannual variation of the atmospheric density has been accounted for in an approximate way by decreasing the model densities by 18 percent for May and June 1963. A visual average of the data shows (*a*) that the relation between Δ log ρ and A_p is nonlinear, the steepest slope being applicable to the smaller A_p values, and (*b*) that the atmospheric density values are more sensitive to geomagnetic disturbances than has previously been reported. Very recently, *Jacchia and Slowey* [1964*a*] found independently that for near-quiet geomagnetic conditions the reaction of the atmosphere to variations in A_p is considerably larger than that expected on the basis of their previous analyses.

Figure 3 shows the logarithm to the base 10 of the gauge densities at the average time and altitude of the pass plotted versus local time and normalized to 280 km using the Harris and Priester model for $S=90$ as a differential altitude transformer. Shown for comparison are the densities obtained from drag observations of Injun 3 [*Jacchia and Slowey*, 1964*b*] and Explorer 17 [*Bryant*, 1964], and the Harris and Priester model with $S=90$. The drag data have also been normalized to the 280-km altitude.

The Injun 3 drag data, indicated by squares, were selected for quiet geomagnetic conditions ($A_p\pm2$) for the time interval of February 18 through June 30, 1963, when the latitude of the satellite varied between $-40°$ and $+60°$. The Explorer 17 drag data, indicated by crosses, correspond to the time interval from April 3 to July 6, 1963, when the satellite perigee was between $+58°$ and $-20°$.

The relation shown in Figure 2 has been used to adjust both the Explorer 17 drag-determined and gauge-measured densities to geomagnetically quiet conditions ($A_p=2$). The Explorer 17 densities also have been normalized to a 10.7-cm solar index of 83, a small adjustment compared to those associated with the A_p. The A_p adjustment resulted in: (*a*) a decrease of approximately a factor of 2 in the apparent scatter between the gauge-measured density values, (*b*) a lowering of the average of the gauge-measured densities by a factor of 0.7, and (*c*) a lowering of Bryant's drag densities by approximately 60 percent.

It is seen in Figure 3 that the atmospheric densities determined by satellite drag techniques appear to be systematically higher by a factor of 2 than the adjusted gauge densities. This difference is greater than the combined uncertainties

assigned to the separate sets of data and would seem to be due to a systematic error in one or both of the measurements. While the difference is not regarded as a serious discrepancy between the two techniques, it is large enough to require a re-examination of the measurements made by each.

A more detailed presentation of the atmospheric density data from these five minitrack stations and their geophysical interpretation is in preparation [*Newton et al.*, 1964]. The presentation will include (1) data of considerably greater altitude and local-time coverage and (2) density scale-height computations. In addition, data from the other eight minitrack (perigee 255 km, initial apogee 920 km, 58° inclination) are currently being analyzed and will be reported.

ACKNOWLEDGMENTS

We wish to thank Mr. Nelson W. Spencer, Goddard Space Flight Center, for helpful discussions in the preparation of this letter.

One of us (W. Priester) is grateful to the National Academy of Sciences—National Research Council for a Senior Research Associateship.

STRATOSPHERIC TEMPERATURE PATTERNS BASED ON RADIOMETRIC MEASUREMENTS FROM THE TIROS VII SATELLITE*

W. NORDBERG, W. R. BANDEEN, G. WARNECKE AND V. KUNDE

The TIROS VII meteorological satellite carried a sensor to map the emitted terrestrial radiation in the 15 micron carbon dioxide band. The spectral response of the sensor ranged from 14.8 to 15.5 microns. The radiation observed by the satellite is a function of the temperatures of the atmosphere varying along the optical path. Atmospheric layers at various altitudes contribute to the observed radiation in varying amounts. More than 96 percent of this contribution stems from altitudes above 10 km and more than 60 percent from a layer ranging in altitude from 18 to 35 km; thus, the radiation measurements were interpreted in terms of average temperatures of a major portion of the stratosphere.

Temperature patterns were analyzed from June 1963 to March 1964. The measurements demonstrate on a global scale, the varying patterns of stratospheric temperatures and circulation. Smooth temperature gradients were found to coincide closely with latitudinal circles on both summer hemispheres. Temperatures increased at high latitudes toward the summer pole (250° K) and rapidly decreased toward the winter pole (200° K).

A fairly uniform region with temperatures generally around 230° K extended between 25° latitude of the summer hemisphere and 40° latitude of the winter hemisphere during solstices. During both equinoxes, the large latitudinal temperature gradients at high latitudes disappeared and differences of about 10–15° K existed with latitudes as well as with longitude. Winter temperature patterns in both hemispheres exhibit strong temperature gradients between the pole and 40°, but a completely uniform pattern never existed in either winter hemisphere. A warm area over the Indian Ocean, though initially small, seemed to play a similar role in the southern winter as the Aleutian warm center during the northern winter. The morphology of a stratospheric warming which occurred over southwestern Asia and penetrated to Europe immediately after the tropical belt had cooled by about 10° K was observed.

I. INTRODUCTION

A radiometer aboard the TIROS VII satellite measured infrared radiation emitted mainly by carbon dioxide in the earth's atmosphere at wavelengths ranging from 14.8 to 15.5 microns. The instrument in this measurement was very similar to the 5 channel radiometers flown on previous TIROS satellites and described by Bandeen, et al. (Reference 1), except that one of the optical channels was modified to have a spectral response as shown in Figure 1a. The initial objective of radiation measurements in this region of the spectrum was to study the characteristics of the earth's horizon as described by Hanel, et al. (Reference 2) and later reported by Bandeen, et al. (Reference 3). Now, with continuous observations over a period of more than six months, covering daily the global zone from 65° N to 65° S, it is possible to use the radiation measurements to describe a number of interesting features of the atmosphere. It will be shown that most of the radiation reaching the satellite in this spectral region is emitted within a defined altitude interval in the stratosphere whose average temperature can be derived from the observed radiation intensities. Quasi-global maps of these average temperatures for different seasons not only reflect the expected variations in the mean stratospheric temperatures, but also reveal the development and behavior of major synoptic systems in that region of the atmosphere. A complete description

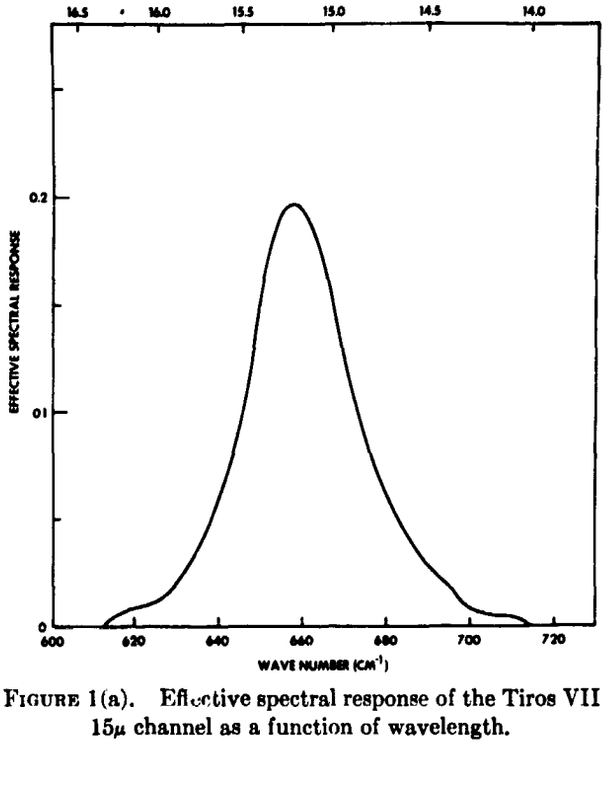

FIGURE 1(a). Effective spectral response of the Tiros VII 15μ channel as a function of wavelength.

of the 5 channel radiation experiment on TIROS VII as well as a critique and summary of all data resulting from this experiment will be contained in the TIROS VII Radiation Data Catalog and Users' Manual (Reference 4).

II. RELATION BETWEEN RADIATION AND STRATOSPHERIC TEMPERATURES

The spectral response of the instrument was chosen to coincide as closely as possible with the 15 micron absorption band of carbon dioxide. The radiance N from the earth and atmosphere measured by the radiometer whose spectral response function $\phi(\lambda)$ is shown in Figure 1a can be expressed as:

$$N=\frac{1}{\pi}\int_0^{\infty}\int_{\lambda=\lambda_1}^{\lambda_2}\phi(\lambda)B(\lambda, T)\frac{\partial\tau}{\partial s}(\rho, p, T, \lambda)d\lambda ds \qquad (1)$$

where

ρ = carbon dioxide density

B = Planck function

s = distance along radiation path

λ_1 and λ_2 = wavelengths between which $\phi\neq 0$

p = atmospheric pressure

T = atmospheric temperature

τ = atmospheric beam transmissivity

It is reasonable to assume that a constant ratio $r=0.000471$ exists between the densities ρ for carbon dioxide and ρ_{air} for air: $\rho=r\,\rho_{air}$. Furthermore, a number of typical distributions for temperature with height h for surface pressures of 1013.25 mb were chosen so that ρ_{air}, p and T could be expressed as functions of h where ρ_{air} and p were computed as a function of h from T by the hydrostatic equation. A relationship between s and h, $s=s(h)$, was established through the choice of several angles at which the satellite at approximately 635 km viewed the earth. The integration of (1) over λ was then performed for seven nadir angles, 0°, 29°, 40°, 47°, 52°, 55°, and 58°. The function $\tau(\lambda, h)$ was determined using, in principle, the method described by Hanel, et al. (Reference 2). That method is based on the general treatment by Elsasser (Reference 5) of the absorption within the 15 micron CO_2 band. Thus,

$$\int_{\lambda_1}^{\lambda_2}\phi(\lambda)B(h, \lambda)\frac{\partial\tau}{\partial s}(h, \lambda)\frac{\partial s}{\partial h}d\lambda=\Psi(h). \qquad (2)$$

Hence,
$$\bar{N}=\frac{1}{\pi}\int_0^{\infty}\Psi(h)dh. \qquad (3)$$

$\bar{N}$ was then computed for each of the assumed temperature profiles and for each nadir angle from (3). The assumed temperature distributions with height and the resulting distribution functions $\Psi(h)$ are shown in Figures 2a through 2c. In accordance with previous practices of reporting TIROS radiation measurements (References 4, 6–8) $\bar{N}$ may be expressed by the temperature T_{BB} of a blackbody whose radiant emittance $\bar{W}$ is given by:

$$\bar{W}=\int_{\lambda_1}^{\lambda_2}\phi(\lambda)B(T_{BB}, \lambda)d\lambda=\pi\bar{N} \qquad (4)$$

Indeed, since the radiometers were calibrated using such blackbodies at various temperatures, the measurement of T_{BB} may be considered as the

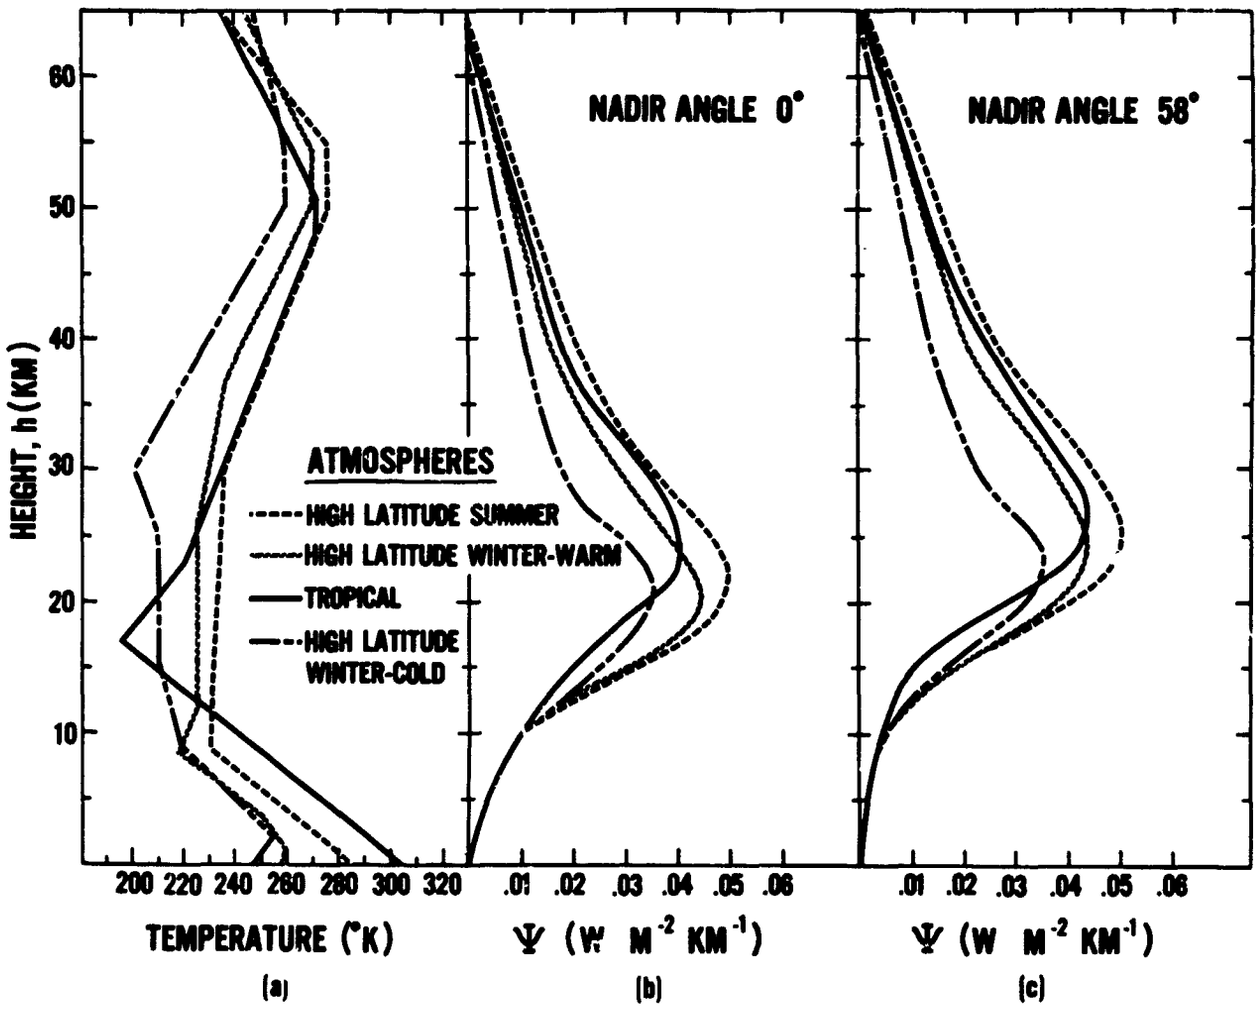

FIGURE 2(a).—Typical temperature profiles based on proposed supplements to the "U. S. Standard Atmosphere 1962" for 60° North summer, 60° North winter (warm and cold) and 15° North. The "warm" and "cold" temperature profiles for 60° N ("high latitude winter") can be considered typical at these latitudes depending on the state of the stratosphere in these regions. The supplements to the U. S. Standard Atmosphere 1962 are in the process of preparation by the U. S. Committee for Extension of the Standard Atmosphere and were summarized by Cole, et al. Reference 16).

FIGURE 2(b).—Weighting functions ψ (h), applying to the measured outgoing radiance $\bar{N}$; nadir angle = 0°

primary quantity while N requires a derivation by means of equation (4). The values of T_{BB} corresponding to the temperature profiles of Figure 2a are summarized in Table I.

The radiation measurement expressed by T_{BB} thus represents a mean temperature of the atmosphere in which the vertical temperature distribution is open to choice and where the temperature at each altitude must be given a different weight regarding its contribution to the measured mean. The weighting function is given by Ψ (h), and although Ψ (h) depends to a certain degree on the

TABLE I.—*Computed Mean Temperatures (T_{BB}) Expected to be Observed by 15 Micron Radiometer for Temperature profiles shown in Figures 2a at Nadir Angles of 0° and 58°.*

Nadir Angle	Tropical	High Lat. Summer	High Lat. Winter Cold	High Lat. Winter Warm
0°	227° K	238	213	229
58°	231	240	214	231

assumed vertical temperature profile, it may be seen that for most realistic temperature profiles at a nadir angle $\eta=0$ (Figure 2b), temperatures between 20 and 25 km are weighed most heavily with about 65 percent of the weight being concentrated in the region from 15 to 35 km and more than 96 percent of the weight lying at altitudes above 10 km. It may, also, be seen from Figure 2c that the maximum weight shifts to somewhat higher altitudes for a nadir angle of 58°. But, since this shift amounts to less than 5 km from $\eta=0$ to $\eta=58°$, it is not possible to make a precise quantitative determination of the variation of temperature with altitude from measurements of T_{BB} at various nadir angles. However, it will be shown in the section below that from such measurements one may infer qualitatively whether the temperature is increasing, decreasing, or constant with height over the altitude range where the Ψ functions reach their maxima. Furthermore, with a prudent and realistic choice of assumed vertical temperature profiles, such as shown in Figures 2a, one can easily determine from the T_{BB} measurements which one of these profiles represents the best fit qualitatively to actual conditions at a certain location on the globe and; more important, one may determine from continuous observations how the choices of such "best fits" vary with time. Thus, the maps of T_{BB} measurements plotted for the "quasi-global" (65° N to 65° S) zone for different times of the year, presented in Figures 3–12, enable the synoptic analysis of phenomena related to the temperature structure in the stratosphere between about 15 and 35 km. The occurrence of such events as explosive warmings, the establishment of the Aleutian anticyclone in winter, the onset of the seasonal circulation reversals and similar events may be categorized as such phenomena. Although the TIROS VII radiometer views the entire global zone from 65° N to 65° S during the course of 12 hours, data from only about 60 percent of the orbits during any one

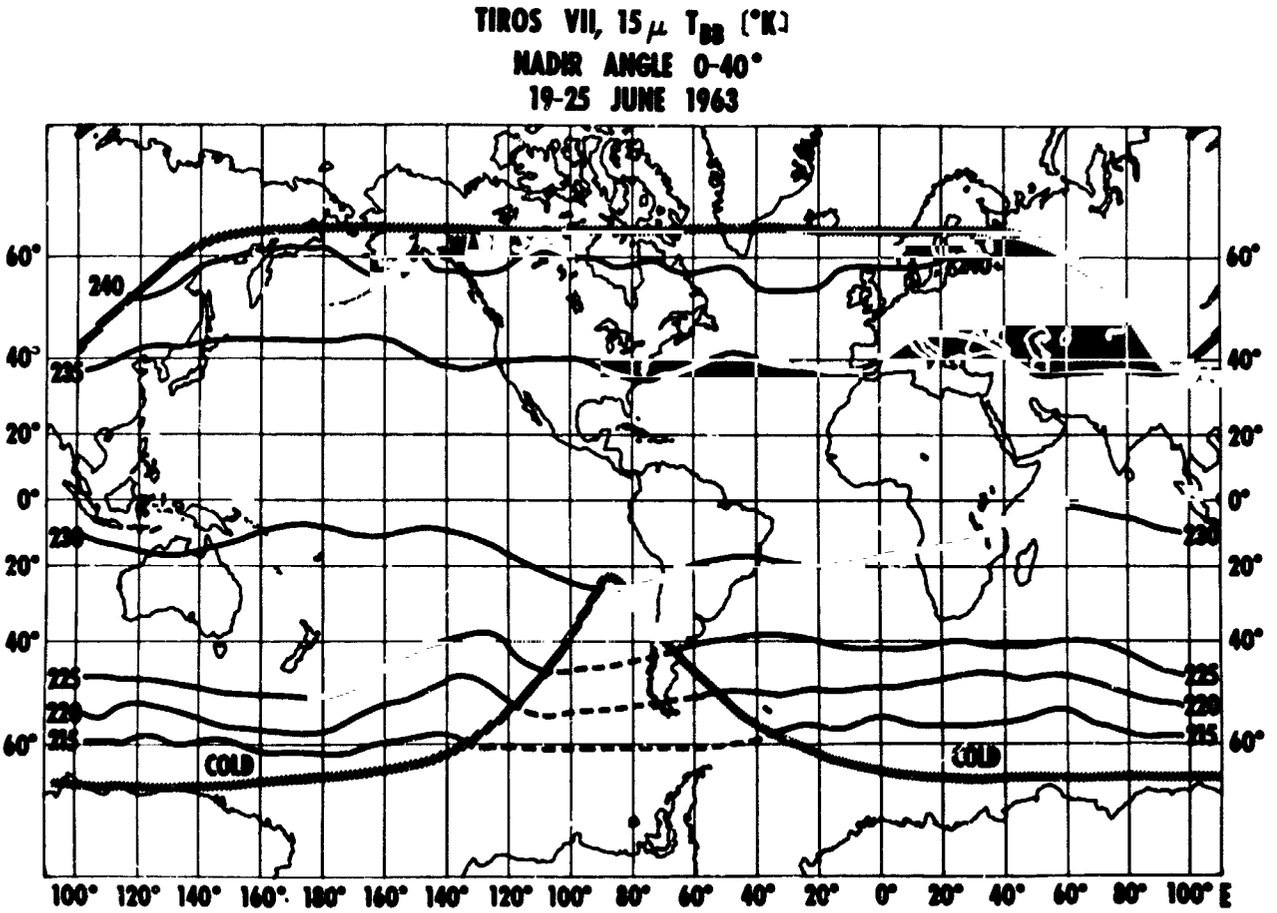

FIGURE 3(a).—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 19–25 June 1963; nadir angle 0°–40°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

day can be acquired because only stations within the United States are capable of receiving the data which are stored aboard the satellite for no longer than one orbital period. This causes two significant gaps in the data displayed in the maps, Figures 3–12. One such gap exists at 90° W just off the west coast of South America, the other is at 90° E over the central Soviet Union.

As will be stated in the TIROS VII Radiation Data Catalog and Users' Manual (Reference 4), the precision of each individual measurement is probably not much better than ±3°K. However, one may assume that the physical properties of the stratosphere remain generally constant for several days and are uniform over distances of less than 500 km. Since the field of view of the radiometer is about 5 degrees, covering an area of about 50×50 km on the surface of the earth for small nadir angles, and since in general measurements for the entire quasi-globe are obtained at least once every 24 hours, up to about 1000 measurements may result within one week within an area of about 500×500 km. Therefore, a precision of better than 1°K can be estimated for the temperature values shown in the maps, Figures 3–9 and 11–12, which were obtained by averaging measurements within each grid element (ranging from 5° latitude×5° longitude at the equator to 2.5° latitude×5° longitude at 60° latitude) over the period of one week.

Although the precision of the temperature measurement is greatly enhanced by reducing the random error in the averaging process, there are a number of systematic errors which must be considered. It has been attempted to reduce these errors by applying the appropriate corrections, but uncertainties still remain, causing the overall accuracy to be considerably poorer than the fraction of 1°K stated for the precision. Aside from correcting for an instrumental degradation which will be discussed later, a correction was applied to the data for an as yet unexplained deviation from

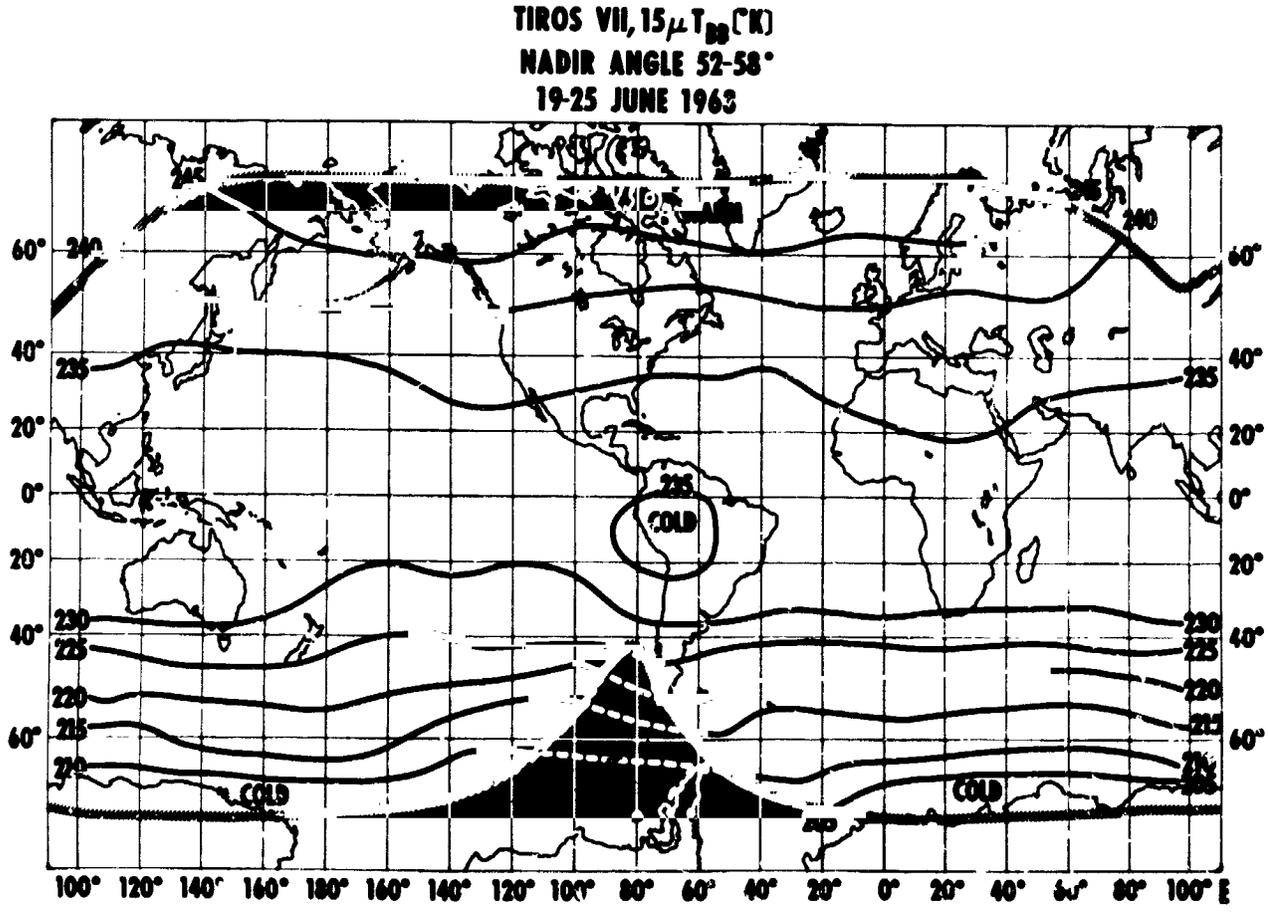

FIGURE 3(b).—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 19–25 June 1963; nadir angle 52°–58°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

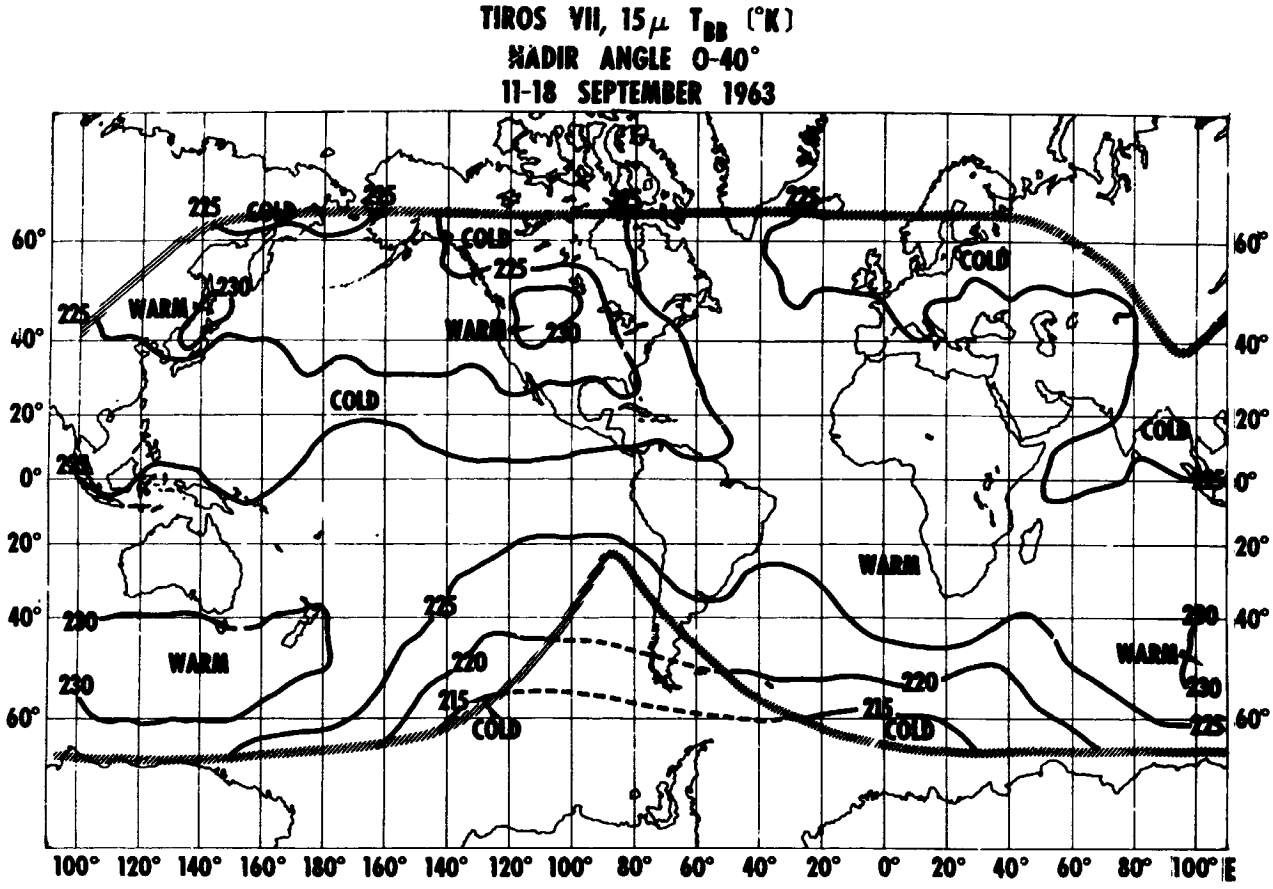

FIGURE 4.— Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 11–18 September 1963; nadir angle 0°–40°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

the original preflight calibration. The radiometer, which alternatingly views the earth through one of two viewing ports showed that a consistently lower response on one of these viewing ports with respect to the other were apparently causing half of the measured temperatures to be too low and half to be too high. According to the preflight calibration, there should be no such difference. For lack of a better correction procedure, the difference between the temperatures measured through the two viewing ports over the same area at the same time were determined for all cases shown in the maps in Figures 3 through 12. Temperatures for the lower side were then corrected upward by half this difference, while those for the higher side were corrected downward by the same amount. Total differences were generally 5 to 8°K, so that the corrections were in the order of 2.5 to 4°K.

The maps were prepared from the magnetic tapes (FMRT's) containing all the TIROS VII radiation data (Reference 4) by an IBM 7094 computer and contour lines were drawn manually. This mapping procedure was the same as the one used in previously published similar maps (Reference 9).

III. ANALYSIS OF STRATOSPHERIC TEMPERATURES, JUNE 1963 TO MARCH 1964

A. Solstice June 1963

A typical temperature pattern at the start of the northern hemisphere summer and southern hemisphere winter for the quasi-globe is shown in Figure 3a. Stratospheric mean temperatures averaged over nadir angles between 0° and 40° and averaged over the week from 19 June to 25 June, the first week of TIROS VII, range from 240°K near 60° N to 215° near 60° S. The generally zonal structure of the temperature pattern, with isotherms running practically parallel with

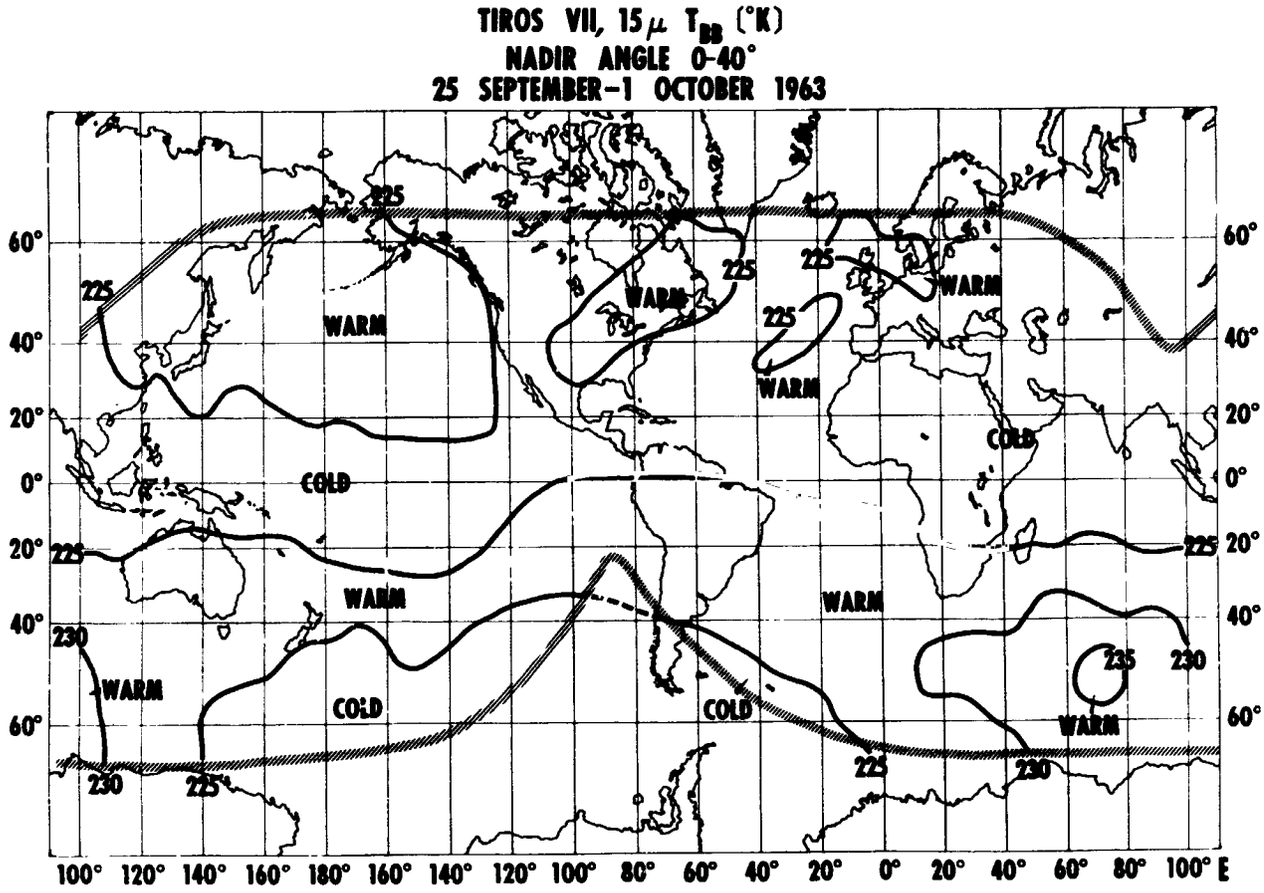

FIGURE 5.—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 25 September–1 October 1963; nadir angle 0°–40°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

latitude circles, confirms the established knowledge of the physics of the lower stratosphere; namely, the existence of a very strong cyclonic circulation system around a low pressure core centered near the winter pole. This low pressure is caused by the intense cooling of the stratosphere over the winter pole. Conversely, anticyclonic circulation prevails over the summer pole where solar heating causes a warm stratosphere resulting in a high pressure system. The predominantly zonal isotherms at high northern latitudes (summer) suggest that solar heating is primarily responsible for this pattern. At high southern latitudes (winter) however, there are slight but apparently significant disturbances in this zonal pattern. Isotherms over the South Pacific between 30° S and 60° S deviate from a perfect zonal course; they show a definite slope from the southwest to the northeast in that area. Temperatures increase rapidly from the winter pole toward the equator causing very steep temperature gradients with latitude in the winter hemisphere. A temperature of about 230°K is reached near 20° S. From there to the summer pole, the temperature increases gradually, and the gradients are not as steep as over the winter hemisphere. This is expected and it demonstrates clearly that the winter cyclone is considerably stronger than the summer anticyclone. The measured mean temperatures of 215°K near 60° S and of 240°K near 60° N agree reasonably well with the computed values of 213° and 238°K respectively (Table I) for the temperature profiles for high latitude cold winter and summer shown in Figure 2a. The measured temperatures of 230°K within the belt 40° S to 25° N are 3°K higher than those computed (Table I) for the tropical temperature profile shown in Figure 2a. This disagreement with the computation seems to be consistent with the cases at 60° N and 60° S where the measured temperatures were 2°K too high. The reason for this consistent discrepancy could be due to a number

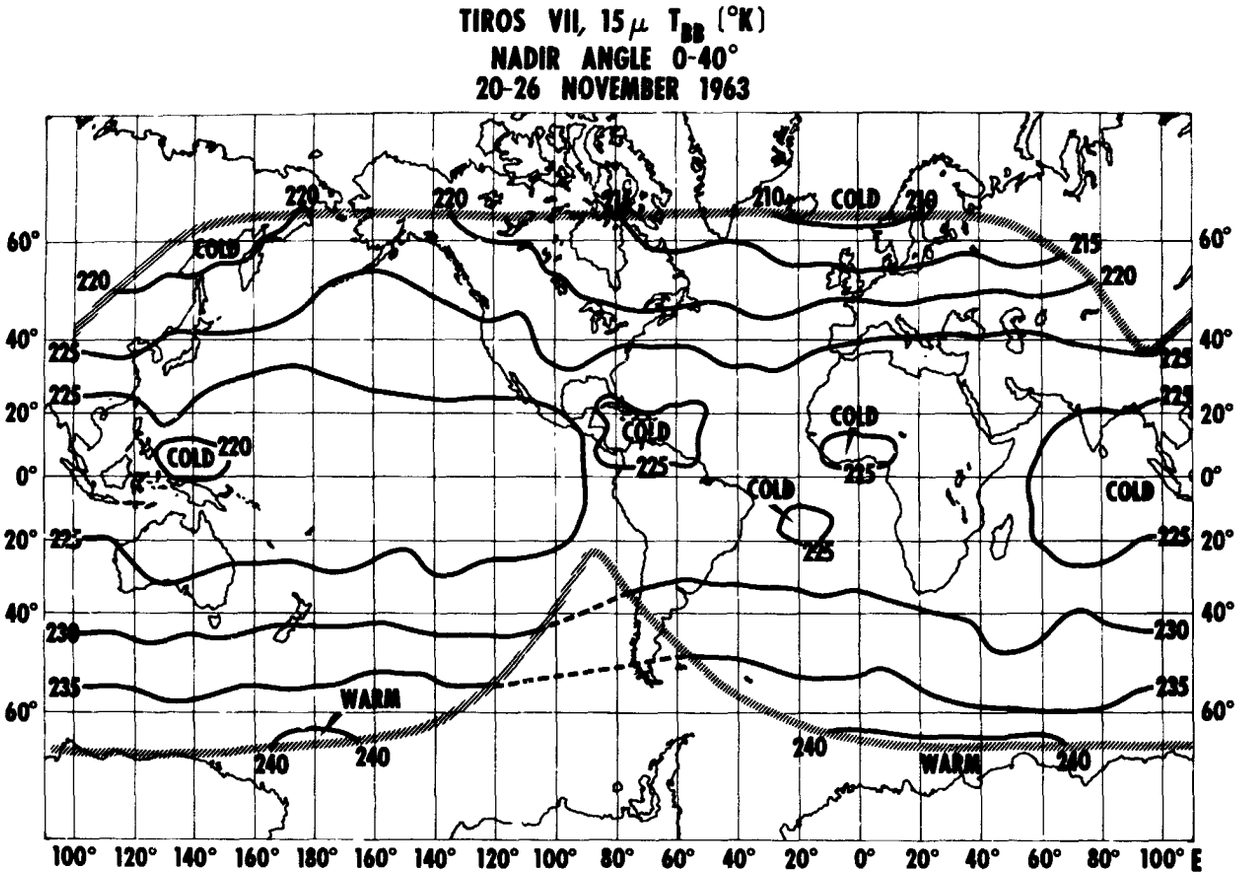

FIGURE 6.—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 20–26 November 1963; nadir angle 0°–40°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

of assumptions contained in the radiative transfer calculations which may have resulted in the computed values of T_{BB} being several degrees too low.

A coarse picture of the temperature gradient with altitude can be obtained by comparing Figures 3a and 3b. In Figure 3b, temperatures measured at nadir angles between 52 and 58 degrees were plotted. The weighting functions in Figures 2b and 2c show that all measurements shown in Figure 3b reflect temperatures at altitudes approximately 3–4 km higher than the temperatures shown in Figure 3a. Thus, by comparing Figures 3a and 3b, one may distinguish three categories in the temperature profiles:

1. Increasing temperatures with altitude between 15 and 35 km where the measured temperature differences are positive.

2. Decreasing temperatures with altitude between 15 and 35 km where the measured temperature differences are negative.

3. Isothermal regions between 15 and 35 km if the temperature differences are close to zero. It can be seen that differences of about +2°K occur in the tropics where strongly positive temperature gradients with altitude prevail. This difference agrees reasonably well with the values calculated for a tropical profile (Table 1). Over the higher northern latitudes (summer) moderately increasing temperatures with altitude and over high southern latitudes (winter) isothermal temperatures are suggested. This is in fair agreement with the calculations (Table I).

B. Seasonal Reversal, September–October 1963

As the solar illumination gradually becomes symmetrical with respect to northern and southern hemispheres during September, 1963, temperature patterns at high latitudes markedly reflect the resulting change in solar heat input. In some areas, this change takes place rapidly while other regions undergo a much slower transition. During the first two months following the

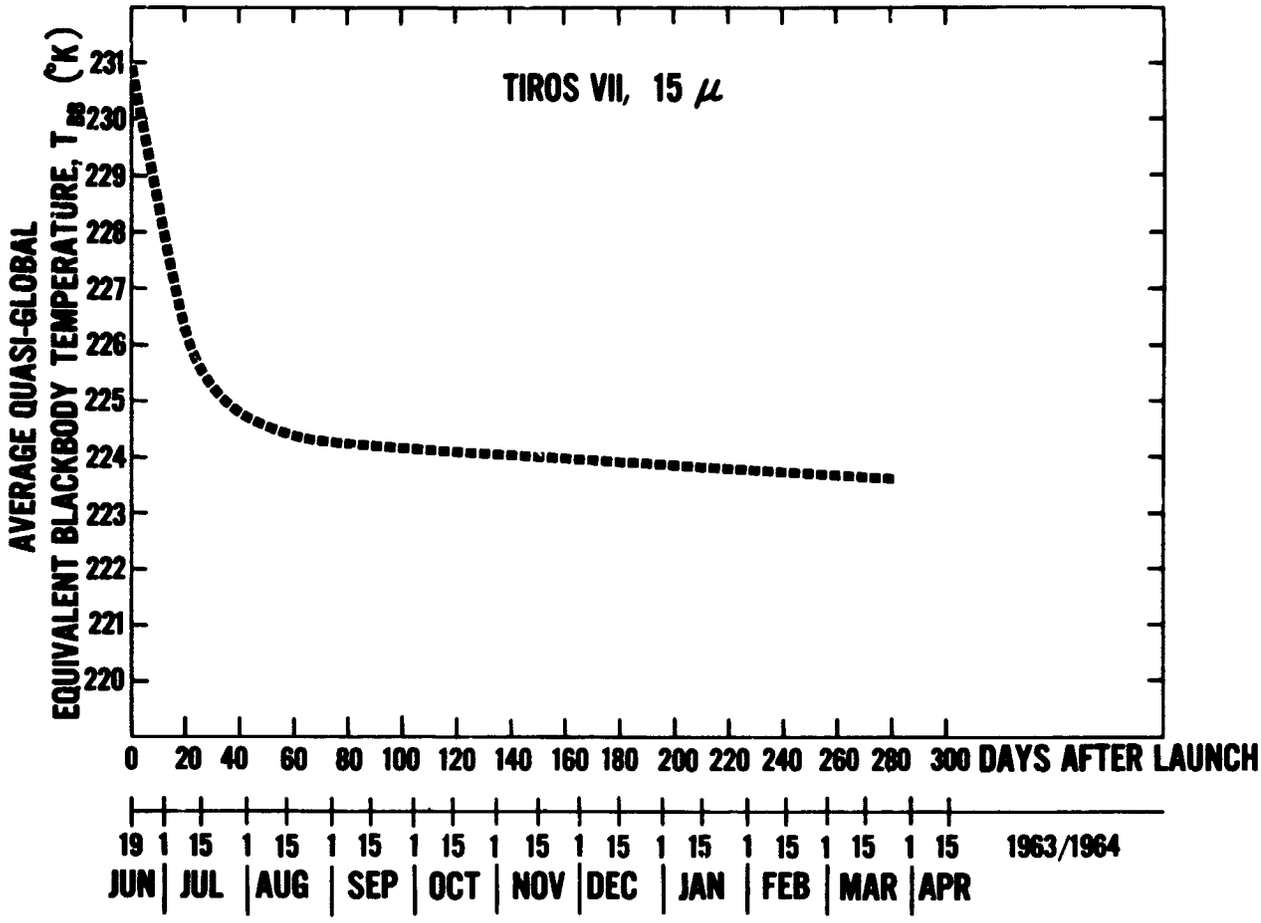

FIGURE 1(b).—Average quasi-global equivalent blackbody temperatures vs. time. The heavy dashed curve indicates the derived apparent degradation in the instrumental response.

solstice, there were practically no temperature gradients along any given latitude circle in the northern hemisphere; but strong longitudinal temperature patterns begin to develop now during the transitional season, especially after the September equinox. During July and August, the temperature patterns remain essentially the same as those during 19–25 June, shown in Figure 3a. There is one important change, however, which exhibits the same characteristics as similar changes observed on measurements in other spectral regions in previous TIROS satellites (References 7 and 8). *All* measured temperatures over the entire world seem to decline during the first three weeks of observation. It is extremely probable that a gradual degradation in the response of the radiometer is the cause for this decline. By mid-July 1963, the magnitude of this sensitivity decrease is about 7°K. After that, the degradation seems to have leveled off and continued at a much lesser rate. An approximate time history of this instrumental degradation based on the preliminary information available at this time is given in Figure 1b. A more complete version will be given in the TIROS VII Radiation Data Catalog and Users' Manual (Reference 4). An appropriate correction based on Figure 1b should, therefore, be added to all temperature measurements quoted thereafter and shown in the maps, Figure 4 to 12. Although this degradation leaves some uncertainties in the exact absolute magnitudes of the temperature measurements, it does not appreciably affect the ability to assign the appropriate temperature profile (Figure 2a) to a measurement at a given location or the implications drawn from the distribution of relative temperature patterns.

The first indication of any significant change in the post solstice temperature pattern occurs during the week 28 August to 3 September: the temperatures at high northern latitudes decrease by about 5°K to a temperature of about 228°K (+7° correction) at 60° N. At northern

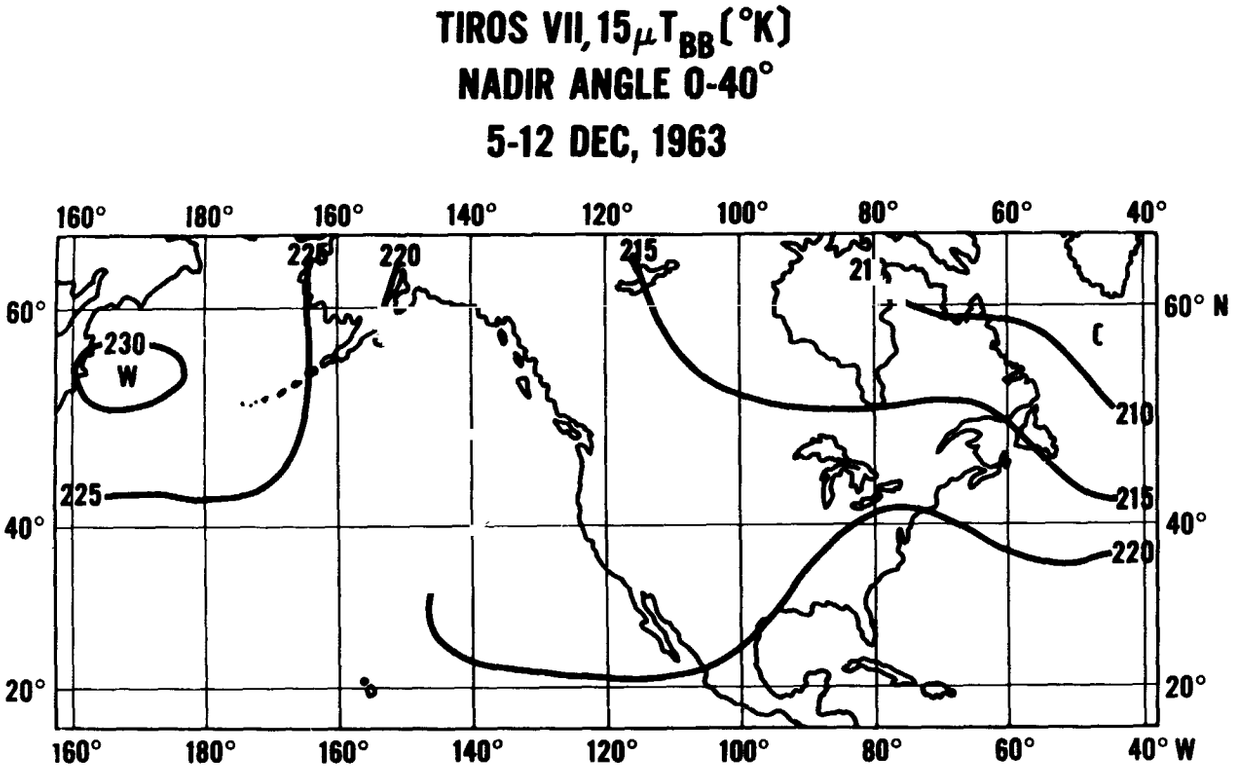

FIGURE 7(a).—Map from the North Pacific to the North Atlantic of 15μ equivalent blackbody temperatures averaged over the week 5–12 December 1963; nadir angle 0°–40°.

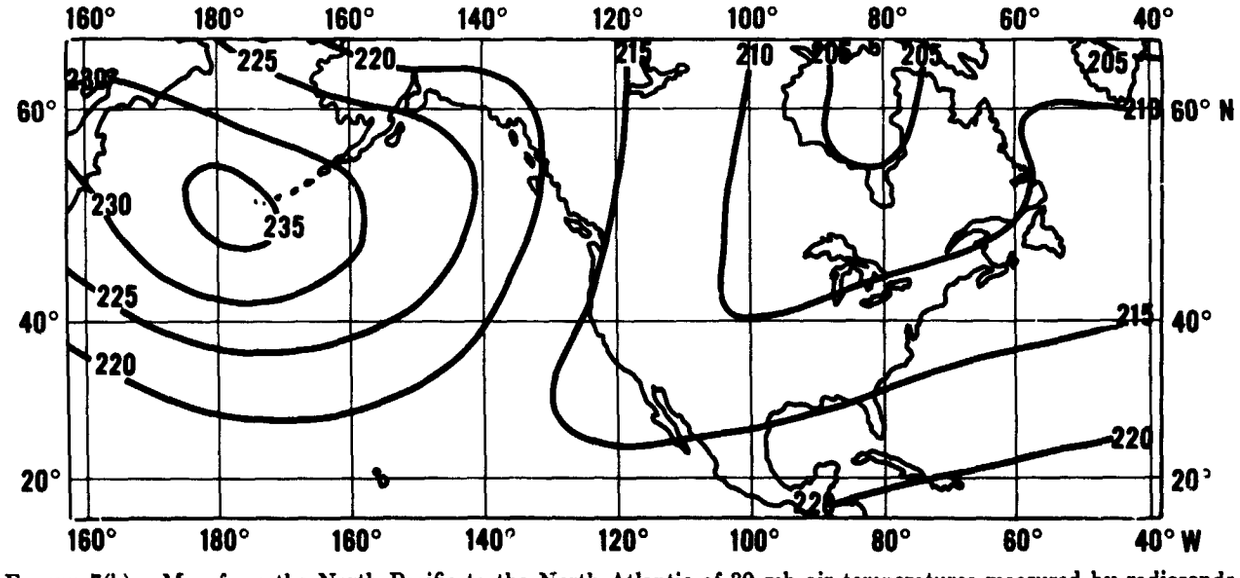

FIGURE 7(b).—Map from the North Pacific to the North Atlantic of 30 mb air temperatures measured by radiosonde balloons averaged over the week 5–12 December 1963 (Reference 16).

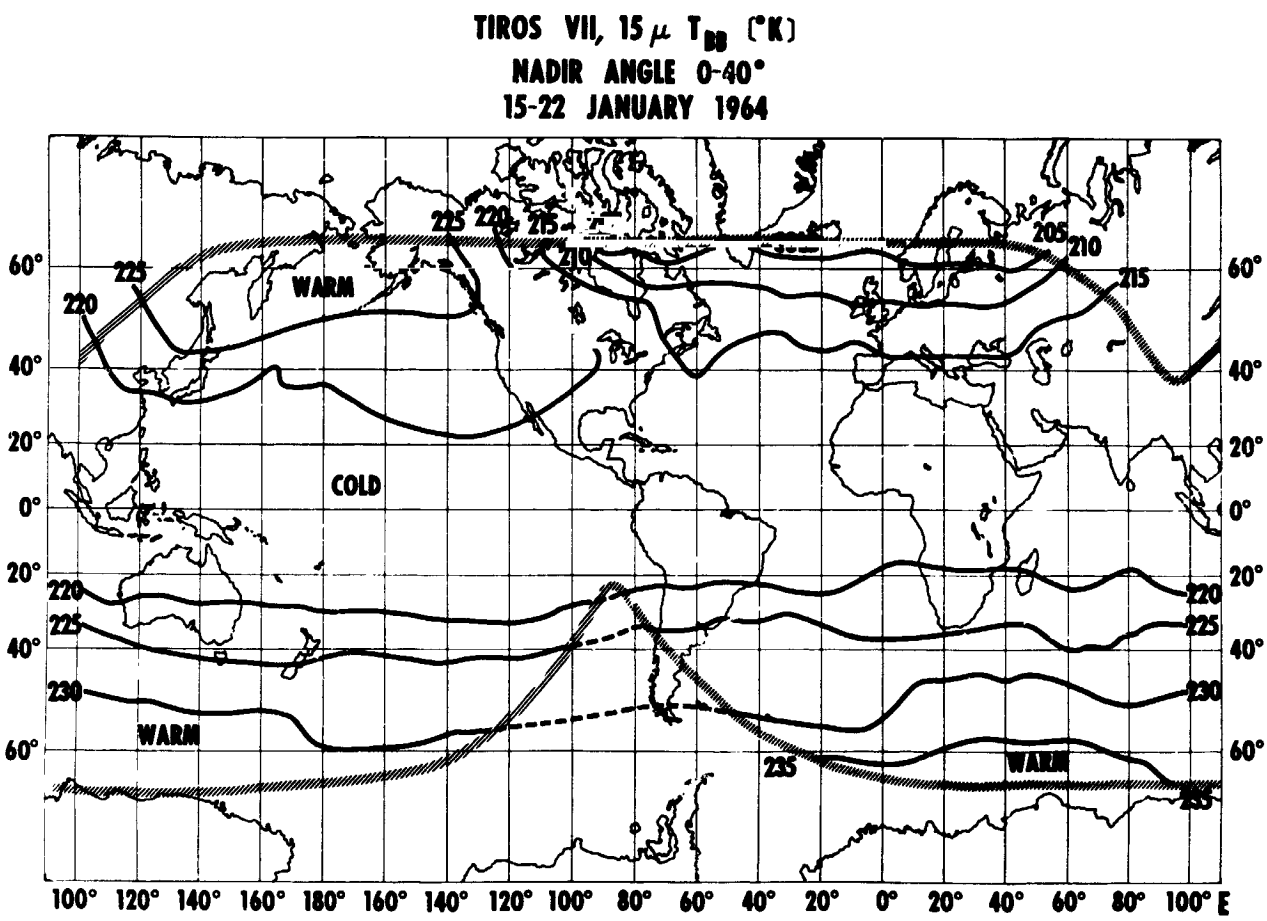

FIGURE 8(a).—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week of 15–22 January 1964; nadir angle 0°–40°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

mid-latitudes (20°−50° N) there is also a slight temperature decrease from the summer (19–25 June) conditions. However, here this decrease does not take place uniformly at all longitudes. There are pocket-like regions where warmer temperatures seem to persist longer than over other regions causing some inhomogeneities in contrast to the quite uniform zonal pattern observed in June. Going southward, temperatures in general decrease very gradually from about 228+7°K at 60° N to about 223+7°K at 40° S with the latter temperatures prevailing over most of the zone from about 25° N to 40° S. From there southward temperatures decrease rapidly with latitude. Thus, the remainder of the southern hemisphere remains essentially unchanged, still reflecting typical winter conditions (205+7°K at 60° S) except for a warm region of 225+7°K, which developed during later winter over the Indian Ocean between 40° to 50° S. The disturbance noted during June at these latitudes over the western South Pacific has grown throughout July and early August, and a warm region extends now over the entire Indian Ocean showing a definite longitudinal pattern. For example, temperatures over the southern Indian Ocean at 60° S are about 216°+7°K. At the same latitude over the Atlantic and central South Pacific, temperatures are 213+7°K and 203+7°K respectively.

During September, the European and West Asian portions of the northern hemisphere and parts of North America begin to cool off rapidly. There temperatures at 60° N have cooled to about 223+7°K while over the northwest Atlantic and North Pacific somewhat warmer temperatures still prevail (228+7°K) during the week of 11–18 September (Figure 4). At the same time, the breakdown of the winter over the southern hemisphere is gaining impetus. The same, even intensified longitudinal patterns as observed in

August are apparent. Temperatures in the Indian Ocean warm area amount up to 234+7°K. This area has now spread out between the longitudes of 95° to 180° E along the 50th parallel, yet temperatures at this latitude over the South Atlantic and the eastern South Pacific still remain relatively cold (220+7°K). Temperatures at low and mid-latitudes, in general, range around 225+7°K (Figure 4).

The week following the equinox (25 September–1 October) shows that the temperature gradients between the two hemispheres (Figure 5) have reached their minimum during this transition period. With the exception of the very warm region at 50–55° S over the Indian Ocean reaching maximum temperatures of 236+7°K at 70° E temperatures over the entire quasi-globe are nearly constant at 225+7°K. It is significant to note that at most longitudes the temperature gradient along a given latitude belt can now be much greater than gradients between 60° N and 60° S: temperatures along 50° S vary from 236+7°K at 70° E to 223+7°K near 170° W, while along the 180th meridian, for instance, temperatures at 60° S are about 222+7°K, at 60° N about 228+7°K and at the equator about 223+7°K. This is a total variation of 6°K along the meridian compared to a variation of 13°K along the 50° S parallel (Figure 5). The phenomenon of very pronounced temperature differences between the Indian and Pacific Oceans at all latitudes between 40° S and 65° S persists during the entire transition period from winter to summer. The maximum temperature difference is about 15°K throughout this time, with the Indian Ocean area showing the warmest and the eastern South Pacific showing the coldest temperatures (Figure 5). This phenomenon first appears in large scale during the middle of August and lasts until about 20 October. During early and middle October, the eastern portion of the southern hemisphere (40 W to 120 E) is relatively warm (230+7°K at 60° S) with a warm center of

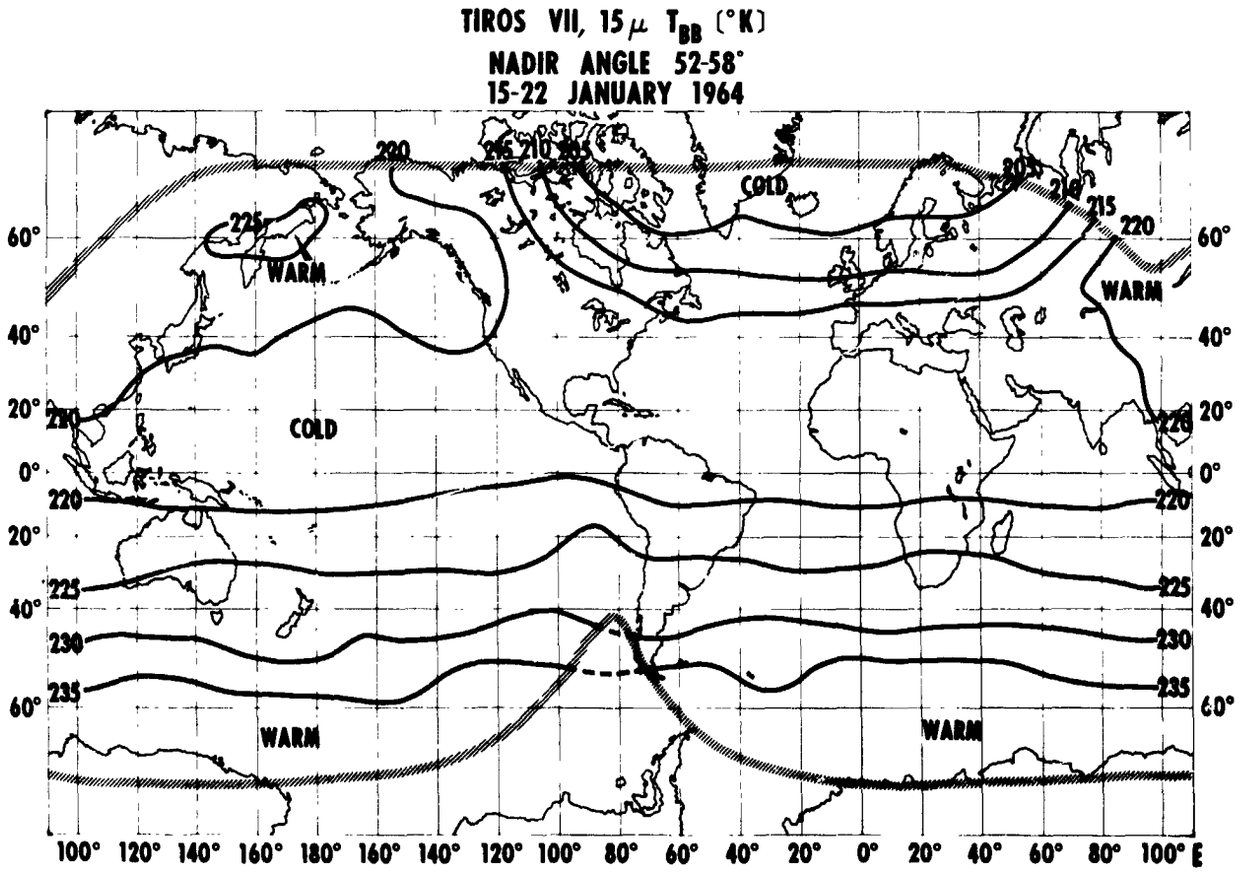

FIGURE 8(b).—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 15–22 January, 1964; nadir angle 52°–58°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

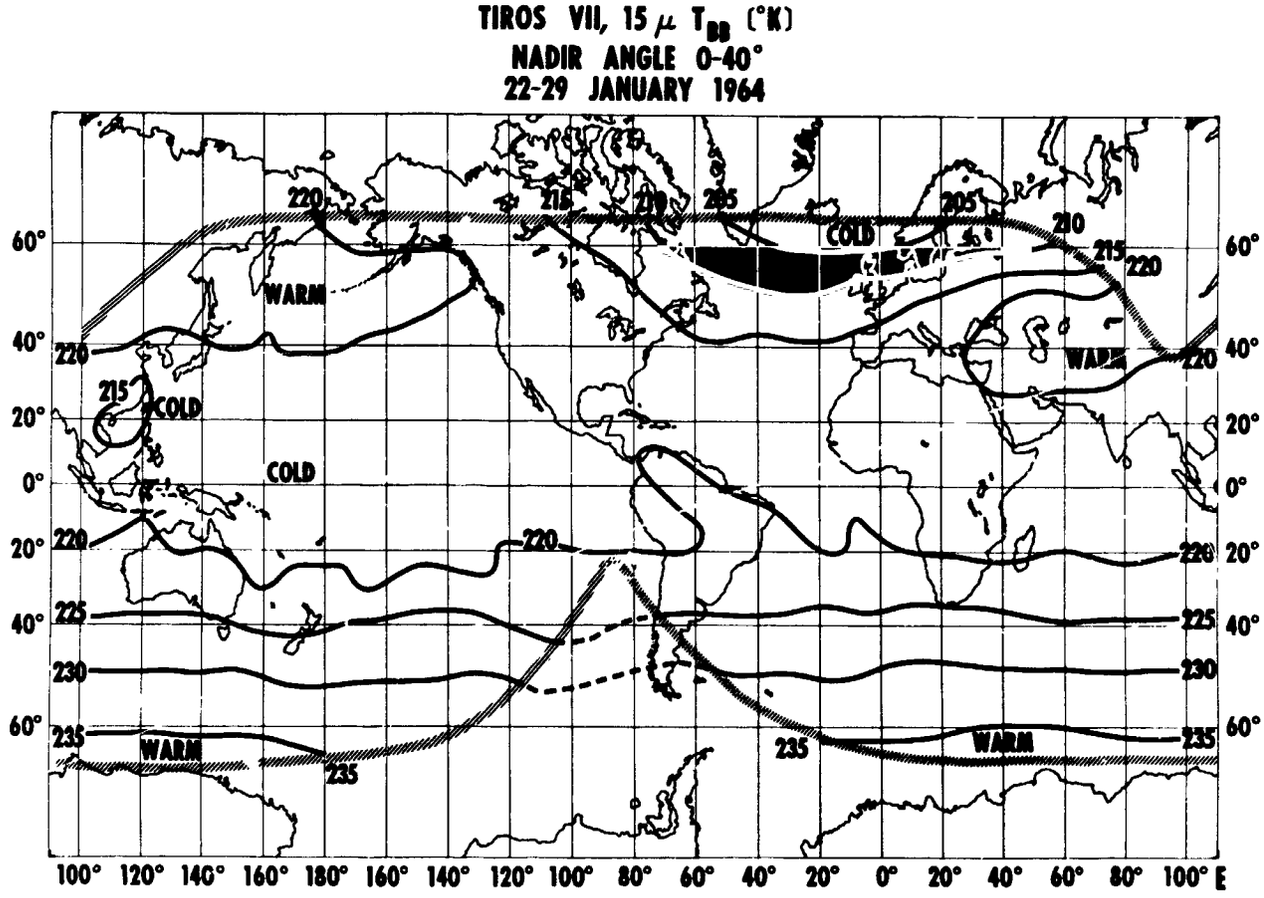

FIGURE 9(a).—Quasi global map of 15μ equivalent blackbody temperatures averaged over the week 22–29 January, 1964 nadir angle 0°–40°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

234+7°K at 80° E, while the western portion remains relatively cold with the cold center at 220+7°K at 170° E. During late October, the week of 23rd to 29th, the entire southern hemisphere finally achieves a typical summer temperature pattern with wide and uniform latitudinal temperature belts ranging from about 230+7°K at 60° S to about 225+7°K at 30° S. There is a uniform belt with temperatures of almost exactly 225+7°K between 30° S and 30° N. Over the Atlantic, Europe and Western Asia, temperatures drop rapidly from 225+7°K at 30° N to 215+7°K at 60° N, while over the Pacific they remain at 225+7°K up to 60° N.

During the entire fall transition period, the north Pacific area has not cooled off as rapidly as the rest of the northern hemisphere and in general remains warmer throughout much of the winter. During the course of October, this pattern intensified whereby temperatures in all northern regions except over the north Pacific and eastern Asia continue to decline. Finally, at the end of October, as stated above, the northern hemisphere shows a typical winter pattern with the same tight gradients with latitude as observed three months previously in the southern hemisphere. At 60° N, temperatures are uniformly cold (215+7°K) over Eurasia, the North Atlantic and North America, but warm over Alaska and the Bering Sea (225+7°K). The global picture does not change appreciably between the end of October and the week 20–26 November shown in Figure 6. Although the warm area (224+7°K) over the North Pacific has somewhat diminished in size compared to the end of October, and it is now located over the Gulf of Alaska, the isotherms over the area still show a very definite departure from a zonal pattern and run northwest to southeast over North America and northeast to southwest over east Asia. While temperatures are still uniform with latitude over the Atlantic and Eurasian continent and range from 213+7°K at 60°N

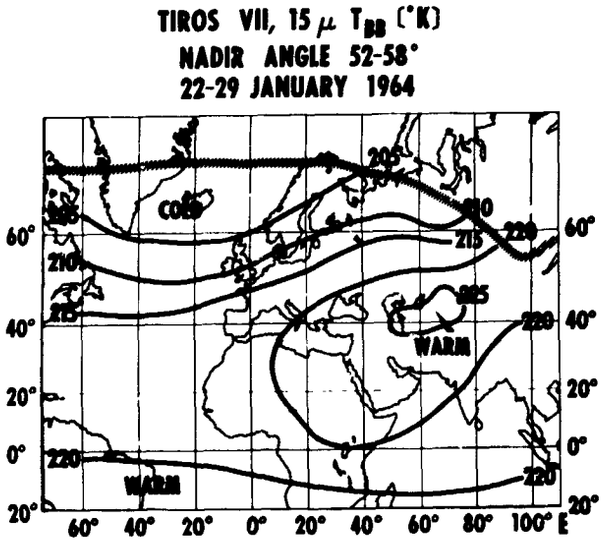

FIGURE 9(b).—Regional map of 15μ equivalent blackbody temperatures averaged over the week 22–29 January, 1964; nadir angle 52°–58°. The effects of a stratospheric warming over Eastern Europe are illustrated. No essential change in the temperatures occurred in other areas of the quasi-globe relative to Figure 8(b).

to 225+7°K at 40° N, the summer temperature pattern in the southern hemisphere is perfectly uniform with latitude and temperatures range from 235+7°K at 60° S to 225+7°K at 25° S (Figure 6). This pattern is identical to the temperature pattern during June, however, with northern and southern latitudes reversed.

C. The "Aleutian Anticyclone", December 1963

An unexpectedly warm stratosphere occurring as a regular climatological feature during winter in the general area of the Aleutian Island chain has long been recognized as the cause of a strong anticyclonic stratospheric circulation system in that area (Reference 10). Such circulation is unusual because in winter one would expect a very cold stratosphere resulting in a cyclonic circulation symmetric around the winter pole. Indeed, this cyclone exists, but in the northern hemisphere during mid-winter it is strongly disturbed and displaced by the Aleutian anticyclone. The morphology of this stratospheric warming over the North Pacific has received much attention in the past and a number of theories have been advanced attempting to explain its origin on the basis of dynamic processes (Reference 11). The satellite temperature measurements made it possible to follow the variation of mean temperatures in the lower stratosphere over this entire region throughout the winter of 1963. Figure 7a shows the temperature measured by the satellite between 40° W and 160° E and 20° N and 65° N averaged for the week from 5 to 12 December. Globally, there is practically no change from the patterns shown in Figure 6, except that the warm North Pacific region, which previously had remained at higher temperatures because it simply cooled slower than the other areas, has now actually warmed between the end of November and early December. It is centered at the end of the Aleutian Island chain and stands out clearly with temperatures of 232 +7°K. An analysis of temperatures at the 30 mb level from conventional radiosonde observations analyzed and obtained from the Freien Universität Berlin for the same area and time is shown in Figure 7b for comparison. The excellent agreement in the patterns between the two maps can serve as a measure of the validity of the satellite data. As can be seen from Figures 8, 9, 11, and 12, the Aleutian warm region is a permanent feature of the entire winter from the week of 5–12 December on. However, although temperatures within the warm center had not shown an

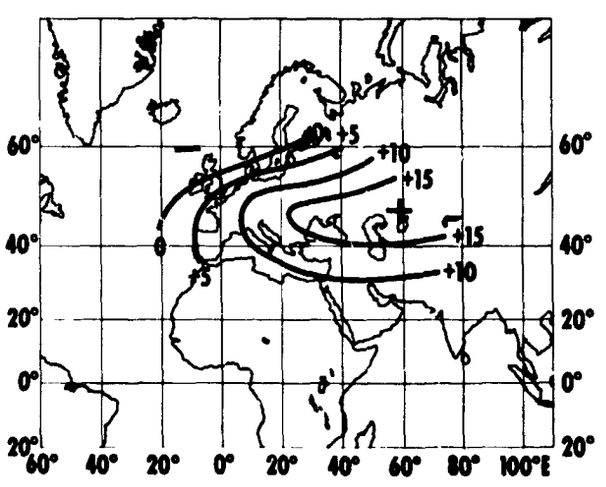

FIGURE 10.—Regional map of the differences between the 15μ equivalent blackbody temperatures measured on 27 January 1964 and those averaged over the week 9–15 January; nadir angle 0°–40°. The effects of a stratospheric warming over Eastern Europe are illustrated.

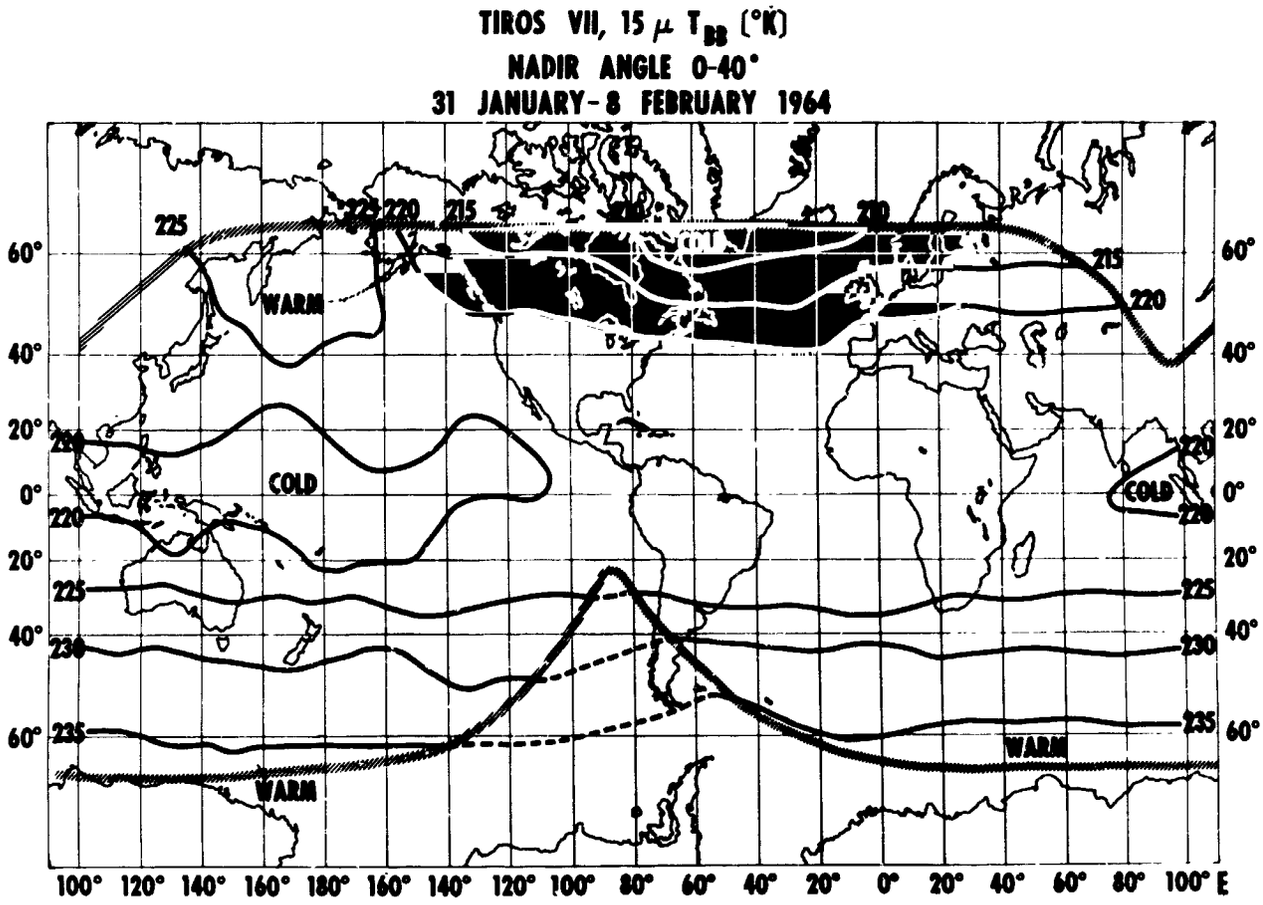

FIGURE 11(a).—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 31 January-8 February 1964; nadir angle 0°–40°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

actual increase until 5–12 December, a warm area in one form or another was present since the end of summer over the North Pacific as described above and shows in Figures 4, 5, and 6. This means that during this year the winter anomaly over the Pacific, though variable in extent during early winter, grows directly out of the summer conditions without ever reaching as low temperatures as other portions of the northern hemisphere do. Although, during early December, the system takes on a more permanent form and location and intensifies somewhat, it originated not because of a sudden heating phenomenon during winter, but simply because it refused to cool off at the end of summer. Naturally, there must be a mechanism to maintain the higher temperature during winter, while other regions at equal latitudes cool rapidly. It should be noted that those dynamic mechanisms which would have to depend on the existence of the complete winter cyclone could not explain the warm regions which already exist even before the cyclone is fully established. It might be interesting to investigate mechanisms by which the warm regions can be maintained throughout the winter by absorption of infrared radiation.

The satellite measurements show that the situation in the northern hemisphere is actually not vastly different from the southern hemisphere where a warm region over the southeastern Indian Ocean, though not quite as intense as the Aleutian one, persisted throughout the winter and then spread to make one half of the hemisphere almost 15°K warmer than the other. In the northern winter, almost a mirror image of this process occurs: the Pacific is warm and the Atlantic and Eurasia are cold, while in the south the Pacific is cold and the Atlantic and Indian Ocean areas are warm. In the north, the temperature gradients between warm and cold regions are somewhat greater (about 20°K between 180° W and 40° W at 60° N). Of course, so far satellite data exist only for the seasonal cycle 1963/64, and the ob-

servations described here must be tested by experiments in future years.

D. Solstice, December 1963

Between November 1963 and the middle of January 1964, there is very little change from the temperature patterns shown in Figure 6. As discussed above, the Aleutian warm center becomes somewhat stronger and quite stationary during early December and, in contrast, the Atlantic and Eurasian cold regimes remained unchanged with very tight latitudinal temperature gradients and isotherms aligned with latitude during the week 15–22 January 1964 (Figure 8a). It is interesting that the temperature difference of about 15°K between 60° N and the tropical belt over the eastern portion of the northern hemisphere is less than the longitudinal temperature difference between the Aleutian warm center and the North Atlantic at 60° N. A similar situation existed in the southern hemisphere at the end of winter (Figure 5); but during the solstice, the Australian warm area did not extend to such high latitudes as the Aleutian area does. As shown in Figure 8a, the mid-latitude and tropical regions have cooled considerably; and the temperature between 25° S and 40° N is now about 218+7°K, while earlier temperatures in the same zone ranged near 225+7°K. This remarkable cooling over so wide an area is particularly significant since it precedes by about one week the occurrence of a stratospheric warming over western Asia. Instrumental degradation cannot be responsible for such a temperature decrease, since Figure 12 does indicate higher temperature again in March. Also, ever since November temperatures at high southern latitudes remained unchanged. Relatively moderate and very uniform temperature zonal temperature gradients exist at all longitudes. Temperatures at 60° S are 235+7°K.

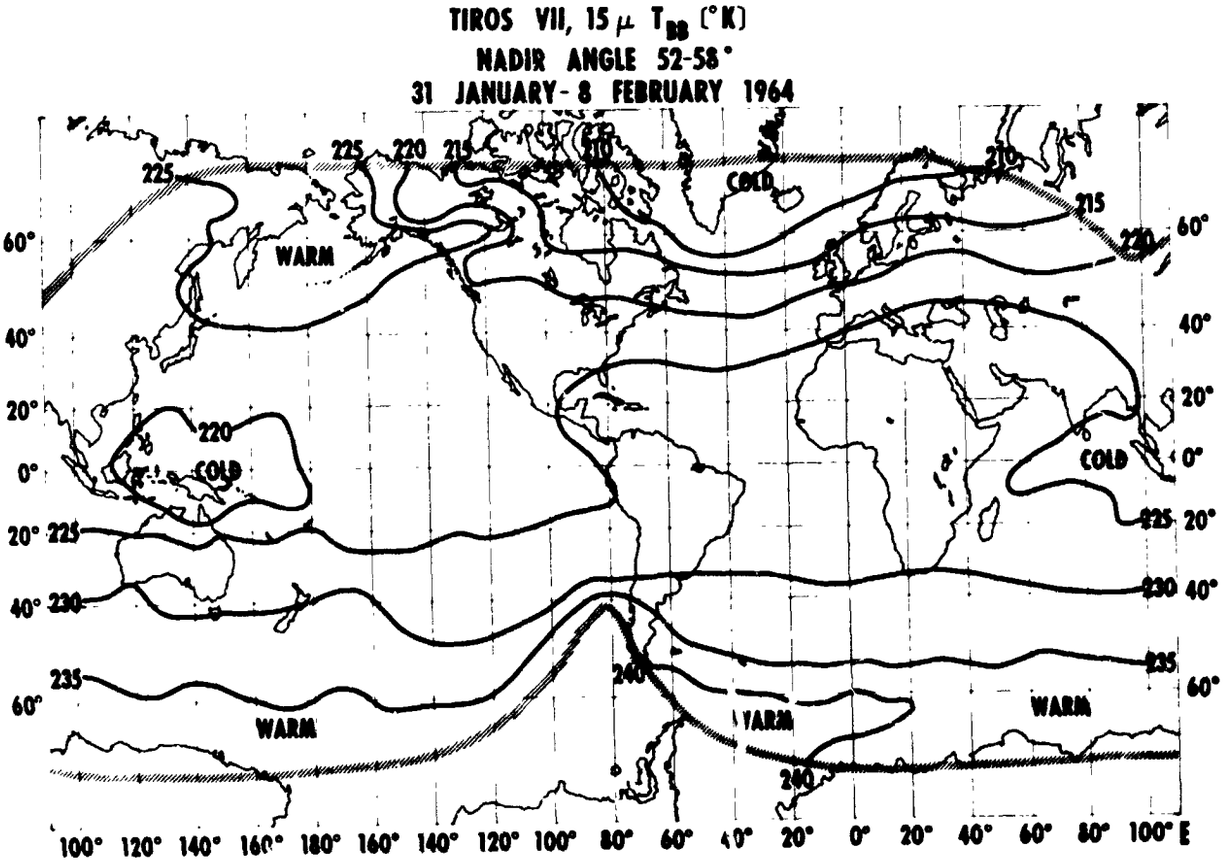

FIGURE 11(b).—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 31 January–8 February 1964; nadir angle 52°–58°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

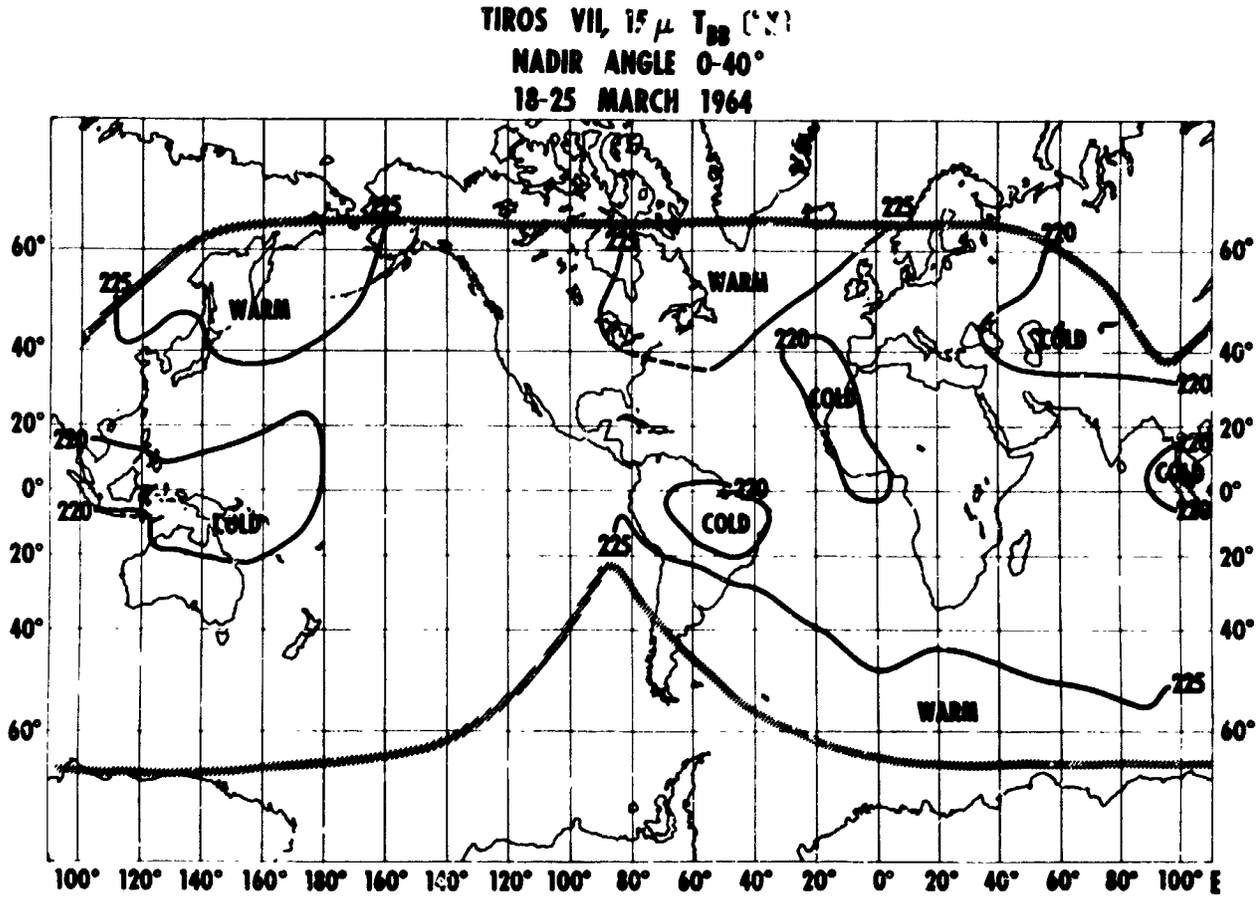

FIGURE 12.—Quasi-global map of 15μ equivalent blackbody temperatures averaged over the week 18–25 March, 1964; nadir angle 0°–40°. Radiation data cannot be obtained outside the area enclosed by the dashed border.

Temperatures of 231+7°K at 50° S and of 206+7°K at 60° N (eastern portion only) are compatible with the computed temperatures of 238 and 213°K respectively for the "summer" and "cold winter" profiles (Table I). Temperatures calculated for the "tropical" profile (227°K, Table I) are about 2°K higher than those measured in the now cold mid-latitude belt (218 +7°K). Mean temperatures of 232+7°K in the center of the Aleutian warm region measured during December suggest that the average temperature of the stratosphere in the 15 to 35 km region was about 12°K higher than that shown in the "warm winter" profile of Figure 2, which yields a mean temperature of only 229°K (Table I). Of course, such a temperature profile in this partic[illegible]ar altitude region is merely postulated since, for example, a low average stratospheric temperature of 205°K in the altitude region from 15 to 35 km, such as shown in the "cold winter" profile, Figure 2a, could be balanced by an extraordinarily high average temperature of 300°K in the region from 35 to 60 km to produce the measured radiation temperature of 239°K. But, such a temperature profile is much less probable than the one postulated. The validity of the assumption of an average stratosphere temperature increase of 12°K between 15 and 35 km is also suggested by comparing the satellite measurements at low nadir angles (0–40°, Figure 8a) to those at high nadir angles (52–58°, Figure 8b). Temperatures over the Aleutian warm area are practically the same at both nadir angle ranges indicating a nearly isothermal or at least a very slowly varying temperature gradient with altitude in the region where the weighting functions $\Psi(h)$ are at their maximum (15–35 km, Figures 2*b* and 2*c*). A temperature profile such as the one mentioned above with a mean temperature of 205°K between 15 and 35 km and 300°K between 35 and 60 km would produce a difference of 9°K between the radiation temperatures measured at 0° nadir and

at 58° nadir angle. Figures 8a and 8b, however, indicate no temperature difference at all over the Aleutian warm area. Thus, one finds that the difference in the mean temperatures between 15 to 35 km level and the 35 to 50 km level cannot be excessively large, and with that restriction, a temperature increase of 10°K for the standard "warm winter" profile from 15 to 35 km follows for the North Pacific area. Similarly, one finds that there is no temperature differences for the two nadir angles over the North Atlantic and Northern Europe (Figures 8a and 8b) which agrees well with the calculated differences of 1°K for the "cold winter" profile. The larger temperature differences over the tropics—the 220°K isotherm is about 10° further north in Figure 8b than in Figure 8a—indicate the rapid temperature increase with altitude above 15 km and agree well with the computed difference of 4°K for the "tropical" profile (Table I); while the calculated values of 238 and 240°K for "high latitude summer" (Table I) agree well with the observed temperatures (+7° correction) and temperature differences between 50 and 55° S.

This picture has changed considerably during late January (Figures 11a and 11b) where temperature differences at mid-latitudes and in the tropics over the entire eastern hemisphere are as high as or exceed the differences observed previously within the tropics. Such large differences exceeding 5°K extend particularly into North Africa, the eastern Mediterranean and the Near East (Figures 11a and 11b). This indicates that neither the "tropical" nor the "summer" temperature profiles (Figure 2a) apply in this case. In that area, temperatures at 15 km must be somewhat higher than those given by the "tropical" profile; and there must be a pronounced increase of temperature with altitude resulting in a very warm upper stratosphere, i.e. a very strong vertical temperature gradient between the lower and upper stratosphere. It is significant that this change has occurred over the area into which the sudden warming, described below, has moved in its decaying stages.

E. Sudden Warming, January 1964

The type of temperature measurement from a satellite described here was expected to be most useful for the detection of the occurrence and the observation of the behavior of stratospheric warmings. These warmings were first observed over Berlin by Scherhag (Reference 12) and have since then been the subject of intensive observation and analysis (Reference 13). The sudden warmings have now been observed almost every year during the northern hemisphere winter and, during their occurrence, the lower stratosphere over a limited area may be heated by as much as 30°K within a few days. Causes for such warmings have thus far not been explained. In contrast to the Aleutian warm center described above, the sudden warmings show no regularity in their time and location of occurrence. In order to be detectable by the TIROS radiometer, the warming must occur at altitudes between 15 and 35 km, or, if it occurs at other levels, it must be unproportionally intense. Calculations based on the "warm winter" temperature profile of Figure 2a show that a uniform temperature increase of 12°K between 15 and 35 km will increase the radiation temperature by 10°K, while a similar change of the temperature profile between 34 and 44 km will cause a rise in the radiation temperature of less than 1°K.

A number of small and weak warmings occurred over America and Europe during December 1963 and January 1964, but those did not penetrate to altitudes below 30 km (Reference 14). Therefore, they could not be detected by the satellite. During the last week of January (22–29), however, a warming of apparently moderate intensity occurred over the region of the Caspian Sea, extending between the Himalayan Mountains and the Black Sea (Figure 9a). Radiation temperatures over that area have increased by about 8°K over the previous week (Figure 8a). During that week (15–22 January), there was practically no indication of any disturbance in the perfect latitudinal temperature structure over that region, except perhaps for a very small area over Iran where a temperature increase of about 2–3 degrees could be observed; but in the high nadir angle measurements, there is an indication of increased temperatures over South Central Asia (Figure 8b) inferring that the subsequent warming might have originated in the upper stratosphere (above 30 km) in that area. Unfortunately, the warming developed in an area where no conventional meteorological data at these altitudes are

available, and the satellite observations provide the only method of analyzing the event. Furthermore, even the satellite observations are limited in coverage, since this area is located near the data gap over the central Soviet Union which exists because of the particular geometry of the data readout stations for TIROS (see above). The satellite data were, therefore, analyzed for individual days of 22, 24, 25, 26, 27, and 29 January. These daily analyses showed that the temperatures within the warm center were as high as 230+7°K on 29 January, but because they extended only over very small regions and because of the motion of the center from day to day, these high temperatures became obscured in the weekly averages (Figure 9a). The first definite indication of the warming occurs on 22 January, where a small and relatively weak warm center of 225+7°K appears over Pakistan, Afghanistan and Eastern Iran. This is already a few degrees higher than the average temperature over the same area for the preceding week of 14–22 January (Figure 8a). Two days later on 24 January, the warm region had spread out somewhat to the north, and the center had also moved in that direction but had not significantly intensified. On 25 January, temperatures of 225+7°K range over the entire middle East extending as far eastward as central China. The center is now just east of the Caspian Sea and has just barely reached a temperature of 230+7°K. On 26 January, the same situation prevails with the center becoming slightly warmer and larger. On 27 January, the center has grown considerably larger and temperatures of 230+7°K extend over an area of at least 30° longitude and 10° latitude northeast of the Caspian Sea. The 225+7°K isotherm has advanced to a latitude of 50° N, causing a tremendously tight temperature gradient over northern Europe where temperatures increase by more than 20°K from southern Norway to the Black Sea. Due to the warming, isotherms have been tilted to follow a course from southeast to northwest instead of the perfect eastwesterly direction still prevailing on 22 January. Finally, on 29 January a warm center extending over 10° great circle arc with temperatures of 230+7°K stretches from the Black Sea eastward to China. One 225° isotherm now runs east-west along the 40th parallel between 40° E and 80° E. The other runs southwest to northeast from the Black Sea to about 50° E and 55° N. The center is located near 65° E and 50° N. This situation is summarized in Figure 10 which shows that on 27 January the radiation temperatures had increased by 15°K over the averages for the week 9–15 January near the center and that the periphery of the warming extended as far west as the North Sea, and the Atlantic and as far south as North Africa and Arabia. Figure 11a shows that during the week 31 January to 8 February the warming had passed its climax. Rather homogeneous temperature patterns with latitude return over northern Europe and eastern Asia, but south of 40° N a broad warm area of about 223+7°K now covers the entire region between 40° N and 25° S latitude and 110° W and 80° E longitude (Figure 11a). This means that the mid-latitude belt which had cooled so drastically before the warming had been restored close to its normal temperature of about 223+7°K between 25° S and 40° N. Figures 8, 9, and 11 show that the Aleutian warm center had remained undisturbed during the entire period of the warming. On 30 January, the warming was detected by a radiosonde ascent over Berlin, the only one available for this analysis (Reference 15). This radiosonde temperature profile, when compared to a prewarming profile shows that the warming over Berlin occurred primarily above 30 km. For the week of 22–29 January, temperatures at high nadir angles are about 5°K higher than at low nadir angles not only over the warm center, but also extending far beyond the center, particularly along the southern and western periphery of the warming (Figures 9a and 9b). This means that over the center temperatures have increased not only in the lower stratosphere but more so in the upper stratosphere. The much greater extent of the warming in the high nadir angle temperature patterns compared to the low nadir angle patterns suggested that along the western and southern periphery the warming occurred only in the upper stratosphere. This confirms the above mentioned radiosonde observation over Berlin. Since the much larger warming (13°K) in the center would require an unreasonably large temperature if the warming were confined to altitudes above 30 km, and since such a strong vertical temperature gradient would be clearly noticeable as a much

greater temperature increase at the larger nadir angles, it must be concluded that the warming near the center penetrated to much lower altitudes where the Ψ functions are at maximum. If the warming occurred uniformly at altitudes from 15 to 35 km, a temperature increase of about 15°K would satisfy the radiation measurements. Such an increase is quite commensurate with a moderate stratospheric warming.

F. Equinox, March 1964

The global temperature structure undergoes a major change during the period from early February (Figure 11a) to the week of 18–25 March shown in Figure 12. The steep zonal winter time temperature gradients at high northern latitudes, particularly over the eastern hemisphere as well as the zonal summer pattern in the southern hemisphere have disappeared. The southern hemisphere has cooled considerably, and parts of the northern hemisphere have warmed. This results again, as during the September equinox, in an almost constant temperature over the entire quasi-globe. In fact, temperature gradients, longitudinally or latitudinally are even shallower than during September. Over the eastern Pacific, there is no temperature gradient at all between 60° S and 60° N, with temperatures of about 223+70°K prevailing at all latitudes. As the southern hemisphere cools, a temperature gradient along 60° S seems to develop similarly as during the previous winter. The South Indian and Atlantic Oceans are now about 5°K warmer than the South Pacific.

In the northern hemisphere near 60° the North Atlantic and northeast North America have warmed rapidly by about 20°K since February, while the region east of the Black Sea, where the sudden warming occurred in January, has returned to its pre-warming winter temperatures of 217+7°K. Temperatures in the Aleutian region have remained practically constant throughout the winter and are still at about 228+7°K. This produces temperature differences of about 10°K between the Atlantic and Pacific warm regions and central Asia at 50° N. That is the largest temperature difference found during this equinox (Figure 12). Since these data have been reduced only very recently, there has not yet been an adequate opportunity to analyze the January to March transition as thoroughly as the June to October period. Such an analysis will be made in the future.

IV. CONCLUSIONS AND SUMMARY

Satellite measurements of emitted radiation in the 15 micron carbon dioxide band have demonstrated that mean temperatures in the lower stratosphere can be mapped on a global scale. By comparing measurements at high and low nadir angles, a qualitative inference can be made about the vertical temperature gradient between the lower and upper stratosphere. Analysis of global temperature patterns from June 1963 to March 1964 revealed that temperature patterns in both hemispheres remain relatively undisturbed during summer. These patterns are oriented very precisely along latitude circles with the temperature maximum occurring at the summer pole. Near maximum temperatures are reached in the southern summer about one month after the equinox. After that, temperatures increase only slightly through the solstice and remain high until the next equinox. The northern summer could only be analyzed through its peak and declining phases, June to September 1963. Temperatures decline very slowly during the first two months following the solstice. Then, a rapid decline occurs just before the equinox. During both equinoxes, temperatures were relatively uniform and differences of about 10–15°K may exist both with latitude and longitude. Winter temperature patterns in both hemispheres exhibit strong temperature gradients between the pole and 40°, but a completely uniform pattern never exists in either winter hemisphere. A fairly uniform region with temperatures generally around 230°K extends between 25° latitude of the summer hemisphere and 40° latitude of the winter hemisphere during solstice. The satellite measurements not only permitted for the first time a continuous analysis of the southern hemisphere from June 1963 to March 1964 up to a latitude of 65° S, but also demonstrated the usefulness of uniform and continuous data coverage over the entire quasi-globe. A warm area over the Indian Ocean, though initially small, seems to play a similar role in the southern winter as the Aleutian warm center during the northern winter. During winter 1963, this warm region grew out of a disturbance in the isotherms

during June and finally divided the entire stratosphere of the winter hemisphere into a "warm" and "cold" portion with the warm portion located between Africa and Australia. Temperature differences between these warm and cold areas amounted to about 15°K and disappear with the warming of the South Pacific area during late October, giving way to the homogeneous summer pattern. Similarly, there is no homogeneous winter pattern in the northern hemisphere. A large region over the North Pacific does not cool off as rapidly after the equinox as the rest of the stratosphere. Just before the solstice, this region becomes well established and intensifies in the area where the Aleutian anticyclone is usually found.

The morphology of a stratospheric warming over southwestern Asia and its penetration to Europe was observed by the satellite indicating that heating of possibly 20°K penetrated down to at least 20 km over the center of the warming, but at the periphery warming of perhaps somewhat greater magnitude remained at altitudes above 30 km. The persistent climatological inhomogeneities of warm cells over both winter hemispheres lead to the speculation that during winter the stratospheric temperatures may be influenced by radiation from underlying surfaces, while during summer solar heating is dominant.

A study was also made of the effect of how high altitude clouds on the measured temperatures, since the weighting functions (Figure 2b) are not negligible at 10 km. The result indicated that very large and high cloud systems such as hurricanes do decrease the measured temperatures by as much as 10°K if the clouds reach above 10 km and by less than 4°K if the clouds, filling the field of view are at 6 km; but it was shown that such effects are only isolated and are averaged out by the weekly analyses which formed the basis for this investigation.

ACKNOWLEDGMENTS

Experiments resulting in findings such as the ones presented here always require the efforts of many hundreds of dedicated individuals. We gratefully acknowledge the contributions of those who have contributed to the success of the TIROS VII experiments. We are particularly indebted to Mr. Robert Hite and his team for the computational efforts in reducing the vast amount of radiation measurements to the maps presented here.

CLOUD HEIGHTS AND NIGHTTIME CLOUD COVER FROM TIROS RADIATION DATA*

S. I. RASOOL†

Radiation data obtained from TIROS III have been analyzed, separately for day and for night, for the period July through September 1961. The global distribution of the average effective temperatures measured by the 8–12μ channel of the satellite radiometer shows a close correlation with the cloud cover data.

An estimate of the latitudinal distribution of cloud heights has been obtained using the TIROS radiation data for daytime and the distribution of cloud cover recently obtained from the TIROS photographs. Combining these values of the cloud heights with the nighttime radiation data determines the latitudinal distribution of nighttime cloud cover.

The results indicate that in the Southern Hemisphere the percentage cloudiness at night is considerably higher than in the day, while in the case of the Northern Hemisphere the cloudiness appears to decrease at night.

1. INTRODUCTION

In a recent paper, Arking (1964) has derived the global distribution of cloud cover by the analysis of TIROS III video pictures. In Fig. 7 (Curve 1) is plotted the latitudinal distribution of average *daytime* percentage cloud cover as obtained by Arking for the period of 12 July through 10 September 1961.

In the present study we attempt, using these data and the simultaneous radiation measurements by TIROS III, to derive the average latitudinal distribution of *cloud top heights* and thence the *nighttime* cloud cover. Curve 2 in Fig. 7 shows the resulting percentage cloud cover during the night as a function of latitude.

2. TIROS INFRARED DATA

The radiation instrumentation in TIROS and the physical significance of this experiment have already been described by several authors (Bandeen *et al.*, 1961; Nordberg *et al.*, 1962). Three of the five channels of the TIROS radiometer measure terrestrial radiation in the far infrared corresponding to wavelength intervals of 5.8–6.5 μ, 8–12 μ, and 7–30 μ. The other two channels record the solar radiation in the visible, as reflected by the earth, to obtain an estimate of the albedo of any region. The wavelengths of the infrared channels have been chosen so as to provide information on the temperature at different levels of the atmosphere and to give an estimate of the total outgoing radiation in the infrared. In this discussion we shall only be concerned with Channel 2, sensitive in the 8–12 μ region of the infrared.

The main absorber of infrared radiation in the earth's atmosphere is water vapor. The absorption coefficient, however, varies considerably with wavelength between 4 and 50 μ, where almost all the energy of the terrestrial radiation is confined. In the 8–12 μ spectral interval the absorption by water vapor and also by CO_2, the other important absorber of the infrared radiation, is at its minimum. Consequently, *in the absence of clouds*, Channel 2 of the satellite radiometer, measuring in this atmospheric "window," records energy originating from very near the ground corresponding to an effective temperature only ~5–10 deg K less than the ground temperature (Wark, Yamamoto and Lienesch, 1962; Prabhakara and Rasool, 1963).

Reasonably thick clouds, however, are practically opaque to infrared radiation of wavelengths >4 μ (Shiffrin, 1961). As there is very little water vapor above the clouds, and if we may assume that the albedo of the clouds in the far

*Published in *Journal of the Atmospheric Sciences*, 21(2):152–156, March 1964.

†Goddard Space Flight Center and New York University, New York.

infrared is negligible, the radiometer *in the presence of thick clouds* will record energy corresponding to the cloud top temperature. This may be as much as 40–50 deg K lower than the surface temperature.

If, therefore, for any given instant, both the TIROS measured temperatures in this "window" channel and the actual surface temperatures are available, a knowledge of the temperature lapse rate in the atmosphere will enable one to obtain a quick estimate of cloud top height. On the other hand, on a climatological basis, if the satellite-measured temperatures for a given region are averaged over a season, then the departure of this temperature from the mean ground temperature will be mainly dependent on three variables—cloud amount, cloud height, and water vapor distribution in the atmosphere. As mentioned earlier, the effect of water vapor is comparatively small, and from our knowledge of climatological distribution of the water vapor over the globe, its effect on the temperatures measured by the satellite can be accounted for.

The strong effect of clouds on the TIROS III measured temperatures in the "window" channel is demonstrated by Fig. 1. In this figure are plotted the regional and temporal averages of the temperatures measured by Channel 2 of TIROS III during daytime (0600–1800 hours Local Time) for the period of July 12 through 10 September 1961. Measurements for the polar regions are not available because the inclination of the orbit was only about 48°. The surface of the earth between 50N and 50S has been divided into a 10 deg latitude by 10 deg longitude grid, and all measurements taken by the satellite in each grid at nadir angle <25 deg, between local time 0600 and 1800, have been averaged for this period.

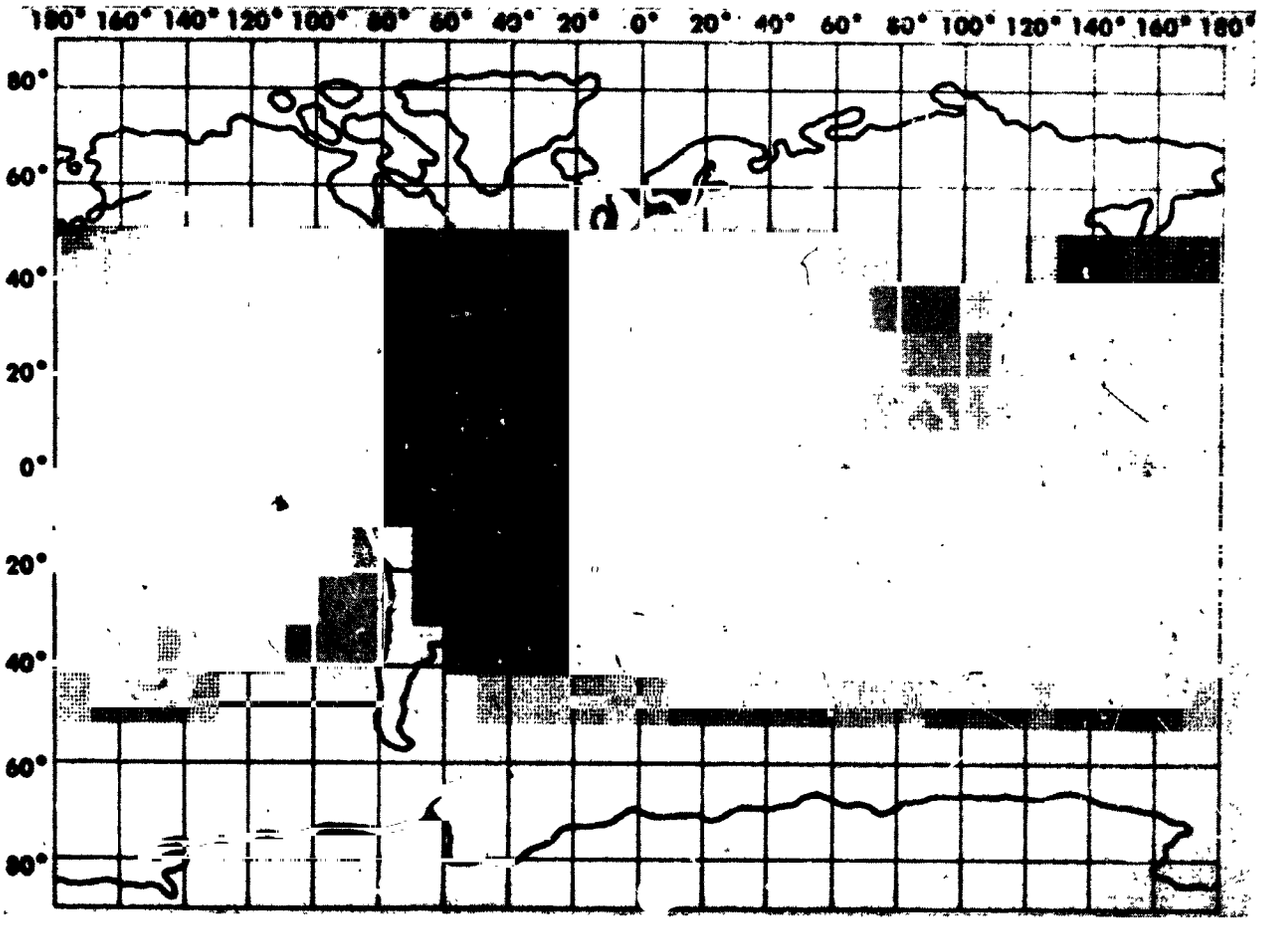

FIGURE 1.—Global distribution of average temperatures measured by Tiros radiometer channel 2 for the period 12 July through 10 September 1961. Darkest shade, $T > 295$K, lightest, $T < 255$K.

In most cases there are more than 500 observation points per grid. The observations were corrected for the instrumental degradation (Bandeen, private communication).

The very dark shades correspond to high radiation intensities with effective temperatures ranging above 290K. The lightest shades correspond to temperatures of the order of 240K. The two triangular areas, which are diagonally opposite and comprise a part of South America and Southern Siberia, have been left blank because of the unavailability of the telemetry from the TIROS for these regions.

Several interesting features are revealed by examining this figure. 1) The relatively cold temperature belt near the equator corresponds to the high cloudiness usually observed in the equatorial region. 2) The subtropical belt in each of the hemispheres show relatively higher temperatures and, therefore. probably fewer clouds than in the equatorial regions. 3) Extremely low temperatures measured over East Pakistan and India imply a heavy cloud cover over these regions which is, in all probability, the monsoon activity of this season. An almost quasipermanent cloud cover over central Africa is also indicated from this diagram.

These conclusions are supported by comparing Fig. 1 with Fig. 2 in which is plotted the global distribution of cloud cover, also in a 10×10 degree grid, taken from the climatological estimates of Haurwitz and Austin (1944). In Fig. 2, the darkest shades correspond to 20 percent cloudiness, and the lightest to 70 per cent cloudiness. The agreement in the main features of the two figures is striking, except that the TIROS III measured extremely high temperatures over the South Pacific, indicating a relatively clear area which is not noticeable in Fig. 2, undoubtedly due to lack of observational data in this region.

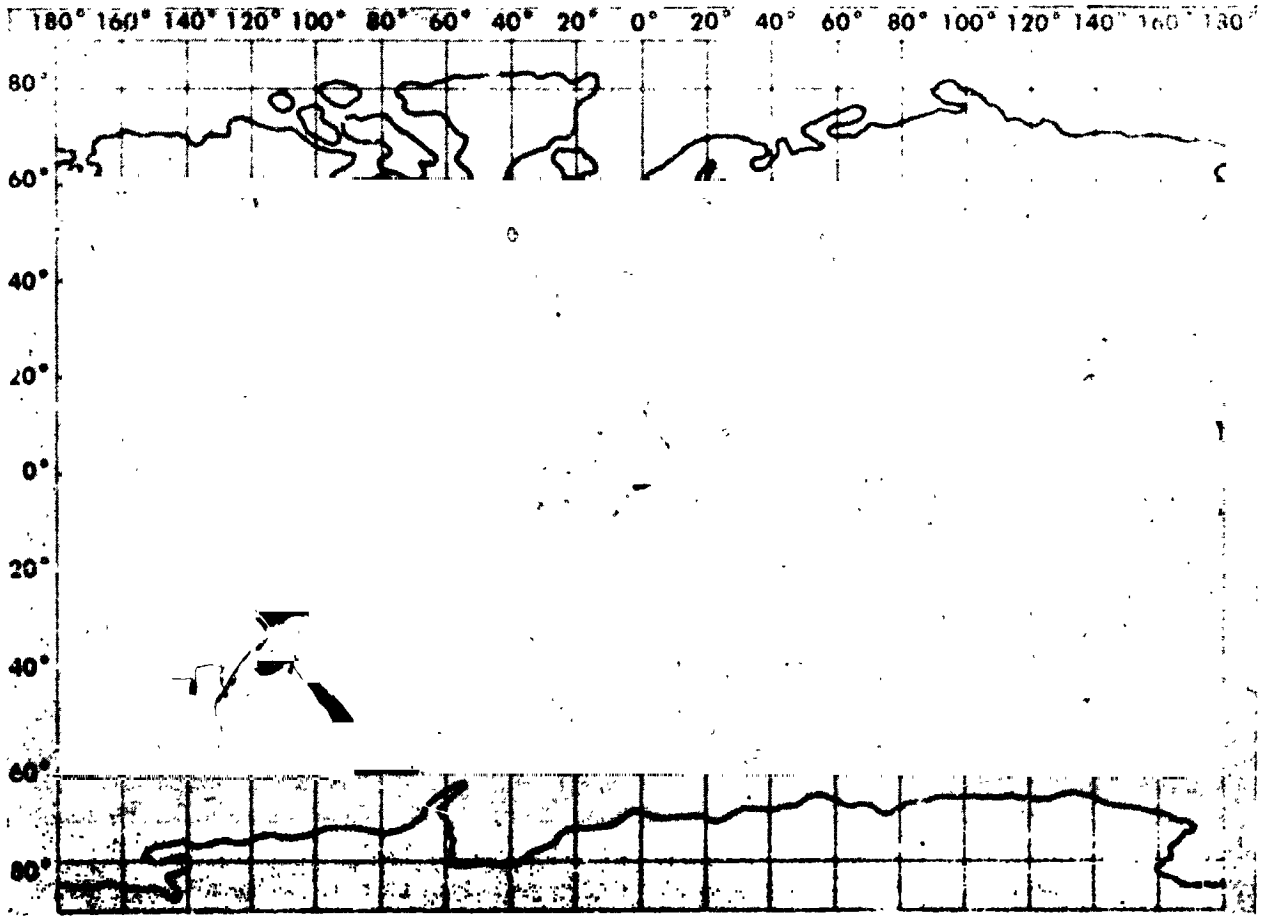

FIGURE 2.—Global distribution of average cloud cover for July (after Haurwitz and Austin, 1944). Darkest shade—cloud cover <20 percent, lightest shade—cloud cover >70 percent.

3. DEDUCTION OF CLOUD HEIGHTS AND CLOUD COVER

Although it is interesting to note the resemblance between Figs. 1 and 2, the actual derivation of cloud amounts from the TIROS radiation data is fairly involved. As mentioned earlier, several factors, viz., cloud amount, cloud height, surface temperature, vertical distribution of water vapor and of temperature, influence the 'effective' temperatures measured by the satellite. By the method described below we have, however, attempted to separate the effect of these parameters in order to obtain a reasonable estimate of cloud height from TIROS radiation data.

Using the climatological estimates of the global distribution of surface temperature (Haurwitz and Austin, 1944), the latitudinal variations in the vertical distribution of temperature (Davis, 1962, London, 1957), the total amounts of water vapor and ozone and their vertical distributions, we have constructed ten different model atmospheres which correspond to the ten latitudinal belts between 50N and 50S for the months of July and August.

The radiation flux in the 8–12 μ region, which would be emitted from such atmospheres, was then calculated following a method described in an earlier paper (Prabhakara and Rasool, 1963). The flux values thus calculated give the equivalent black body temperatures TIROS will observe above these atmospheres *if the atmosphere were completely cloudless.* Similar calculations were then repeated assuming the presence of thick clouds at various altitudes and of varying proportions. It is assumed that the clouds are completely opaque to the far infrared and the radiation is emitted only from the top of the clouds.

In Figs. 3 and 4 the results obtained for two such model atmospheres are shown. The family of five curves shows the difference (ΔT) between the surface temperature and the effective black body temperature observed by the satellite in the presence of different amounts of clouds located at altitudes of 2, 3, 4, 5, or 6 km. The intersection point of these curves with the ordinate in Fig. 3 is at 11.5 deg. This indicates that in a hot and humid atmosphere, even in complete absence of clouds, the satellite would observe an effective temperature about 12 deg lower than the surface

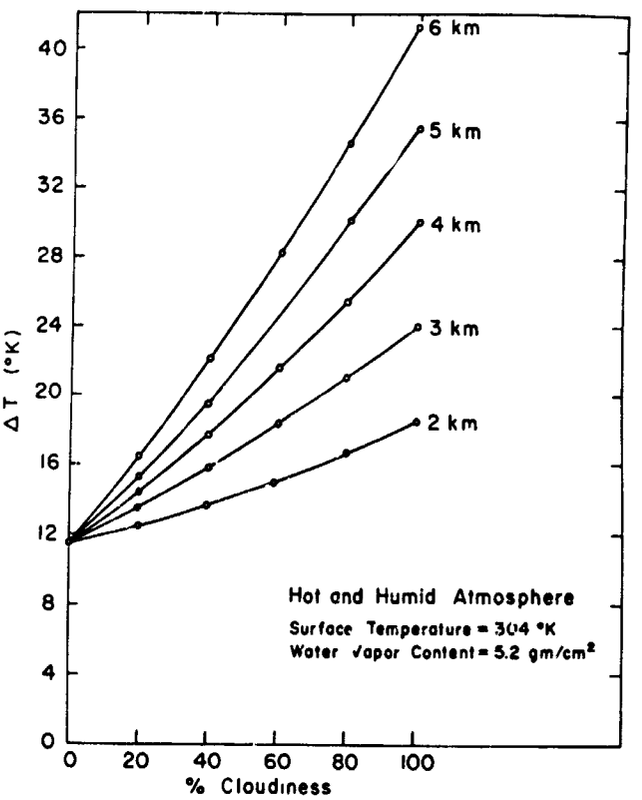

FIGURE 3.—ΔT as a function of percentage cloud cover with cloud tops at various altitudes. ΔT is the difference between the average surface temperature and the equivalent blackbody temperature measured by the Tiros III, channel 2. A case of hot and humid atmosphere.

temperature. In Fig. 4 is shown another extreme case, this time of a dry and cold atmosphere where the ΔT, in the absence of clouds, is only 3.5 deg.

If, therefore, for any given region, one has an estimate of surface temperature, of the amount of water vapor in the atmosphere and of the percentage cloud cover, then with such a family of curves, combined with the TIROS radiation data of the "window" channel, one can derive an approximate value for the effective height of the cloud tops.

In order to determine the latitudinal distribution of the effective cloud heights for the months of July and August 1961, we calculate the following parameters for each 10-deg latitudinal belt between 50N and 50S.

The satellite-observed temperatures in the "window" channel are averaged separately for day and for night for the period 12 July through 10 September 1961.

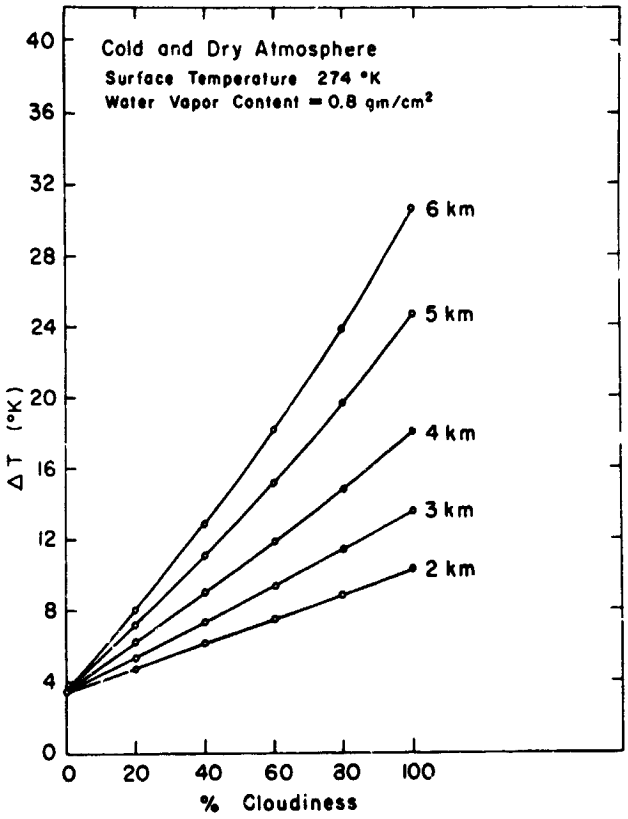

FIGURE 4.—Same as Figure 3—a case of cold and dry atmosphere.

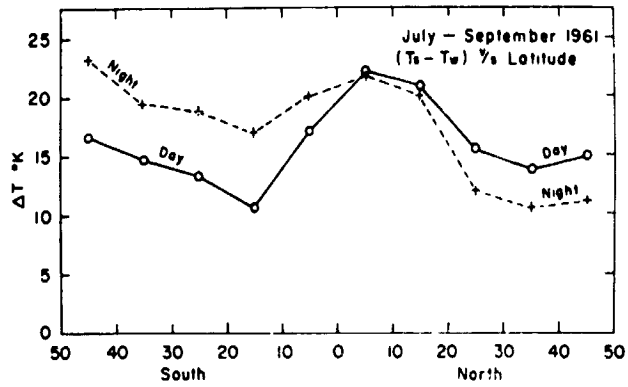

FIGURE 5.—ΔT as a function of latitude—for day and for night.

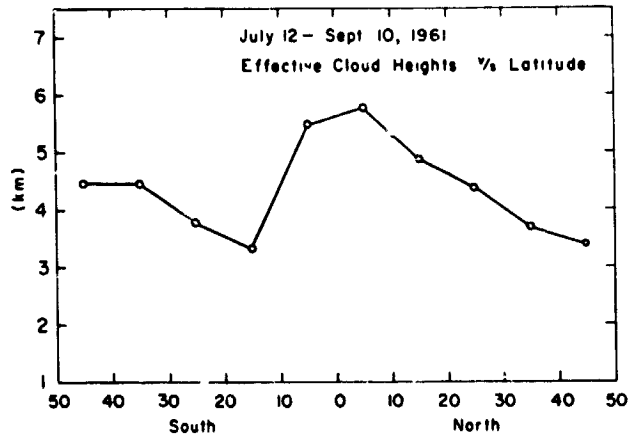

FIGURE 6.—Effective cloud top heights deduced from the daytime observation of Tiros III as a function of latitude.

The latitudinal means of day and night surface temperatures for the same period were determined from the *Monthly Climatic Data of the World* (U. S. Weather Bureau); supplementing these data were climatological estimates of Haurwitz and Austin (1944) for the oceanic regions.

The difference (ΔT) between the mean surface temperatures and the average effective temperatures measured by the TIROS channel 2 in each latitudinal belt is plotted in Fig. 5 separately for day and for night.

Latitudinal averages of daytime percentage cloud cover for the same period given by Arking are shown in Fig. 7 (Curve 1).

Now with both the ΔT and percentage cloud cover being known for daytime, we can use our nomograms (e.g., Figs. 3 and 4) to determine the average daytime cloud height for each latitudinal belt. The heights thus deduced are plotted as a function of latitude in Fig. 6.

If we assume that, on an average, cloud heights derived from the daytime measurements are also valid for the night, we can now use the ΔT values for the night (Fig. 5) and the heights plotted in Fig. 6 to determine the nighttime cloud cover as a function of latitude.

The resulting latitudinal distribution of the nighttime cloud cover is plotted as Curve 2 in Fig. 7.

A comparison of the day and night curves immediately shows that in the Southern Hemisphere, which is largely oceanic, the percentage cloudiness is much higher at night than during the day. In the Northern Hemisphere, on the other hand, the nocturnal cloud cover could be as low as ~20 percent for the latitudes of 20 to 40 deg.

These results are based on the debatable assumption that, on an average, for a given latitudinal belt the cloud-top heights do not change from day to night. In case this assumption is not correct, our results would then indicate that,

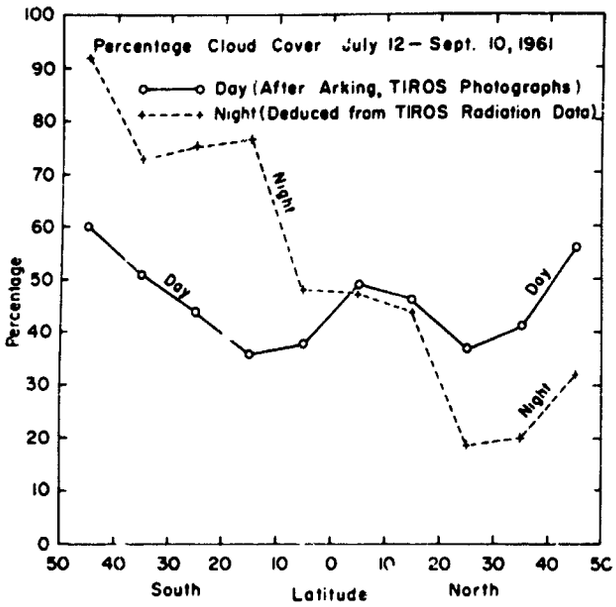

FIGURE 7.—Curve 1. Daytime average percentage cloud cover for the period 12 July through 10 September as a function of latitude (after Arking). Curve 2. Nighttime average percentage cloud cover for the same period deduced from Tiros window channel data.

in order to have the same amount of cloudiness for both day and night, the cloud heights in the Southern Hemisphere should be 2 to 4 km higher at night than in the daytime, and lower by 1 to 3 km in the Northern Hemisphere.

Similar analysis of the TIROS radiation data can also be made to determine the longitudinal as well as latitudinal distribution of nighttime cloud cover, but it requires more detailed information on the global distribution of surface temperatures, water vapor, and variations in the emissivities of land areas (Beuttner and Kern, 1963).

ACKNOWLEDGMENT

I wish to thank Professor R. M. Goody for reading over the manuscript and making valuable comments, L. Umscheid for programming and computing on an IBM 7094 and A. Liebman for his valuable assistance during the preparation of this paper.

GLOBAL DISTRIBUTION OF THE NET ENERGY BALANCE OF THE ATMOSPHERE FROM TIROS RADIATION DATA*

S. I. RASOOL†

The radiation data from Tiros II and Tiros III have been analyzed to obtain the monthly averages of the global distribution of the total outgoing radiation from the earth. These data have been combined with climatological estimates of the incoming radiation for the same periods to obtain monthly averages of the regional distribution of the net energy balance. The results show that these data could be useful in studies of the meridional circulation and the evolution of large-scale weather systems.

We have carried out an analysis of the radiation data acquired by the Tiros meterorological satellities, in order to determine the regional and time variations in the energy balance of the earth and its atmosphere.

The energy balance of the earth-atmosphere system is made up of the difference between the incoming solar radiation, mostly in the visible, and the outgoing terrestrial radiation in the infrared. It is well known that the latitudinal variation of the energy balance shows an excess of incoming solar radiation over outgoing radiation near the equator, and a deficiency at the poles. It is this variation of the energy balance with latitude that drives the atmospheric heat engine. Thus, through the determination of the latitudinal average of the energy balance with the aid of the Tiros data, we obtain the information which is necessary to understand the general circulation of the atmosphere.

At the same time, we have obtained some information regarding the regional variations in the energy balance of the earth-atmosphere system. Knowledge of these variations gives us a very important source of information for the understanding of large-scale weather systems.

Simpson (*1*) carried out the first extensive studies of the atmospheric energy balance, by the application of a simplified radiation theory to empirical physical models of the atmosphere. This problem has since been re-examined by Houghton (*2*), London (*3*), Budyko (*4*), and others.

The radiation instrumentation in Tiros, and the physical significance of this experiment, have already been discussed in detail by Bandeen *et al.* (*5*) and Nordberg *et al.* (*6*).

Three of the five channels of the Tiros radiometer measure terrestrial radiation in the far infrared, corresponding to wavelength intervals of 5.8 to 6.5 μ, 7 to 13 μ, and 7 to 30 μ. The other two channels record the solar radiation reflected by the earth, in the visible spectrum, which gives an estimate of the albedo of any region.

In Tiros II and Tiros III, which were active for 5 and 3 months, respectively, the channels which measure the reflected visible energy degraded very quickly, and almost no data are available for these channels. It is also possible to obtain information regarding the solar input by the statistical analysis of the Tiros cloud-cover photographs (*7*), but this analysis is still in a preliminary stage. Therefore, for this first study of the energy balance, we have used the climatological estimates of Budyko (*4*) for the incoming radiation. These give the monthly averages of solar radiation reaching the ground as a function of latitude and longitude, as derived from ground-based pyrohelimeter data.

For the outgoing radiation we have used the Tiros data in the infrared channels. Channel 4, which is sensitive in the 7- to 30-μ interval, and thus records almost 80 percent of the total outgoing radiation from the earth, also degraded after approximately 1 month in each of the

*Published in *Science*, 143(3606):567-569, February 7, 1964.

†Goddard Space Flight Center and New York University, New York.

satellites. The data from channel 2, sensitive in the 7- to 13-μ interval, however, is available from 23 November 1960 to 12 April 1961 for Tiros II and from 12 July to 10 September 1961 for Tiros III. There was some degradation in this case also, but fairly good estimates of the correction factors for this channel are now available.

Wark *et al.* (*8*) have shown that data from this channel can be used to obtain reasonably good estimates of the total outgoing radiation from the earth. Numerical factors for converting channel 2 measurements to total outgoing radiation are now available for both Tiros II and III. A comparison between the values of total outgoing radiation derived from channels 4 and 2 for the overlapping period give satisfactory results.

To obtain an estimate of the temporal as well as regional variations in the total outgoing flux, we have divided the surface of the earth into intervals of 10° latitude by 10° longitude between 50°N and 50°S. Because the inclination of the satellite orbit is 48° the data for polar regions are not available. All measurements made by the satellite in each of these intervals, at nadir angles less than 25°, have been converted to the total outgoing flux and averaged separately for each month. There are approximately 500 observation points per month in each 10° square.

The total outgoing flux estimated in this manner is, however, liable to have a small diurnal bias. This is because the orbit of the satellite precesses in right ascension at a rate of 6° per day, or it has a precession period of 9 weeks. Therefore our results for the total outgoing radiation are affected by the diurnal variation of the ground temperature. However, this effect is small for the particular case of this study which is concerned with the long-period averages over large areas. Because of the cloudiness and the presence of water vapor, the average of the channel-2 data over large regions and extended periods of time does not give the ground temperature, but has been shown (*9*) to give the effective temperature at a height of about 3 km, and therefore the effect of the diurnal variation is much reduced.

As mentioned earlier, for the incoming radiation we have used the climatological estimates of Budyko (*4*), which are based on the ground observations of solar radiation, and are given as monthly averages, also in 10° by 10° grids. These values were corrected for the absorption of solar radiation by the atmosphere, which, according to London (*3*), varies with latitude and season and is about 30 to 40 percent of the radiation which reaches the ground. The energy balance for each 10° by 10° grid, that is, the difference between these corrected values of incoming energy and the Tiros-measured values of the outgoing energy, is plotted on a month by month basis in Figs. 1 through 6.

These correspond to the months of December 1960 and January, February, March, July, and August 1961, respectively. The dark areas correspond to a positive energy balance, that is, an excess of incoming radiation over the outgoing. The light areas indicate regions of negative balance. In these figures, the darkest shade (for example, southwestern United States in July) has a value of $>+1.75\times10^5$ ergs cm^{-2} sec^{-1}, while the lightest shade (for example, 40°N to 50°N belt in December) corresponds to $<-1.65\times10^5$ ergs cm^{-2} sec^{-1}. The intermediate values of the energy balance are plotted, in steps of about 0.5×10^5 ergs cm^{-2} sec^{-1}, as seven gradations of the shading level.

The two triangular regions comprising parts of South America and Siberia have been left blank because data from Tiros are not available in those regions. Also the several other 10° by 10° grids left blank in March and July are due to nonavailability of data from Tiros for these regions.

A preliminary examination of these figures reveals several interesting features.

1) In December and January, the regions of maximum positive energy input are located in the latitudinal belt of 20°S to 50°S, while in July and August it is the 10°N to 40°N belt which has a high excess of energy. The evolution of this phenomenon is revealed by the charts for February and March.

2) The geographical distribution of the energy balance appears to be such that the desert areas of Africa, Australia, the Middle East, and southwestern United States show extreme positive energy inputs in the local summer.

3) The effect of the monsoon over India is noticeable in comparing the charts for March and August 1961. The net energy input over India is lower in August than in March, presumably

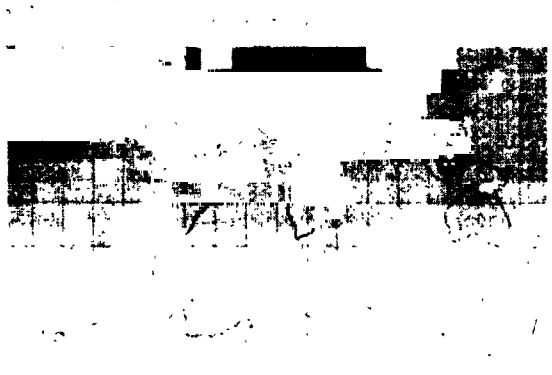

FIGURE 5.—July 1961

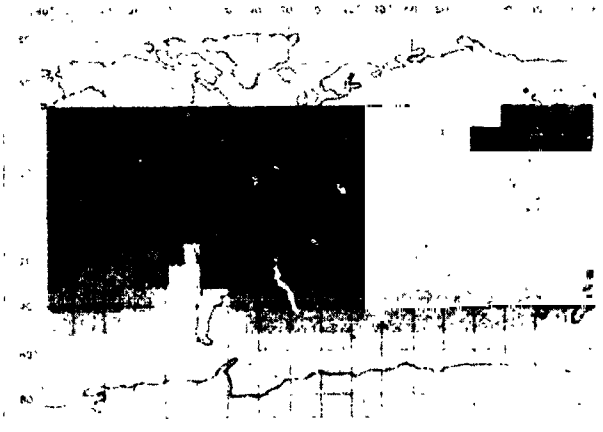

FIGURE 6.—August 1961

FIGURES 1–6.—Distribution of net energy balances for the months of December 1960 (Figure 1), January 1961 (Figure 2), February 1961 (Figure 3), March 1961 (Figure 4), July 1961 (Figure 5), and August 1961 (Figure 6). Extreme dark shade $\sim > +1.75 \times 10^5$ ergs cm^{-2} sec^{-1} and extreme light shade $< = 1.65 \times 10^5$ ergs cm^{-2} sec^{-1}.

because of the heavy monsoon cloud cover, although if it were not for the monsoon, one would expect a very high excess of energy in the summer month of August.

4) In the Northern Hemisphere, the region of the western Pacific appears to show a relative deficit in energy during all the 6 months. This area is well known for strong cyclogenic activity.

As in the case of the monsoon, the high cloudiness produced by the cyclogenesis probably accounts for the observed low input in energy.

A detailed analysis of these charts, in conjunction with the actually observed global distribution of the weather patterns for the respective months, may provide a better understanding of the role played by the energy balance of the atmosphere in the evolution of weather systems.

INTENSITIES OF 9.4μ AND 10.4μ CO_2 BANDS*

S. I. RASOOL

The intensities of the 9.4 μ and 10.4 μ CO_2 bands have been computed theoretically using, as the basis of our calculations, the line profiles at the centers of these bands published by Migeotte, Neven, and Swensson (1957). The band intensity values thus obtained are as follows:

9.4 μ band -0.0180 cm^{-2}-$atm.^{-1}$ at 265°K

10.4 μ band -0.0098 cm^{-2}-$atm.^{-1}$ at 265°K

The ratio of the two band intensities is 1.84 which is closer to the value of 1.7 given by Kostkowski (1955) than to 2.4 reported by Penner (1959).

The 9.4 μ and 10.4 μ CO_2 bands are extremely weak, and for the amount of CO_2 present in the earth's atmosphere ($\sim$0.03 percent) they do not play any significant role in the radiation processes within the terrestrial atmosphere. For this reason theoretical and experimental investigations of these bands have been rather limited. Also the two results available in the literature (Penner, 1959 and Kostkowski, 1955) differ rather significantly from each other.

For the purposes of studying radiative properties of the atmospheres of the other planets, Venus and Mars for example, where the amount of CO_2 in the atmosphere may be greater than in the earth's by several orders of magnitude, these bands do become important (Jastrow and Rasool, 1963). Therefore, in the absence of generally accepted values of the intensities of 9.4μ and 10.4μ bands, we have attempted to estimate them independently.

The method used is as follows: The solar infrared spectrum published by Migeotte *et al.* (1957) contains many lines at the center of the 9.4 μ and 10.4 μ bands due to absorption by CO_2 present in the earth's atmosphere. Measuring the total absorption within these lines and applying the Ladenburg and Reiche (1911) solution we calculate the intensities of lines in the P and R branches of the bands. The half width of the lines was assumed to be 0.09 cm^{-1} at NTP, and the amount of CO_2 in the absorption path was determined on the assumption that the total CO_2 in the earth's atmosphere is 2.40 m-atm. These line intensity values were then used to obtain a mean value of the band intensity using the classical relation (see, for example, Goody, 1963).

Internal consistency in the band intensity calculations was achieved when the effective temperature of the atmosphere above Jungfraujoch observing station was assumed to be 265°K. This is $\sim$6°K lower than the recorded surface temperatures during these observations.

In the following table we give the band intensity values determined by the method mentioned and values give by the other authors.

Intensities in cm^{-2}-atm^{-1} of CO_2 *Bands at* 9.4 μ *and* 10.4 μ

	9.4 μ (S′)	10.4 μ (S″)	T	S′/S″
This work	0.0180	0.0098	265°K	1.8
Kostkowski (1955)	0.0465	0.0281	329°K	1.7
Penner (1959)	0.0532	0.0219	297°K	2.4

The band intensity values given by Kostkowski, when reduced to 265°K, compare fairly well with our results, but those of Penner, especially of the 9.4 μ band, are significantly higher than ours.

I wish to thank Professor R. M. Goody of Harvard University for suggesting this method of calculation.

DATA FROM EXPLORER 17 ON COMPOSITION OF THE UPPER ATMOSPHERE*

CARL REBER

INTRODUCTION

The Explorer 17 aeronomy satellite carried two double-focusing magnetic mass spectrometers designed [*Meadoes*, 1960; *Hall et al.*, 1960; *Spencer and Reber*, 1962] to measure the concentrations of the major neutral-particle constituents of the earth's upper atmosphere. The ambient densities of helium, oxygen, and nitrogen were obtained between north and south latitudes of 58° and from the perigee altitude of 257 km to an altitude in excess of 700 km. Data for various local times, altitudes, and geographic locations have been combined to provide a broader altitude coverage than could have been experienced at any single

location. Data are presented for helium, atomic oxygen, and molecular nitrogen; molecular oxygen and atomic nitrogen data will be presented and discussed in a later report along with other data obtained under more varied conditions.

EXPERIMENT

The mass spectrometer measured the number densities of the various species which were in its ionizing, or sampling, region. Before reaching this sampling region, however, some of the neutral particles underwent collisions with various parts of the spectrometer structure; thus the number measured by the spectrometer was generally different from the ambient number density. The relationship between the spectrometer measurements and the ambient number densities was found to be a function of particle species, satellite velocity, and the angle between the spectrometer axis and the satellite velocity vector (angle of attack α). Using satellite velocity and angle of attack, both obtained from the tracking stations and the satellite's optical aspect system, calculations have been carried out for each species and have been used to convert the measured quantities to the ambient values presented here. The contribution of residual gas has also been taken into account.

The absolute accuracy of the number density data is ± 40 percent, reflecting laboratory vacuum calibration error and the uncertainties in the ambient number density calculations. The relative accuracy of the data obtained for similar angles of attack is about 5 percent; for data obtained when the angles of attack differ by 70° or more, the relative accuracy is about 30 percent. The mean mass data and the concentration ratios are good to ± 10 percent. Since the relative accuracy of the number density varies with the angle of attack, this quantity, the local sun time, and other pertinent information are given in Table 1.

DATA

Figure 1 shows the ambient number densities of the major constituents plotted as a function of

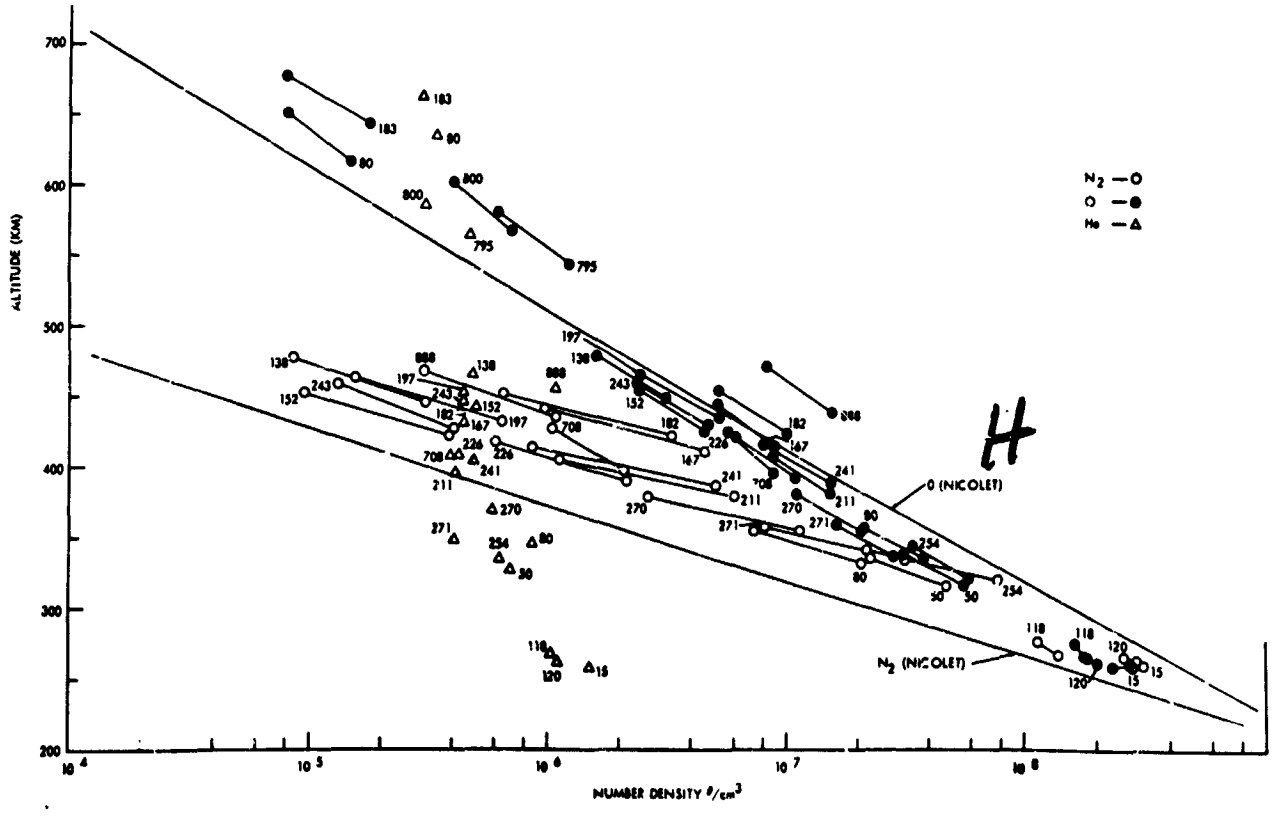

FIGURE 1.—Ambient number densities of the major constituents versus altitude. These data include many local times and geographic locations. The orbit numbers refer to Table 1. Nicolet's model for $T = 700°K$ is included for reference.

altitude for a number of different local times and locations. A single satellite interrogation (pass) is indicated by two data points joined by a straight line for molecular nitrogen and atomic oxygen and by one point for helium. The Nicolet model (private communication) is included for reference.

For the times concerned, the number densities of helium and atomic oxygen are comparable at about 600 km, with helium predominant at higher altitudes. Between 300 and about 600 km, atomic oxygen is the major constituent; in the 250- to 300-km region, molecular nitrogen and atomic oxygen have nearly equal concentrations.

There is, at present, insufficient daytime data to determine scale heights for the sunlit atmosphere. However, during the night at higher altitudes the concentration gradients are consistent with the scale heights for temperatures of 700° to 750°K.

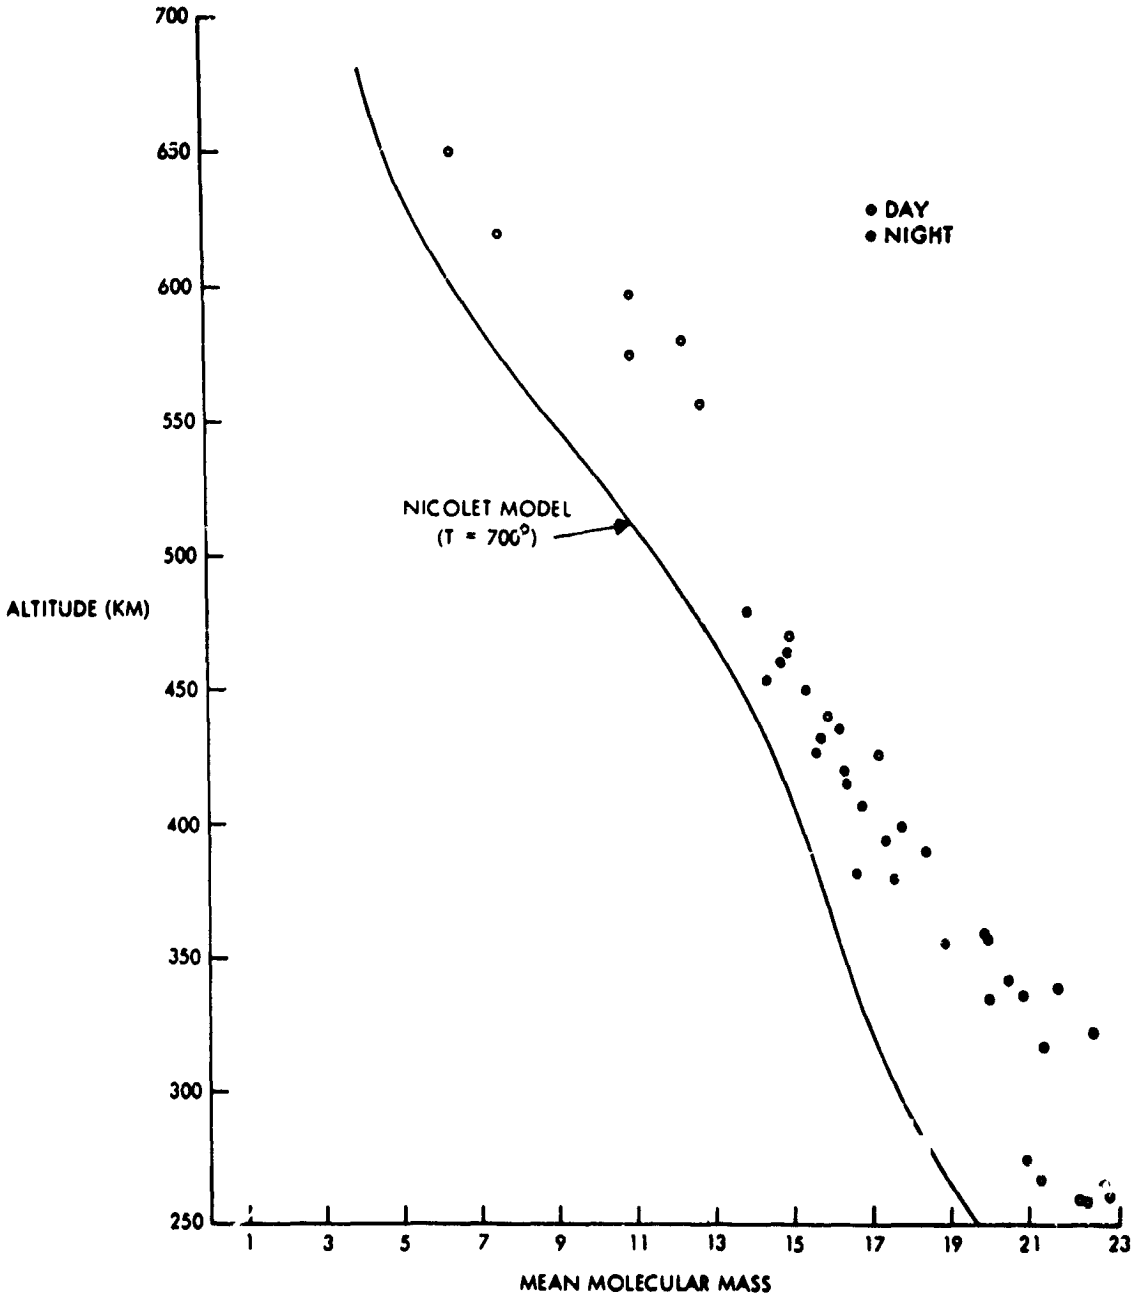

FIGURE 2.—Mean molecular mass versus altitude. The mean mass was calculated using the three major constituents measured, N_2, O, and He. Nicolet's model is included for reference.

There appears to be a deviation from nighttime diffusive equilibrium in the 300- to 350-km altitude range for N_2. This may be indicative of longer times required for N_2 to diffuse at these altitudes; however, as noted above, the data shown are representative of many time and geographic locations and may not provide an accurate instantaneous vertical distribution. It is interesting to note that the data from passes 167, 182, and 183, for which the densities are higher than for other nighttime passes, were obtained shortly after a minor magnetic disturbance which occurred on April 14. All data shown are measured values and are not averaged or smoothed in any way.

Figure 2 shows the variation of mean molecular mass with altitude. These data were calculated using the measurements of helium, atomic oxygen,

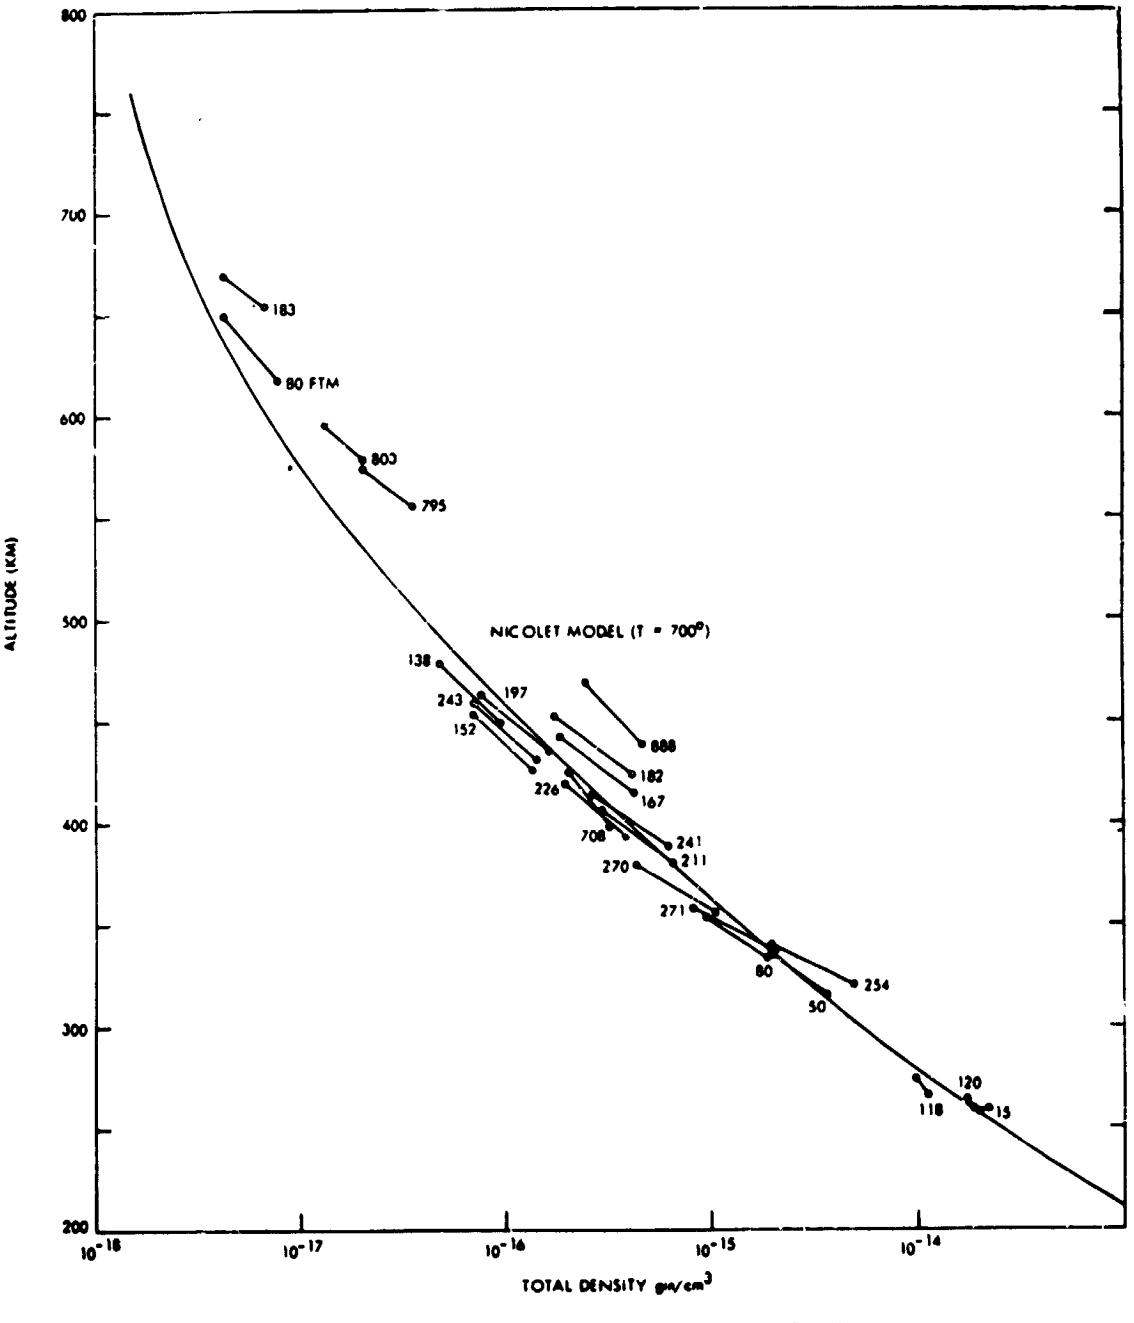

FIGURE 3. Total mass density versus altitude. The total mass density was calculated using the densities for N_2, O, and He. The orbit numbers refer to Table 1. Nicolet's model is included for reference.

and molecular nitrogen only, other measured gases providing a negligible contribution ot the mean mass. The presence of hydrogen, which the instrument was not designed to measure, would reduce the value of the mean mass somewhat at higher altitudes.

The total mass density, shown in Figure 3, was computed by summing the contributions from molecular nitrogen, atomic oxygen, and helium. The results obtained in this way agree with the densities obtained independently by the pressure gage experiments on Explorer 17. This agreement lends support to the calculations relating the concentrations in the sampling region to the ambient number densities, as the pressure gage kinetics have been studied extensively [*Horowitz,*

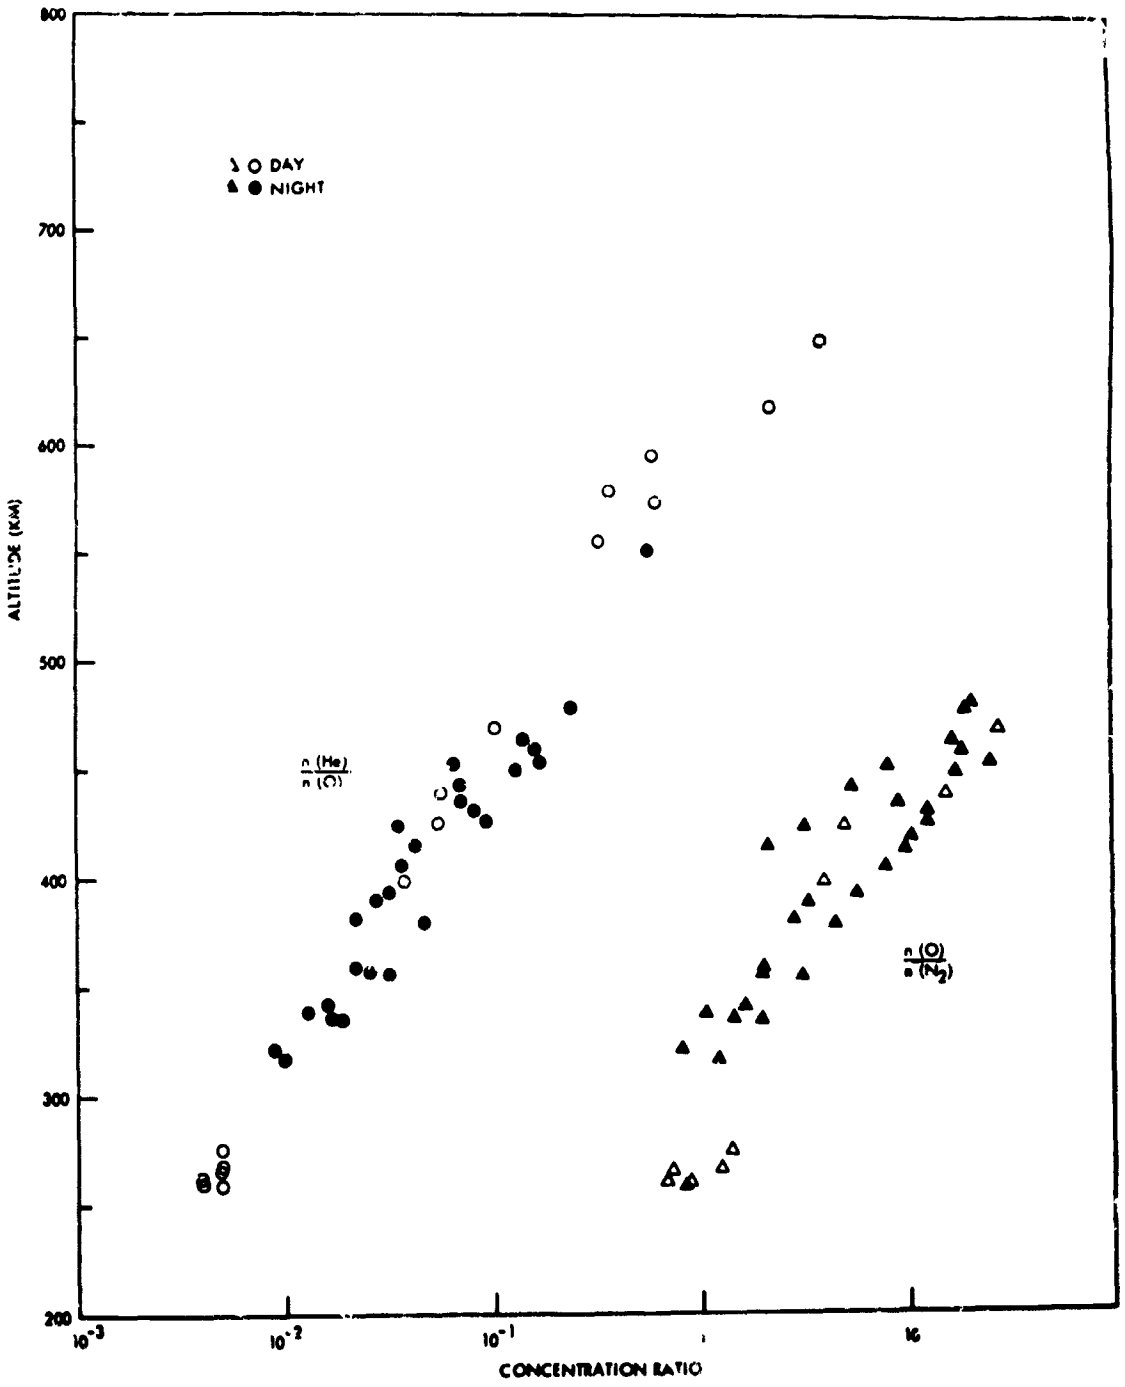

FIGURE 4.—Concentration ratios of the major constituents versus altitude.

1953]. Also, the total density measurements from the mass spectrometers agree in general within a factor of 2 with atmospheric density calculated from satellite drag observations [*Bryant*, 1964].

Figure 4 shows the variation with altitude of the concentration ratios of helium to atomic oxygen and atomic oxygen to molecular nitrogen.

ACKNOWLEDGMENT

I an indebted to Professor Marcel Nicolet for many hours of stimulating discussions about the data from Explorer 17, particularly with respect to extracting the scientifically interesting from the technically involved.

A NIGHT-TIME MEASUREMENT OF OZONE ABOVE 40 KM*

EDITH I. REED AND REUBEN SCOLNIK

The ozone distribution between 40 and 70 km was measured near midnight, May 27, 1960, from Wallops Island, Virginia by means of photometers sensitive to the ultraviolet airglow at wavelengths between 2400 and 2900 A. Below 60 km, the densities are within a factor of two of the daytime photochemical equilibrium, as represented by Johnson's late afternoon measurement of June 14, 1949. Above 60 km, the ozone density increased with altitude, with its maximum increase, a factor of 6 over the day time value, occurring at 63 km.

INTRODUCTION

At high altitudes, above the principal ozone maximum, ozone concentration as a function of altitude should be governed principally by the presence or absence of sunlight, and vary in a predictable manner from day to night and from season to season [*Chapman*, 1930][a,b]. The first direct measurement of the daytime profile was a result of studies of the sun conducted by the Naval Research Laboratory on a V-2 rocket in 1949. Ozone densities up to 70 km were deduced from solar spectra and were consistent with computed photoequilibrium profiles [*Johnson, et al*, 1952]. Chapman also suggested that at high altitudes, above the ozone maximum and below the atomic oxygen maximum, ozone would increase at night as a result of a reaction between atomic and molecular oxygen. Several have treated this problem numerically, including *Nicolet* [1957], *Barth* [1961], *Dütsch* [1961], *Paetzold* [1961], *Wallace* [1962], and *Hunt* [1964], but with varying results, depending on the set of reactions, reaction rates, and initial concentrations which were chosen. Of particular difficulty is the computation of the effects of minor constituents such as hydrogen, nitrogen oxides, and the hydroxyl radical.

Ground based measurements of ozone content at these altitudes have not been satisfactory. Measurements of total ozone content are not particularly helpful since variations in the ozone content below 30 km due to air movements are comparable to the expected night time increase at higher altitudes. However, the discovery of the ultraviolet airglow and a general improvement in the techniques of ultraviolet photometry made a night time measurement of ozone feasible.

In 1957, the Naval Research Laboratory flew an ultraviolet photometer with a response from 2600 to 2900 A, and did observe an ultraviolet airglow layer centered at 101 km [*Tousey*, 1958]. This had been predicted from laboratory observations which showed that the Herzberg bands of molecular oxygen, the visible end of which had been observed in the airglow [*Chamberlain*, 1955], extend to 2563 A in the ultraviolet [*Broida* and *Gaydon*, 1954]. But because an unknown amount of the observed airglow could be due to an OI line at 2972 A, where the filter transmission is still 10 percent of its maximum; the ozone density could not be determined unambiguously.

In May 1960, Goddard Space Flight Center flew a number of ultraviolet photometers, including some whose filters were centered at 2620 A and narrow enough so that the absorption cross section of ozone varied by only 50 percent over the bandwidth of the filter. These data, when interpreted with the aid of an airglow spectrum obtained by T. Stecher (of GSFA), provide an ozone density profile between 40 and 70 km.

INSTRUMENTATION

NASA Aerobee 4.05, one of a series of payloads designed for stellar photometry [*Boggess*, 1961],

*Published as *Goddard Space Flight Center Document X-613-64-267*, September 1964.

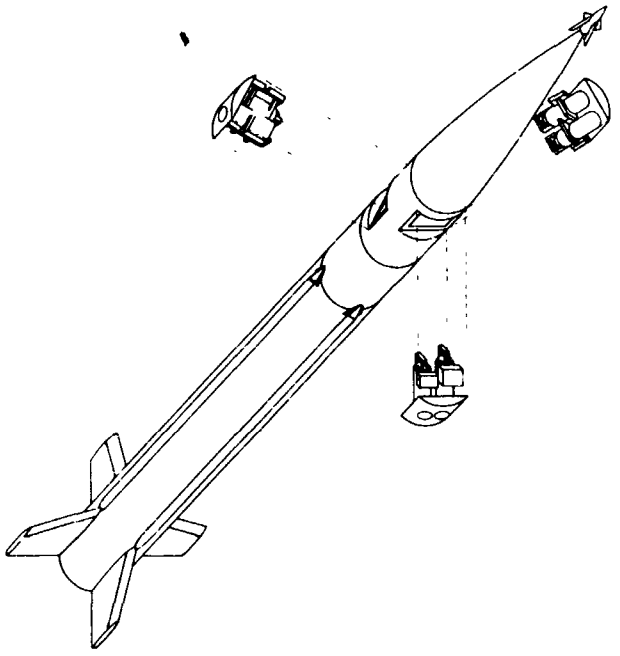

FIGURE 1.—Location of photometers on Aerobee 4.05.

contained three pairs of photoelectric photometers, each pair mounted 120 degrees apart around the rocket axis (See Figure 1) looking out at three different angles to that axis: nominally, 75°, 90°, and 105°. One photometer of each pair was sensitive to light in the spectral region centered near 2620 A, while the response of the other was centered near 2260 A, but with their optical axes parallel. Each pair was mounted on a removable door, which, when installed, became an integral part of the rocket skin. Since the principal purpose of this instrumentation was ultraviolet star spectroscopy, 2620 A photometers were preferred to the 2680 A ones (to reduce ambiguity in the interpretation of stellar data due to the strong magnesium doublet at 2800 A). However, to correlate the data from this flight with that of earlier flights, one 2680 A photometer was included. This was mounted on the door containing the 90° photometers, and also looked at 90° with respect to the rocket axis.

The optical system of each photometer was similar and is shown in Figure 2. Calcium fluoride was used for all lenses in the 2260 A units; quartz for those in the 2620 and 2680 A photometers. The field of view had a total width of between 4 to 5°.

Isolation of the 2600 A region was achieved by combining two millimeters of 0.05 percent lead-

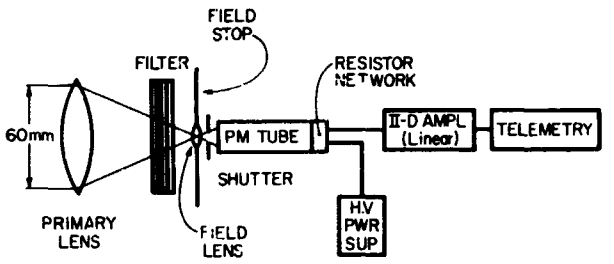

FIGURE 2.—Optical-electrical schematic of a photometer.

doped KCl:KBr (1:1) crystal with Cation-X in thin sheets of polyvinyl alcohol [*Childs*, 1961]. Three millimeters of nickel sulfate hexahydrate provided a sharp cutoff for longer wavelengths; one Corning No. 7–54 and one Corning 9–54 filter sharpened the shorter wavelength cutoff. A typical filter had a transmittance of 0.18, an effective wavelength of 2620 A and a 200 A bandwidth.

The 2700 A filter consisted of three Corning 7–54 filters, one sheet of Cation-X and 5 millimeters of nickel sulfate hexahydrate. It has an effective wavelength of 2680 A, a transmittance of 0.16, and a bandwidth of 320 A.

The relative spectral response of the filters (see Figure 4) was measured by C. Childs, formerly of this laboratory, with a recording spectrophotometer, Cary Model No. 14, with an analytical accuracy of ½ of 1 percent for relative spectral transmission, a wavelength calibration of 4A, and a resolving power of 1A. Over the wavelength regions covered by each filter, the photomultiplier was assumed to have a constant sensitivity and the lenses a constant transmissivity. The rela-

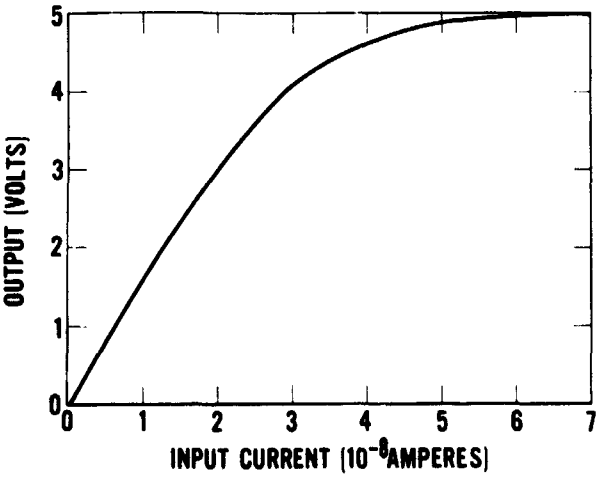

FIGURE 4.—Calibration curve for converter-amplifier.

tive response of the photometers was determined by use of the 2537 A line, to which all three types of photometers respond with an easily measured signal.

The 2680 A photometer used RCA's well-known 1P28 as a detector; all others used EMI's No. 6256B, an end-on fused silica window multiplier with cesium antimonide photocathode. A solenoid-operated shutter between the field stop and multiplier gave optical zero signals several times during the flight. The 1P28 and 6256B's were operated at 1000 and 1200 volts respectively; each detector had its own solid state DC to DC inverter power source with a resistor divider network at the base of each multiplier.

Each photomultiplier output was amplified to the zero to five volt range required by the telemetry system with what was essentially an impedance converter. Designed by G. Baker of the laboratory, the converter-amplifier had an electrometer tube (5886) input stage and ended with an emitter follower, with an overall voltage gain of 2.5 for small signals. It was purposely nonlinear in order to extend the dynamic range. A typical calibration curve is shown in Figure 3. The output voltage went directly to a pulse position modulation telemetry transmitter which relayed the data to the ground receiving equipment.

BASIC DATA

Aerobee-Hi NASA 4.05 was launched at 0030 EST on May 27, 1960 from Wallops Island, Virginia (37°50′ N, 75°29′ W). The vehicle performance was normal: propulsion ended at 52.4 sec after launch at an altitude of 36.6 km with a vertical velocity of 1.84 km/sec and a horizontal velocity of .260 km/sec at an azimuth of 111°. The rocket spun about its longitudinal axis at a rate of 2.16 rps and soon entered a precession cone of 5.7° half angle, whose axis was 15.6° from zenith at an azimuth of 96°, with a period of 75 sec. Aspect during the ascent and free-fall portions of the flight was determined from a combination of data from magnetometers, trajectory information, and horizon and star data from the photometers. Down-leg aspect could not be determined with useful accuracy below the free-fall region. A peak altitude of 215.3 ± 0.2 km was reached 249.4 seconds after launch. Telemetry ceased at 468 sec; no recovery of instrumentation was attempted.

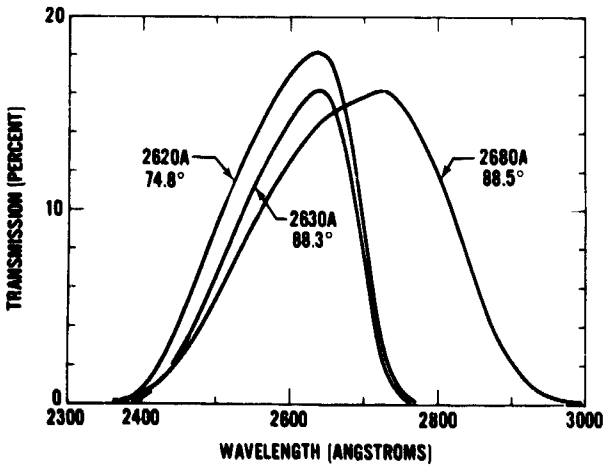

FIGURE 3.—Spectral characteristics of flight filters.

In Figure 5 is a sample of the telemetry record from two of the photometers for a period corresponding to three revolutions of the vehicle, while the airglow layer is still above the rocket. Since these photometers are nearly perpendicular to the rocket axis, the zenith angle of the photometer axis changes from a minimum (76° for the time in Figure 5) as the photometer points skywards, through 90° as it scans the horizon, and to a maximum of 100° as it points earthward. Ozone is relatively opaque around 2600 A, and the airglow in Figure 5 can be seen only when the zenith angle of the photometer is near a minimum. The ozone is relatively transparent to the light passed by the 2260 A filter, and the brightening of the airglow at the horizons can be clearly seen. (The light is probably of wavelengths longer than 2700 A, passed through the long wavelength tail of the 2260 A filter.) The southern horizon appears wider because it is merged with several bright stars in the Milky Way. As the vehicle increased in altitude, the signal from the 2620 A photometer resembled that from the 2260 A photometer, with bright horizons, a less bright sky toward zenith, and a dark earth. Above the airglow layer, the sky was dark (except for the brighter stars) and the earth appeared light. The noise in the record is due partly to the photomultiplier and partly to stars. The records were read at the midpoint between horizons, and analyzed to yield both a distribution of ozone with altitude and the volume emission of the airglow versus altitude.

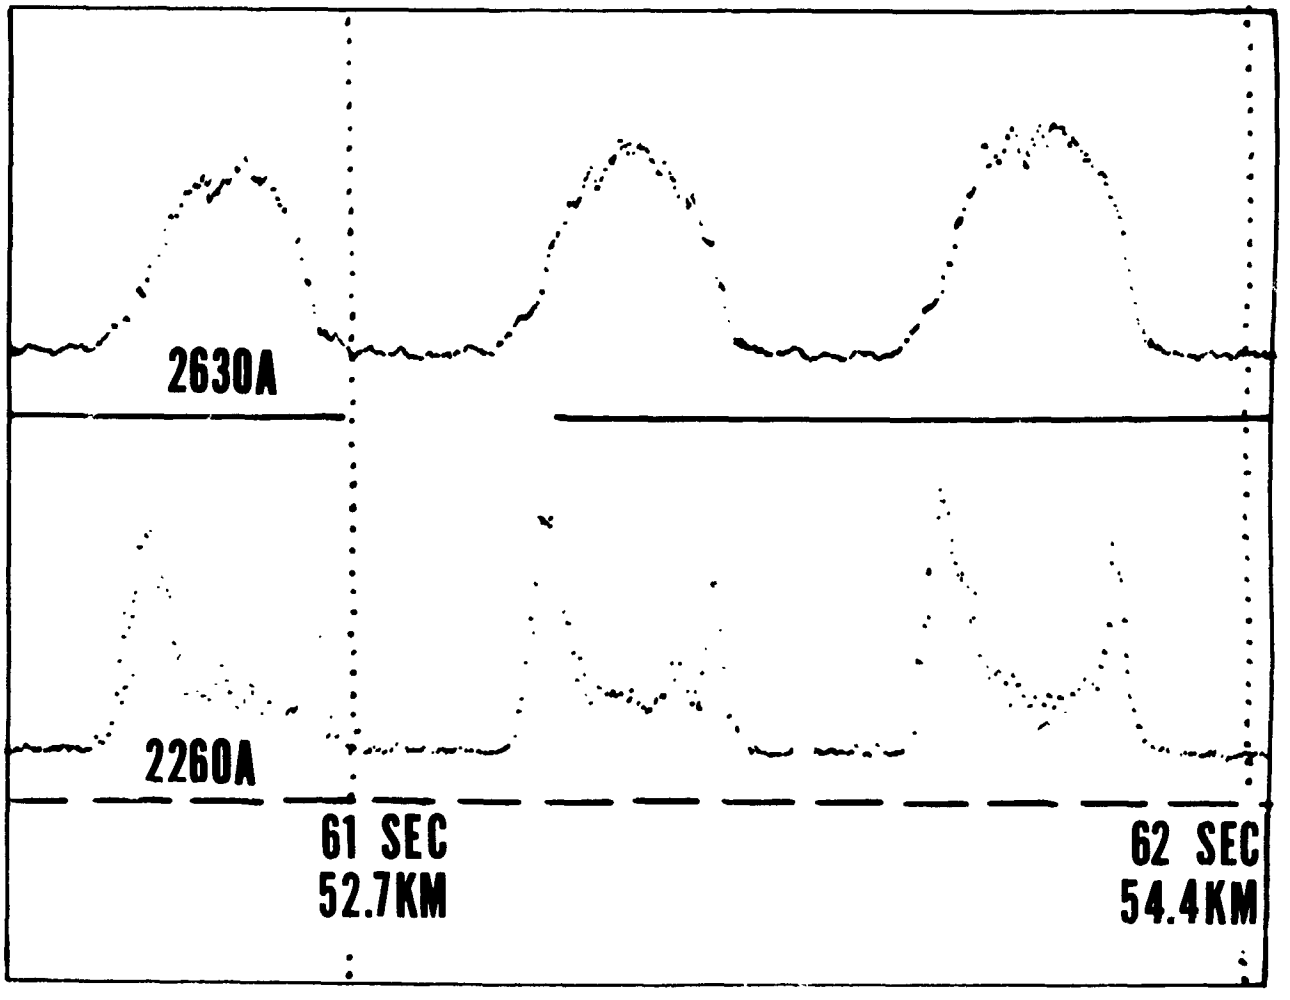

FIGURE 5.—Sample of telemetry record showing roll modulation of the airglow signal. Increasing signal represents increasing light.

The data obtained in the region of interest is shown in Figure 6. Data from 3 of the 7 photometers proved to be useful for ozone measurements. The pass band of the three 2260 A photometers was too wide to permit an accurate determination of an effective cross section for ozone; the down looking 2620 A photometer could not see the airglow while the vehicle was below the airglow layer. Data points for the photometers are shown to indicate the scatter in the raw data. As would be expected, the scatter increased rapidly as the signal rose into the non-linear portion of the amplifier response curve. In addition to the data, the angle of the rocket's longitudinal axis with respect to local zenith is given. The rocket took a spiral path with a zenith angle of 8° at thrust termination (52.4 sec) until it entered

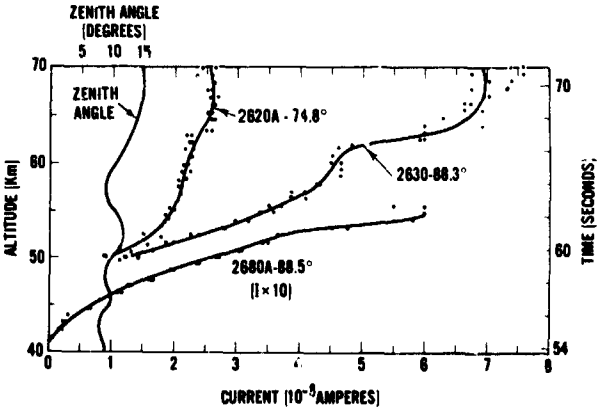

FIGURE 6.—Data from three photometers during the ascent of the rocket. The zenith angle is the angle between the longitudinal axis of the rocket and local zenith; the angle stated for each photometer is the angle between the photometer's optical axis and the rocket's longitudinal axis.

its regular precession cone of motion at about 75 seconds.

OZONE

The ozone content of the atmosphere is obtained from the rate of increase of the airglow signal as the vehicle rose. The energy observed is related to the ozone density in the following manner:

$$n(O_3)=\frac{(\log E_2-\log E_1)n\cos\gamma}{a(h_2-h_1)}$$

where $n(O_3)$ is the number of ozone molecules per cm^3

h_1 and h_2 are the lower and upper ends of the altitude interval,

E_1 and E_2 are energies observed at the corresponding altitudes,

n is Loschmidt's number, 2.687×10^{19} cm^{-3},

γ is the angel between the photometer axis and zenith, and

a is the absorption coefficient, cm^{-1}, base 10.

This was applied to the smooth curves in Figure 6 at one-second intervals.

Since the cross section of ozone varies appreciably over the wavelength interval passed by each filter, some assumption must be made concerning the spectrum of the airglow. For this purpose, the spectrum observed by T. Stecher (private communication) was used, and the absorption coefficient, a, computed for each photometer where

$$a=\frac{\Sigma E_i R_i a_i}{\Sigma E_i R_i}$$

where E_i is the energy in a particular wavelength interval, i,

R_i is the corresponding relative transmission of the filter, and

a_i is the corresponding absorption coefficient.

The absorption coefficients used were from the tabulation of *Inn* and *Tanaka* [1953, 1959] which in the region of interest here are about 10 percent higher than those of Vigroux [1953] and 1 or 2 percent lower than those of *DeMore* and *Raper* [1964]. The effective absorption coefficients calculated on this basis are: 2620 A (88.3°), 114.4 cm^{-1}; 2620 A (74.8°), 113.8 cm^{-1}; and 2630 A (88.5°), 79.48 cm^{-1}.

The resulting ozone density is shown in Figure 7 as a function of altitude. It is felt that the spectral characteristics of the photometers, the airglow and the ozone absorption coefficient are sufficiently well known such that they contribute no more than a total of about 20 percent uncertainty to the number density of ozone. This would be a systematic error which would not affect the shape of the curve.

The angle of the photometers with respect to zenith could easily contribute an uncertainty of 20 percent to both the absolute and relative values of the ozone densities. It is based upon magnetometer data and the assumption that at the end of thrust the rocket axis was aligned with the velocity vector.

The largest source of error is in the character of the data, which contains noise from the photomultiplier dark current, stray pulses, and stars. It is difficult to separate this from the possible temporal and spatial variations of the airglow itself. A temporal variation could be responsible for some of the shape of the curve, but it is unlikely that the airglow would vary sufficiently in the 16 seconds of time that the ozone curve represents, to be responsible for its major features. Spatial variation is not thought to be a major

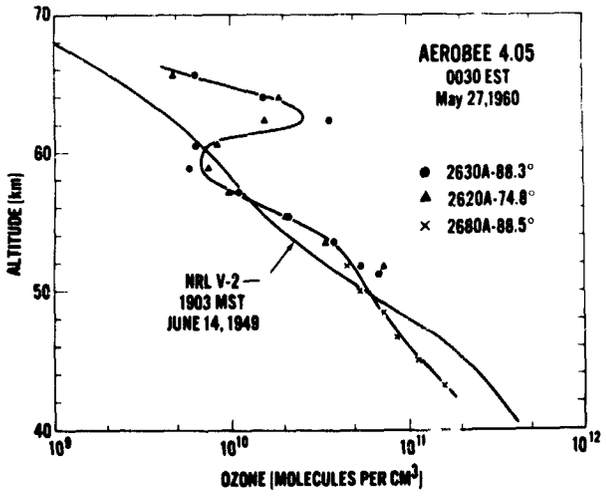

FIGURE 7.—Altitude distribution of ozone.

source of uncertainty in the data since the numbers derived from the two photometers which were looking at different portions of the sky agree reasonably well. The magnitude of the noise-like errors is apparent from the scatter of points about the curve and is on the order of 50 percent.

For comparison the daytime ozone distribution as measured by absorption of the solar spectra between 2500 and 3400 A [*Johnson, et al*, 1952] is shown. The daytime profile was computed using the ozone absorption coefficients of *Ny* and *Choong* [1933], which in the spectral region of interest are 10 to 15 percent higher than those of Inn and Tanaka used for the night time profile.

The most important feature of the profile is the factor of 6 increase in ozone density over the daytime profile above 60 km. While this may be in error by 50 percent or more, it is believed that the shape of the curve does indicate an increase of ozone density at night in this region, and that it is on the order of a half of a magnitude.

Techniques are being developed by various workers to use satellites for the measurement of ozone in this region. *Venkateswaran* [1961], observed the sunlight reflected from Echo I as it emerged from the earth's shadow, using various wavelength pairs between 4700 and 7000 A. His results above 55 km are about a factor of 15 higher than the measurements by *Johnson, et al.* However *Venkateswaran* [1963] states that this method probably gives too high values at levels above the principal ozone maximum.

The second type of observation was made at sunrise and sunset by a satellite borne radiometer with a response center at about 2630 A [*Rawcliffe, et al*, 1963]. At 60 km his data are about 20 percent lower than Johnson's, but approach Johnson's data, and above 80 km are somewhat higher than the trend of Johnson's data.

It is expected that the night time values would be higher. The magnitude of the effect, besides depending on reactions among the various oxygen species and third bodies, depends critically on such things as the initial hydrogen concentrations chosen [*Bates* and *Nicolet*, 1950, and *Wallace*, 1962] and possible reactions involving atomic nitrogen [*Barth*, 1961]. Perhaps the most recent computation of ozone densities has been done by *B. G. Hunt* [1964] using an atmosphere in which he assumes the only reactive constituent is oxygen. (The effects of atomic nitrogen and hydrogen would be to lower the calculated 0 and 0_3 concentrations.) Between 40 and 50 km, Hunt's curve for just before sunrise conditions is as much as 30 percent lower than Johnson's daytime profile, crosses it at 53 km, and reaches a maximum value of 5×10^{10} molecules of 0_3 per cm at 69 km.

AIRGLOW

The other principal result from the analysis of data from these photometers is information concerning the distribution of the airglow. Volume emission can be deduced from the data obtained as the vehicle passes through the emitting region. The energy calibration of the photometers has been used in preparing these curves, (Figure 8) so that they do rightly represent the relative energy in the portion of the spectrum passed by the different filters. Ten arbitrary units represent on the order of one photon cm^{-3} sec^{-1} per A. The airglow as measured by the 2680 A photometer is 2.3 times that sensed by the 2620 A photometers. The airglow measured by the 2260 A photometers is 0.15 times that of the 2620 A photometers; nearly all the energy measured by the 2260 A photometers has come through a long wavelength tail of the filters. This pattern is completely consistent with a spectrum of the airglow horizon obtained by T. Stecher with a spectrograph flown at 0030 local time on July 19, 1963.

The 2680 A filter was similar in construction and characteristics to those flown in March 1957 [*Tousey*, 1958] and November 1959 [*Friedman*, 1961, *Packer*, 1961]. The altitude of maximum

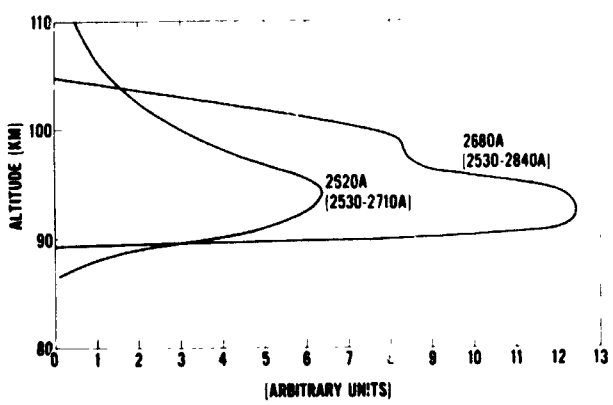

FIGURE 8.—Altitude distribution of the ultraviolet emission.

emission were 101 and 96 km respectively, compared to 92 km for this flight. The zenith intensity for the 1957 flight was 3.4 rayleighs per Angstrom (Dunkelman, private communication) and for the 1959 flight was 1.94 rayleigh per Angstrom. The airglow during the flight of Aerobee 4.05 was somewhat brighter, but within a factor of 10 of these values.

The brighter stars and the Milky Way were readily noted in the records as the photometer scanned across the sky. The signal in the absence of obvious stars indicated that less than 15 percent of the light from extended sources originated above the emission layer indicated in Figure 8.

ACKNOWLEDGMENTS

We thank the following colleagues at Goddard Space Flight Center for their help: Dr. A. Boggess III for making the data from this rocket payload available to us for this purpose; G. Baker and R. M. Windsor for the electronic instrumentation; E. Serra for engineering assistance in the payload preparation; T. Stecher for an advance copy of his airglow spectrum, wlthout which the effective absorption cross section could not have been determined with significant accuracy; L. Dunkelman for the absolute values of the night airglow measurement in March 1957; and Dr. J. E. Kupperian, Jr. for his encouragement and suggestion of analysis of this data.

SOME ASPECTS OF WIND SHEAR IN THE UPPER ATMOSPHERE*

R. G. ROPER

The wind motions responsible for the shearing of sodium vapor trails ejected from rockets in the 70 to 140 km region of the upper atmosphere are subjected to an analysis based on generally accepted theories of hydrodynamic turbulence. The region from 80 to 100 km is of particular interest in that here the predictions of shear turbulence theory are well substantiated. The energy spectrum of the height shear is found to follow the 4/3 power law proposed by Tchen, and is associated with a vertical correlation distance of approximately 6 km. The existence of an isotropic inertial region of maximum scale 3 km, previously indicated by analysis of meteor data, is confirmed. The vertical scale of the turbulent eddies is found to be the atmospheric pressure scale height, a phenomenon which has been observed by others, but which, as yet, has no satisfactory explanation.

1. TURBULENCE THEORY

The complete development of the relationships used in the analysis of wind shear is beyond the scope of this work; the following, used in conjunction with the references quoted, should provide an adequate background for consideration of the subsequent analysis.

1.1 Energy Spectrum Analysis

If there exists in a turbulent flow field a range of scales which receive energy from larger scale motions and pass it on undiminished to smaller scale motions, then, for this so-called inertial (non-dissipative) range of scales, the only form of energy spectrum function dimensionally possible is

$$E(k)=\alpha\epsilon^{2/3}k^{-5/3} \quad \text{(Kolmogoroff, 1941)}$$

where ϵ is the rate at which the turbulent energy is received by (and leaves) the inertial range of scales, k is the wavenumber vector corresponding to the real space scale r, and α is an absolute constant of order unity.

Batchelor (1953) has shown that, for such an inertial region which also possesses the property of isotropy, the fluid velocity differences measured as a function of the separation r follow the relation

$$[u(x)-u(x+r)]^2=4.82\alpha(\epsilon r)^{2/3} \tag{1}$$

In real space, the energy spectrum function $E(r)$ is defined by

$$E(r)=[u(x)-u(x+r)]^2 \tag{2}$$

Tchen (1954) has considered an otherwise isotropic region subjected to a mean shear, and finds that equation 1 is modified, becoming

$$[u(x)-u(x+r)]^2=a\,r^{4/3} \tag{3}$$

where a involves α, ϵ, and the mean gradient. Thus, for what may be termed shear turbulence, in real space

$$E(r)\sim r^{4/3} \tag{4}$$

1.2 Correlation Analysis

An energy spectrum function equivalent to that based on velocity differences can be formulated from the lateral or longitudinal velocity correlations defined as

$$f(r)=\frac{u_f(x)u_f(x+r)}{u_f^2}$$

and

$$g(r)=\frac{u_n(x)u_n(x+r)}{u_n^2} \tag{5}$$

where $u_f(x)$, $u_f(x+r)$, $u_n(x)$, $u_n(x+r)$ are the turbulent components of the velocity at two points x and $x+r$ respectively, measured parallel (suffix f) and normal (suffix n) to the vector separation r.

*Published as *Goddard Space Flight Center Document* X-651-64-337, November 1964.

In isotropic turbulence, $u_f^2 = u_n^2 = u_0^2$, the velocity characteristic of the energy bearing eddies of the Kolmogoroff spectrum.

Introduction to the equation of continuity for incompressible fluids leads to the relation

$$g(r) = f(r) + \frac{1}{2} r \frac{\partial f}{\partial r} \tag{6}$$

(von Karman and Howarth, 1938)

between the functions f and g, or, if the turbulence is isotropic in two dimensions only,

$$g(r) = f(r) + r \frac{\partial f}{\partial r} \tag{7}$$

These functions, f and g, may be called Eulerian space correlation functions, and either may be denoted by $R(r)$. If the range of scales under observation is inertial, then $R(r)$ must depend only on ϵ, and the only form dimensionally possible is

$$u_0^2[1 - R(r)] \sim \epsilon^{2/3} r^{2/3}$$

i.e.
$$1 - R(r) \sim r^{2/3}$$

(for any given flow field, u_0 and ϵ are constant).

Introduction of the relations 6 and 7 above gives, with c a constant

$$f = 1 - cr^{2/3} \tag{8}$$

and
$$g = 1 - 4/3\ cr^{2/3} \tag{9}$$
for three dimensional isotropy

or
$$g = 1 - 5/3\ cr^{2/3} \tag{10}$$
for isotropy in two dimensions only.

Since the variations of the correlation difference function $[1 - R(r)]$ with r is the same as that of $E(r)$ in equation 1, we may suppose that the dependence of $[1 - R(r)]$ on r will be similarly modified in the presence of a mean shear

i.e.
$$[1 - R(r)] \sim r^{4/3} \tag{11}$$

If, in fact, equation 11 is pertinent, then the relationships between f, g, and r (equations 8, 9, 10) will now become

$$f = 1 - ar^{4/3}$$

and
$$g = 1 - 5/3\ ar^{4/3}$$

or
$$g = 1 - 7/3\ ar^{4/3}$$

An indication of the degree of isotropy can be obtained by considering the ratio

$$S = \frac{1 - f}{1 - g}$$

For two dimensional isotropy

$S = 0.60$ without mean shear

and $S = 0.43$ with mean shear

For three dimensional isotropy

$S = 0.75$ without mean shear

and $S = 0.60$ with mean shear

The relative importance of mean shear will be indicated by the form of either the energy spectrum function $E(r)$, or the correlation difference function $[1 - R(r)]$.

2. THE PRACTICAL APPLICATION OF TURBULENCE THEORY

2.1 The Mean Wind Profile

In applying the relations developed above to the wind vectors measured by means of sodium vapor trails ejected as a tracer into the upper atmosphere, the relative importance of the mean motion must not be overlooked. The velocities used in the energy spectrum and correlation analyses of the previous section must be the turbulent velocities, or departures from the mean motion. In normal correlation analysis, the mean value of a set of observations is usually taken as the mean value of the measured data, which, when applied to wind height shear data, would be tantamount to the assumption of a mean wind profile which is constant with height. Such a profile is the exception rather than the rule in meteorological phenomena.

Practically any attempt to prescribe a mean wind profile to the measured winds will be subjective to a certain extent. If one uses a polynomial fit, for example, it must be truncated before it can assume any of the features of the measured profile which are due to the turbulent motions present. From experience based on the measurement of winds in the 75 to 105 km region by means of radio reflections from meteor trails (Elford, 1958, 1964), a quadratic change with height of the mean wind over any given 20 km interval should best

describe the contribution of the mean motion without destroying any of the characteristics of the turbulent flow field. In the present analysis, the windspeed/azimuth data are converted to zonal and meridional components, and a polynomial profile of order $Z+1$, where

$$Z=\frac{\text{Total height range covered by data (km)}}{20},$$

is fitted to each. The profiles thus determined are subtracted from the relevant measured profiles to give zonal and meridional turbulent velocities.

2.2 The Determination of E[Δh]

The available sodium trail data lists wind speed and azimuth against height, and usually involves irregularly spaced height intervals. The sampling irregularity exists for two reasons:

a) there is an occasional difficulty in absolutely identifying the same point on the trail in consecutive photographs;

b) the wind profile between consecutive observational heights is linear. This is usually obvious from the photographs, and can easily be allowed for in subsequent analysis.

Whereas equal height interval sampling is not absolutely necessary for subsequent reduction, it does simplify the analysis, and so linear interpolation between the listed data points is used to provide a profile with data points spaced 0.2 km in height.

The energy spectrum function is computed as

$$E(\Delta h_i)=\frac{1}{N}\sum_{k=1}^{N}(u_{k+i}-u_k)^2 \qquad (12)$$

in which

$$N=5(H_2-H_1)-i$$

where $i=1, 2, 3....N$

such that $\Delta h_1=0.2$ km.

$\Delta h_2=0.4$ km

etc.

and H_1, H_2 (in km) are the lower and upper bounds respectively of the region for which $E(\Delta h)$ is being determined. Such partitioning of the height range is necessary since there is considerable variation in the characteristics of the flow over the total height range sampled (usually some 70 to 200 km).

Energy spectrum functions may be calculated using

a) zonal turbulent velocities

b) meridional turbulent velocities

and c) turbulent windspeed.

The turbulent windspeed w is defined here as

$w=$ measured windspeed $-$
((mean zonal wind)$^2+$
(mean meridional wind)$^2)^{1/2}$

2.3 Correlation Analysis

The two correlation functions f and g defined in 1.2 refer to turbulent velocity components measured parallel and normal to the separation vector. Since vertical velocities in this region of the upper atmosphere are so much less than the associated horizontal components, the magnitude of the vertical component cannot be determined from sodium trail photographs. (Most workers in this field consider the upper limit for mean plus random vertical motions to be some 10 metres/sec). However, we may redefine f and g in terms of the orthogonal zonal and meridional flow fields, with a view to investigating possible isotropy. This has been done by meteorologists in the past, with at least partial success (see, for example, Hutchings (1955)).

The normalizing factors $\bar{u}_f^2$ and $\bar{u}_n^2$ are best estimated by the standard correlation function definition. The correlation functions f and g then become

$$f(\Delta h_i)=\frac{\sum_{k=1}^{N} u_{k+i}u_k}{\left[\sum_{k=1}^{N} u_{k+1}^2 \sum_{k=1}^{N} u_k^2\right]^{1/2}} \qquad (14)$$

where u are the zonal turbulent wind velocities and

$$g(\Delta h_i)=\frac{\sum_{k=1}^{N} v_{k+i}v_k}{\left[\sum_{k=1}^{N} v_{k+i}^2 \sum_{k=1}^{N} v_k^2\right]^{1/2}}, \qquad (15)$$

where v are meridional turbulent wind velocities, and N and i are as previously defined for equation 12.

3. PRELIMINARY RESULTS

The analysis of Section 2 has been applied to data obtained from a sodium trail release over the Eglin Air Force Base, Florida (29.6° N, 86.6° W) at 1910 CST on May 21, 1963 (Edwards et al., 1963). In this experiment, wind speed and azimuth were obtained over a height range of 69 to 140 km.

3.1 The Mean Wind Profile

Since the data covers the height range from 69 to 140 km, polynomials of order 4 are fitted to the zonal and meridional measured profiles. These yield mean zonal and meridional profiles

$$u_{\text{mean}} = 38.6 - 126h - 244h^2 + 174h^3 + 205h^4$$

$$v_{\text{mean}} = -30.4 + 19.8h + 148h^2 - 16.8h^3 - 125h^4$$

where u, v are in metres/sec and h is the normalized height given by

$$h = (2z - z_{\min} - z_{\max})\,(z_{\min} - z_{\max})$$

where z is the height variable

$z_{\max}$ the maximum and

$z_{\min}$ the minimum heights of the available data, all heights being in kilometers.

Normalization of the height range stabilizes the least squares fitting process, and makes the relative importance of the individual terms of the fitted polynomials more obvious than is the case when the mean velocities are expressed as power series in the actual height z. Results are plotted in Figs. 1 and 2.

The meteorological significance of these profiles, in particular the reversal of both the zonal and meridional components above 110 km, cannot be evaluated from consideration of this single firing.

3.2 The Turbulent Wind Profile

As mentioned in Section 2, the 70 to 200 km height range covers a number of characteristically different regions. The wind motions observed below approximately 105 km indicate the presence of small-scale structure, while those above 110 km do not appear to be at all turbulent, even though vertical shear is present. In the results presented here, discussion is confined to the consideration of

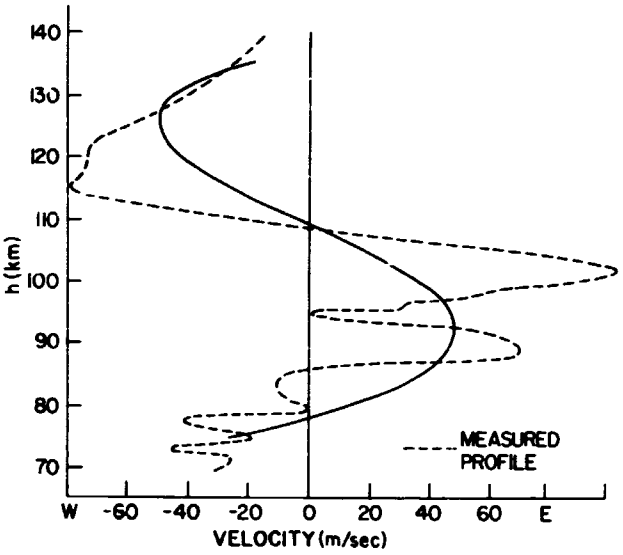

FIGURE 1.—Mean zonal profile.

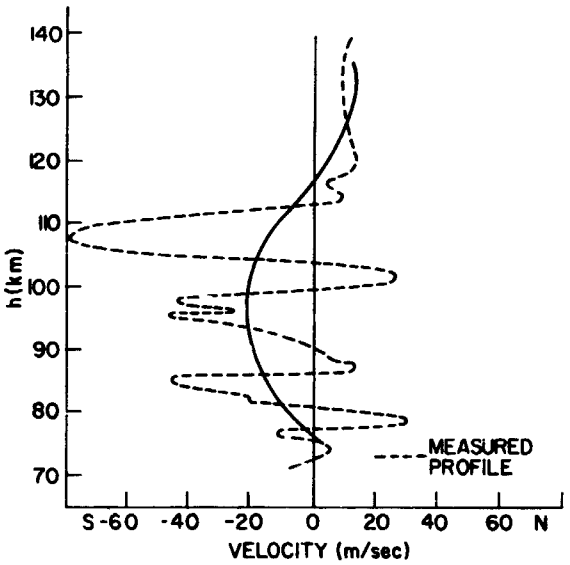

FIGURE 2.—Mean meridional profile.

the region from 80 to 100 km, which has been found to be representative of a turbulent region which can be adequately described by available statistical theories of hydrodynamic turbulence (Lamont and Jager, 1961; Zimmerman, 1962; Roper, 1962).

The measured zonal and meridional profiles, and the deviations from the mean wind for the height range 80 to 100 km are plotted in Figures 3 to 6. Whereas the immediately obvious wave-like nature of the turbulent profile would suggest a wave theory approach as likely to be the most profitable for consideration of the wind motions

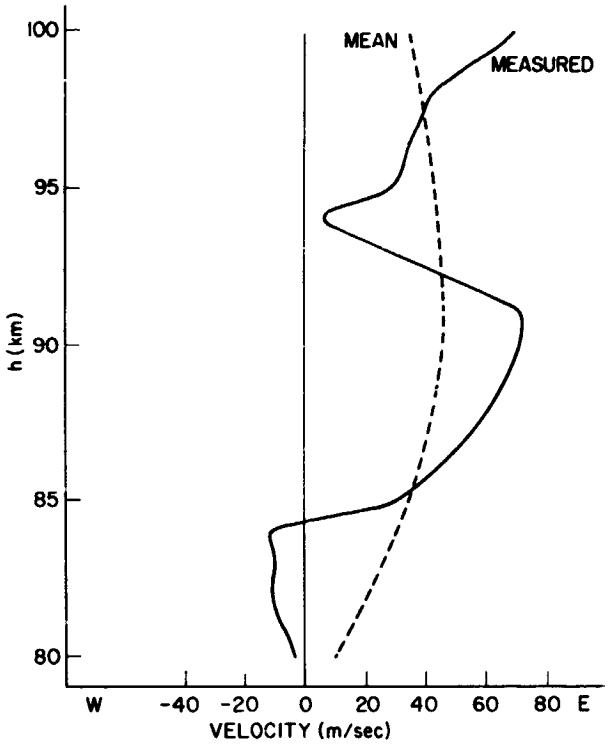

FIGURE 3.—Zonal profile, 80-100 km.

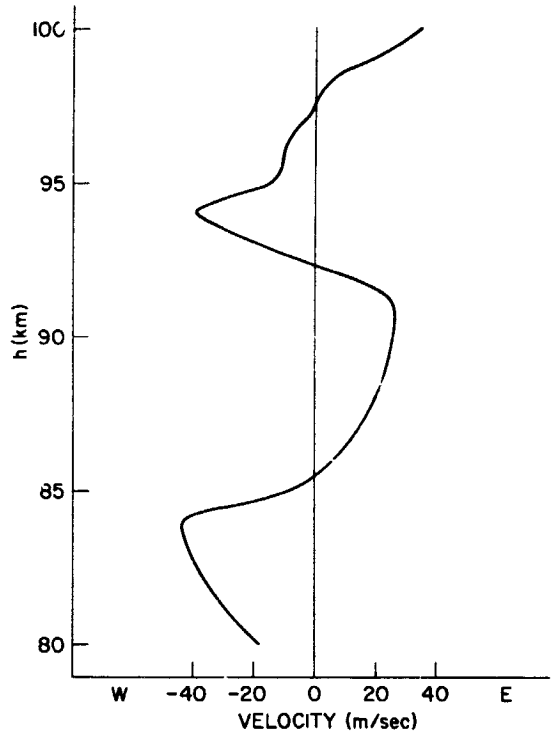

FIGURE 5.—Turbulent zonal profile.

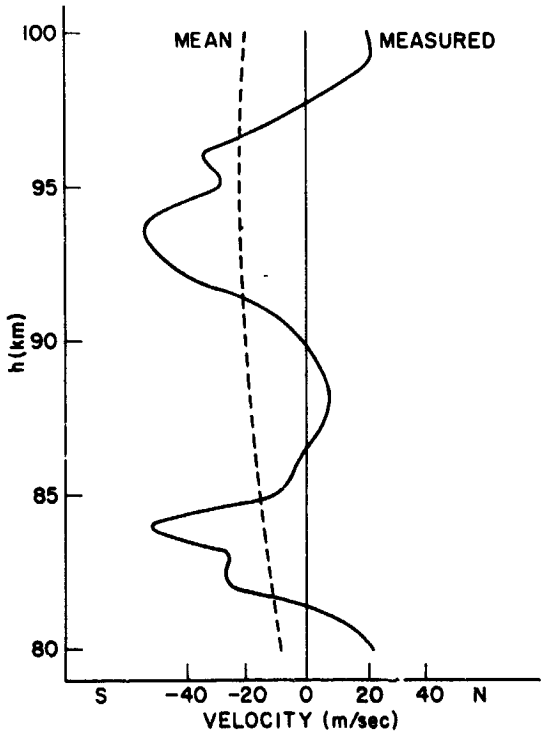

FIGURE 4.—Meridional profile, 80-100 km.

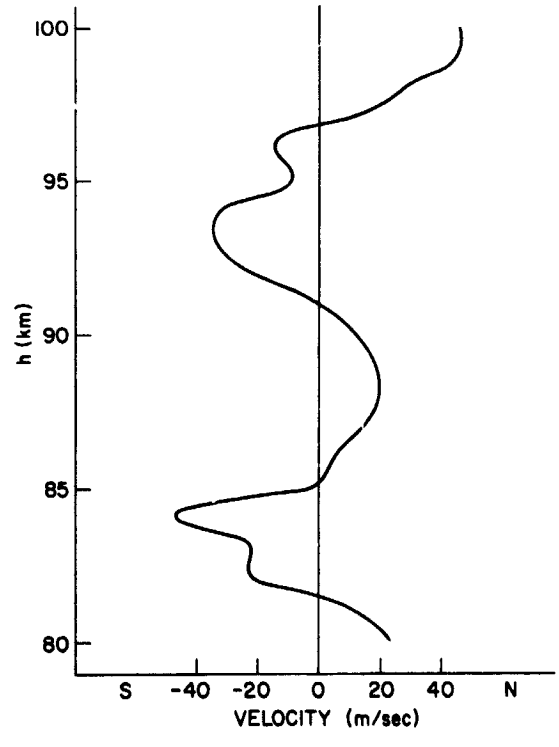

FIGURE 6.—Turbulent meridional profile.

in this region, applications of available wave theories (e.g., Hines, 1959) have not produced consistent results. The possibility of generation of turbulence in the 80 to 100 km region by vertically propagating gravity waves has been proposed by Hines (1963). The purpose of the present work, however, is not to determine the source of the turbulent energy, but rather to substantiate the evidence that the observed shears characterize a region of hydrodynamic turbulence.

3.3 The Energy Spectrum Functions

The energy spectrum functions for the zonal and meridional turbulent wind profiles for the 80 to 100 km region have been computed using the methods described in Sections 2.2 and 2.3. As can be seen from Figures 7 and 8, the velocity difference spectrum $E(\Delta h)$ and the correlation difference function $[1-f(\Delta h)]$ for the zonal turbulent velocities are completely equivalent. This is not surprising, since both functions are solutions of the same equation

$$F = a\Delta h^m$$

(see Sections 1.1 and 1.2).

Similarly for the meridional spectra of Figures 9 and 10. The slope m of the log log plots of both the zonal and meridional $E(\Delta h)$ (or $[1-R(\Delta h)]$) spectrum functions against height difference Δh is constant at 4/3 for separations Δh up to 3 km, indicative of an isotropic region subject to a mean wind shear (Tchen, 1954).

3.4 Isotropy

Since the energy spectrum functions and the correlation difference functions all follow an established (shear) law at small scales in the height range from 80 to 100 km, it is possible to determine the nature of the isotropy at these scales in this region.

Figure 13, curve A, is a plot of the variation of

$$S = \frac{1-f}{1-g}$$

against Δh.

In the region up to a scale of 3.5 km, S has a value of approximately 0.7, indicating an isotropy lying somewhere between two and three dimensional. The increase in S at scales greater than approximately 3 km is due to the breakdown

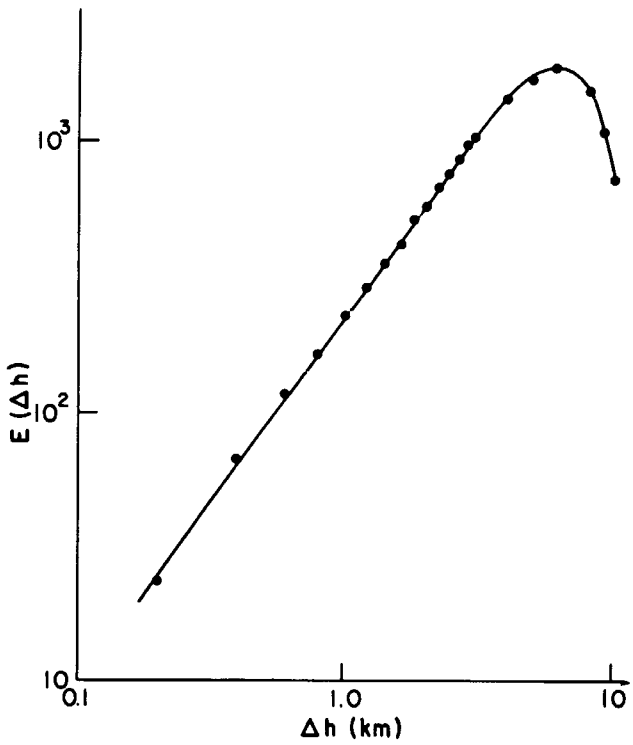

FIGURE 7.—The zonal energy spectrum function.

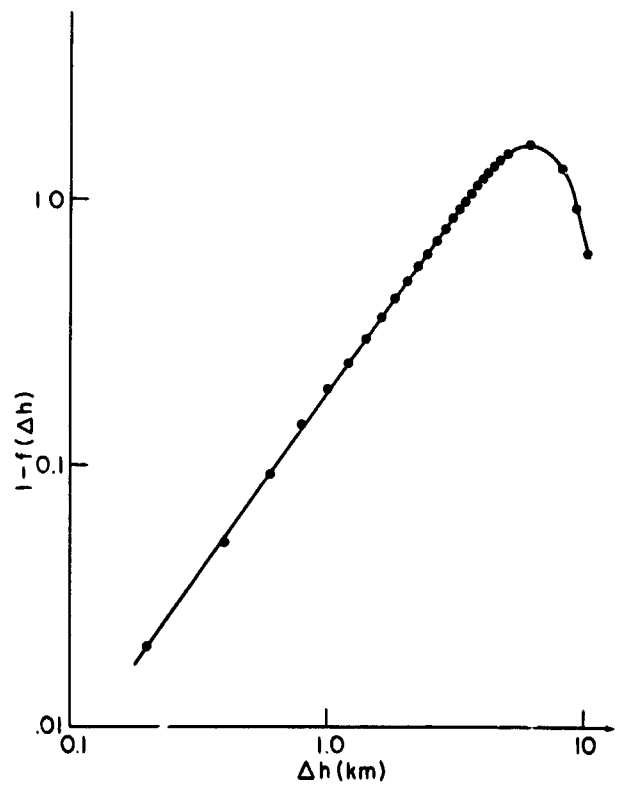

FIGURE 8.—The zonal correlation difference function.

at this scale of the 4/3 power law in both zonal and meridional spectrum functions.

The function S has been found to be quite sensitive to variation in the parameters specifying the mean wind profiles. For example, if, instead of the fourth order polynomial fits to the total height range of the zonal and meridional data, linear mean wind profiles are fitted over the height range 80 to 100 km only, subsequent spectrum analysis yields the S function of curve B of Figure 13. This curve would indicate the existence of three dimensional isotropy for scales up to 3 km. It is possible that the 4th order polynomial fits are, in fact, attributing a small fraction of the random wind variations to the mean motion. However, in order to correlate spectra obtained for different height strata (as is done in the next section), a continuous mean profile is required, and has therefore been used throughout the analysis.

3.5 Vertical Scale

The vertical scale associated with the turbulent wind structure is conveniently defined by the Δh corresponding to the maximum value of either $E(\Delta h)$ or $[1-R(\Delta h)]$. As can be seen from Figures 7, 9 and 11, which are plotted using zonal, meridional and windspeed turbulent velocities respectively, the vertical correlation distance as defined above is not the same for each component, i.e., the wind motions are not isotropic at the maximum of $E(\Delta h)$. However, for the purpose of comparison with stratospheric and lower mesospheric data, where meridional winds are, for the most part, negligible, consideration need only be given to the zonal energy spectrum.

The variation of vertical scale with height in the stratosphere has been determined by Webb (1964) from a series of Robin soundings at Eglin. His results indicate an exponential increase of the vertical scale with height, from approximately 800 metres at 35 km to 2 km at 55 km. He has extrapolated this exponential to a height of 90 km, and finds a vertical scale of 6 km which is the value determined for this height by Greenhow (1959) from a correlation analysis of wind shears determined by means of radio reflections from meteor trails at Jodrell Bank (53°N).

In order to investigate the change with height of the vertical correlation distance in the 80 to 130 km region, the sodium trail data was sub-

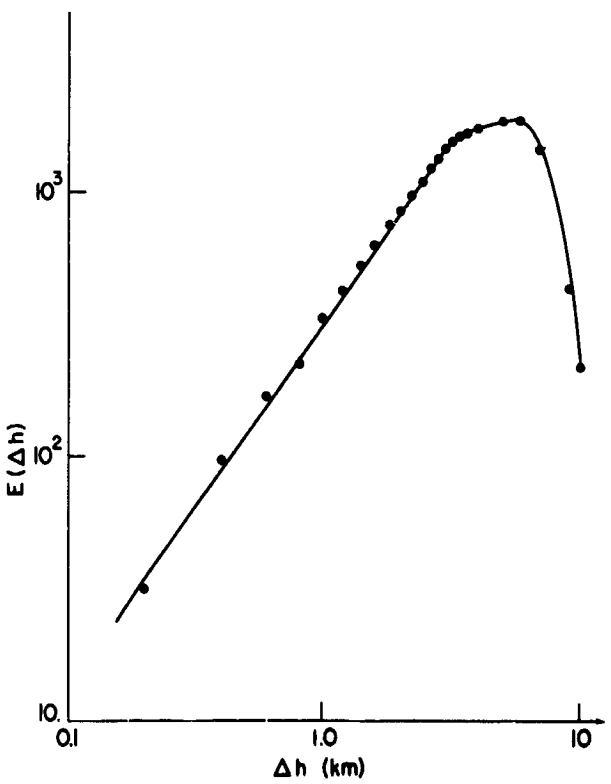

FIGURE 9.—The meridional energy spectrum function.

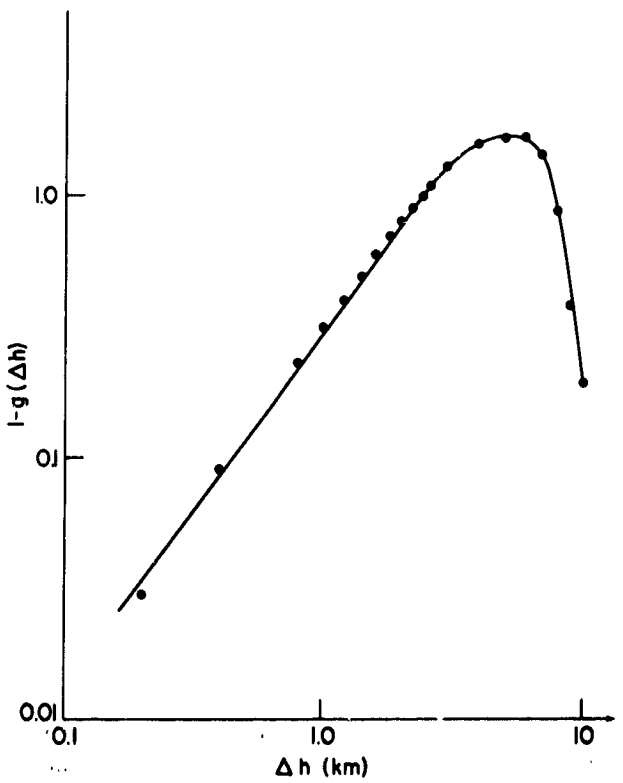

FIGURE 10.—The meridional correlation difference function.

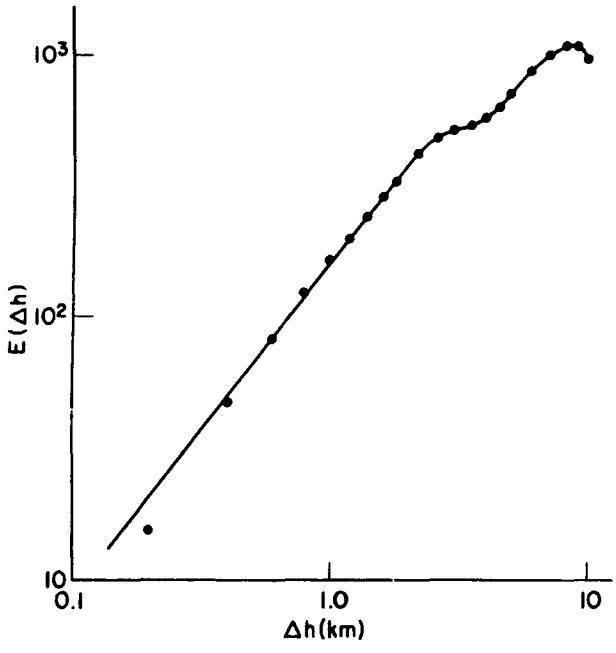

FIGURE 11.—The windspeed energy spectrum function.

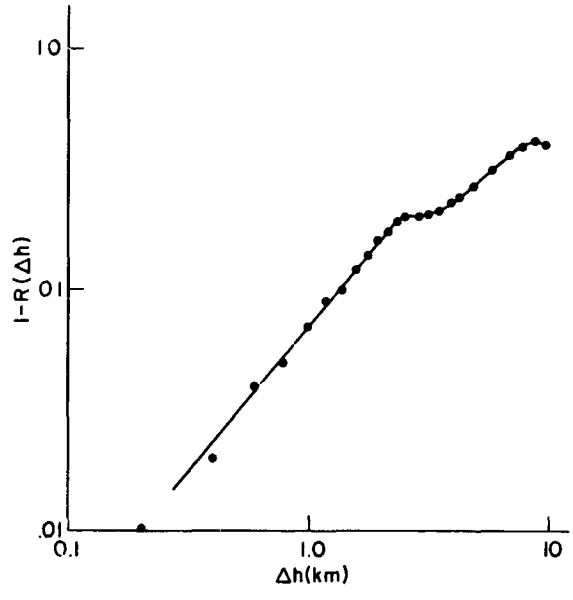

FIGURE 12.—The windspeed correlation difference function

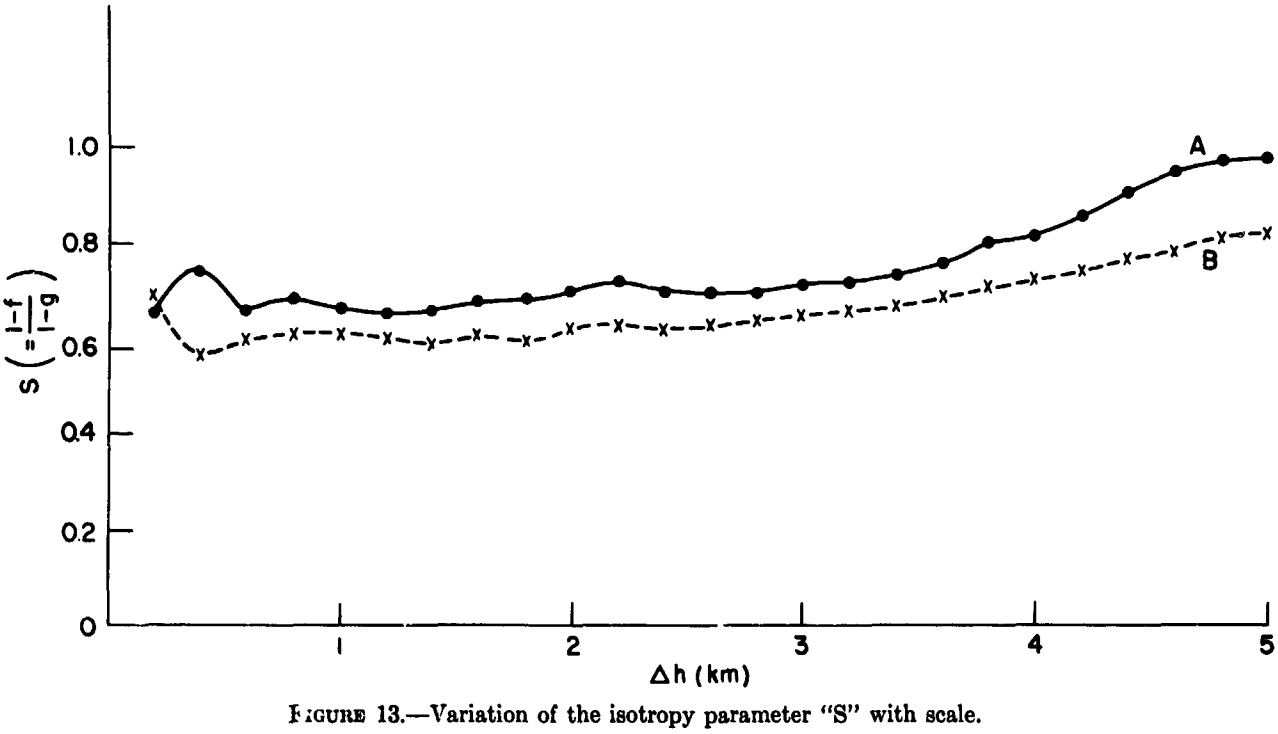

FIGURE 13.—Variation of the isotropy parameter "S" with scale.

jected to a stepwide analysis, starting with the 75 to 95 km height range, and proceeding via the 80 to 100, 85 to 105, etc. ranges to 115 to 135 km. The maxima of the resultant $E(\Delta h)$ curves were then plotted as the vertical scales at the midpoints of the respective height ranges. The results are shown in Figure 14, together with Greenhow's determination, and the 7.8 km at 94 km (October, 1961) determined from radio meteor trail shears at Adelaids (35°S) (Roper, 1962). The dashed line is Webb's extrapolated variation. While there is excellent agreement with Webb's proposed exponential increase, there is also good agreement between the vertical scales measured

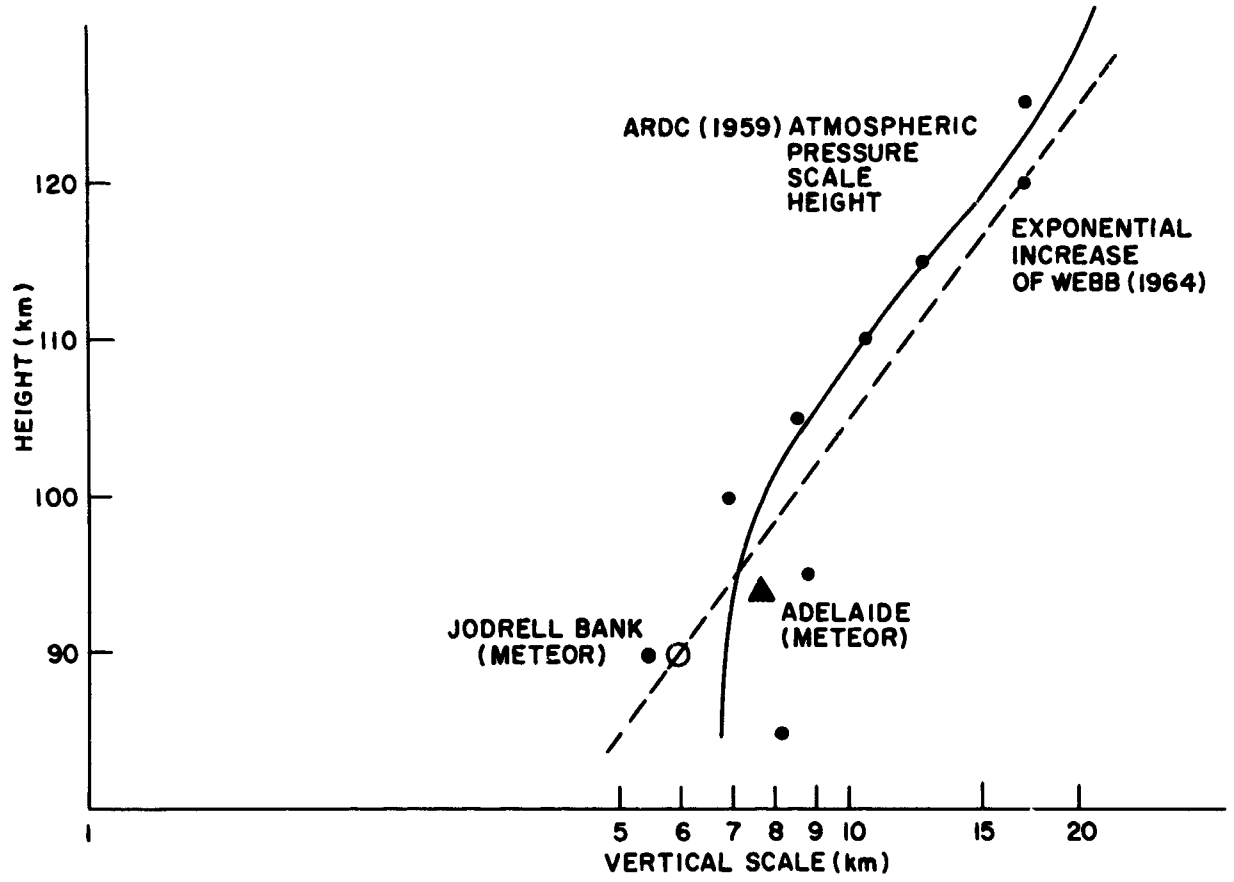

FIGURE 14.—Variation of the vertical scale of the zonal turbulent wind component with height.

at various altitudes for the Eglin firing, and the atmospheric pressure scale height (also shown in Figure 14). This phenomenon has also been observed by others (e.g., Zimmerman (1964)). As yet, no satisfactory explanation for such a dependence has been proposed.

Above 125 km, the magnitudes of the deviations of the measured winds from the mean wind values becomes insignificant. Wind motions at these heights for this particular firing are characteristically nonturbulent.

CONCLUSIONS

The techniques of spectrum analysis based on hydrodynamic turbulence theory can be profitably applied to wind data obtained from sodium trail rocket firings, at least in the height range from 80 to 100 km. The analysis of further firings should indicate whether or not the mean profiles determined as a prelude to spectrum analysis have any meteorological significance.

APPENDIX I

RESUME OF THE COMPUTER PROGRAM

The computer program has been written in FORTRAN IV for execution on an IBM 7094, and consists of the following routines:

1. The main program SHEAR which reads and does some processing of the input data (which is punched on cards).

SHEAR calls subroutines

a) FIT, which fits polynomial profiles to the zonal and meridional wind velocity/height profiles by the method of least squares, utilizing

b) MATS, to solve the set of independent linear equations

c) The total wind speed profile is calculated by TRADE.

d) OUTPUT performs the energy spectrum and correlation analyses, and printout of same.

e) PAGE is a utility routine which turns and numbers the output pages, and prints an appropriate heading on each.

Input Data

The input data is on punched cards, and is read as follows:

1. Header Card; the information punched on this card is printed at the top of each page of output. The full 72 columns can be used for any type of alphanumeric heading.

2. The parameters specifying the mean zonal and meridional profiles. These determine the order of the polynomial fitted to

a) the zonal (punched in columns 2, 3) and

b) the meridional (punched in columns 5, 6) measured data to determine the mean profile. e.g., a 5 punched in column 3 will fit a polynomial of the form

$$a_1+a_2h+a_3h^2+a_4h^3+a_5h^4$$

to the zonal wind data.

The maximum allowable value of the subscript i in the a_i above is 10.

3. The height range (must be integral, and in km) over which the energy spectrum and correlation analyses are to be performed. This can be any fraction of the height interval covered by the input data, but must not be less than 10 km unless an appropriate spectral range is punched in column 13. The minimum of the height range interval is punched in columns 2 to 5, the maximum in columns 6 to 9. If OUTPUT is required to produce spectra over height differences to other than a maximum of 10 km, the required maximum height difference can be punched in columns 10 to 13. This entry must not exceed the height range specified in columns 2 to 9. If this last field is left blank, spectra to 10 km are output.

4. The trial data, which must not exceed a maximum to minimum height range of 150 km. The data is punched as year, month, day, hour (local time, 24 hour clock), height (km), windspeed (metres/sec), and zaimuth (degrees) as follows

YR	MO	DAY	HOUR	HEIGHT	WINDSPEED	AZIMUTH
3	3	9	14	19	24	29

all integer

must be right adjusted if integer; anywhere in appropriate field if decimal punch is included.

5. After all data of 4. a blank card to flag "end of data."

6. Further height ranges as for 3 as required.

7. a) If a change in the mean wind profile is required a card with a 2 punched in column 1 may be substituted for any of the cards 6, and followed by a card of format 2 above which specified the new profile. This card is then followed by further height ranges (as for 6.) as required.

7. b) If a completely new set of header plus data cards is to be processed after either stages 5, 6, or 7a, a card with a 1 punched in column 1 will return control to the start of the program, which will then read in the new set of data cards sequenced as from 1 above.

TEMPERATURE, PRESSURE, DENSITY, AND WIND MEASUREMENTS WITH THE ROCKET GRENADE EXPERIMENT, 1960-1963*

W. SMITH, L. KATCHEN, P. SACHER, P. SWARTZ, AND J. THEON

Complete data from 28 rocket grenade experiments at Wallops Island, Virginia, and Fort Churchill, Canada, are presented. Pressures, temperatures, densities, and winds have been derived directly from the recorded times of explosions and sound arrivals; but no attempt has been made to analyze the meteorological significance of these measurements. Error analyses on 16 of the Wallops experiments are also included.

INTRODUCTION

During the period 1960–1963 a total of 28 rocket grenade experiments were carried out by Goddard Space Flight Center at Wallops Island, Virginia, and Fort Churchill, Canada. It is the purpose of this report to present the complete data from these experiments. The data have been reduced but not analyzed, i.e., the physical measurements (pressure, density, temperature and winds) have been derived directly from recordings of the times of grenade explosions and sound arrivals, and from the rocket trajectories; but no attempt has been made to analyze the measurements for their meteorological significance. Rather, this report should be considered as a record of the unsmoothed, raw measurements which may serve as the basis of further investigation and interpretation of the structure of the atmosphere. This is the first such report since the program started in 1960. As the program continues, future results will be documented in similar fashion.

The grenade experiment is one of the several techniques employed in NASA's Meteorological Rocket Sounding Program, the objective of which is to obtain as representative as possible a sample of the synoptic structure of the mesosphere and lower ionosphere. In order to extend the findings over the widest possible geographic area, and perhaps eventually to attain a global network of soundings, the NASA launchings are coordinated whenever possible with soundings in other parts of the world. The instrumental details and methods of data reduction have been thoroughly described elsewhere.†

EXPERIMENTAL METHOD

One and two pound explosive charges (grenades) are carried aloft in the nosecone of a Nike-Cajun sounding rocket. The grenades are ejected and exploded at 4–6 km intervals. Either a precise radar such as the FPS–16 or a doppler tracking system, or both, are used to determine the rocket position and hence the exact position of the explosion. The time of the explosion is detected by small rocket borne infrared photocells and telemetered to the ground. A ground based array of hot wire microphones with frequency response peaked at 4 cycles per second is used to detect and record the sound waves from each exploding grenade. The measured experimental parameters are the times of the grenade explosions, the positions of the grenade explosions, and the times of arrival of the sound waves at the ground based microphones.

Elevation and azimuth angles are computed for each arriving sound wave front by applying a least-squares fit to the arrival times at the various microphones. Each wave is then analytically traced up through the atmosphere by means of Snell's law. Data from radiosonde ascents or

*Published as *NASA Technical Report* R-211, October 1964.

†Nordberg, W., and Smith W., "The Rocket Grenade Experiment," NASA Technical Note D–2107, March 1964.

from small meteorological rockets obtained at the time of the grenade soundings are used for this tracing up to the first explosion; above this, the results of the experiment itself are used for each successive explosion. This *apparent* position of the *wave* is then compared with the *known* position of the *wave source*, the grenade explosion. The amount by which the sound wave has been displaced horizontally from one explosion to the next is a measure of the average wind velocity vector in the layer between any two adjacent explosions. The average speed of the sound, and hence average temperature between two adjacent explosions, may also be determined. This analysis yields an altitude profile of temperatures and winds as a direct measurement. The temperature profile consists of discrete points, each representing an average value for an altitude layer between grenade explosions. It may be used to derive density and pressure profiles, if the pressure or density is known at a given level at the bottom of the temperature profile; and the latter data are available from the accompanying radiosonde. Pressure is calculated by use of the hydrostatic equation, and the ideal gas law; an integration is performed over the temperature profile starting at the known pressure. The density at any level is then computed from the pressure, temperature, and universal gas constant.

During the period between July 8, 1960 and December 7, 1963, 23 successful rocket grenade soundings were conducted from Wallops Island, Virginia (37° 50′N, 75° 29′W). In addition to offering excellent launch and tracking support, the geographical location of Wallops Island makes it a good middle-latitude observation site. Five soundings were conducted from a sub-arctic range, Fort Churchill, Canada, (58° 47′N, 94° 17′W) in the period between December 1962 and March 1963. Originally, it was planned to distribute

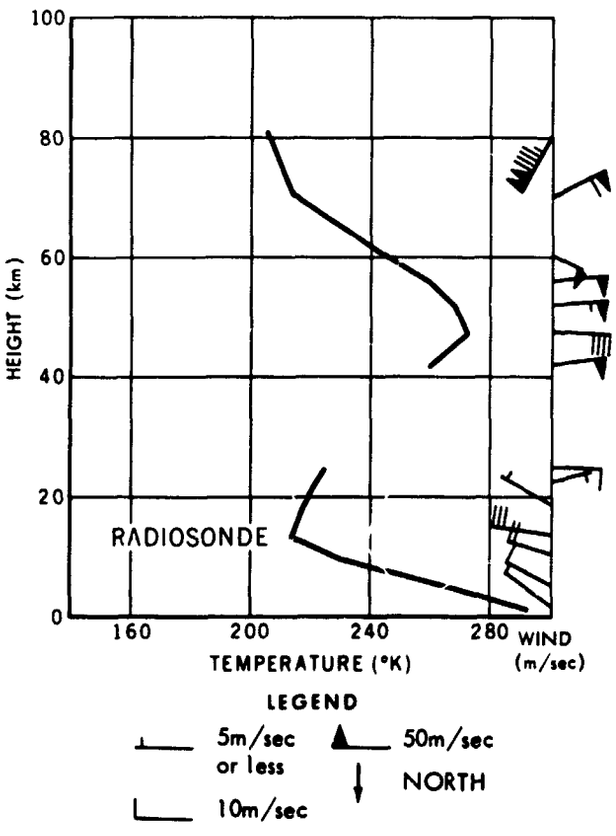
the number of firings about equally between the two sites, but a fire early in 1961 destroyed part of the Fort Churchill launch facility, and it was not operational again until November 1962. Table 1 lists the soundings conducted. Four of the recent firings from each site were conducted nearly simultaneously.



The results of the 28 soundings are presented in Figures 1 through 43. In Figures 1 through 28, the *directly measured* parameters of temperatures and winds are tabulated (actual computer printouts) in the columns on the left side of the page immediately above the graph. Tables of pressure and density *derived* from the temperature profiles are also shown. The temperatures were linearly interpolated between each of the measured points.

Winds and temperatures below 30 km obtained from radiosondes, and below 50 km from smaller meteorological sounding rockets (Arcas* and Haspt whenever available) launched nearly

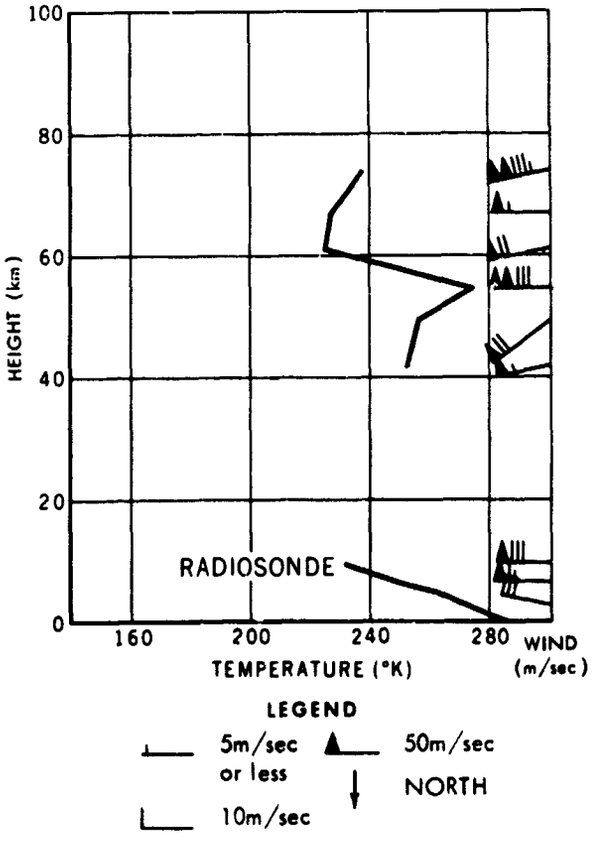

FIGURE 1

simultaneously with the grenade soundings are shown graphically. Winds and temperatures above 40 km from the grenade soundings are shown on the graph.

RESULTS

In the results from these soundings all data points, regardless of our degree of confidence, are presented in tabular form. Some individual data points may be subject to later revision, as there may be occasional errors in some of the records which have not yet been detected. In the preparation of these graphs some data points, where such errors seem obvious, were omitted and the graphs note the omissions. For the most part, these occur at the upper altitude limit of the experiment where the signal-to-noise ratio of detected acoustic waves is poor. Random errors contained in either the measurements or in the data reductions can usually be recognized by comparing two adjacent data points. Since these errors will generally be contained in the parameters (time and space coordinates of the explosion) associated with one individual grenade explosion, the temperature data points both below and above this explosion will contain errors of approximately equal magnitude but opposite sign. Therefore, if large excursions of this nature occur between two adjacent data points, it is very likely that the recordings from the explosion between these two data points were in error.

FIGURE 2

ERROR ANALYSIS

An error analysis was run with the aid of a digital computer on 16 of the 28 experiments reported. The firings considered were the first 16 conducted from Wallops Island. The following nomenclature is used in the error analysis:

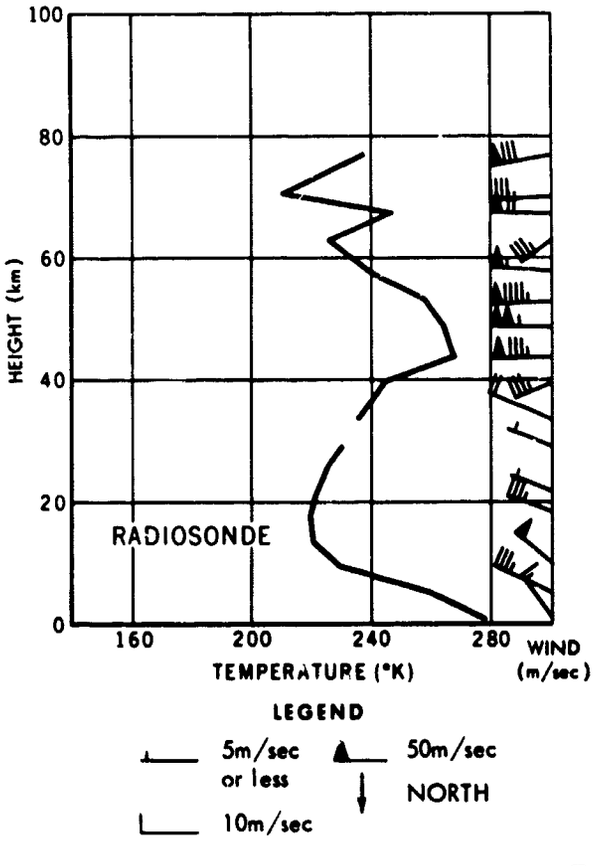
Δw = Difference in west coordinate between successive grenade explosions.

Δn = Difference in north coordinate between successive grenade explosions.

h = Difference in altitude between successive grenade explosions.

ω = Wind direction in the layer.

W = Wind speed in the layer.



c = Speed of sound in the layer $= k(T)^{1/2}$, where k is a proportionality constant depending on molecular mass, the ratio of specific heats, and the universal gas constant.

ϕ_μ = Azimuth angle of sound wave for upper explosion.

τ = Travel time of sound wave in layer.

$K = c_0 \sec\theta_u + W_0 \cos(\phi_u - \omega_0) - W \cos(\phi_u - \omega)$, where c_0 is the mean speed of sound over

FIGURE 3

the microphone array; θ_u is the elevation angle of sound wave for upper explosion; W_0 is the wind speed over the microphone array; and ω_0 is the wind direction over the microphone array.

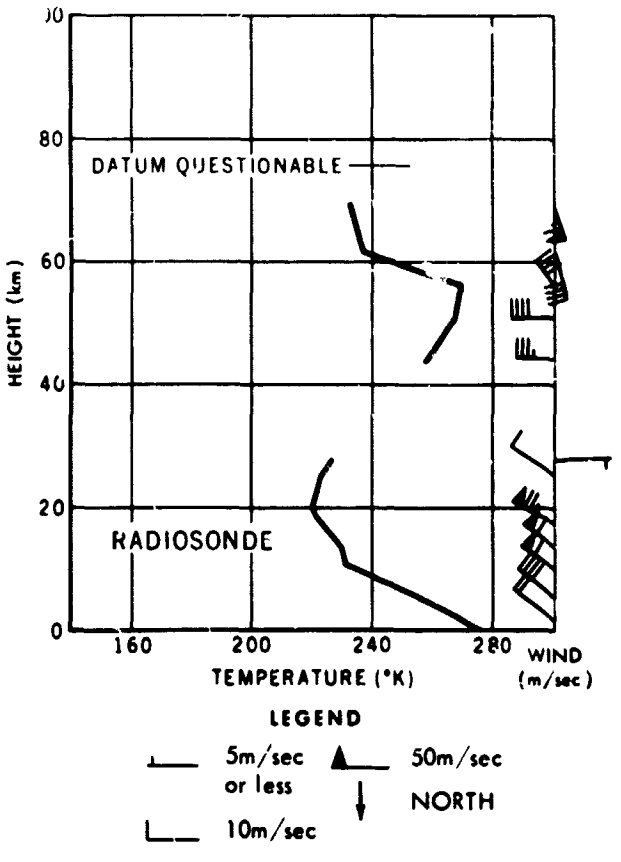
t = Travel time of sound wave from grenade explosion to ground.

T = Mean temperature in layer.

Δt = Time difference between microphones introduced by changing the time of arrival at one microphone.

ϕ'_u = Elevation angle from ground to apparent position of upper grenade explosion as obtained by ray tracing.

In order to determine the error function, deliberate errors were introduced in the following experimental parameters:



A. Position of grenade explosions

1. North: 200 meters
2. West: 200 meters
3. Up: 50 meters

B. Travel time of sound from explosions to ground: 0.3 second.

C. Time of arrival at one of the 6 microphones relative to the other five microphones: 0.02 second.

FIGURE 5

It was determined that an error in one of the foregoing parameters for any given grenade will cause wind and temperature errors in the two layers adjacent to the grenade. The temperature errors, in general, will be of opposite sign and approximately equal in magnitude. There are slight errors introduced in the remaining layers above the grenade; however, these are negligibly small. The errors in the temperatures and winds due to errors in the coordinates of the explosions are given by:

$$\frac{\partial W}{\partial \Delta w} = \frac{\sin \omega}{\tau}; \tag{1}$$

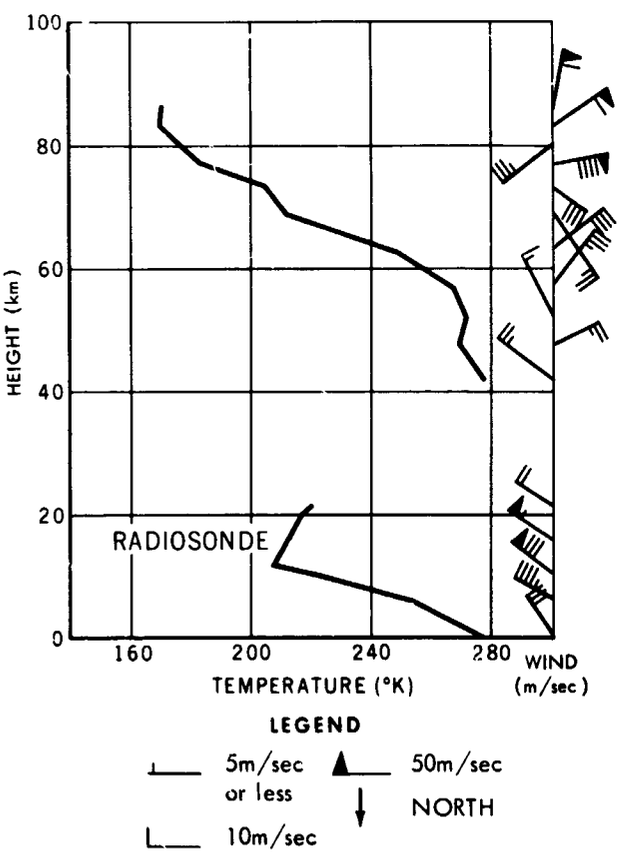
$$\frac{\partial W}{\partial \Delta n} = \frac{\cos \omega}{\tau}; \tag{2}$$

$$\frac{\partial W}{\partial h} = \frac{\cot \theta'_u}{\tau} \cos (\omega - \phi_u); \tag{3}$$

$$\frac{\partial c}{\partial \Delta w} = \frac{\sin \phi_u}{c\tau} \left[\frac{h^2 K}{\tau^2 (K^2 - 2c^2)} - \frac{c^2}{K} \right]; \tag{4}$$

$$\frac{\partial c}{\partial \Delta n} = \frac{\cos \phi_u}{c\tau} \left[\frac{h^2 K}{\tau^2 (K^2 - 2c^2)} - \frac{c^2}{K} \right]; \tag{5}$$

$$\frac{\partial c}{\partial h} = \frac{1}{c\tau} \left[\frac{h^2 K \cot \theta'_u - hK^2 \tau}{\tau^2 (K^2 - 2c^2)} + \frac{c^2 \cot \theta'_u}{K} \right]. \tag{6}$$



In the error analysis, the north and west coordinates of alternate grenades were changed by −200m, and the up coordinates were changed by −50m. This means that $d\Delta w$ and $d\Delta n$ for adjacent layers were alternatingly +200 and −200, and dh for adjacent layers were alternatingly +50 and −50. The azimuth angle changes slowly with altitude. Generally, $\sin\phi_u$ and $\cos\phi_u$ do not change sign during an experiment; thus the signs of $(\partial c/\partial \Delta w)d\Delta w$ and $(\partial c/\partial \Delta n)d\Delta n$ alternate regularly from layer to layer *as the coordinates of alternate grenade explosions are changed.* This accounts for the regular alternation of the temperature error, since all other signs in the equation for $\partial c/\partial \Delta w$, $\partial c/\partial \Delta n$ remain constant during an experiment. Similarly, it can be seen from the expression for $\partial c/\partial h$ that all the quantities retain the same sign throughout an experiment. Thus, the same regular alternation for the signs of the $(\partial c/\partial h)dh$ will occur for successive grenades.

The situation is different, however, for $\partial W/\partial \Delta w$, $\partial W/\partial \Delta n$, $\partial W/\partial h$. The sign of $\partial W/\partial \Delta w$ depends on the sign of $\sin \omega$ which in turn depends on the value of ω. Since ω may vary from 0 to 360°, $\sin \omega$ may be either positive or negative. The same is true for the sign of $\partial W/\partial \Delta n$, which depends on $\cos \omega$. Hence, we expect no regular alternation from layer to layer in the sign of the wind error. The sign of $\partial W/\partial h$ depends on the sign of $\cos (\omega - \phi_u)$ which in turn depends on the value of $\omega - \phi_u$. Although ϕ_u changes slowly and in general remains in the same quadrant, ω can vary from 0 to 360°, and hence $\omega - \phi_u$ can be positive or negative. Thus, $(\partial W/\partial h)dh$ exhibits no *regular* alternation in sign. In summary, we can see that the signs of $\partial c/\partial \Delta w$, $\partial c/\partial \Delta n$, $\partial c/\partial h$ are constant and hence an error in the coordinates of one individual grenade exposion will cause a positive error in the measured temperatures in the layer below the explosion if a negative error is caused in the layer above the explosion, and vice versa. In general, the magnitudes of the temperature errors caused by an error of the explosion coordinates between two adjacent layers are approximately equal.

However, this does not hold for wind errors. The error functions for the wind speed are proportional to $\sin \omega$, $\cos \omega$ and $\cos(\omega - \phi_u)$, which may vary considerably from layer to layer. The error functions of c, however, are proportional to ϕ_u and θ'_u which do not vary greatly from layer to layer.

The two other parameters of importance to the errors in addition to the grenade explosion coordinates were investigated in a similar manner. These parameters were: the time differences, Δt, between arrival of the sound wave at any two microphones within the array of six; and the travel time, t, of the sound from the explosion to the ground. The parameter Δt is important because the direction of the arriving sound wave front is derived from those differences, while t enters primarily in the calculation of the speed of sound in the layer. An error of .02 second was introduced into the arrival time at one microphone without altering the arrival times at the remaining five microphones, while an error of

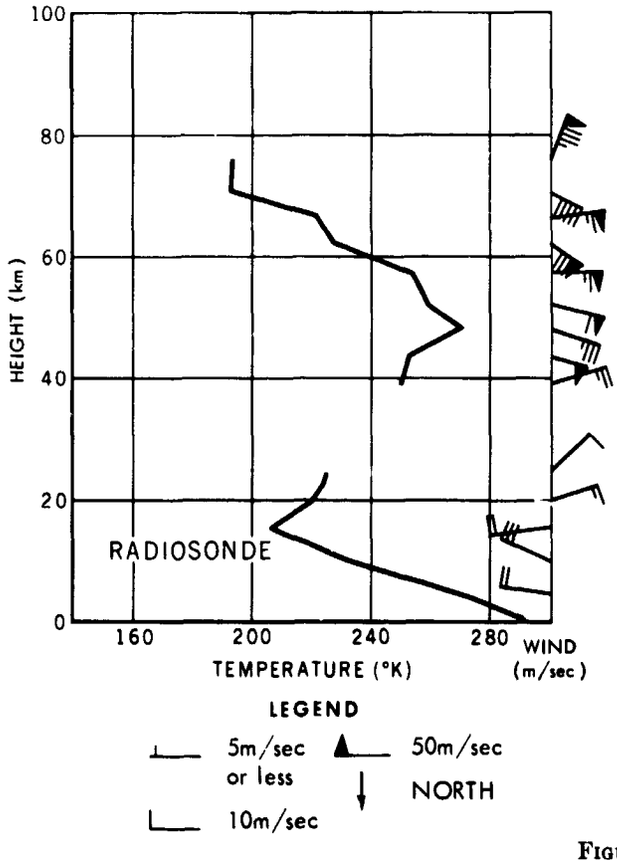

FIGURE 7

.3 second was introduced into t. As in the case of the coordinates of the grenade explosions, these errors were introduced only for alternate grenades.

A typical result of the error analysis is presented in Figures 29 through 38. From a study of these figures, the following conclusions can be reached:

1. Relative errors in the North and West coordinates of 200 meters will significantly affect only winds by about 10 m/sec but not the temperatures.
2. Relative errors in the up coordinates of 50 meters will cause significant errors of about 5°K in temperature, but not in winds.
3. An error of .3 second in t will give rise to large temperature errors—about 10°K—but in general only very small wind errors.
4. An error of .02 in the relative arrival times between microphones will cause the largest errors in both winds and temperatures: 10–40 m/sec and 10–25°K. The error analysis clearly shows that an error introduced into the input parameters of a grenade significantly affects only the layers adjacent to the particular grenade. No significant error is introduced into the calculated winds and temperature for suc-

FIGURE 8

ceeding grenades, and hence only the layers adjacent to the grenade in question need be considered.

Table 2 gives the average error functions for the 16 firings tabulated by layers. Figures 39 and 40 are graphs of the two functions which are most strongly altitude dependent, $\partial T/\partial \Delta t$ and $\partial W/\partial \Delta t$, showing quite clearly the increase of the error function with altitude.

$\partial W/\partial \Delta h$, etc., by the value of the actual errors in Δw, Δn, h, Δt, and t. The maximum error is calculated by summing all the partial errors:

$$\left(\frac{\partial W}{\partial \Delta w}\, d\Delta w + \frac{\partial W}{\partial \Delta n}\, d\Delta n + \frac{\partial W}{\partial \Delta h}\, d\Delta h + \ldots \text{etc.}\right)$$

The actual errors in coordinates and times are estimated in the following manner:

The position of the grenade explosion is determined by two totally independent tracking meth-

Figure 41 shows the dependence of $\partial T/\partial \Delta t$ upon zenith angle. As the zenith angle increases, the error function increases nearly linearly. Thus, to make the experiments as accurate as possible, it is desirable that the sound propagation be as nearly vertical as possible. A zenith angle of 0° would, of course, be ideal; however, range safety considerations make this impossible, and at Wallops Island the zenith angles usually lie in the range from 15°—30°. The zenith angles at Fort Churchill are generally less than 10°, and the probable error in the Fort Churchill data is therefore correspondingly less.

The magnitudes of the errors assumed in this analysis were chosen arbitrarily large for convenience in calculation. The actual resulting errors will be much smaller, as will be shown below. The magnitude of the actual errors in the rocket grenade experiment is determined by multiplying the error functions $\partial W/\partial \Delta w$, $\partial W/\partial \Delta n$,

ods, DOVAP and radar. The agreement of these two systems with regard to the coordinates Δn, Δw and h in general is better than 20 meters. The result is a maximum temperature error of 1°K and maximum wind error of 1–2 meters/sec, according to the error functions. The time of the grenade explosion, determined primarily by rocket borne infrared photocells, is telemetered to the ground equipment. The time of grenade explosions may also be determined by ground based flash detectors or radar signal strength records. It has been shown that this time can generally be determined within $\pm$.001 second. The errors in determining the arrival time of the sound at the ground range from $\pm$.001 to $\pm$.010 second. Thus, the maximum error expected in determining the travel time (t) of the sound between explosion and ground is approximately .01 second, which results in a temperature error of 0.3°K and virtually no errors in winds. By far the largest contribution

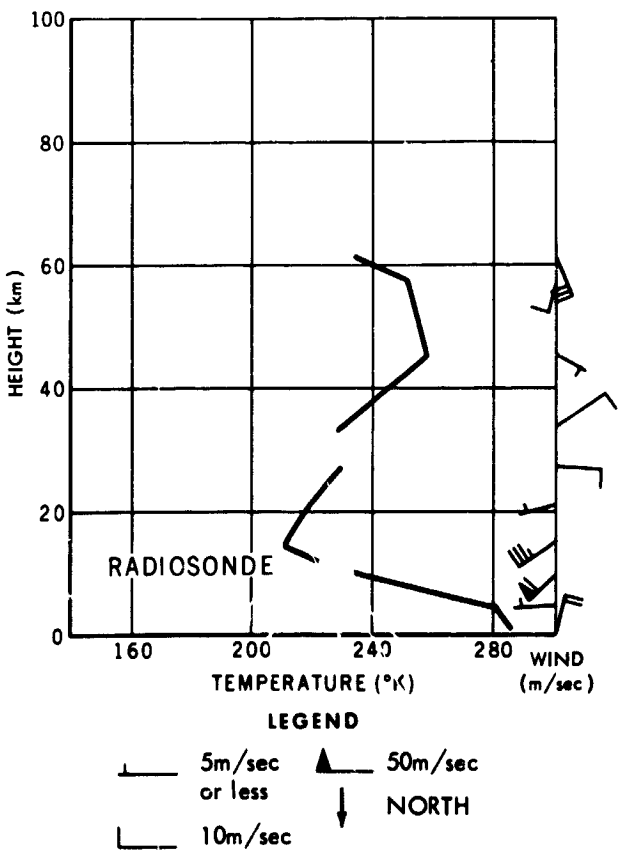
FIGURE 9



to the total error comes from errors in Δt, which also range from .001 to .010 second, depending upon the background noise level and the altitude of the explosion. The error in Δt is obtained by determining typical discrepancies among a number of independent Δt readings for each explosion. These errors result in temperature errors ranging from 1°K at 40 km to 15°K at 90 km, and wind errors from 1 to 16 m/sec over the same altitude range.

The maximum errors in the 16 soundings considered in this error analysis are presented in Figures 42 and 43, which clearly show the increase of the maximum errors with altitude. This increase is to be expected, since the amplitude of the sound waves will decrease rapidly with increasing altitudes, making it difficult to distinguish the grenade explosion from the background noise level. Since the determination of the relative arrival times between microphones is by far the most critical measured parameter, the largest part of the maximum error is due to the attenuation of the sound wave with altitude.

ACKNOWLEDGMENTS

The authors greatly appreciate the contributions of: Superior Engineering Company in designing and constructing the payload instrumentation for the grenade experiment; Texas Western College in conducting the sound ranging portion of this experiment; and New Mexico State University in operating the DOVAP tracking system.

NEW KNOWLEDGE OF THE EARTH'S ATMOSPHERE FROM THE AERONOMY SATELLITE (EXPLORER XVII)*

N. W. SPENCER, G. P. NEWTON, C. A. REBER, L. H. BRACE AND R. HOROWITZ

The Explorer XVII satellite performed direct, very localized measurements of the total neutral particle density, the concentration of neutral particle masses 4, 14, 16, 28, and 32 and the temperature and concentration of thermal electrons, between the altitudes of 258 km and 920 km over those regions of the earth where the satellite was accessible to the Minitrack network, and in particular between $\pm 58°$ latitude. Pressure gages on the satellite showed that the total density at 280 km was about 50 percent lower than is given by the appropriate atmospheric models based on satellite drag measurements. Daily variations in total density are more strongly dependent on a_p (the magnetic index) than had been believed previously. Neutral mass spectrometers showed that *He* is the predominant neutral constituent above 600 km, 0 is predominant between 250 km and 600 km, and N_2 is predominant below 250 km. The scale heights of the various constituents agree in general with the corresponding model atmospheric scale heights. Langmuir probe results confirmed the global extent of thermal non-equilibrium ($T_e > Tg$) and provided high resolution of the diurnal variation of electron temperature and density at several stations. For example, the electron temperatures near the F_2 maximum over Blossom Point show a nighttime value of about 1100° K, followed by a mid-morning maximum of 2800° K and an afternoon plateau of 2200° K. A consistent and strong latitude effect, evident particularly at Blossom Point, caused a significant positive gradient in electron temperature (the order of 25° K/degree of latitude) and an inverse gradient in electron density in a manner approximately in accord with recent theories of Hanson and Dalgarno.

INTRODUCTION

The Explorer XVII satellite, Figure 1, was designed to provide direct measurements of aeronomic parameters as a basis for new studies of the physics of the Earth's upper atmosphere. Thus, instruments were selected for the satellite which would provide both total and relative concentration of the neutral particles, and high-resolution measurements of the electron temperature and density; all of considerable significance in studies of the physical processes controlling the upper atmosphere. These data would help also to (a) clarify and define the structural properties of the atmosphere, previously established primarily through inferences from satellite drag measurements, and (b) investigate the variability and dependence of the atmosphere on solar conditions.

The technological advance of measurement techniques was also an objective of the project, as part of a continuing effort to improve experimental capability. The application of laboratory-developed techniques required engineering as well as measurement technique refinement and adaptation to new environments. The atmospheric data to be obtained, if it were to be of maximum benefit consistent with its timeliness, required computer usage for processing the large quantity of data (the order of 2×10^9 bits of information).

EXPERIMENTS

The choice of experiments to obtain the desired data was based mainly upon laboratory vacuum technique experience; thus both thermionic and cold-cathode pressure gages, derived from proven laboratory sensors, were selected for the measurements of the total neutral particle density. Double-focusing magnetic mass spectrometers were chosen for the measurements of neutral particle concentrations. Two Langmuir probe experiments were employed for measurements of the electron temperature and ion density.

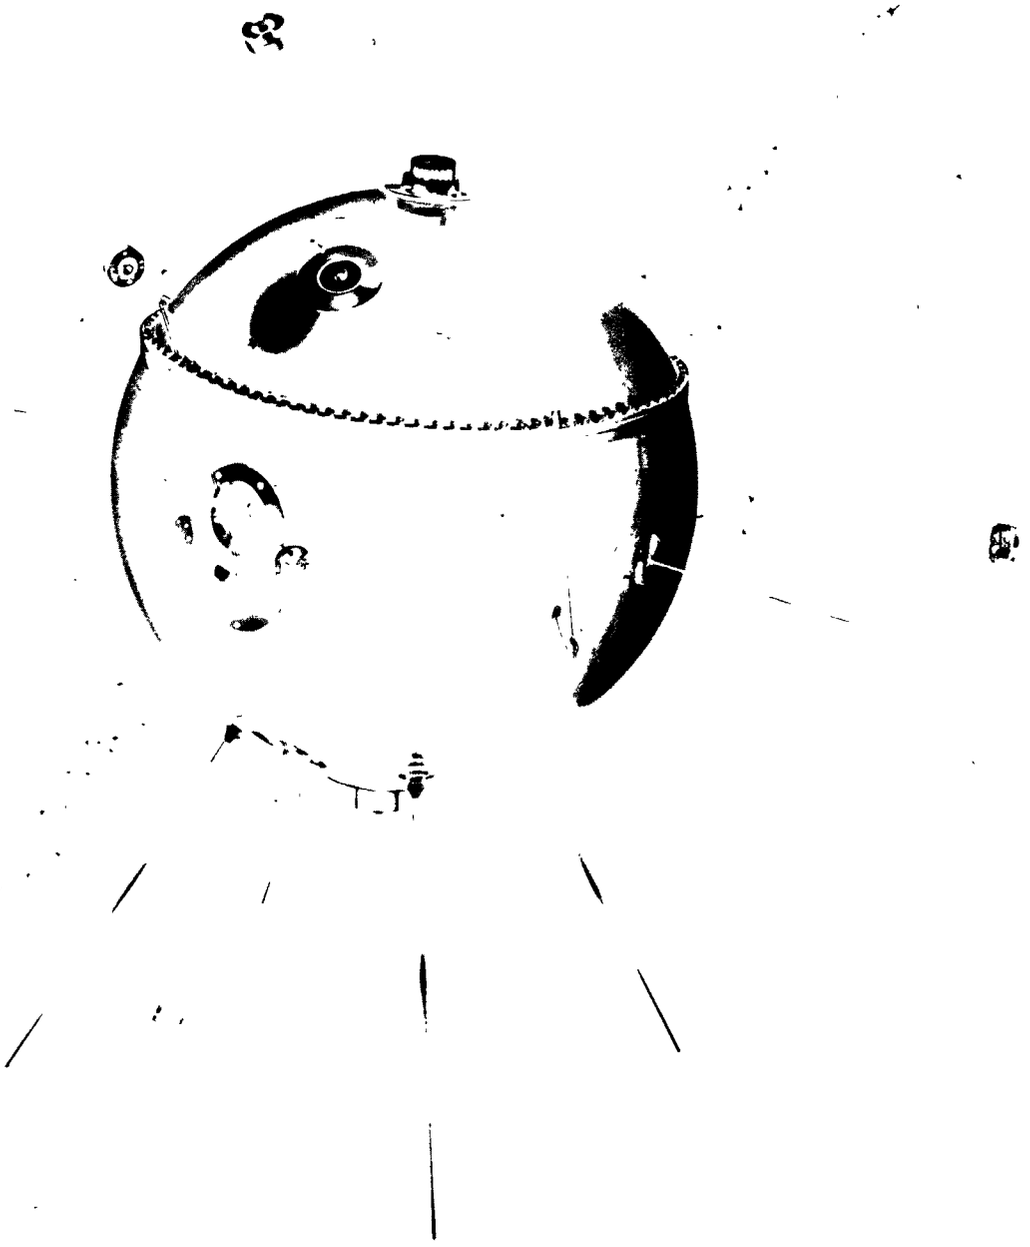

FIGURE 1.—Artist's conception of Explorer XVII in orbit.

It is of special significance from the point of view of determining local values of the ambient concentrations of constituents that proven laboratory vacuum system techniques were employed in construction of the satellite. For example, to minimize potential sources of contaminating gases, nearly all external surfaces were constructed of stainless steel, and all satellite joints were either welded or utilized copper shear gaskets for vacuum sealing. A significant effort was thus devoted to making the satellite-sensor system a true inside-out ultra-high vacuum system so that the experimenter could be confident that the atmospheric samples measured were not contaminated by materials carried aloft by the satellite.

Pressure Gage Experiments

The density measurements made by the Explorer XVII ionization gages extended to satellite usage the technique employed in rocket manometer experiments (Schultz, Spencer, Reifman, 1948) (Horowitz, Kleitman, 1953) to measure the total atmospheric density. The description of the instrumentation, the calibration technique, and the flight response of the Explorer XVII sensors have been reported (Newton, Pelz, Miller, Horowitz, 1963).

Four independent pressure gage experiments were employed: two Bayard-Alpert type (thermionic cathode) ionization gages and two Redhead type (cold-cathode, magnetic) gages. Each sensor was equipped with a special vacuum-sealed orifice that could be opened after the satellite was in orbit. Thus it was possible for the sensor to be properly cleaned, calibrated, sealed under vacuum, and opened on command to the space environment. This procedure, whose validity was previously established through rocket experience, assured the necessary high degree of vacuum cleanliness for the sensors.

The use of both cold and thermionic cathode gages was considered essential because of uncertainties in (a) the response of a hot-cathode gage in a sometimes predominately atomic oxygen environment (not subject to adequate laboratory calibration) and, (b) the general applicability of ionization gages to the high-velocity satellite environment. At the same time, a desirable redundancy was accomplished and valuable studies of the usefulness of the two fundamentally different sensors were made possible. Each pressure gage was provided with an appropriate electrometer amplifier and other electronic support devices which enabled conversion of the sensor output current to a voltage suitable for telemetry. The electronic systems also included provision for in-orbit current calibration of the amplifiers once during each operation of the gages.

Neutral Particle Mass Spectrometers

Two identical double focusing magnetic mass spectrometers were employed for the determination of the local concentrations of atmospheric helium (mass 4), atomic nitrogen (mass 14), atomic oxygen (mass 16), molecular nitrogen (mass 28) and molecular oxygen (mass 32). Although detailed descriptions of the spectrometers are provided elsewhere (Meadows, 1960) (Hall, Howden, Iwasaki, 1960), (Spencer, Reber, 1962), (Reber, Hall, in prep.), the significant features are summarized here. The external ion source, designed to reduce the interactions of the sampled particles with the sensor, was followed by an electrostatic ion lens which focused the relatively high energy ions on the entrance slit of the analyzer. In this way, it was possible for the instrument to accept particles from a 2π steradian solid angle, and up to 12 *ev* kinetic energy. In the magnetic analyzer the beam of ions was separated according to mass, a given mass falling on the appropriate collector electrode in spectrograph fashion.

Each of the spectrometers was provided with a sensitive electrometer and logarithmic amplifier for conversion of the collected ion current to the proper telemetry voltages. Electronic logic circuitry accomplished the required changes in sensitivity and mass-number selection. As with the pressure gages, a vacuum-seal arrangement was adopted which permitted exposure of the spectrometer ion source to the atmosphere after orbit was attained.

The primary data analysis task was to determine the relationship of the measured ion currents to the ambient neutral particle densities. Particles could enter the region of ionization in one of three ways: (1) directly with no collisions; (s) after suffering one or more collisions with surfaces in the source region; (3) by entering the spectrometer analyzer, becoming thermalized, and

subsequently being re-emitted. The relationships between the measured ion currents and the ambient atmosphere were computed on the basis of these three mechanisms and the laboratory gas calibrations. The validity of these calculations is demonstrated by the fact that the total mass-density measured by the spectrometer is in satisfactory agreement with that obtained independently by the companion pressure gage experiments described above.

Langmuir Probes

Two independent Langmuir probe systems, based on established techniques and previous rocket usage (Spencer, Brace, Carignan, 1962), (Brace, Spencer, Carignan, 1963), (Nagy, Brace, Carignan, Kanal, 1963) were employed to provide measurements of the ion concentration (N_i), and the electron temperature (T_e) of the ionosphere. Each probe system used a cylindrical electrode (projecting into the plasma) whose potential was varied with respect to the satellite shell. The resulting current to the probe was converted to a voltage suitable for telemetry.

Using the following equation, the temperature was derived from the electron current to the probe as it was swept from the satellite potential to the plasma potential:

$$\frac{d \log_e i_e}{dV} = \frac{e}{kT_e} \tag{1}$$

To localize the T_e measurement, the electron temperature probe was swept at a rate of 10 sweeps per second; and to maximize the resolution, the voltage was swept in two ranges, 0 to ¾ V and 0 to 1½ V, respectively. As a result, each temperature measurement was completed in less than 400 meters of the satellite path, and to that extent represents a point measurement. The telemetry sampling rate was sufficiently high to permit determination of temperature values as low as 400°K (although the lowest temperatures actually recorded were about 900°K).

The ion density probe was swept from −3 to +2 volts in a 2-second period, which was long compared with the satellite spin period of 0.7 seconds. N_i was derived from the ion current maxima which occurred each time the probe axis was perpendicular to the velocity vector.

Sensor Location

As noted above, the capability to provide measurements of the constituents of the space environment required close adherence to established laboratory vacuum techniques. Thus, in addition to providing a sealed housing which would not itself contaminate the local atmosphere, the eight sensors were located so as to provide maximum separation from each other.

Consideration of sensor orientation with respect to the direction of motion required that the mass spectrometers be located at the two ends of the spin axis to minimize changes in orientation during each mass-sampling sequence. The four pressure gages were distributed uniformly about the spherical satellite to insure that at least one gage would always experience pressure variations due to satellite spin, regardless of the spin axis orientation. One of each type of pressure gage was located on the satellite equator to enable a comparison of the gage responses under identical conditions. The two Langmuir probes were also located on the equator at points nearly diametrically opposite each other.

SUPPORTING SYSTEM

Interpretation of the data from the various sensors required detailed knowledge of the instantaneous angle between any sensor and the direction of motion of the satellite. This information was provided through the use of a multiple optical sensor arrangement, which enabled sensing the direction of the sun and/or moon and the instants of passage, during spin, of the Earth's horizons.

Direct measurement sensors like those employed in Explorer XVII provide time rates-of-change of data requiring high telemetry sampling rates. For example, the spectrometers and pressure gages required 60 samples per second and the "high speed" Langmuir probe required 180 samples per second. To meet these needs a pulse code modulation (PCM) telemetry system capable of 1000 samples per second was selected. This system had the additional advantage of providing a digital format which facilitated computer data processing.

The satellite was powered exclusively by silver-zinc cells, since solar cells presented the possibility of local contamination of the atmosphere. The

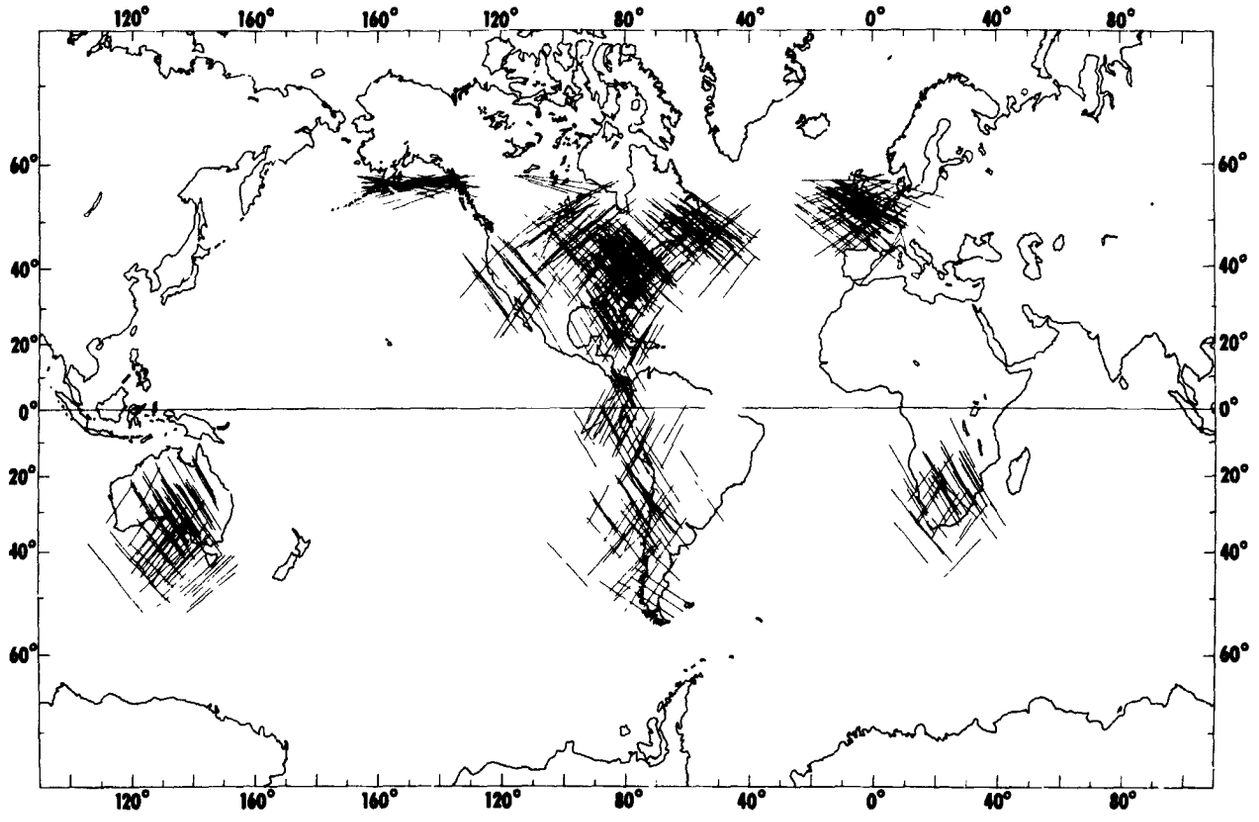

FIGURE 2.—Explorer XVII geographic coverage.

150 pounds of cells which were employed provided adequate energy to operate the entire satellite system for a total of 75 hours. A command-control system permitted the experiments to be turned on for four-minute periods, each of which was terminated by an internal programmer. Because a tape recorder was not employed, responses were confined to geographic regions of approximately 4000 kilometers diameter about each minitrack command station. Figure 2 illustrates the geographic coverage attained by showing the path of the satellite during each data-producing response. Table I summarizes some of the pertinent statistics of the satellite, and other information.

TABLE I.—*Explorer XVII Statistics*

Launch Date	April 3, 1963
Inclination	58°
Perigee	258 km
Apogee Range	920–870 km
Useful lifetime	100 days
Perigee motion	+39° to +58° to −18°
Data responses	650 on command
Telemetry	PCM—8640 bits/sec
Spin rate	90 RPM
Power supply	Chemical
Size and shape	1 meter sphere
Weight	410 pounds

EXPERIMENTAL RESULTS

Pressure Gage Results

As noted above, four independent gage systems were employed on the satellite, and all gages operated in orbit. Three of the gages gave useful and meaningful data during the active lifetime of the satellite. The fourth gage, however, experienced an apparent decrease in sensitivity after opening in orbit and no atmospheric structure data is available at present from this gage. Some of the results from the other three gages for five northern mid-latitude stations, representing approximately 25 percent of the total available data are presented here.

Figure 3 shows the measured atmospheric density over Grand Forks, Minnesota, during a pass at 2000 hours local time and demonstrates typical resolution of the density gage data. It may be

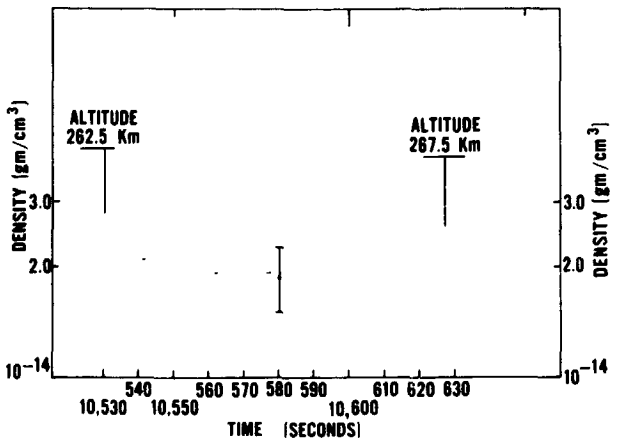

FIGURE 3.—Density data derived from a single pass over Grand Forks, Minn., demonstrating the resolution of the pressure gauge data.

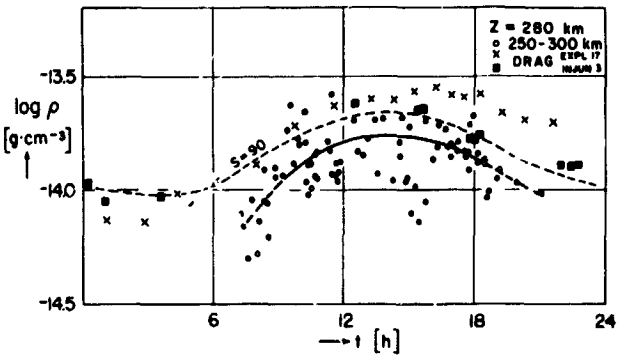

FIGURE 4.—Comparison of directly-measured and drag-derived atmospheric densities.

seen that the total altitude change was only 5 km for this pass, and at the average altitude of 265 km, the atmospheric density was 2×10^{-14} gm/cm^3. Each point shown is the average of the three independent density measurements. The resolution of the density data from each gage is such that the density was measured every 700 milliseconds or once every six kilometers along the satellite orbit. The observed small scatter of the density data makes quantitative density scale-height determination possible for passes possessing significant altitude changes. The magnitude of the error in the absolute value of the density is ±25 percent for this pass and can be attributed primarily to uncertainty in the absolute calibration of the sensors in the laboratory. At an altitude of 600 km, the error in the absolute value of the measured density is ±55 percent for some passes. Generally, the precision of the density measurements is better than ±20 percent.

Figure 4 (Newton, Horowitz, Priester, 1964) provides a comparison of the atmospheric densities directly measured by the gages in the altitude range 258 to 300 kilometers, to the density obtained from drag observations of Explorer XVII (Bryant, 1964) and Injun 3 (Jacchia, Slowey, 1964). All data are normalized to a height of 280 kilometers for comparison purposes, by using density gradients obtained from the Harris and Priester model with $S=90$.

The Injun 3 data, indicated by squares, were selected for quiet geomagnetic conditions ($A_p=2$), for the time interval of 18 February through 30 June 1963. During this period, the latitude of the satellite perigee varied between $-40°$ and $+60°$. The drag data from Explorer XVII, indicated by crosses, correspond to the time interval from 3 April to 6 July 1963, when the latitude of the satellite perigee was between $+58°$ and $-20°$. All Explorer XVII data in the figure have been reduced to quiet conditions ($A_p=0$) by using the preliminary linear reduction relation:

$$\log \rho = 0.006\, A_p$$

Further analysis of the gate data indicates, however, that the correlation between density and geomagnetic activity should be a steeper, nonlinear relation with the steepest portion applicable for low A_p (Newton, Horowitz, Priester, 1964). Application of the modified relation is expected to (a) remove some of the scatter from the gage data (which reflects real atmospheric variations), and (b) lower the average value of the directly measured densities by a small amount.

It is observed that the densities determined from drag are systematically 40 percent to 50 percent greater than the normalized densities measured by the gages, and that this separation is just outside the combined, stated uncertainties of the two sets of data. This difference is significant but at this time is not considered serious, since it could be accounted for by modest changes in the altitude to which the drag data are assigned, the drag coefficient, or the gage calibration constants.

Figure 5 shows measured atmospheric density-versus-altitude for the altitude range 258 to 600 km. These data result from approximately 60 passes for an A_p between 0 and 10, $F_{10.7}$ between

70 and 100, and most local times. It is seen that considerable variation in the atmospheric density occurs, resulting primarily from the differences in local time, a factor of 5 diurnal variation at 360 km being observed. The Harris and Priester model densities ($S=90$) for 0400 and 1400 hours are shown for comparison purposes.

Continued analysis of the Explorer XVII data is currently underway to further define:

(1) The quiet atmosphere and its variation with local time.

(2) The variations from the quiet atmosphere resulting from solar and geomagnetic disturbances.

(3) Other effects not now apparent.

Mass Spectrometer Experiment Data

Concentrations as a function of altitude are shown in Figure 6 (Reber and Nicolet, 1964) where Nicolet's model (private communication) is lincluded for reference. The data points shown are measured values, converted to ambient number densities. Measurements of each mass taken on the same satellite interrogation are made approximately one minute apart and are shown in the figure joined by straight lines. The numbers refer to orbit numbers. Table II lists pertinent information for the passes shown in the figure.

Of particular interest a.e the helium concentration vs. altitude, and the altitude regions where helium, atomic oxygen and molecular nitrogen are predominant. It is seen that helium is the major constituent above 600 km, molecular nitrogen is predominant below 250 km, and atomic

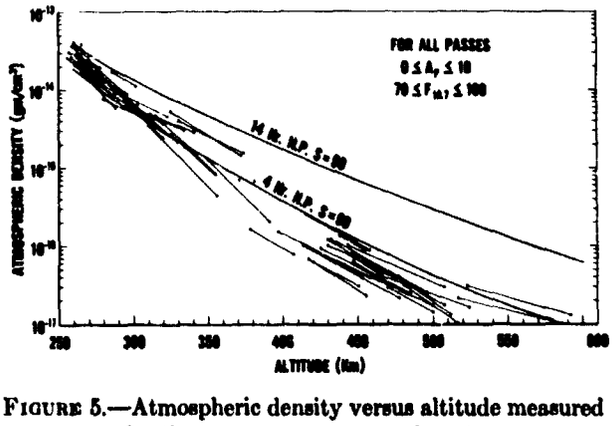

FIGURE 5.—Atmospheric density versus altitude measured by the pressure gauge experiment.

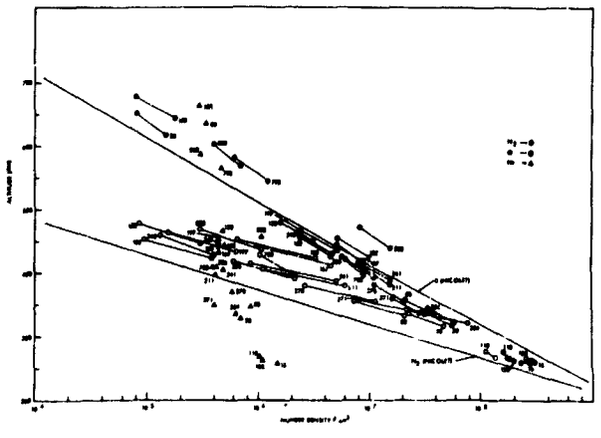

FIGURE 6.—Average daytime and nighttime concentrations of He, O, and N_2 from Explorer XVII mass spectrometer experiment.

oxygen is predominant between these levels. It should be noted that the scale heights of the constituents at higher altitudes correspond to temperatures of about 700° at night.

A possible deviation of the nighttime N^2 distribution from a diffusive equilibrium condition at altitudes less than 400 km is also suggested by this figure. One possible explanation is that the diffusion time in this altitude region is the same order of magnitude as the diurnal variation period. It should also be kept in mind, however, that these data represent a variety of times and geographic locations and thus do not accurately present an instantaneous vertical profile.

Figure 7 shows the variation of mean mass with altitude. The mean mass was computed using the major constituents, N_2, O and He. Hydrogen, which the instrument was not designed to measure, could significantly reduce the value of the mean mass at higher altitudes.

The variation of concentration ratios of helium-to-oxygen and atomic oxygen-to-molecular nitrogen with altitude is shown in Figure 8. The solid lines drawn through the points are averages; as in all the data presented, the points are measured values and are not averaged, nor do they reflect any smoothing. It can be seen here again that helium is the dominant component above 600 km and that molecular nitrogen is predominant below about 250 km.

Langmuir Probe Experiment Results

The local sun time, angle of attack (α), geographic latitude and longitude are averaged over the four minute pass. The stations involved are: BP—Blossom Point, Md.; COL—College, Alaska; FTM—Fort Myers, Fla.; GF—Grand Forks, Minn.; QUI—Quito, Equador; MO.—Mojave, Calif.; NFL—Newfoundland; OOM—Woomera, Australia; JOB—Johannesburg, South Africa.

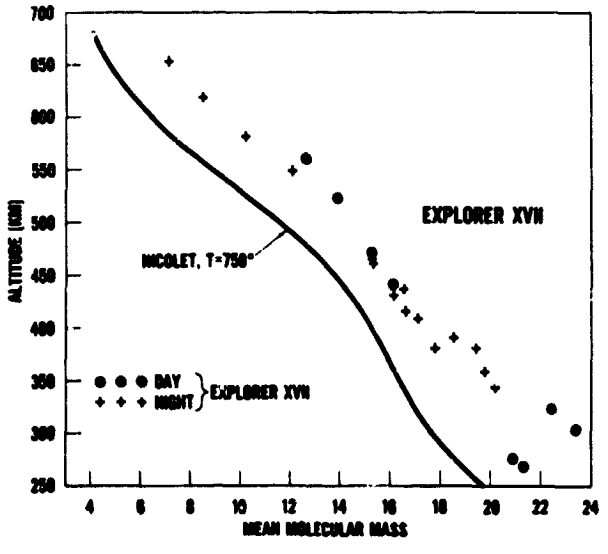

FIGURE 7.—Mean molecular mass versus altitude from mass spectrometer.

N_t, measured during a series of near perigee passes near the F_2 maximum over Blossom Point, Maryland. These data were obtained over the three month satellite lifetime during which the rotation of the orbit plane caused a complete diurnal variation to occur. The data are shown as points or pairs of points, the latter corresponding to the measured values at the beginning and at the end of individual satellite passes.

At first glance one is struck by the lack of correlation between the gross diurnal variations (smoothed curves) and the changes during the individual passes, especially in the afternoon. Since perigee passes such as these can exhibit very little altitude change, this in-pass variation must be largely latitude dependent (10° change in latitude within average pass). The average in-pass change in T_t implies a latitude gradient near Blossom Point of approximately 25° K per degree of latitude, coresponding to about a 10 percent change in T_t within a pass. With few exceptions the changes in T_t within a pass are accompanied by an inverse change in N_t which is even greater than 10 percent.

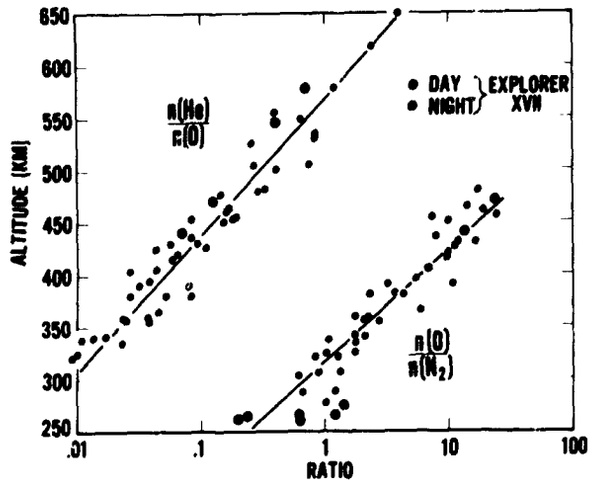

FIGURE 8.—Ratios of n(He)/n(O)n(N_2) versus altitude from mass spectrometer experiment.

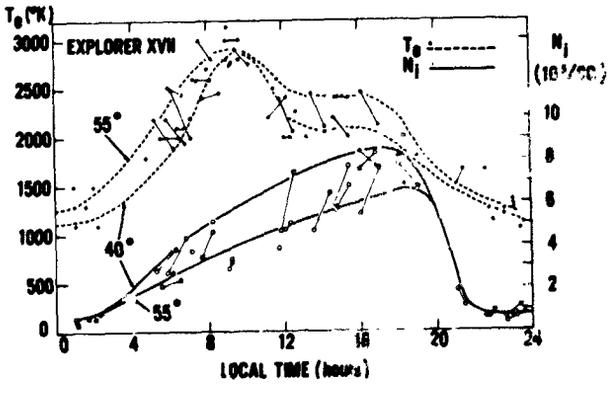

FIGURE 9.—Diurnal variation of T_e and N_i for magnetic latitudes 40–50°N and altitudes 258 to 350 km, from the Langmuir probes.

Plots similar to Figure 9 have been prepared from T_e and N_i measurements at two other latitudes (10° N at Quito, 60° N at College), and the resulting gross diurnal variation curves at all three latitudes are shown in Figure 10. These data also correspond to the region of the F_2 maximum (below 400 km).

The T_e variation at the F_2 maximum at all latitudes shown is characterized by a steep morning rise, a midmorning maximum, and afternoon plateau, and a gradual decrease near sunset. The nighttime values of T_e are somewhat variable but are always significantly above the neutral particle temperature (Harris and Priester, 1962), particularly at College, Alaska where the summer night at F_2 altitudes is short or non-existent.

The values of N_i rose gradually throughout the

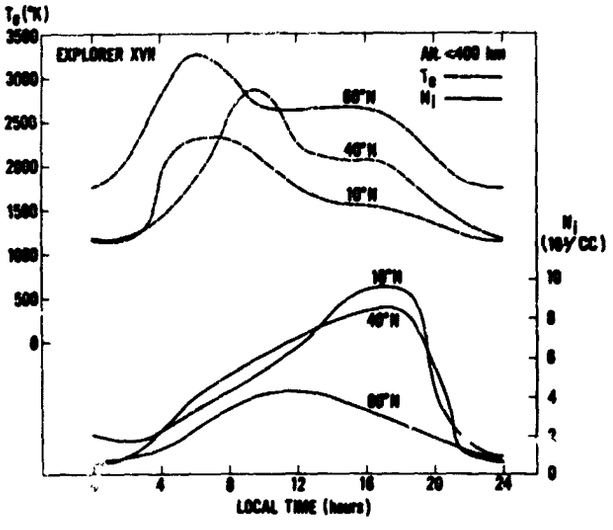

FIGURE 10.—Averaged T_e and N_i showing the diurnal variation above three selected stations; Quito (10°N), Blossom Point (40°N) and College (60°N).

day, reaching a maximum density in the late afternoon, except at College where the maximum occurred in the early afternoon.

It should be noted that the curves in Figure 10 represent direct "in situ" measurements above specific geographic locations during the late spring and summer of 1963, and therefore should not be considered models of the diurnal variation at other altitudes, longitudes, and seasons. However, the analysis of higher altitude data from these sites, as well as data from other sites is now in progress, and it is hoped that these data will help provide a better understanding of the global structure of the ionosphere.

In conclusion, it is clear from the simultaneous measurements that T_e and N_i are related in a generally inverse manner which agrees reasonably well with the inverse square relationship predicted by Hanson (1962) and Dalgarno, et al (1963). The elevated nighttime values of T_e show that there is a heat source for the electrons at night, although its energy content is only a few percent of that required to cause the electron temperatures observed in the daytime (Brace, Spencer, Dalgarno, 1964).

ACKNOWLEDGMENTS

The success of a satellite laboratory such as discussed above results, clearly, from the efforts of many individuals. The authors gratefully and

sincerely wish to acknowledge these efforts and specifically mention the major contributing group leaders: James S. Albus—aspect system, Joseph P. Corrigan—tracking and data systems, James L. Cooley—coordinator, Paul C. Donnelly—batteries, Donald F. Fitzpatrick—mechanical design, William D. Hoggard—environmental testing, Robert E. Kidwell—thermal systems, John N. Libby—electronic control, Chris C. Stephanides—spacecraft system and integration engineer, Virginia Zanner—computer data analysis.

THE REFLECTIVITY OF JUPITER IN THE ULTRAVIOLET*

THEODORE P. STECHER

Four spectral scans of Jupiter were obtained by means of objective grating rocket spectrometers. The geometrical reflectivity is interpreted in terms of Rayleigh scattering by obtaining a numerical relationship between reflectivity and optical depth. This gives an upper limit to the amount of molecular hydrogen above the cloud layer of 10.2 ± 1 km. atm. The effect of Raman scattering by molecular hydrogen increases this to a 10.6 ± 1 km. atm. An absorption feature is found to be consistent with its identification being photodissociation of H_2.

I. THE OBSERVATIONS

The spectrum of Jupiter in the ultraviolet was obtained from an Aerobee rocket on July 23, 1963 at 06^h02^mU.T. Three additional spectra were obtained in a similar manner on November 14, 1964 at 10^h28^mU.T. The instruments used were objective grating photoelectric stellar spectrometers similar to those described by Stecher and Milligan (1962). Spectral scanning is the consequence of the spin of the rocket. The observations were telemetered to the ground. The exit slit widths were between 50Å and 90Å. The total spectral range covered was from 1050Å to 4000Å. The instruments were calibrated in both a relative and an absolute sense prior to flight in the laboratory. The accuracy of the absolute calibration is believed to be considerably better than the limit set by noise in signal for these observations. A complete description of the instrumental techniques will be included in a forthcoming paper on stellar energy distributions.

The discussion of planetary photometry by Harris (1961) is now followed. In Figure 1 the geometrical reflectivity, p, as a function of wavelength is given between λ2000 and λ3000. The mean error for each value of p was determined in the standard manner from the observations, no measurable signal was detected below λ2000. The solar flux values used in obtaining p are those given by Tousey (1963) and were obtained by photographic spectrophotometry. The necessary geometry was obtained using the appropriate Ephemeris values. The phase angle of Jupiter was 11.72 degrees on July 23, 1963 and almost zero on November 14, 1964.

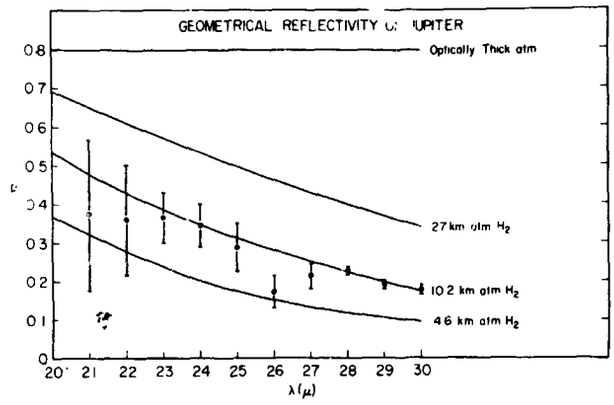

FIGURE 1.—Circles: Observed average geometrical reflectivity of Jupiter as a function of wavelength with mean errors as determined from four spectra. Solid curves: Computed geometrical reflectivities for various amounts of molecular hydrogen.

II. INTERPRETATION

The literature on Jupiter, in particular recent polarization measurements and molecular hydrogen quadrupole line measurements, indicates the possible presence of a Rayleigh atmosphere at ultraviolet wavelengths above the cloud layer. Upper limits for the number of atoms or molecules above the cloud layer may be derived immediately for each species if the reflectivity is known in terms of optical depth. Tables have been tabulated for the total intensity emerging from the top of a Rayleigh atmosphere by Coulson, Dave and

*Published as *Goddard Space Flight Center Document X-613-64-391*, December 1964.

Sekera (1960). This tabulation is for optical depths, τ, up to unity as a function of zenith distance of the sun, μ_0; zenith distance of the emergent rays, μ, and the azimuthal angle, φ. From these values p may be obtained as a function of τ.

For our purposes, Jupiter is assumed to be at opposition even through one observation was made at quadrature, since the phase integral is almost constant for small phase angles. This approximation makes less than three percent difference for that observation (Talley and Horak, 1956). The plane parallel atmosphere is made tangent to a unit sphere at each point on the illuminated hemisphere by the restraint $\mu_0=\mu$. The value of the emergent intensity is then projected onto a unit disk. Integration over the surface then gives the geometric reflectivity for a given value of optical depth. The aximuthal angle is 180°. Curves in the $p-\tau$ plane were constructed in this manner in the range $\tau=0$ to $\tau-1$ for ground reflectivities of 0, 0.25, and 0.8. The values of p for the optical thick case are given for Rayleigh scattering and for isotropic scattering by Harris (1961). The extrapolation from $\tau=1$ to $\tau=\infty$ was made with the aid of geometric reflectivities calculated in a similar manner from the available X-Y functions for isotropic scattering given by Mayers (1962) and by Sobouti (1963). Over the range of τ to be used in this paper the extrapolation error is probably negligible.

The total number of atoms or molecules in a column of unit area perpendicular to and above the cloud layer is now obtained from $\tau=n\sigma$ under the assumption of only one constituent. Here n is the number of atoms or molecules and σ is the Rayleigh scattering cross section per atom or molecule. The Rayleigh scattering cross section for molecular hydrogen is given by Dalgarno and Williams (1962)[1]. The Rayleigh scattering cross section for helium is given by Dalgarno (1962). The molecular scattering cross section for these gases does not follow the Rayleigh law in the ultraviolet. This is physically due to the increased probability of inducing a dipole moment as a resonance is approached. In the range of interest here the deviation of molecular hydrogen is greater than that of helium. This in principle would allow an abundance ratio determination but would require more accurate observational material at the shorter wavelengths.

In Figure 1 the observed geometric reflectivities as a function of wavelength (circles) are compared with ones calculated for a given atmosphere. The best fit to the data under the assumption of zero reflectivity in the clouds is a 10.2 km. atm. of H_2 or a 200 km. atm. of He or any combination of the two resulting in the same total reflectivity. If the clouds are assumed to form a Lambert surface with a reflectivity of 0.25 the total number of scattering atoms or molecules is reduced by a factor of ten and the form of the reflectivity curve becomes incorrect for Rayleigh scattering. The possibility that the clouds have a small reflectivity can not be excluded. The derived atmosphere is therefore an upper limit.

The above analysis has been carried out under the assumption that the scattering is coherent. In the case of most molecular gases including molecular hydrogen this is known not to be the case. Raman scattering from H_2 in the lowest vibrational state is five percent of the Rayleigh scattering at λ1216 (Dalgarno and Williams, 1962). Isotropic scattering may be used to approximate the effect by setting the particle albedo equal to 0.95 and comparing it with the result for a particle albedo of unity. In the case of an optically thick atmosphere one concludes that 43 percent of the incident photons emerge in the Raman lines. Brant (1963) found 34 percent of the incident Lyman-α photons in the Raman lines by means of an approximation to the Rayleigh phase function.

There is a half electron volt difference between the incident photon and the Raman scattered photon. This energy difference means that the Raman photon has a wavelength several hundred angstroms longer than the incident photon at the wavelengths under consideration here. This would appear as a second order effect except on the longer wavelength side of an absorption feature in the planet or when there is a strong wavelength variation in the source function. The absorption bands of ammonia begin at 2100A and result in an almost continuous absorption at shorter wavelengths reaching an optical depth of more than 10^5 at λ1216 (Kuiper 1952) (Watanabe, et al. 1953). This is apparently indicated by the data although the solar continuum becomes so

[1] The ordinate in Fig. 1, Ap. J. 136, 691, 1962 should read $\lambda^4\sigma(\lambda)$ $\times 10^{44}$ cm^4.

weak here that the determination is unreliable. The effect here is that only the Rayleigh component and not the Rayleigh plus Raman appears up to λ2200. Similarly, the absorption feature between λ2400 and λ2700 reduces the Raman scattered component between λ2700 and λ3000. Using isotropic scattering as an approximation and assuming that the ratio of the Raman scattering cross section to the Rayleigh cross section is a constant independent of wavelength the total scattering atmosphere would be considerably more.

Dalgarno and Williams (1964) have kindly communicated to me in advance of publication the Raman scattering cross section for H_2 between λ2000 and λ3000. They give $Q=2.75\times10^{-46}/\lambda'^4$ where λ' is the wavelength of the scattered radiation in centimeters. This is a smaller cross section than was anticipated and leads to only 0.4 km. atm. increase of H_2. Thus, we have an upper limit of a 10.6 km. atm. of molecular hydrogen. The total mean error is estimated to be ±one km. atm.

There are several possible causes of the absorption feature between λ2700 and λ2400 which appears to be real. If for the sake of conjecture, this absorption is assumed to be the forbidden photodissociation of molecular hydrogen, an empirical absorption coefficient may be derived. This may be done by following the path of the photon by using isotropic scattering for which $X-Y$ functions are available (Sobouti, 1963). A particle albedo of unity is equated numerically to the Rayleigh scattering cross section and the particle albedo giving the observed mean absorption depth is determined. If the Rayleigh scattering is considered to be due entirely to H_2 a cross section of 1×10^{-27} cm^2 is obtained for photodissociation of H_2. Dalgarno (1964) considers 10^{-27} to be a good estimate. Herzberg (1964) points out that H_2S would also absorb in this wavelength region so the identification is by no means certain.

SUMMARY AND DISCUSSION

Zabriskie (1962) determined at 4.6 km. atm. of H_2 from their quadrupole bands. Spinrad and Trafton (1963) empirically derived a 27 km. atm. from these bands. Foltz and Rank (1963) concluded from laboratory measurements and theoretical calculations on the quadrupole bands that both of these determinations are much too small and it should be on the order of a 270 km. atm. The latter value would give an optical depth of nine at λ3000 and correspond to a conservative atmosphere throughout the ultraviolet. This is not observed. Casual inspection of photographs of Jupiter taken on blue plates also indicate this not to be the case since the surface markings would be obscured near the edge of the disk. This large optical depth would also require U and B color intensities several times what is observed (Harris, 1961). Öpik (1962) derives an optical depth by inspection of published photographs which is in remarkably good agreement with that obtained in this paper. Öpik then proceeds to derive an atmosphere that is consistent with the molecular weight he obtained from a rediscussion of the occultation measurement of Baum and Code (1953). His resulting atmosphere consists mostly of helium giving a pressure of 11 atmospheres at the top of the cloud layer. Spinrad and Trafton (1963) find from the widths of methane lines a pressure equal to or less than 2.8 atmospheres at the top of the clouds. If we adopt 2.8 atmospheres at the top of the clouds. If we adopt 2.8 atmospheres as the upper limit then we are limited to less than 50 km. atm. of helium. The cross section for Rayleigh scattering in helium is five percent that of molecular hydrogen. A 50 km. atm. of helium is insufficient to give the observed reflectivity. The amount of molecular hydrogen then becomes at least 8 km. atm. for zero reflectivity clouds.

The conclusion of this paper is that Jupiter has less than 10.6 ± 1 km. atm. of molecular hydrogen above the clouds. If the reflectivity of the clouds is zero in this part of the ultraviolet and the upper limit to the pressure is 2.8 atmospheres at the cloud tops then Jupiter has at least a 8 km. atm. of molecular hydrogen. Inherent throughout this paper is the assumption that the atmosphere has the same physical depth at all wavelengths longer than 2000 Angstroms.

THE UPPER ATMOSPHERE*

JAMES C. G. WALKER

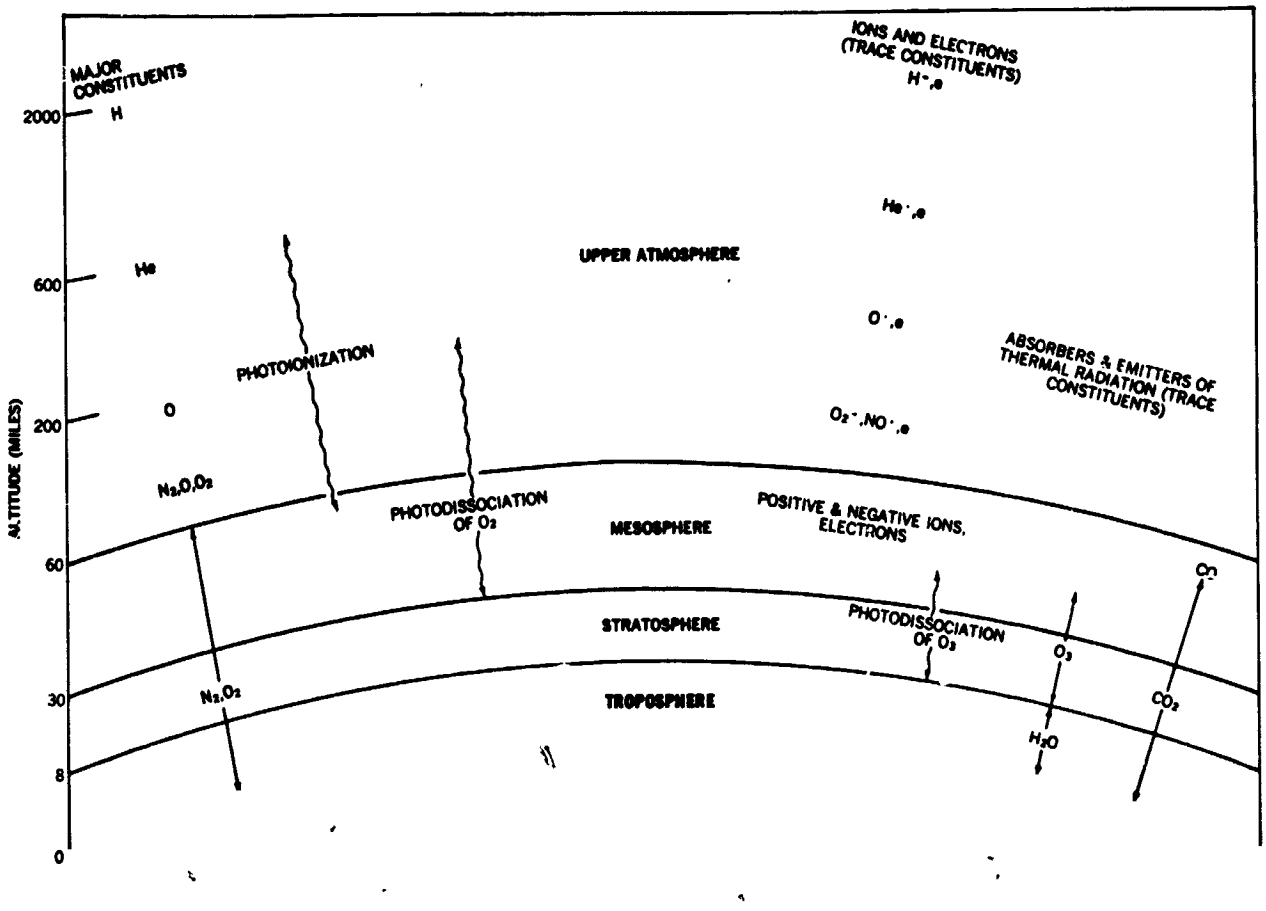
The past four years of rocket and satellite measurements have significantly increased our knowledge of the upper atmosphere. For example, the variation of upper atmosphere density, which can be deduced from the rate of decay of satellite orbits, has been mapped out in considerable detail. It is plain now that the presently available reference atmospheres are seriously inadequate in their description of the atmosphere above 60 miles, especially in describing the variation of atmospheric properties with time. In fact, the international Committee on Space Research (Cospar) is working on a revision of its 1961 reference atmosphere that will reflect this recent information.

So fast is our knowledge of the upper atmosphere changing, however, that the new Cospar model could already be out of date, in some respects, by the time it is published. All of which merely underlines a fact that is often overlooked: while a standard model of the upper atmosphere may provide useful guidance in the design of vehicles and experiments to work in that environment, it is not likely that the model at any time will represent the upper atmosphere as we think it is, let alone represent it as it really is. We do not yet know the upper atmosphere as it really is, although we are much closer than we were four years ago.

FROM 60 TO 40,000 MILES

In looking at the upper atmosphere we are, by definition, concerned with what lies between the lower atmosphere (troposphere, stratosphere, and mesosphere) and outer space. This vast region, which includes virtually all of the ionosphere, extends upward from the top of the mesosphere, at an altitude of about 60 miles, to the magnetopause at 40,000 miles. (The magnetopause separates the region of space dominated by the earth's magnetic field from the interplanetary region dominated by fields and particles of solar origin.)

However, because atmospheric pressure and density decrease exponentially with increasing altitude, our knowledge of atmospheric properties is almost entirely limited to altitudes below about 600 miles. At higher altitudes, the densities are so low that, with few exceptions, our present-day experimental techniques are not able to detect the presence of the atmosphere at all, and we must base our models of this region on theoretical extrapolations from measurements made at lower altitudes.



Thus, most of our discussion of the upper atmosphere of necessity refers to the region between 60 and 600 miles. Even within this range of altitudes the data coverage is not uniform. Very few satellites penetrate to altitudes below 120 miles, because at lower altitudes the atmospheric density and the resulting drag on the satellite are so high that the satellite can remain in orbit only a short while before falling back into the lower atmosphere. Accordingly, we must rely on sounding rockets to provide data on atmospheric properties between 60 and 120 miles, and the coverage in time and space which sounding rockets can provide is limited by the expense of rockets powerful enough to reach up into the upper atmosphere.

ONLY SMALL SAMPLES TO WORK WITH

In summary then, the data on upper atmosphere properties tend to be limited to isolated vertical profiles measured with sounding rockets and extending up to about 150 miles, and a considerable number of horizontal profiles measured with satellites and concentrated largely in the region from 180 to 400 miles.

Both the major atmospheric constituents and the trace constituents change with increasing altitude. How they change, why they change, and how their changes can be related to changes in temperature, pressure, and density, is what

*Published in *Space Aeronautics*, 42(4):56–63, October 1964.

SKETCH 1.—Upper atmosphere extends from mesopause out to magnetopause, as shown to scale in left section. A ten times expansion of scale in the right section shows how small is the layer below the mesopause that we call lower atmosphere.

recent rocket and satellite measurements have helped us to determine.

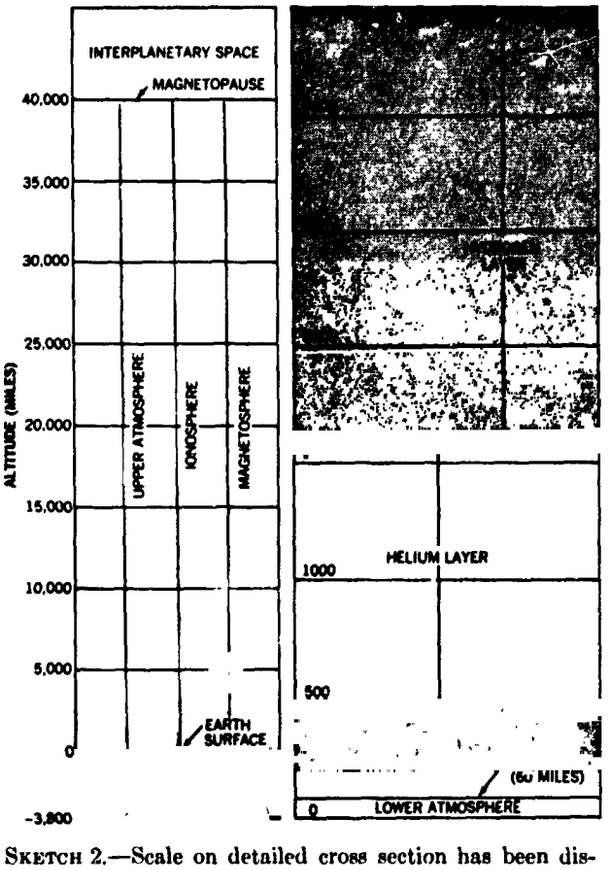
At the higher altitudes, light atoms (oxygen, hydrogen, and helium) are the major consituents. These constituents are atomic, rather than molecular, because their concentrations are so small at great altitudes that atoms seldom collide to form a molecule. The predominance of helium above about 600 miles is one of the new facts uncovered by recent satellite measurements; before this discovery there was thought to be a gradual transition from atomic oxygen to atomic hydrogen with increasing altitude. The important trace elements of the upper atmosphere are ions and electrons, resulting from ionization of the major constituents by solar ultraviolet radiation.

The altitude at which the upper atmosphere begins is defined by a temperature minimum. The temperature of the atmosphere reaches a maximum at 30 miles, the base of the mesosphere, then drops off sharply to the 60 mile base of the upper atmosphere. In the upper atmosphere, temperature rises steadily to around 1200 K (some 900 K above the mesospheric maximum). Because we have not yet found a way to measure upper atmosphere temperatures effectively, the temperature profiles have generally been deduced from measured composition and density profiles.

ENERGY PROCESSES KEY TO UNDERSTANDING

To understand the upper atmosphere—the complex behavior of temperature and composition as a function of altitude—we must consider its energetics. The energy transport processes, and the sources and sinks of energy, are what control the structure of the atmosphere. For the balance between energy gain and loss at any altitude determines the corresponding gas temperature. This temperature in turn controls the rate of change of pressure and density, through the law of

hydrostatic pressure balance. At the same time, energy transfer leads to chemical changes in the atmospheric constituents and thus a variation of chemical composition with altitude.



For all practical purposes, we can consider the sun to be the source of all the energy which influences the structure of our atmosphere. The flux of solar energy reaching the earth's surface is about a million times greater than the flux of energy conducted to the surface from radioactive heat sources in the deep interior. The energy fluxes carried by bombarding meteors and high energy galactic cosmic rays are also negligible.

SOLAR WIND MAY PLAY BIG ROLE

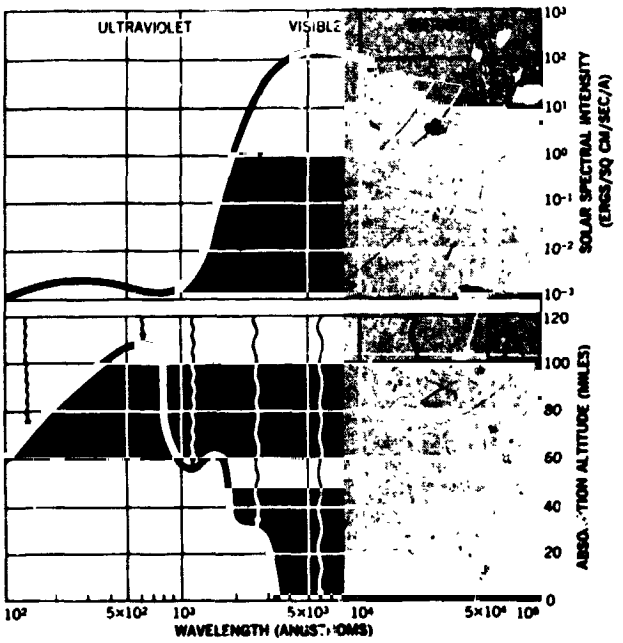
The atmosphere receives solar energy both from the sun's electromagnetic radiation and from the streams of protons and electrons flowing radially outward from the sun. Although the solar wind, as the latter streams are called, carries only one ten-millionth as much energy as the solar electromagnetic radiation, yet it may have an important influence on atmospheric properties at very high altitudes—particularly above 120 miles. This is an important question mark, as we shall see later when we consider how temperature varies with time.

Solar electromagnetic radiation varies in wavelength from infrared through visible, and into the ultraviolet. Although the energy carried by the solar ultraviolet radiation is only a small fraction of that carried by the visible in infrared, this energy is absorbed at fairly high altitudes where the atmospheric density is low and the energy transport processes are relatively inefficient. So there is a substantial temperature increase produced by the absorption of ultraviolet radiation.

There are two basic processes by which ultraviolet radiation is absorbed in the atmosphere. The most energetic photons, with wavelengths less than 1000 Angstroms, are able to knock an electron out of an atom or molecule when they are absorbed. The resulting formation of electrically charged particles, or ions, is known as photoionization. Photons with wavelengths greater than 1000 A do not have enough energy to ionize any of the atmosphere's major constituents. But they do have enough energy to break the weaker molecular bonds, specifically those which unite oxygen atoms into oxygen (O_2) or ozone (O_3) molecules.

SKETCH 2.—Scale on detailed cross section has been distorted for illustration purposes. Ultraviolet radiation from the gun is the principal source of energy in upper atmosphere: it reacts with major constituents by photoionization to produce ions and electrons, shown as Trace constituents at right above. Photoionization processes use up most of the sun's shorter wavelength ultraviolet radiation in the upper atmosphere. What remains to reach the lower atmosphere is less energetic and acts to dissociate molecular oxygen into atomic oxygen—around the mesopause, at 60 miles altitude—and to dissociate ozone at the base of the mesosphere. Very little ultraviolet radiation penetrates below the stratosphere. The solar radiation which penetrates into the lower atmosphere is in the visible and near-infrared portion of the spectrum. Neither of these are absorbed to any extent by the constituents of the atmosphere. The energy for the lower atmosphere comes from infrared radiation that is absorbed by the earth and reradiated in the far-infrared portion of the spectrum with maximum intensity at about 150,000 Angstroms. This radiation is strongly absorbed by water vapor and carbon dioxide in the troposphere and stratosphere. The absorption process is the energy source for the general circulation and weather phenomena that characterize the lower atmosphere. Our most recent knowledge of the upper atmosphere extends up to about 600 miles, but is limited at the lower end of the scale to around 120 miles by the requirement that the satellite last some months at least. Rocket soundings are used between 60 and 120 miles.

The resulting breakdown of the molecule is called photodissociation.

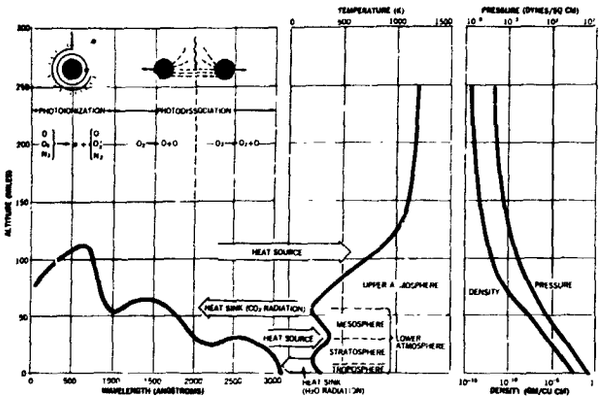


OZONE BREAKDOWN GIVES HEAT SOURCE

Photodissociation of oxygen is produced by the more energetic photons, with wavelengths between 1000 and 2000 A, and is most pronounced at about 60 miles altitude. The less energetic photons, with wavelengths of 2000–3000 A, penetrate even closer to the earth, into the stratosphere; there, they dissociate ozone, which is less tightly bound than oxygen. The temperature maximum at 30 miles attests to the importance of ozone photodissociation as a heat source. There is no corresponding maximum in the temperature profile around 60 miles where oxygen is photodissociated. But while oxygen absorption is not particularly important as a heat source, it does have a profound effect on the chemical composition of both the upper and lower atmosphere.

One result of photodissociation of oxygen is that much of the atmospheric oxygen at high altitudes is in the atomic state. The actual concentration of atomic oxygen is determined by the balance between the rate at which it is produced by photodissociation and the rate at which it recombines to form molecular oxygen. Theoretical treatment has so far failed to provide quantitative information on the relative concentrations of atomic and molecular oxygen in the upper atmosphere. Experimental measurements of atmospheric composition are difficult at high altitudes and at present are of doubtful reliability. Consequently, there is still some uncertainty about the composition of the upper atmosphere.

Below 60 miles, in the lower atmosphere, the atomic oxygen produced by photodissociation combines with molecular oxygen to form ozone. Present only in trace amounts, ozone is only one hundred-thousandth (10^{-5}) of the ambient density—even at 15 miles, where ozone concentration is a maximum.



Although ozone is only a trace constituent it plays a very important role indeed. By absorbing strongly in the near ultraviolet (between 2000 and 3000 A) it is not only shields the troposphere and the ground from this biologically harmful solar radiation, but also provides the energy source responsible for the temperature maximum where the stratosphere and mesosphere meet at the stratopause, 30 miles high. The rate of radiation absorption at any altitude is proportional to the product of the concentration of absorbing constituents and the radiation flux. Very little absorption occurs at high altitudes, where the concentrations are small. But by the time ultraviolet reaches low altitudes where concentrations are high, the radiation is attenuated. Here, the rate of absorption is low because the radiation flux is low. The maximum rate of absorption thus occurs at an intermediate altitude. The altitude at which the rate of absorption of any given wavelength reaches a maximum is called the absorption altitude for that wavelength.

SKETCH 3.—Solar radiation controlling the structure of the atmosphere covers the range from extreme ultraviolet to infrared. Most of this radiant energy is in the visible and near-infrared, as the upper curve shows, and most of the energy in this region penetrates to the ground, rather than being absorbed by the atmosphere. Ultraviolet is absorbed at both high and medium altitudes. Comparison of upper and lower curves shows that greatest amount of absorbed ultraviolet is in the 2000–3000 A wavelength range; it is absorbed at altitudes of 25 to 30 miles.

ION-ELECTRON MAXIMUM 180 MILES UP

For extreme ultraviolet radiation of wavelengths shorter than 1000 A, the absorbing constituents are molecular nitrogen and oxygen, and atomic oxygen, and the absorption altitude is around 110 miles. The absorption occurs by way

SKETCH 4.—Variation of temperature with altitude is not undirectional as are pressure and density variations. Reversals in temperature curve are due to endothermic and exothermic reactions, the latter drawing on the energy created by the absorption of ultraviolet radiation. At the highest altitudes (100 miles or so) photoionization occurs when the most energetic ultraviolet photons (wavelengths below 1000 A) knock an electron out of the oxygen or nitrogen atom. The rapid temperature rise above 60 miles reflects this heat source. The temperature minimum at 60 miles is a consequence of the heat sink provided by the emission of thermal radiation by CO_2. The temperature rise of about 30 miles reflects the photodissociation of ozone.

of photoionization, producing free electrons along with the ions of the absorbing constituents. Because the rate of absorption is a function of altitude, it is to be expected that the concentration of ions and electrons will also be a function of altitude with a maximum at some altitude. This is, in fact, the case. Ions and electrons are present in detectable amounts at all altitudes above 40 miles, with the maximum electron and ion concentration occurring at about 180 miles. This layer of ionization is what is called the ionosphere. The region below the 180-mile ionization maximum is called the bottomside ionosphere; the region above is called the topside.

The greatest electron number density of the ionosphere is about 10^6 per cu cm, which amounts to only a thousandth of the neutral particle number density at the same altitude. Thus the ionosphere comprises only a small fraction of the total number of particles in the upper atmosphere.

Because it is central to an understanding of upper atmosphere energy sources, we would like to have a quantitative theory of the ionosphere which would allow us to calculate its properties and the way they vary in time without having to refer the measurements of these properties. We don't yet have such a theory. But, in the past three years, rocket measurements of the solar flux in the extreme ultraviolet region have made it possible, for the first time, to attempt to formulate one.

The theory is based on "airglow" measurements. Absorption of solar ultraviolet radiation by photoionization not only plays a central role in the formation of the ionosphere, but also leads to the excitation of atoms and molecules when ions and electrons from photoionization recombine. These excited species can radiate in their characteristic spectral lines and bands, which lie mostly in the visible region. This is called the airglow.

Because the airglow is excited predominantly in the chemical reactions and particle collision processes which follow the absorption of solar ultraviolet energy, airglow measurements constitute a valuable source of information on these reactions and collision processes and their occurrence in the upper atmosphere. Ground-based measurements of the airglow are fairly straightforward at night, and the first measurements of this kind were made 80 years ago. In fact, such measurements provided the earliest information about conditions in the upper atmosphere. During the day, however, sunlight scattered in the troposphere is many times brighter than the airglow, and it has not been possible until very recently to obtain any daytime airglow data. In the last two years, sophisticated ground-based and rocket techniques have yielded the first daytime airglow measurements. From these measurements we are gaining new insight into the reactions and energy conversion processes which take place at great altitudes when the atmosphere is sunlit.

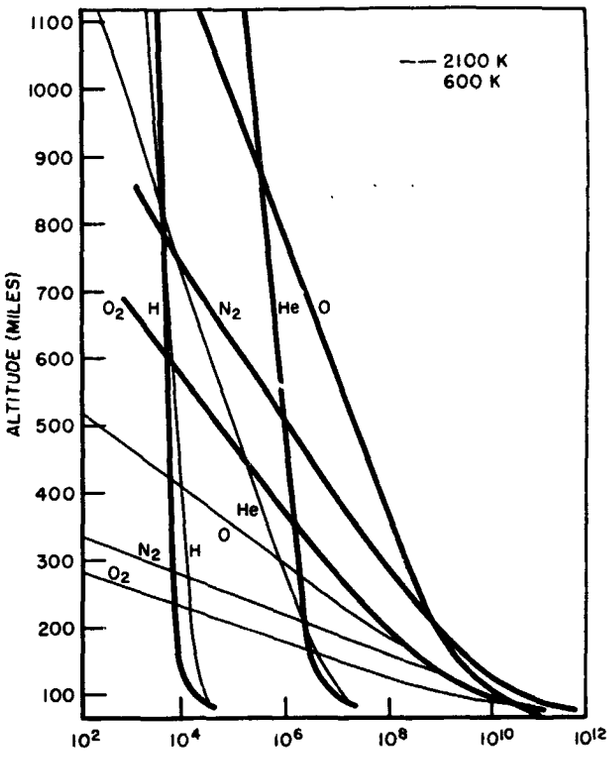
AIRGLOW IS ENERGY SINK

It has been assumed that the theory of the daytime airglow would involve a simple extension of the theory of the night airglow, but the data now available have made it plain that completely unexpected energy transformation phenomena occur during the day.

We are particulary interested in the airglow because it represents an energy sink for the upper atmosphere. Only a part of the absorbed solar ultraviolet energy is released to the atmosphere

in the form of heat; the rest of the energy escapes down to the ground or out into space in the form of airglow radiation.

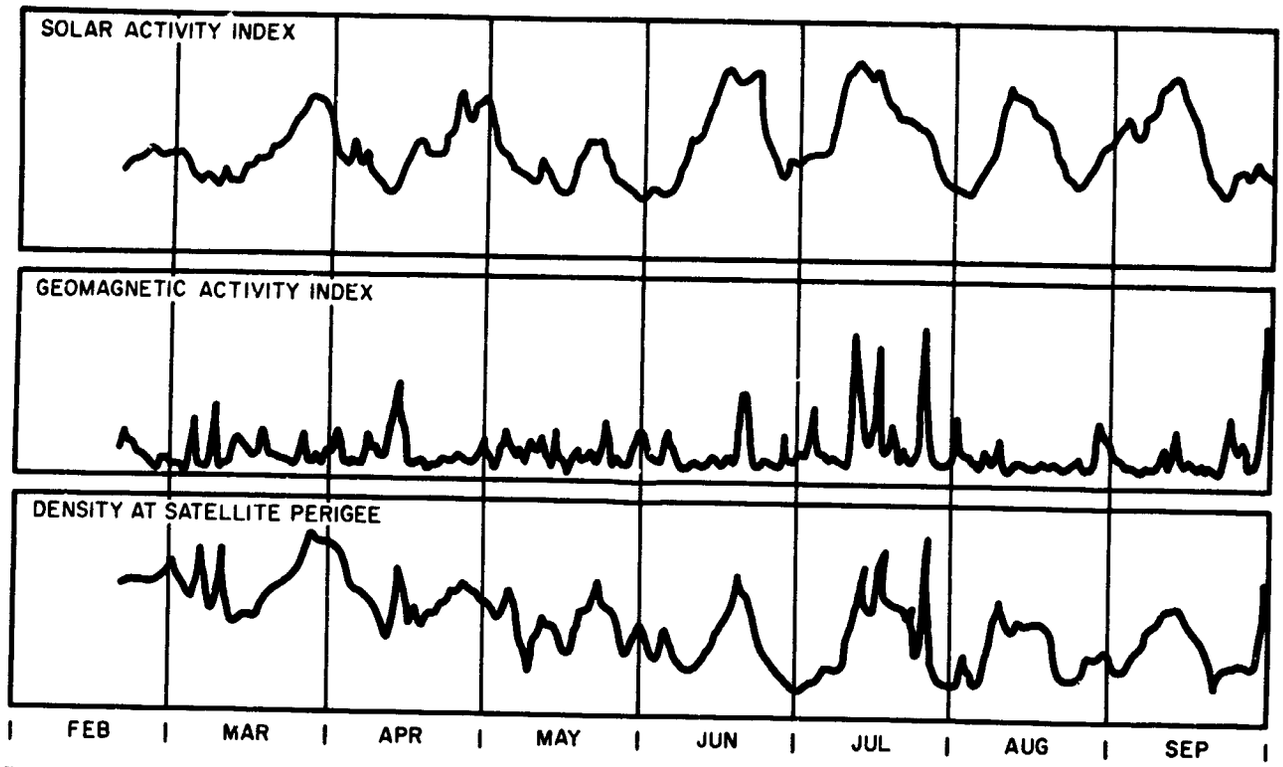
We have been discussing ultraviolet radiation as if it were the only source of energy in the upper atmosphere. That this may not be exactly correct will soon be evident as we discuss the energy transport mechanisms and the implications of recent atmospheric density measurements.



Cooling of the upper atmosphere by the emission of thermal radiation is negligible. The atmospheric molecules which have spectra in the infrared, and can therefore emit thermal radiation at atmospheric temperatures, are water and carbon dioxide. But these molecules are very rare in the upper atmosphere where they are subject to photodissociation by solar ultraviolet radiation.

NO MIXING MECHANISM AVAILABLE

Convection also turns out to be unimportant above 60 miles because temperature increases with altitude, making the atmosphere stable. This inhibition of convection has a profound effect on the composition at great heights. In the absence of convection, and the turbulence which results from convection, there is nothing to keep the atmosphere well-mixed and reasonably homogeneous. Instead, a regime of diffusive equilibrium is maintained. The heavier atmospheric constituents settle out at fairly low altitudes under the action of gravity, while the lighter atmospheric constituents, which are less tightly bound by the earth's gravitational field, rise above them and become increasingly important as altitude increases.



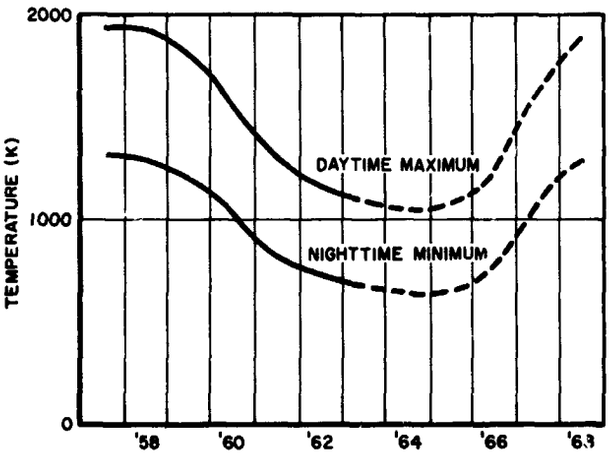
The number densities of these constituents, both light and heavy, decrease with altitude at a rate that depends on the temperature. However, these densities are so low that the temperature at these altitudes cannot be measured directly. Instead, the temperature must be decuced indirectly from measurements of other atmospheric properties. Above 120 miles, atmospheric densities can be deduced from the orbital decay of satellites as the result of atmospheric drag.

Drag studies have been our most prolific source of information on the upper atmosphere, and they have revealed enormous variations of density with time. Because the density at any altitude is sensitive to the temperature, the density variations are believed to reflect variations in temperature that are caused by changing heat sources. Most of the variations can be explained, at least qualitatively, as the result of changes in the ultraviolet heat source caused by changes in the solar ultraviolet flux.

SKETCH 5.—Altitude variation of number density of major constituents in upper atmosphere, plotted for two different temperatures. These curves show how lightest constituents persist to highest altitudes and how rate of fall-off in density is a function of temperature. The relationships, determined theoretically using hydrostatic balance and the ideal gas law, have been confirmed qualitatively by satellite measurements. This confirmation supports the validity of our present indirect method of deducing upper atmosphere temperatures from density measurements.

One phenomenon, however, cannot be explained on this basis and is therefore of particular interest. The satellite drag densities show sharp and sudden increases at times of geomagnetic storms, which show up as spikes in the geomagnetic activity index. Since magnetic storms (unusually large variations in earth's magnetic field, measured at its surface) occur about a day after intense solar flares, it has long been believed that these storms are caused by the impact on the earth's magnetic field of streams of charged particles emitted by the sun at the time of the flare. (These particles

SKETCH 6.—Densities deduced from drag measurements on 12-ft-diameter balloon satellite, Explorer 9 (bottom curve) during February through September 9, 1961, show close correlation with ground-based-measurements of solar, or sunspot, activity (top curve) and disturbance of the earth's magnetic field (center curve). Solar radio flux (10.7 cm), which is used as index of solar activity here, appears to be roughly proportional to flux of extreme ultraviolet radiation which is the heat source (by photoionization) for the upper atmosphere. Curve of temperature at satellite perigree would be essentially identical in shape with density curve.



take just about a day to travel from the sun to the earth.) Because of the coincidence between the density spike and the spike in magnetic storm activity, it is presumed that the heat sources which are responsible for the sudden increase in upper atmosphere temperature and density derive their energy from these streams of charged solar particles.

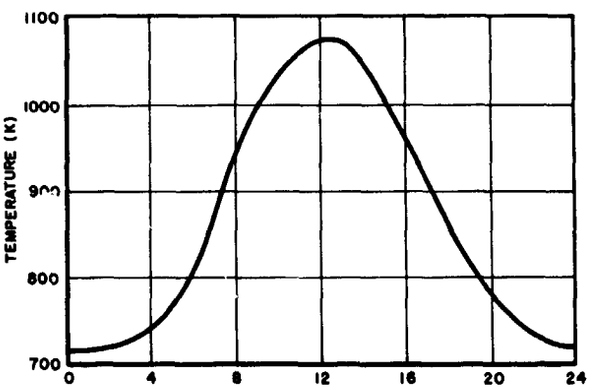
ULTRAVIOLET NOT SOLE ENERGY SOURCE

The geomagnetic activity effect, as this phenomenon is called, provides the strongest evidence we have for an energy source in the upper atmosphere other than that provided by the absorption of solar ultraviolet radiation. Because magnetic storms are comparatively infrequent, this does not constitute evidence for more than an intermittent additional heat source, and it is not yet clear whether this additional heat source (called the corpuscular heat source because it derives its energy from the solar wind) is important in determining the average conditions in the upper atmosphere.

We have mentioned how the inadequacy of our knowledge of upper atmosphere composition may introduce errors in the temperatures deduced from satellite drag data. In an attempt to obtain direct measurements of upper atmosphere temperatures, attention was turned early in the space age to rocket and satellite experiments which could determine the temperature of the electrons in the ionosphere above 60 miles. Measuring the temperature of the electrons in the upper atmosphere is considerably easier than measuring the temperature of the neutral particles (which have no charge), and techniques borrowed from plasma physics have been applied with some considerable success.

It was not clear, when the first measurements were made, whether or not the electron temperature would be equal to the neutral gas temperature. Because the mass of the electron and the

SKETCH 7.—Temperature in isothermal region above 120 miles varies during the solar sunspot cycle. Solid line shows temperature deduced from densities measured by satellite drag. Broken line shows predicted values for remainder of solar cycle (after Harris and Priester). Maximum temperature of 2200K occurs in afternoon during solar cycle maximum. Minimum temperature of 600K at dawn occurs at solar cycle minimum (solar maximum and minimum occur about 11 years apart). Recent discovery of this time variation of temperature is one reason Cospar standard atmosphere model is now undergoing revision.



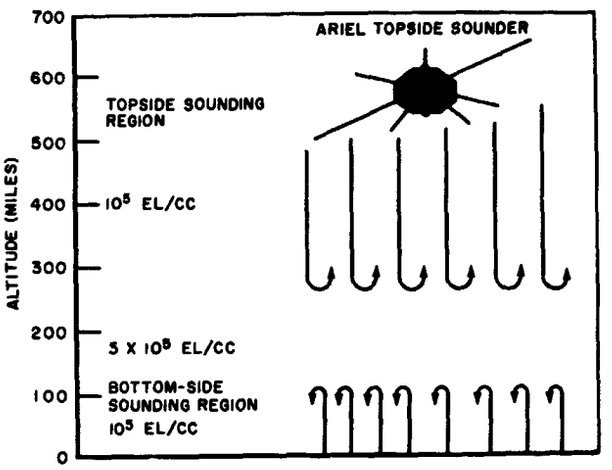
mass of the neutral particles are very different, the electron gas in the upper atmosphere is in poor thermal contact with the neutral particle gas. The early measurements indicated that the electron and neutral gas temperatures were equal above 250 miles but that during the day the electron temperature was considerably higher than the neutral gas temperature at lower altitudes. This finding was in accordance with theoretical studies which predicted that photoionization—concentrated at about 110 miles—heats the electron gas more than the neutral gas.

More recent electron temperature measurements, using the Ariel 1 and Explorer 17 satellites and the ground-based radar backscatter technique, have indicated that the early measurements were misinterpreted. The electron temperature is, in fact, greater than the neutral gas temperature at all altitudes and at all times of day.

This misinterpretation of the early measurements illustrates the danger of trusting the reference atmospheres. The early electron temperature measurements were made in 1960 and 1961 and the results were compared with the gas temperatures contained in the 1962 U.S. Standard Atmosphere—which more or less reflects conditions as they were in 1958. The comparison showed that electron and gas temperatures were approximately the same. However, by 1961 the neutral gas temperature had declined with the decrease in solar activity to values considerably below those given by the standard atmosphere.

So if the early measurements are reinterpreted in the light of our more recent knowledge of neutral gas temperatures, they agree with the latest electron temperature measurements in indicating that electron temperatures are invariably higher than the neutral gas temperatures. It is therefore not possible to determine neutral gas temperatures in the upper atmosphere by measuring the electron temperatures. Just this year, however, it has been realized that the electron temperature data present a more exciting possibility. The electron temperature, it turns out, is so sensitive to variations in the upper atmosphere heat source that it is possible to deduce the absolute magnitude of the heat source from measurements of the electron temperature.

The first work along these lines has been carried out using the Ariel 1 data, and a similar analysis is now being applied to the Explorer 17 results. These analysis provide our first direct information on upper atmosphere heat sources. It is still too



SKETCH 8.—Daily variation of upper atmosphere temperature based on satellite drag measurements of density (after Harris and Priester) in 1962. A recent theoretical treatment of this variation showed it could not be explained on the basis of an ultraviolet heat source; an additional heat source, of approximately equal mangitude, had to be postulated. Presumably this may be a corpuscular source, derived from the solar wind. Very little is yet known about this corpuscular heat source and its importance is controversial. Electron temperature measurements made by Ariel 1 and Explorer XVII may help.

early to tell for sure, but it appears that the daytime heat sources deduced from these data are consistent with the heating that would be expected to result from the absorption of solar extreme ultraviolet radiation. There is no clear evidence in the daytime results of a non-ultraviolet or corpuscular heat source. On the other hand, the electron temperature measurements show clearly that there must be a nighttime source of energy which, while only one percent of the daytime heat source, is still enough to raise electron temperatures a few hundred degrees above the neutral gas temperatures. Since this heat source cannot be attributed to the action of solar ultraviolet radiation, it provides strong evidence for the existence of a non-ultraviolet heat source at night. This nighttime energy source may well be provided by a flux of low energy electrons bombarding the atmosphere from above.

ONLY CONDUCTION IS IMPORTANT

Whether the upper atmosphere heat source is provided by ultraviolet radiation or bombarding electrons or both, the neutral gas temperature is ultimately determined by the rate at which heat transport processes can remove the heat which the sources release. Since both convection and radiation cooling are unimportant, thermal conduction is all that is left to remove heat from the upper atmosphere. In a gas, conduction is a notably inefficient process of heat transport. So it doesn't require a large heat source to maintain the very high temperatures which are found at great altitudes. In fact, the solar extreme ultraviolet radiation, which is believed to provide the major source of heat at high altitudes, carries an energy flux of only about 3 ergs/sq cm/sec. For comparison, the energy flux in the visible region of the solar spectrum—which is responsible for heating the ground and the lower atmosphere—is a million times as large.

The heat which is deposited by the solar ultraviolet radiation at about 110 miles is conducted from this high temperature region down to the very low temperature (200 K) mesopause. At the mesopause a heat sink is provided by infrared-radiating molecules of water and carbon dioxide—which are relatively abundant at low altitudes. The balance between the rate at which heat is conducted to the mesopause and the rate at which heat is put into the upper atmosphere is what determines the temperature of this higher region. The theoretical problem is in principle quite straightforward, although sophisticated computational techniques are made necessary by the fact that the heat sources vary with time and with the density and composition of the upper atmosphere, and the fact that these latter quantities in turn depend on the temperature.

SKETCH 9.—Electron density in ionopshere falls of above and below electron density maximum at 200 miles altitude. Numbers on chart indicate density in electrons per cu cm. Density measurements, made from the ground by radio wave reflections, have long been confined to bottom-side sounding region because no radio waves are reflected to earth from above the density maximum. With advent of satellites capable of making radio soundings from above, electron density measurements of the topside have become possible.

A recent theoretical treatment of the diurnal variation of upper atmosphere temperature showed that the observed temperatures could not be explained on the basis of an ultraviolet heat source alone. It was necessary to postulate an additional heat source, presumably corpuscular, equal in magnitude to the ultraviolet. Although it is too early to say for sure, this conclusion may conflict with the deductions from electron temperature measurements. In any event, we need more positive evidence—not simply a disagreement between experimental and theoretical values of temperature—to prove the importance of the corpuscular heat source.

The problem with postulating a corpuscular source is that the charged particles of the solar wind cannot penetrate beyond the boundary of

the earth's magnetic field at about 40,000 miles altitude and thus cannot interact directly with the upper atmosphere. Although the Mariner 2 measurements have told us what the energy flux in the solar wind is, there have been no similar measurements which could tell us how much of the solar wind energy is able to cross the boundary and travel down through the earth's magnetosphere, to show up as a heat source in the upper atmosphere at altitudes of 100–200 miles.

TURBULENT INTERACTION NOT YET PROVEN

It is presumed that there must be a turbulent interaction between the solar wind and the earth's magnetic field leading to the production of hydromagnetic waves, or fluxes of energetic charged particles, which travel down through the magnetosphere and deposit their energy in the upper atmosphere. But there are no quantitative theoretical treatments of any of these processes which would let us estimate the magnitude of the corpuscular heat source.

Several attempts have been made to locate flaws in the theoretical treatment of the heat conduction equation in the upper atmosphere in the hope that these flaws might account for the disagreement between the measured temperatures and the temperatures calculated with an ultraviolet heat source only. To date none of these attempts have been successful, and the discrepancy stands as one of the most interesting recent results in upper atmosphere physics. What it amounts to is this: we do not yet understand the physics of the upper atmosphere well enough to be able to calculate, from first principles, temperatures which agree with the measurements.

Calculation of the temperature is the fundamental goal of atmospheric structure theory because the temperature profile controls the pressure and density profiles through the requirement of hydrostatic balance. So a calculation of the temperature profile leads at once to the determination of overall atmospheric structure. In addition, because the energy sources responsible for temperature changes also lead to changes in chemical composition, an adequate understanding of the temperature and the energy sources which it reflects necessarily implies a thorough understanding of the chemical composition of the atmosphere. This goal is closely related to the immediate practical problem of predicting the conditions which are likely to be encountered by our space probes in the atmosphere of the other planets.

Selected Bibliography

INFERENCES OF STRATOSPHERIC AND MESOSPHERIC CIRCULATION SYSTEMS FROM ROCKET EXPERIMENTS*

G. WARNECKE† AND W. NORDBERG

Recently performed rocket grenade experiments at Wallops Island and Churchill and MRN data are interpreted to show the existence and movement of conventional circulation systems throughout the upper stratosphere and mesosphere. Evidence of moving pressure systems exists up to an altitude of 70 km where the nature of the circulation changes abruptly. Also, the pattern of the pressure systems in the stratosphere (below 50km) seems to be different from the pattern inferred at higher altitudes (50—70 km.)

INTRODUCTION

Since the early rocket grenade experiments more than ten years ago and the successful firings during the IGY period, the experiments have been continued by NASA at Wallops Island. Thus a large number of soundings is available giving already a climatological survey on the gross features of the winds and the thermal structure in the upper stratosphere and in the mesosphere (1) (2). Experiments have also been performed in Australia, Japan, Sweden, Italy, and France and the United States program will be extended to include simultaneous launchings at Churchill, Wallops Island, and Ascension Island. (3) The number of rocket stations reporting data above the normal Meteorological Rocket Network (MRN) levels is gradually increasing promising an improving global data coverage for the levels between 50 and 90 kilometers during the forthcoming International Geophysical Year (IQSY). In this report, interesting features are derived from the first simultaneous rocket grenade experiments performed at Churchill, Manitoba, and Wallops Island, Virginia, and from simultaneous Meteorological rockets launched at the various MRN sites over North America. While the earlier sporadic experiments enabled a study of climatological gross features of the mesospheric circulation, these simultaneous observations have encouraged us to investigate the dynamic structure of the mesosphere on a smaller scale by means of synoptic presentation of flow patterns for selected days over the North American continent. At the higher altitudes, the acoustic temperature and wind measurements were supplemented by other sounding techniques such as wind measurements by means of sodium vapor release.

THE VERTICAL CHANGE IN STRATOSPHERIC AND MESOSPHERIC WIND STRUCTURE

Considering the seasonal variations of stratospheric and mesospheric winds as measured at Wallops Island over a period of 3 years, one finds a remarkable change in the behavior of mesospheric winds around the height of 70 km. Below this level, the wind follows a consistent and predictable seasonal pattern while above 70 km the wind structure becomes very irregular and does not show the well-known regular features observed at levels up to 70 km (2).

This fact is apparent in figure 1, where all rocket grenade winds for the years 1960 through 1963 are presented in polar diagrams for the lower, middle, and upper mesosphere. The winds in the 45–55 km layer show the same general features as in the stratosphere: strong and relatively steady westerly winds with maximum deviations of $\pm 25°$ about an average direction of 265° and light but equally steady easterly winds in summer. During the transitions between winter and summer sea-

†Goddard Space Flight Center; on leave from Institut für Meteorologie and Geophysik der Freien Universität Berlin, Berlin, Germany, as National Academy of Sciences-National Research Council Research Associate with National Aeronautics and Space Administration.

sons, there is a large variability in wind strength and direction; however, this variability is still part of a consistent seasonal pattern which has been the subject of several previous analyses (4). In the middle mesosphere (60–70 km) one finds qualitatively the same behavior, although varia-

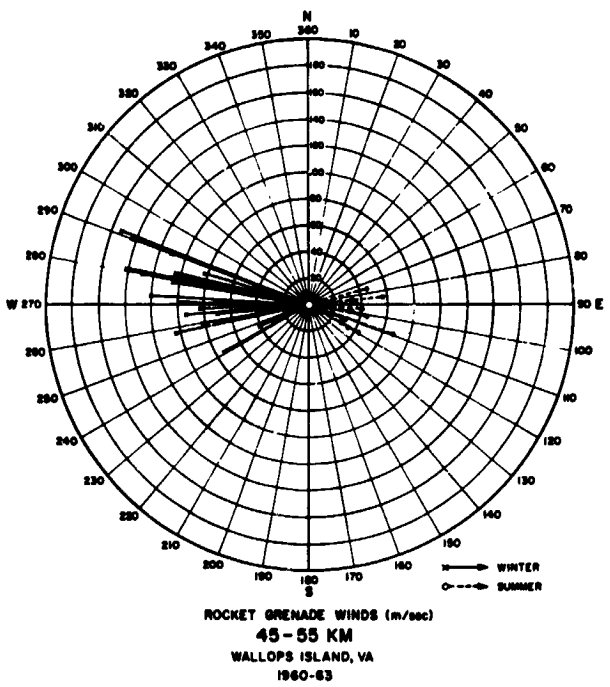

FIGURE 1A.

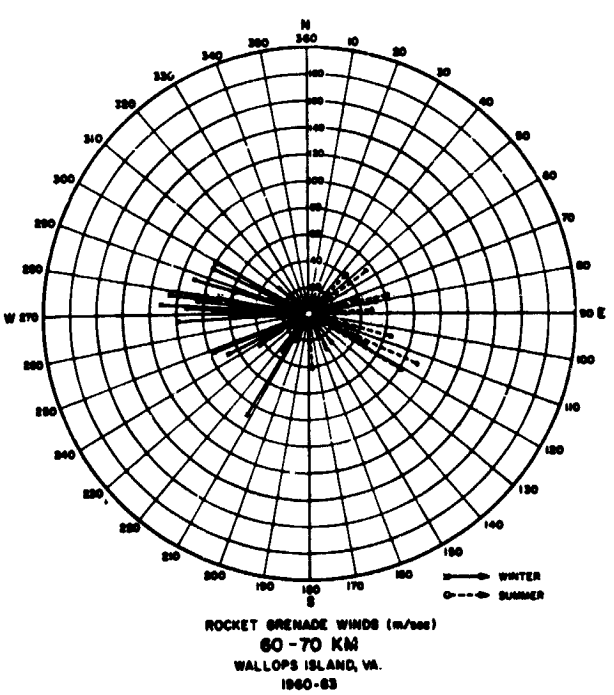

FIGURE 1B.

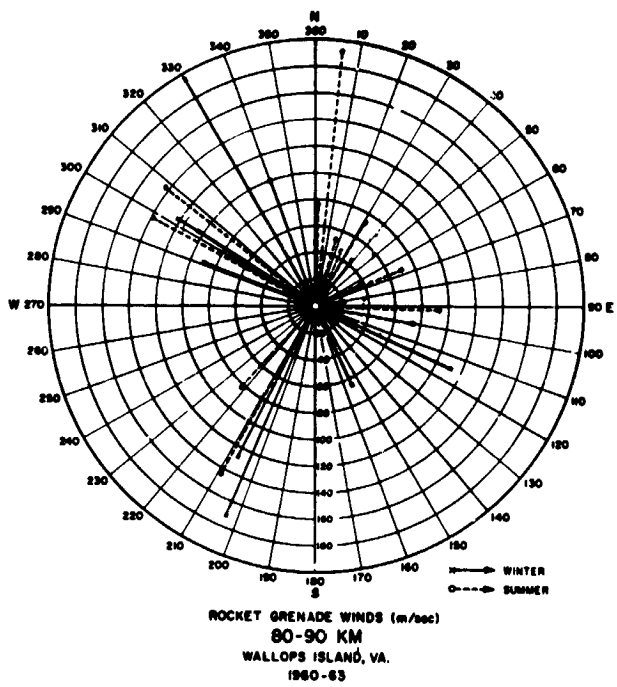

FIGURE 1C.

tions in the wind directions are somewhat larger. In the upper mesosphere (80–90 km), however, the picture changes completely. The winds both in winter and summer are blowing from all directions and in highly variable strengths. The same characteristics are shown by the results of recent sodium vapor release experiments at Wallops Island (5). In figure 2 wind direction profiles from five experiments reaching below 70 km are reproduced, and the drastic change in wind structure between 70 and 80 km is apparent.

From these rocket observations with both the grenade and sodium release methods, one may conclude that above a transition layer between 70 and 80 km the dynamic behavior of the mesosphere becomes so complex that synoptic representations of the flow patterns on a Time scale of days will be meaningless. On that scale, the motions above this layer appear to be highly "disorganized" and it seems that for synoptic presentations Time scales of the order of an hour or so will have to be employed at altitudes higher than 80 km. Therefore, such an abrupt change in the wind structure may very well be due to the increasing importance of tidal motions and possibly in the fact that the atmospheric structure as a whole undergoes basic and major changes at the 80 km level.

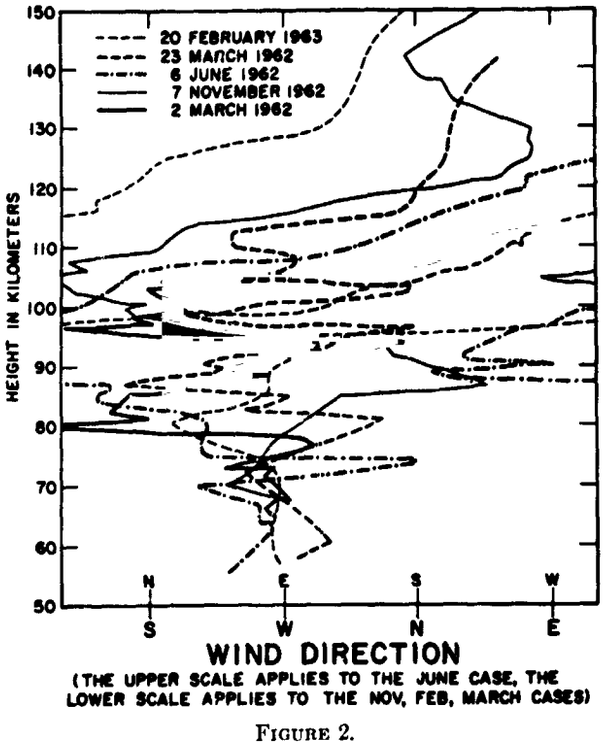

FIGURE 2.

Nevertheless, up to this level the mesospheric motions are still organized in the usual meteorological sense, and synoptic presentations are quite justified and well representative of the strea patterns over periods of several days.

INFERRED MESOSPHERIC SYNOPTIC CIRCULATION SYSTEMS UP TO 70 KILOMETERS

Several investigators have already extended presentation of synoptic weather maps up to the 0.5 or 0.4 mb level (about 55 km) by using Meteorological Rocket Network data (6), (7), (8), (9). In this paper, an attempt is made to construct synoptic maps up to the 0.05 mb level (68 km) for a few special days by making use of recent grenade and MRN data.

Data from the first simultaneous rocket grenade soundings at Churchill and Wallops Island, in early December, 1962, (10) were analyzed in addition to Meteorological Rocket Network data (11) also available for that time period. Variation of flow and pressure patterns for various upper stratospheric and mesospheric levels over the American continent were investigated by constructing synoptic maps for 4 December and 6 December, 1962. In these maps, the pressure fields at constant heights are presented. Using the geostrophic approximation, the isobars were spaced such that each pressure field is in accordance with the observed winds. The pressure values of the isobars were determined by the observed pressures over the discrete points of observation.

The circulation in the lower stratosphere (100 mb or 16 km) around 5 December, 1962, was characterized by the displacement of the cold polar vortex to Siberia, the entire North American continent being under a rather uniform westerly stratospheric flow with a slowly developing trough moving gradually eastward over the United States (figures 3) (12). The middle stratosphere (30 mb or 23 km) (figure 4) shows a quite different stream pattern over the entire western hemisphere (13) with a weak but, nevertheless, unusual quasi-stationary anticyclone over Canada and a zonally oriented trough over the United States along 40 deg. latitude. In the upper stratosphere (10 mb or 30 km) the same contour pattern appears with greater intensity: the easterly wind at the southern flank of the Canadian anticyclone exceeds 25 m/sec (50 knots), whereas a stratospheric jet stream with winds up to 50 m/sec (100 knots) is located over the Gulf coast (figure 5). There are no significant changes of the circulation pattern at 30 km within the period of December 4–6, 1962, so that figure 5 applies to this interval. The North American high pressure systems represent an eastwardly displaced Aleutian anticyclone that governed the Northern hemispheric circulation throughout November (14) and is still apparent at the 5 mb surface, which was constructed for 5 December, 1962, (figure 6). The 40 km pressure maps (figure 7) show the pronounced trough over the Great Lakes area moving slowly southward, whereas the existence of the Canadian anticyclone is not necessarily indicated at this level. Its center may well have shifted to the Pacific region, Alaska and Canada being in the regime of the polar vortex. The anticyclone can still be observed ten kilometers higher (figure 8), and here there is a definite indication that its center has shifted northward, causing a nearly northerly wind over Churchill on 4 December and a southwesterly wind over Alaska. Although the stream pattern remains essentially the same at

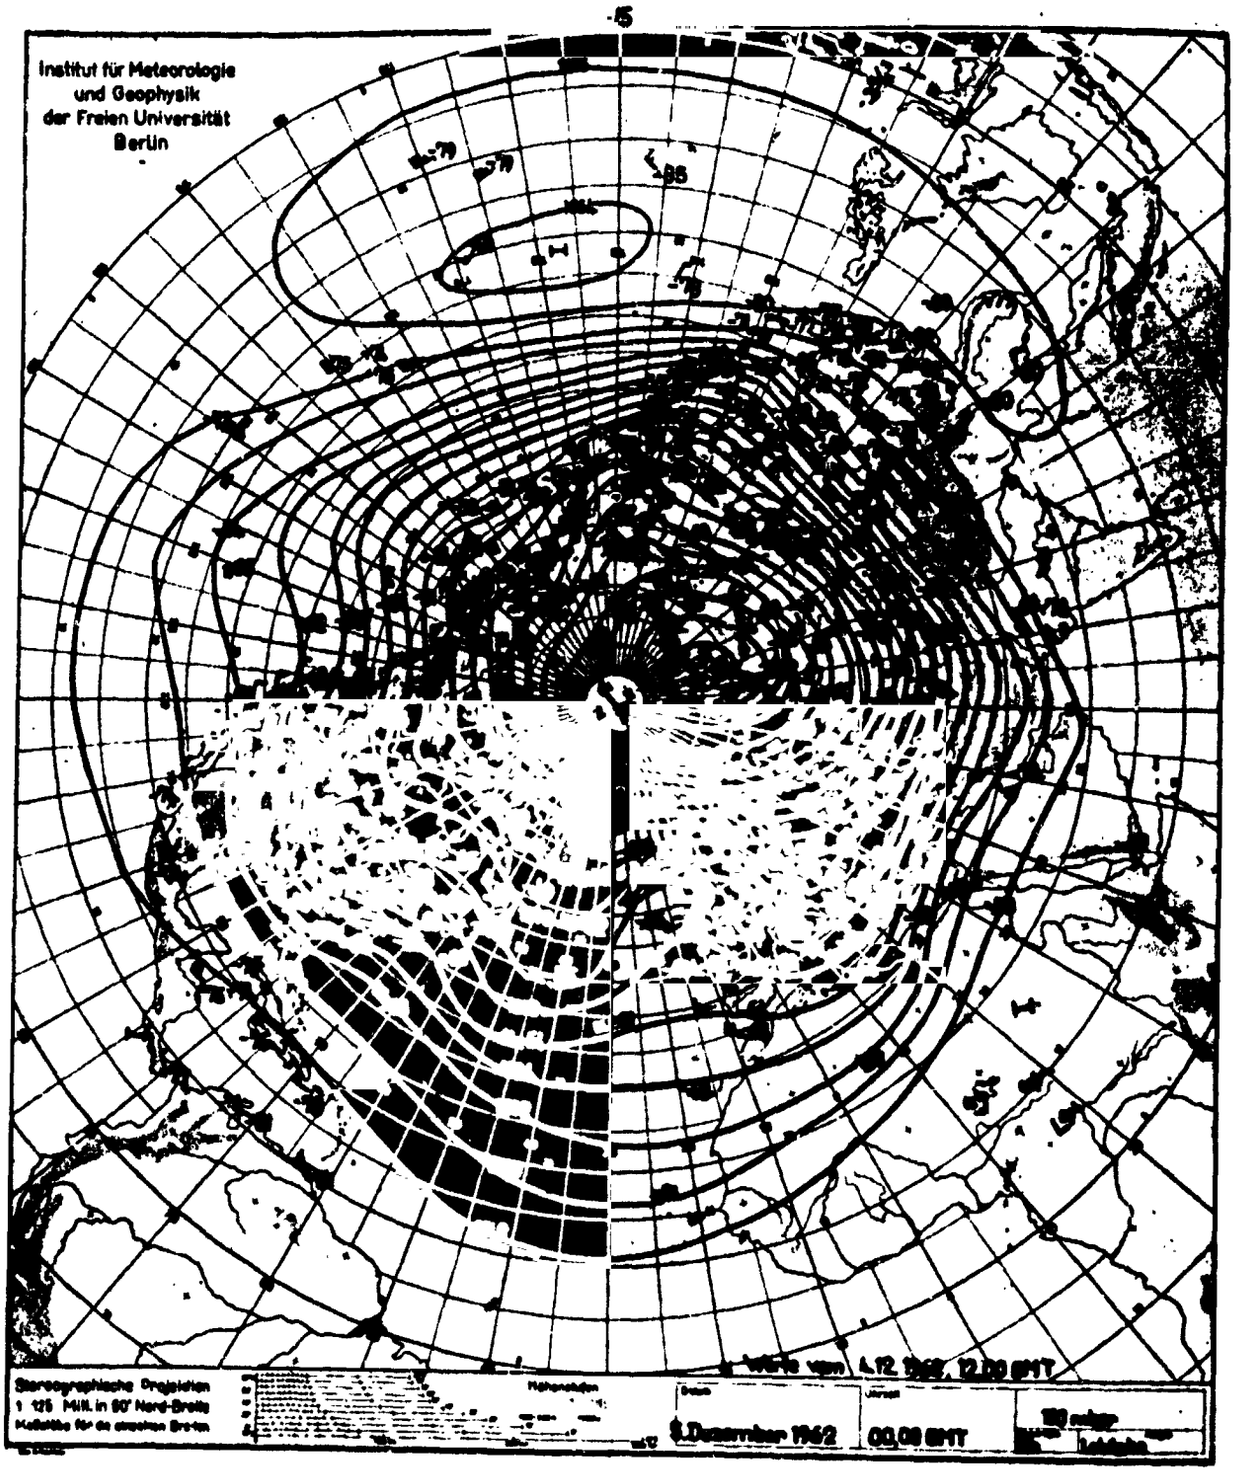

FIGURE 3

60 km (figure 9), there is a distinct further shift in the position of the center of the anticyclone. It is apparently displaced to the Arctic, as indicated by the southeasterly wind over Alaska. The pronounced trough, which has persisted at all altitude levels from 23 km up, is still located over southern Canada; and there is some indication that its vertical axis is slightly inclined to the

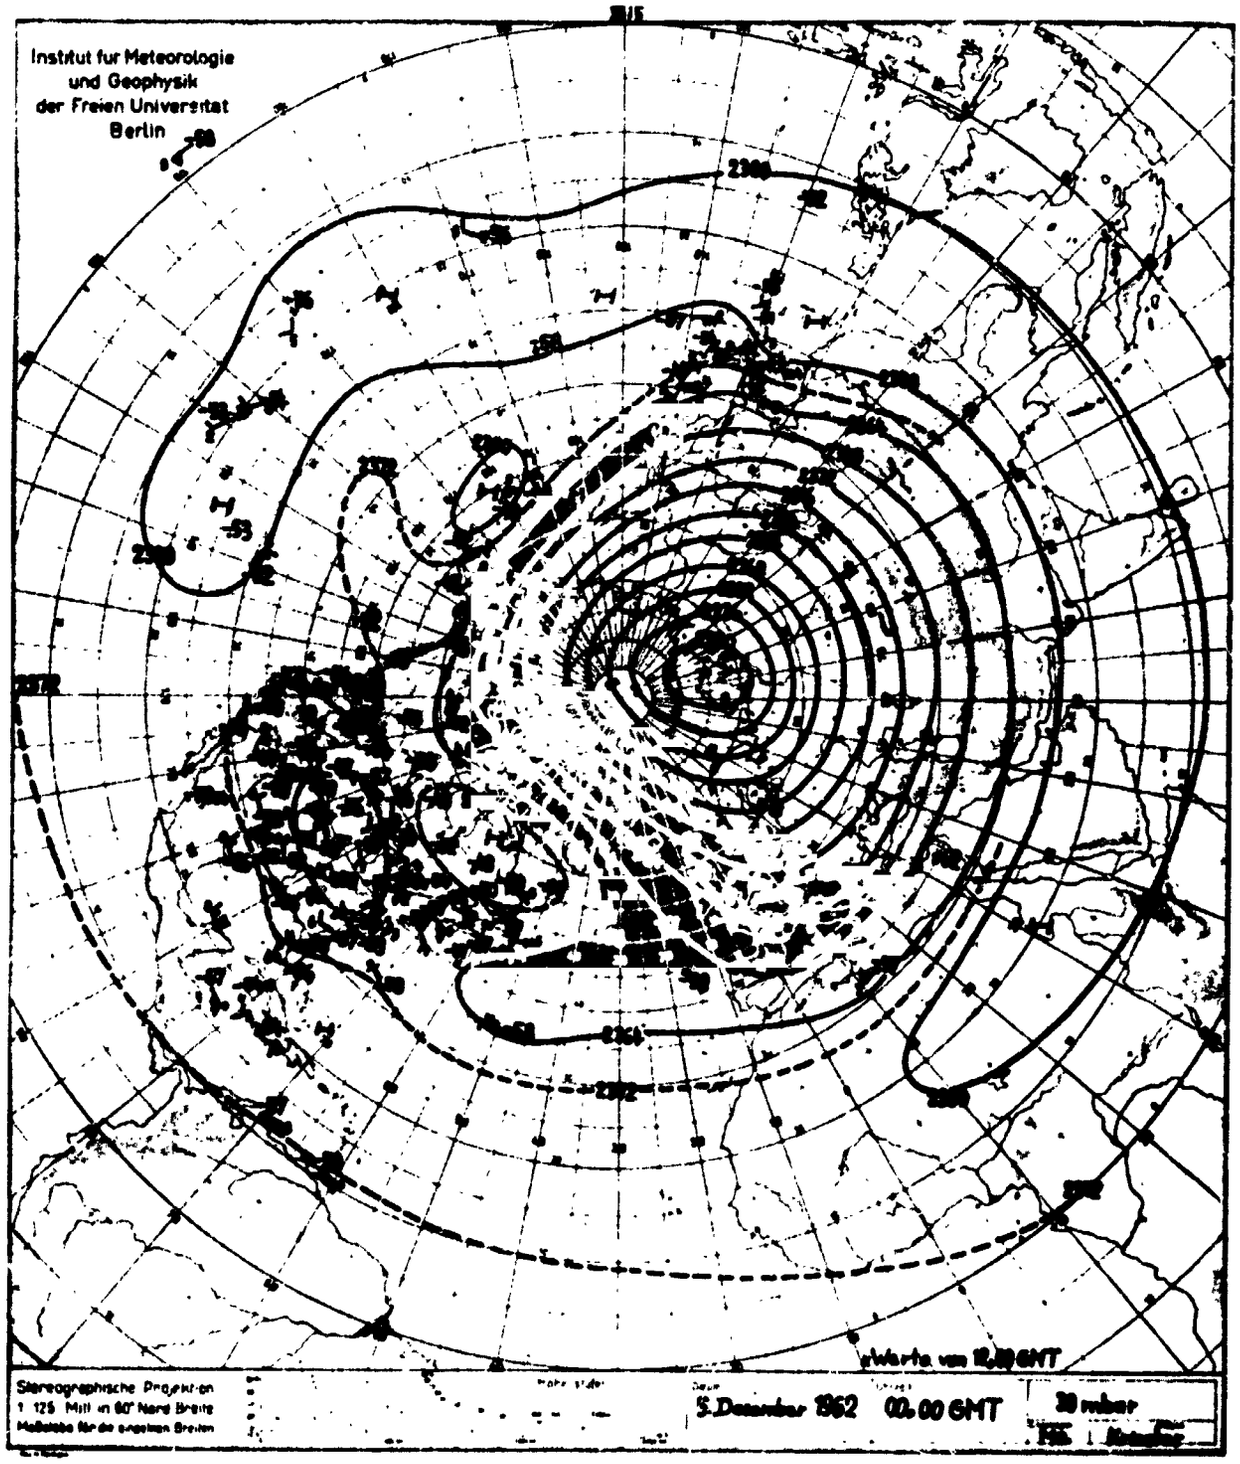

FIGURE 4

north, such that at 60 km the trough has taken the position of the ridge in the stratosphere (20 to 35 kilometers).

At 60 km (figure 10) data are very sparse and are mainly based on grenade soundings at Churchill and Wallops Island. There is evidence that the zonally oriented trough over North America still exists, as indicated by strong winds from the

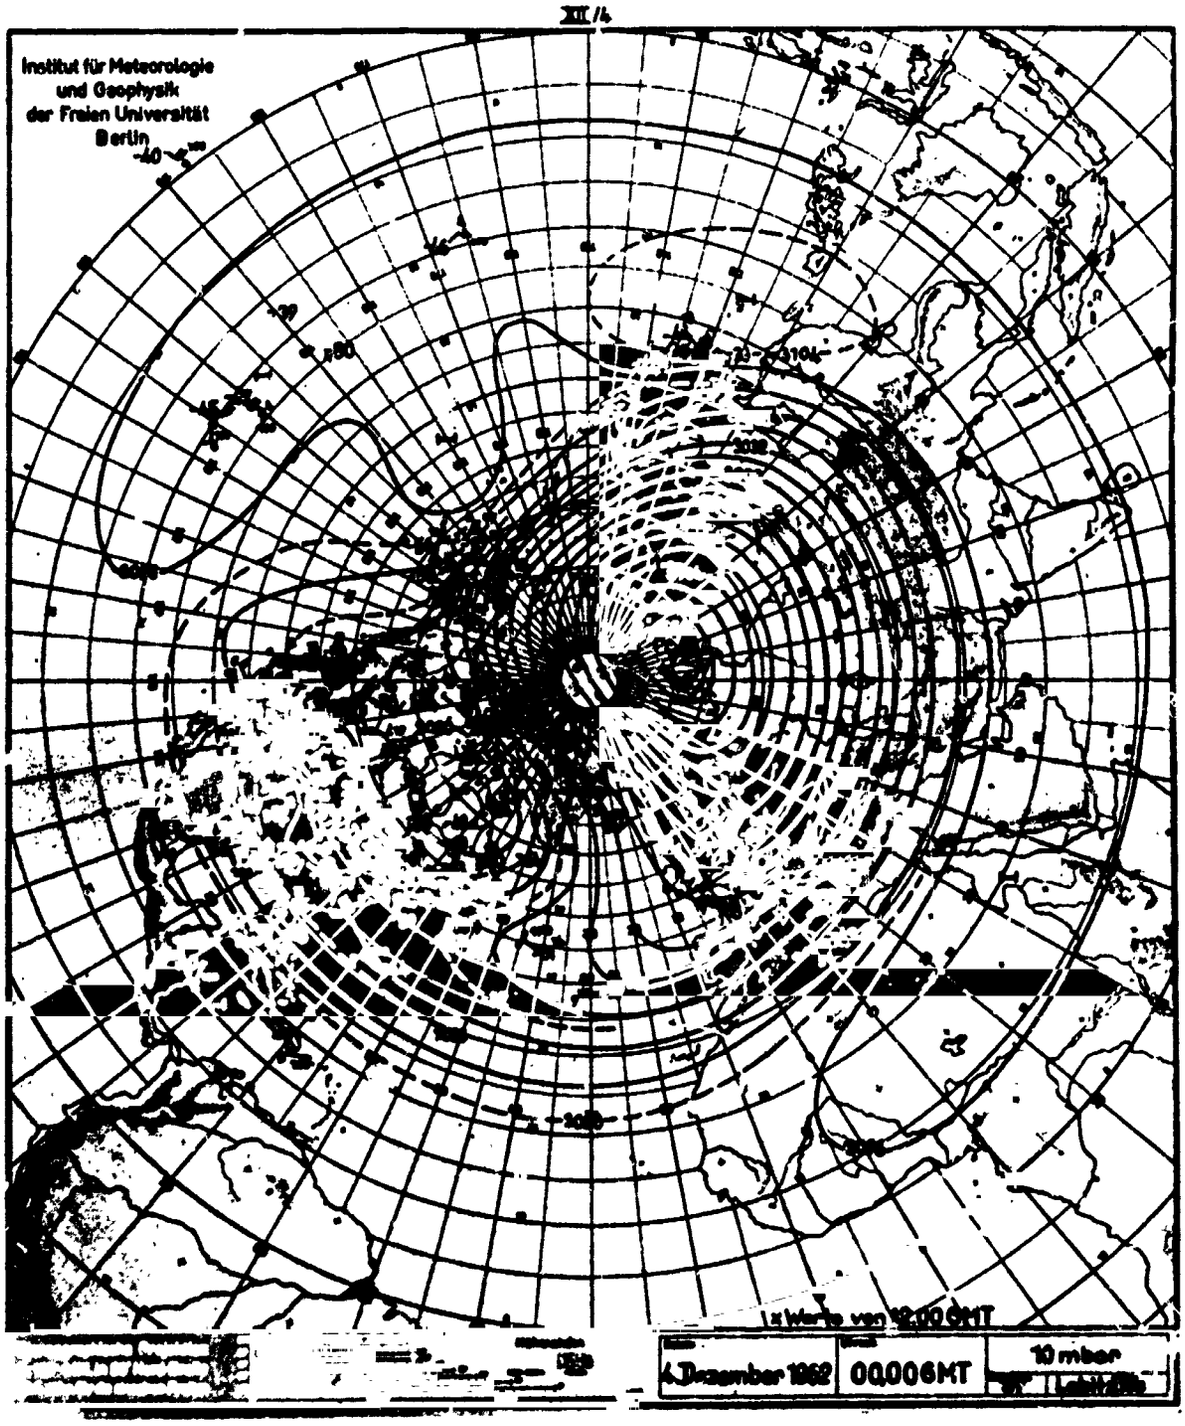

FIGURE 5

west south-west over the United States and very light northwesterly wind inside the trough over Churchill on 4 December, 1962. In general, it is interesting to note the alternation between low and high pressure systems on a vertical scale between the 30 and 60 km levels as shown in figures 5–10. This seems to confirm the theoretical expectation of such alternations previously expressed by Paetzold (15).

Differences in the flow and pressure patterns between 4 December and 6 December were found to be insignificant at 40, 50, and 60 km. This is

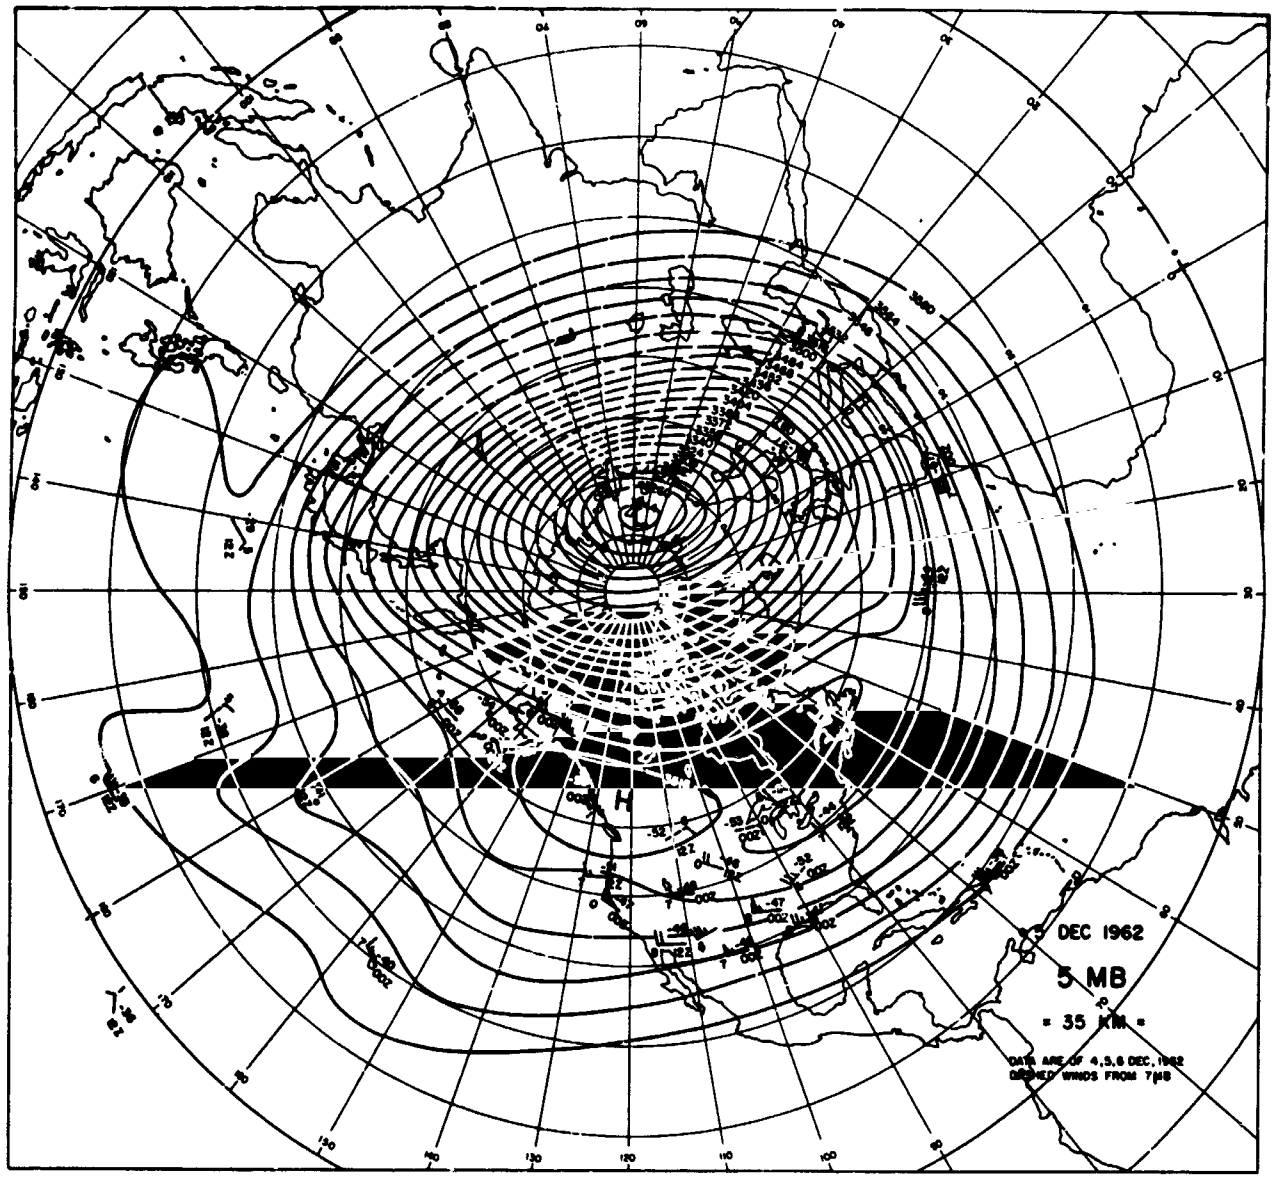

FIGURE 6

not surprising because the patterns in the stratosphere also remained nearly unchanged. At 68 km, however, a significant change seems to have taken place between 4 December and 6 December over Churchill and 1 December and 6 December over Wallops Island. There is a 90 degree rotation of the wind vectors at both stations, but at Churchill this rotation is clockwise, while at Wallops Island it is counter clockwise. This may be interpreted as a southwestward motion of the low pressure system (figures 10A, 10B).

Of course, the sparsity of data permits only a very crude analysis even in this case, which could be considered well documented by rocket sounding standards. Nevertheless, this case shows that significant nonuniformities exist in the slopes of the constant pressure surfaces which are generally inclined downward toward the winter pole. If in the past such uniformity was assumed, it was only because the available data were not sufficient to observe any detail. It is to be expected that systematic rocket observations of the mesosphere extended over the hemisphere and spaced over distances in the order of 1000 km will reveal up to about 70 km circulation systems of similar variability and variety as observed at lower altitudes.

"EXAMPLES OF CERTAIN DATA REDUCTION AND MAPPING PROCEDURES UTILIZING TIROS III FIVE-CHANNEL RADIOMETER DATA"*

LEWIS J. ALLISON AND GUENTER WARNECKE†

Selected examples of current data reduction and mapping procedures are discussed for the purpose of demonstrating their utility as well as their limitations.

INTRODUCTION

In order to analyze and accurately interpret the TIROS radiation data, certain data reduction and mapping processes are described which should be of interest to the researcher and meteorologist alike.

A brief description of the 5-channel scanning radiometer is included for the benefit of the reader who may be unfamiliar with the TIROS radiation experiment.

1. THE FIVE CHANNEL SCANNING RADIOMETER

The TIROS III scanning radiometer consists of a five-channel instrument. The five channels are sensitive in the following spectral regions:[1]

Channel	Spectral Region	
1	6.0 to 6.5μ	(radiation within the ν_2 fundamental water vapor band)
2	8 to 12μ	(radiation emitted in the atmospheric "window")
3	0.2 to 6μ	(total reflected solar radiation (albedo))
4	8 to 30μ	(total infrared radiation of the earth-atmosphere system)
5	0.55 to 0.75μ	(reflected solar radiation within the visible part of the spectrum)

The 5-channel radiometer employs a chopper that causes each sensor to view alternately and at a rapid rate, in two directions 180 degrees apart. At least one direction always views outer space which serves as a zero radiation reference. The response from each channel is proportional to the difference in the irradiation of the sensor bolometer from the two directions. When both optics view outer space, the resultant signal is designated as the "space viewed level". The bi-directional axes of the channels are parallel to one another and inclined to the spin axis by 45 degrees (Figure 1).[2]

2. REMARKS ON THE DATA REDUCTION AND MAPPING PROCEDURES

2.1 Equivalent Blackbody Temperature

The calibration of the infrared channels is in terms of equivalent temperatures, T_{BB}, of a blackbody target filling the 5° field of view, whereas the calibration of the solar channels is in terms of that portion of radiant emittance from a target filling the field of view to which the channel responds through its filters and other optical elements.[2]

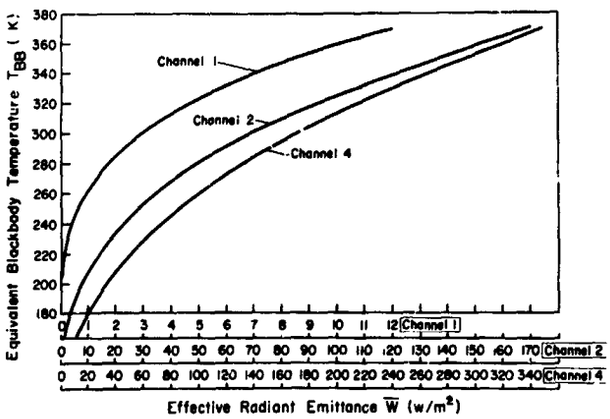

FIGURE 2.—The effective radiant emittance of the thermal channels of the Tiros III radiometer versus equivalent blackbody temperature.

The family of curves of equivalent blackbody temperatures vs effective radiant emittance for TIROS III (Figure 2), were obtained by integrating the Planck function over the spectral response curves for Channels 1, 2 and 4.[1,3] The estimated relative accuracy of equivalent blackbody temperature for Channels 1, 2 and 4 is ±2°K, while the estimated absolute accuracy is ±4° to ±8°K, up to orbits 118, 875 and 130 respectively, after which degradation of the instrumental response becomes appreciable.[1,4]

A degradation correction nomogram for Channel 2 measurements (Figure 3), based upon degradation models inferred from the relevant data obtained by the respective radiometer has been included.[4] The nomogram was developed from a computer program which determined the time rate of change of the measured total emitted radiant power between latitudes 55°N–55°S. The results showed that Channel 2 degraded continuously following the TIROS III launch. The degradation for Channel 2 was determined to be symmetrical, i.e., independent of the side (wall or floor aperture) of the satellite. The nomogram (Figure 3) may be used with some degree of confidence up through orbit 875. Beyond this subjectively determined limiting orbit, the correction nomogram becomes correspondingly uncertain. A more detailed discussion of the factors effecting the response of the scanning radiometer may be found in Reference 5.

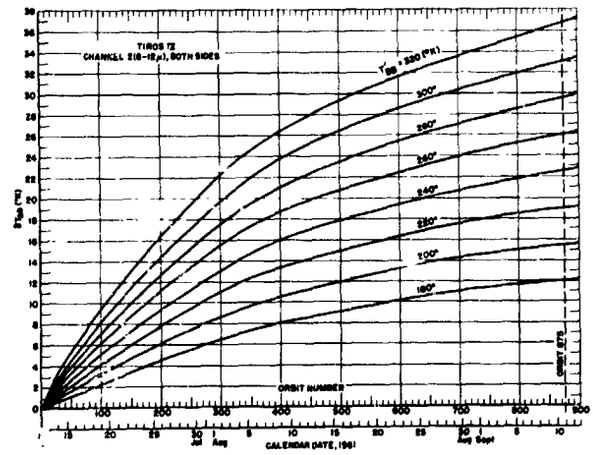

FIGURE 3.—The empirically-developed correction nomogram for instrumental degradation of Channel 2, Tiros III.

2.2 The Radiation Data Processing Procedure

The medium resolution radiometer data that are recorded at the read-out station are demultiplexed, demodulated and fed to an analog-to-digital converter at the Goddard Space Flight Center.[2] This converter produces a magnetic "Radiation Data Tape" made up of 36 bit words suitable for an IBM 7094 computer. Analog records may be produced on a recording oscillograph for special hand analysis. The computer produces a Final Meteorological Radiation Tape (FMRT) when combined with the inputs from the Radiation Data Tape, Orbital Tape and Calibration. The most convenient method of presentation of these FMRT data is to make grid point maps from an IBM 7094 computer. Several problems arising in the composition and averaging of the original radiation data are discussed below.

2.3 Radiation Data Resolution

The data resolution of computer produced radiation maps, printed on a mercator map base is directly affected by the following:

2.3.1 Nadir Angle Variation

Radiation data contained on the FMR Tapes are sampled approximately 8 times per second. Thus, at the nominal 10 rpm spin rate, approximately 48 samples are taken during each satellite rotation. Data sampled during the earth-viewed portion of the scan having the smallest nadir angle will be the most densely located, with progressively greater separation occurring at the higher nadir angles. Additionally, the size of the scan spot varies considerably with the nadir angle and with the height of the satellite. For example, at an 800 km satellite height (Figure 4) the elongated scan spot resolved by the radiometer at a 56.6° scan nadir angle, would enclose approximately 10 times the scan spot area at a scan-nadir angle of zero.[6] Thus the higher the radiometer nadir angle, the lower the data resolution.

Figure 5 shows that the nominal 5 degree field of view of the radiometer pertains to the 50 percent of peak-response level, and that there is some residual response to about ±4 degrees from the optical axis.[7] The percent power scan spots of Figure 4 are directly derived from this response curve.

2.3.2 Grid Print Map Scale

The mesh size of the multi-resolution mercator mapping program is 0.5 inches. Thus, the number of degrees of longitude per mesh interval is in effect the selection of the map scale. A resolution of 0.625°, 1.25° and 2.50° of longitude per mesh interval corresponds to a map scale of approximately 1:5 million, 1:10 million and 1:20 million, respectively, near the equator. On a mercator projection the map scale, the higher the

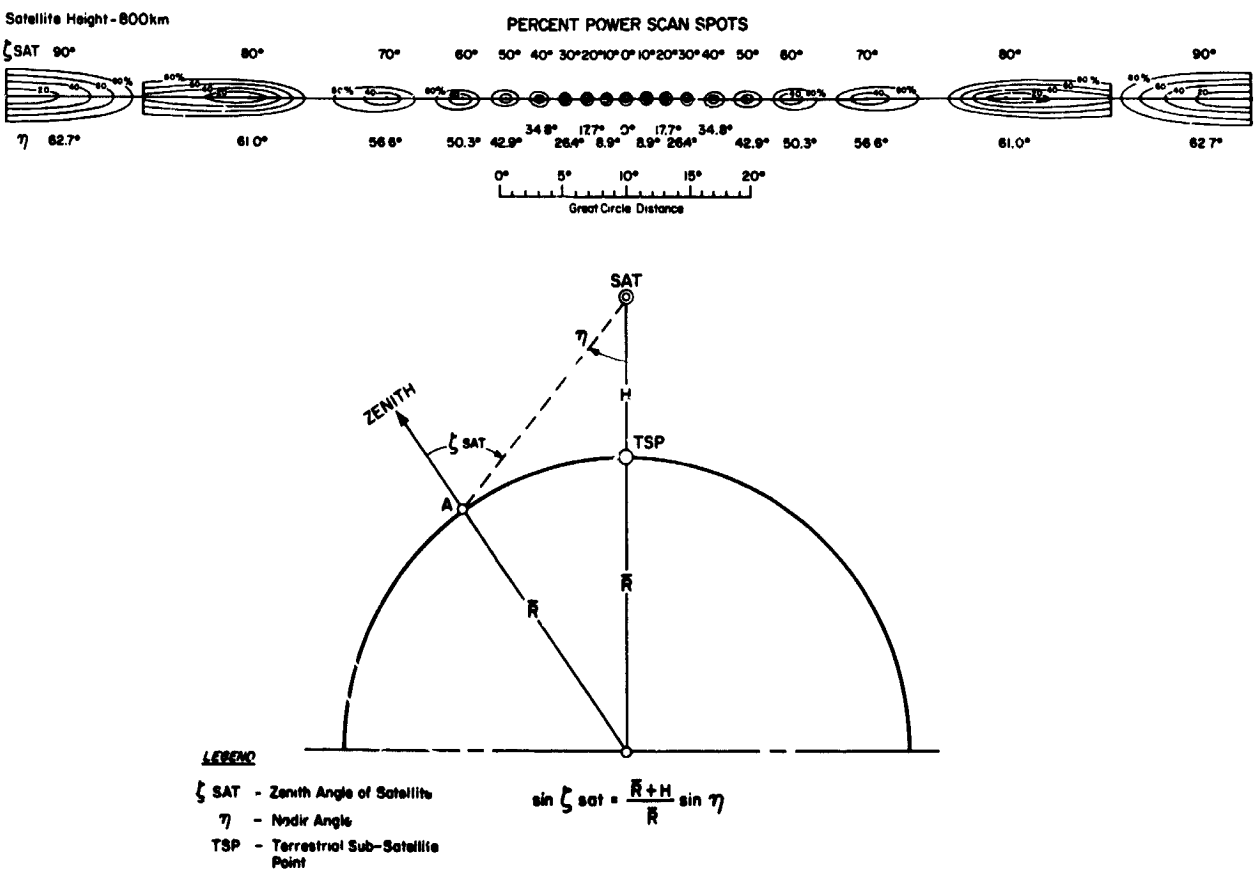

FIGURE 4.—Satellite zenith and nadir angle relationship. a.—Scan spot size as a function of zenith and nadir angle of the sensor and the power distribution within the scan spot. b.—Zenith angle and nadir angle relationship.

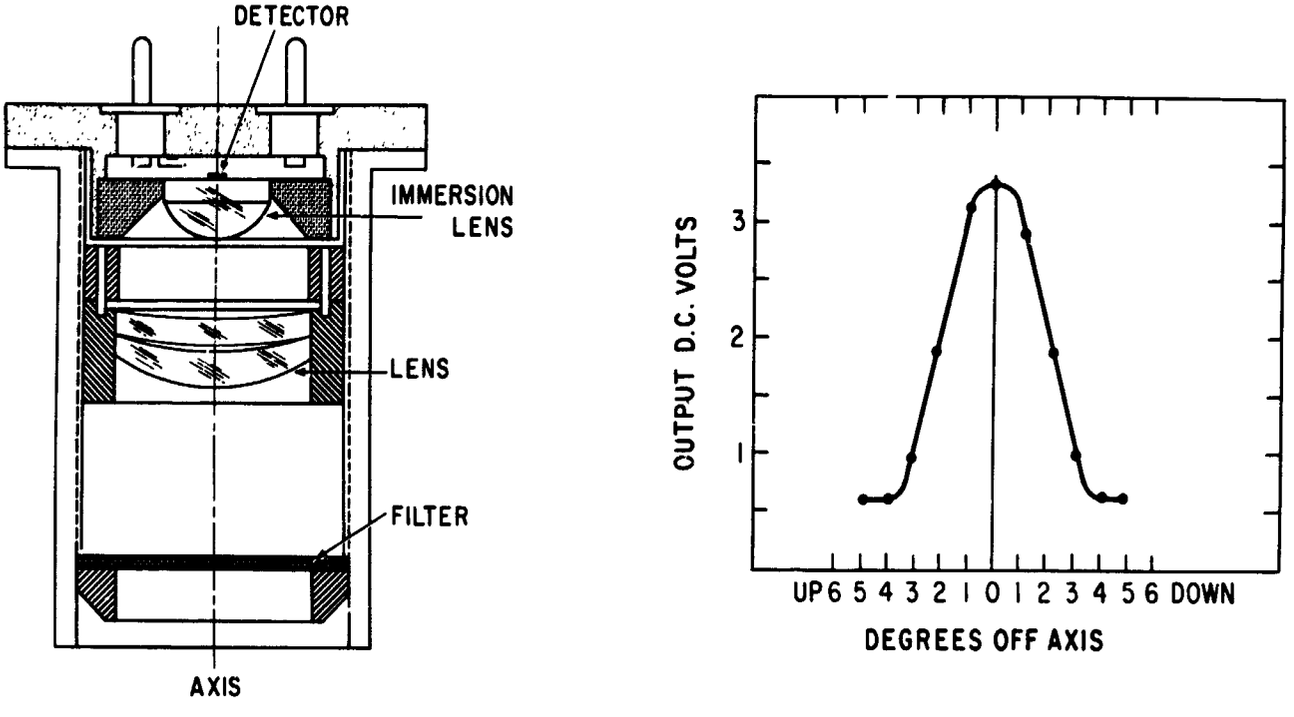

FIGURE 5.—Cross-section through a detector unit of the Tiros III radiometer and response curve within the field of view

resolution, the lower the number of measurements averaged with the ½ inch area around each grid point.

In order to illustrate the effect of map scale on data resolution, several TIROS III television pictures and radiation charts are shown in the following. The well-defined cloud system at 10°N, 40°W on July 16, 1961, which was identified by S. Fritz[8] as being the cloud mass from which Hurricane Anna, later developed in July, 1961, was selected as the example.

Figure 6a shows the "window" radiation analysis based upon hand-plotted data from a computer listing, which contains the geographical location, the nadir and azimuth angles, and the simultaneous readings of all five radiation channels for every single scan spot. The location of each scan spot is indicated by a cross in Figure 6a. This is the most detailed information available from the FMR Tape.

Figure 6b is a composite of the "window" radiation field shown in the previous figure and the gridde TIROS photograph of the same area. The latitude-longitude grid of this picture was obtained from a computer program.

The agreement between the picture information and the radiation field in the "window" region is surprisingly good, even at the fringes of the

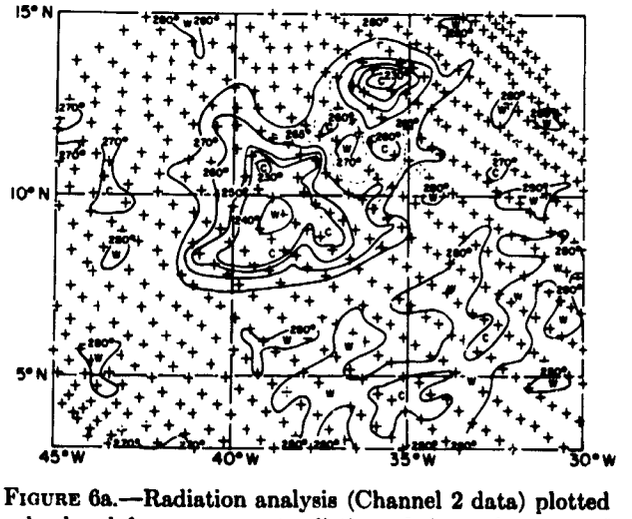

FIGURE 6a.—Radiation analysis (Channel 2 data) plotted by hand from a computer listing of the early stage of Hurricane Anna, which was used for the composite in Figure 6b.

photograph. Considering the range of accuracy of satellite attitude determination and the computer gridding programs, it is interesting to note that the radiation data fit the television pictures within one degree of latitude and longitude. An equivalent blackbody temperature difference of more than 50°K was indicated between the cloudless area and the highest cloud tops.

A similar radiation analysis (Figure 6c) was later performed by L. F. Whitney, Jr. of the

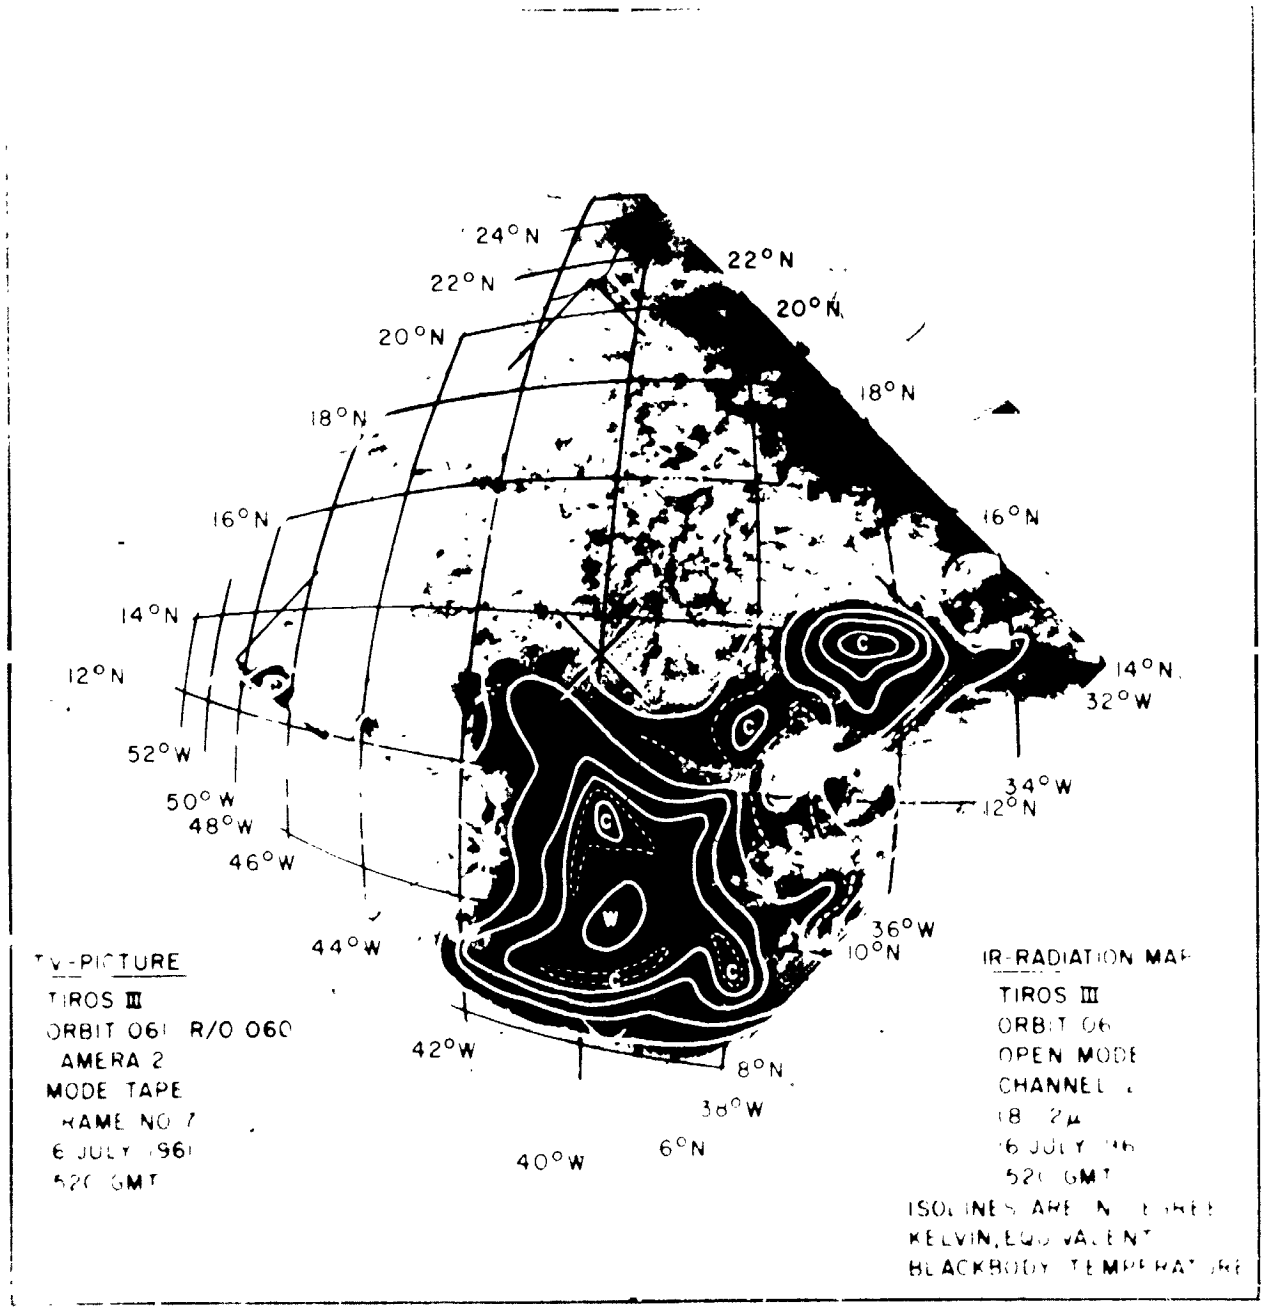

FIGURE 6b.—Composite analysis of Channel 2 radiation data and a gridded television picture of the early stage of Hurricane Anna.

National Weather Satellite Center, U.S. Weather Bureau, using the highly accurate Fujita method.[6] This method employs analog records produced on a recording oscillograph for special hand analysis rather than the automatically processed FMR Tapes. It should be considered, however, that this picture represents another frame of the same series, one minute later in time. From Figures 6b and 6c one can judge, that, at least in this case, the evaluation of the FMRT data does not result in any significant loss of details when compared with the results of the Fujita technique.

Figure 7 shows the radiation analysis of the same storm area based on three different types of computer produced grid maps at three different grid spacings, viz., 0.625°, 1.25°, and 2.50° longitude per mesh interval, corresponding to approximate map scale of 1:5 million, 1:10 million and

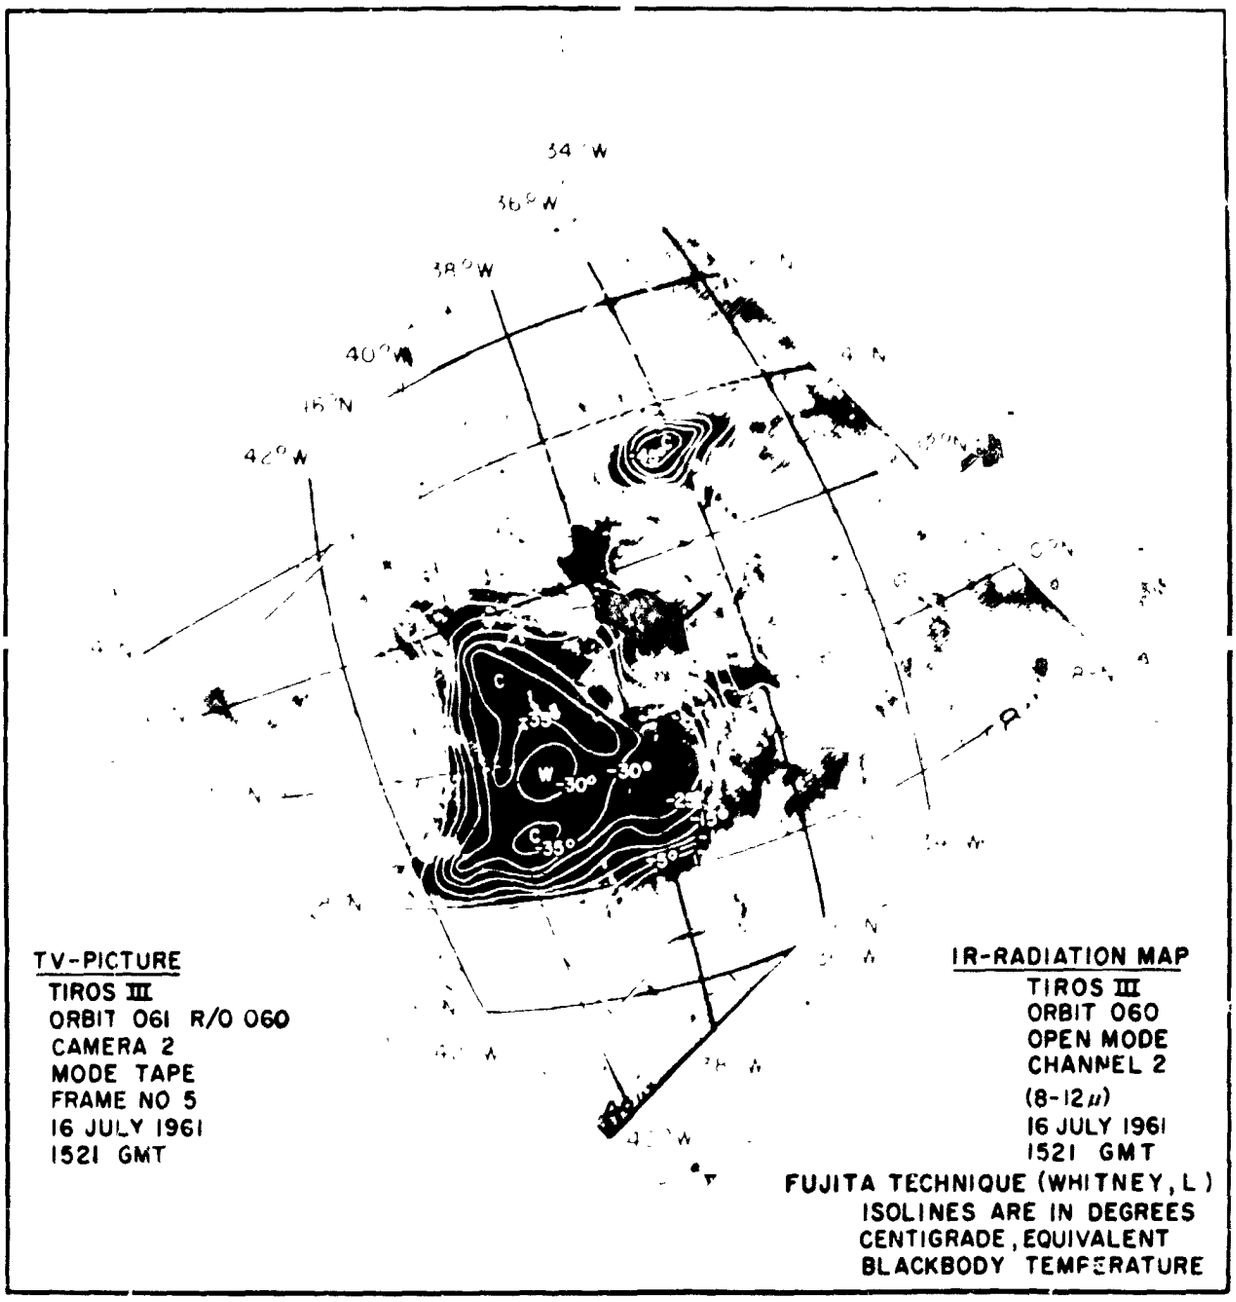

FIGURE 6c.—Composite analysis of Channel 2 radiation data and a gridded television picture of the early stage of Hurricane Anna, using the Fujita Technique by L. F. Whitney, Jr., U.S. Weather Bureau.

1:20 million respectively. The data points are again indicated in each figure. From the left to the right it becomes clear that the appropriate selection of the map scale for each radiation study is of great importance, as detailed features in the isoline configuration and extreme values of equivalent blackbody temperatures become "washed out" by the averaging processes involved at smaller map scales. Thus, for the analysis of more detailed synoptic features, a grid spacing of 0.625° of longitude per mesh interval is the most useful one, but the accuracy in data location is considerably less than by use of hand-plotted maps of the FMRT computer listings and of maps produced by the more precise Fujita method.

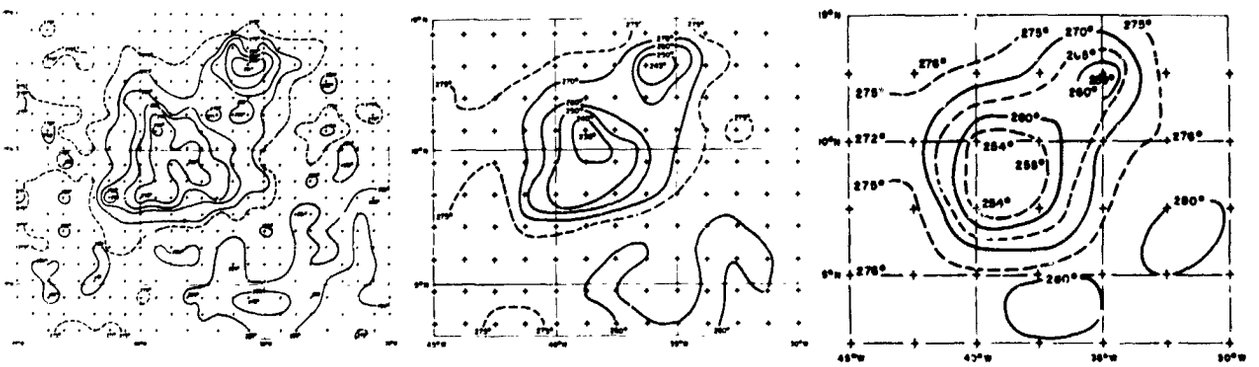

FIGURE 7.—Analysis of Channel 2 radiation data of the early stage of Hurricane Anna, using different resolutions in computer-produced grid print maps (Open mode data only).

b.—1.250° longitude/mesh interval
c.—2.50° longitude/mesh interval

2.4 Radiometer Scanning Modes

Figure 1 showed the basic relationships between the satellite's spin axis and the radiometer axis.

As the satellite rotates on its axis, the radiometer scan pattern is defined by the intersection of a 45° half-angle cone and the earth. This pattern ranges from nearly a circle (closed mode) when the satellite nadir angle is less than17°, to two hyperbola-like branches in the "wall" and "floor" directions, when the spin vector is approximately perpendicular to the orbital radius vector.[1]

Therefore the three patterns of earth scanning modes, (Figure 8) can be distinguished as follows.[9]

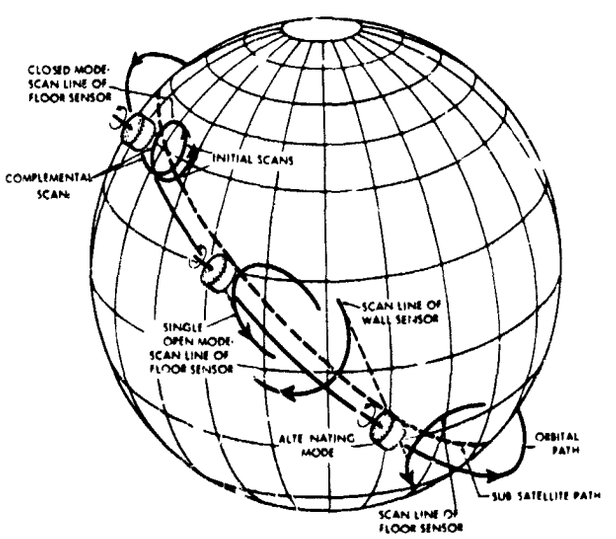

FIGURE 8.—Different types of scan modes of the Tiros radiometer generally occurring in one orbit.

1. Single Open Mode: Some scan spots of a spin cycle are space viewed and the remainder are earth viewed through the wall (side) sensor only or through the floor (baseplate) sensor only.

2. Closed Mode: All the scan spots throughout a number of spin cycles of the satellite are earth-viewed, either through the wall or the floor sensor.

3. Alternating Open Mode: The scan spots of a spin cycle are alternately viewed through the wall sensor and the floor sensor.

The IBM 7094 computer can easily be programmed to distinguish between different modes and to use or omit certain scanning modes. For example, in Figure 9 for orbits 56 and 58, those parts with single open mode data are grey shaded, and it is obvious that large and important parts of the data coverage are lost if closed mode data are omitted. Some examples of actual scan lines and scan spots are indicated on orbit 56. Additionally in this figure, the computer grid print map of orbit 57 is introduced, showing the full data coverage along the orbital path. However, there is a significant difference in accuracy of the geographical location between open and closed mode data, which reduces the applicability of closed mode data unless a very detailed investigation of possible short-term aberrations of the pseudo-spin rate value used in the computer reduction of the closed mode data is performed for every individual case. In the following

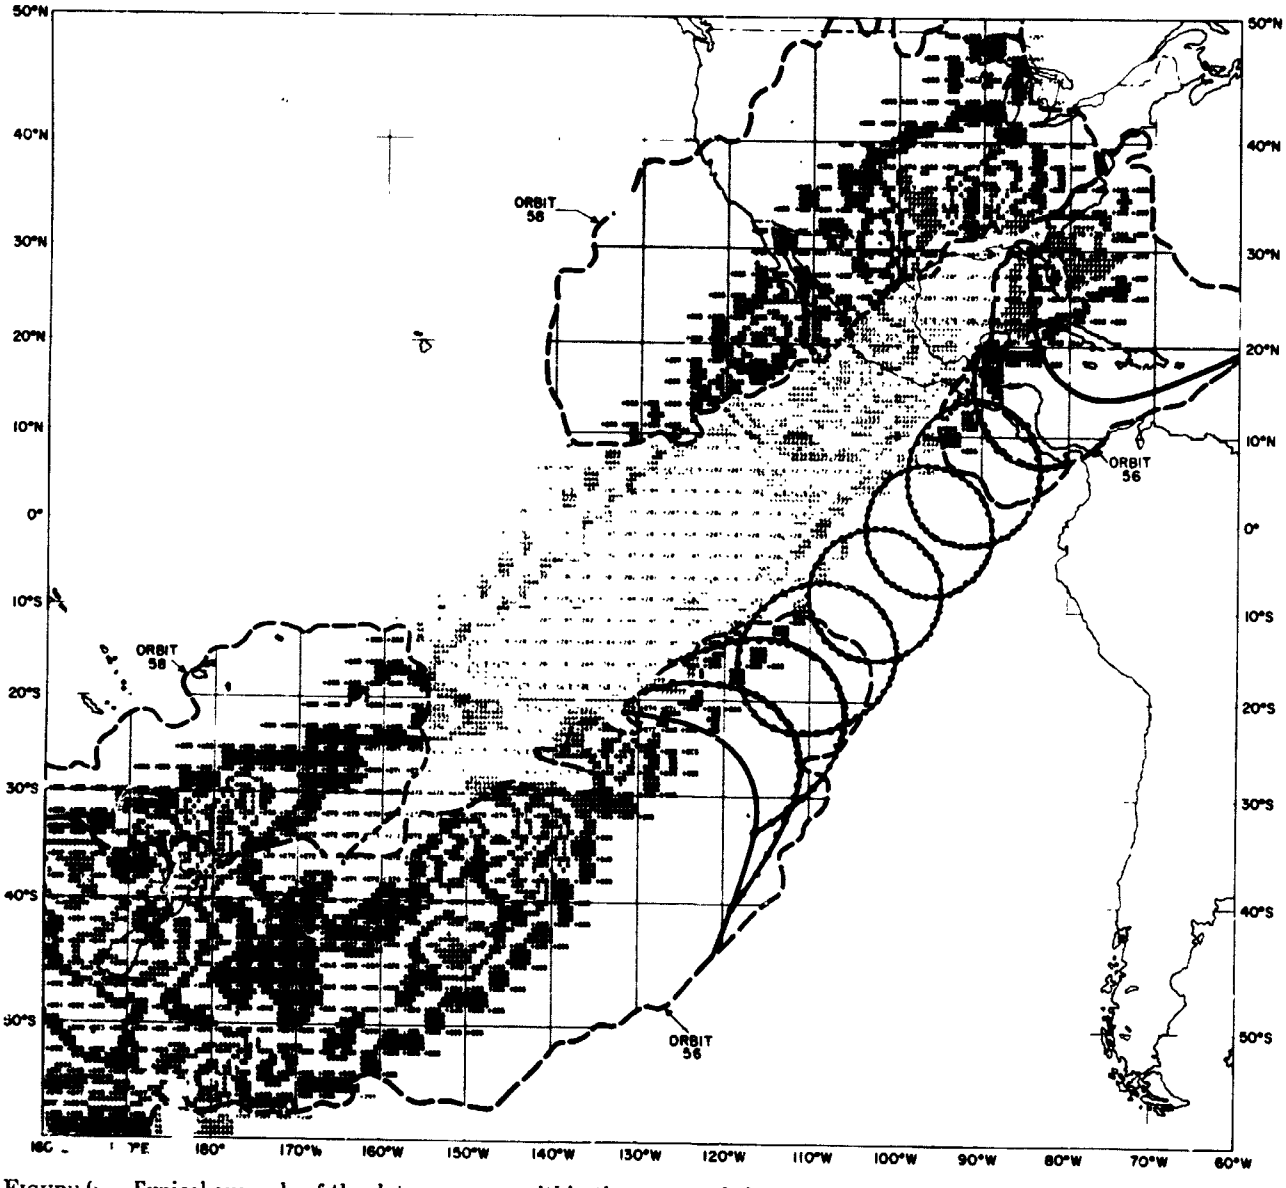

FIGURE 9.--Typical example of the data coverage within the open and closed scanning modes for three orbits of Tiros III. Some typical scan lines and the distribution of computer-selected scan spots along these lines are added for demonstration of some characteristic features of scan line geometry.

sections these practical difficulties will be discussed more in detail.

An example of typical closed mode data mislocation is given in Figure 10. This figure includes 10 minutes of closed mode data and shows the radiation "cloud" pattern of the early stage of Hurricane Anna at the same location within minutes of the same time as shown in Figure 7, which included open mode data only. This longer time period permitted the complemental scans of the closed mode to follow by several minutes the initial scans through the storm area (see Figure 8), resulting in an apparent shift of data leading to the figure. The floor aperture of the satellite was viewing the storm at this time, and a 6 scan spot shift in a counterclockwise direction was confirmed by diagnostic methods. The computer program averaged the displaced scan spot data with the preceding accurately positioned open mode scan spots and presented and erroneously elongated cloud structure.

A separate example of analog presentations of open and closed mode patterns is shown in Figures 11 and 12. Line A identifies the measurement

obtained when viewing the perinadir in an open mode swath. This line is centered between the horizons of the swath and all the scan spots are positioned symmetrically about this line by the computer program, in accordance with the spin rate. Normally there can be little or no error in positioning these scan spots since each swath is processed individually and the horizons for each are determined quite accurately. For the closed mode swaths, mislocation errors do occur simply because there are no horizons detected by the satellite and the location of the data must be determined solely by the spin rate.

The spin rate used in the data reduction program is measured by means of counting cycles of a standard clock at the read-out station between

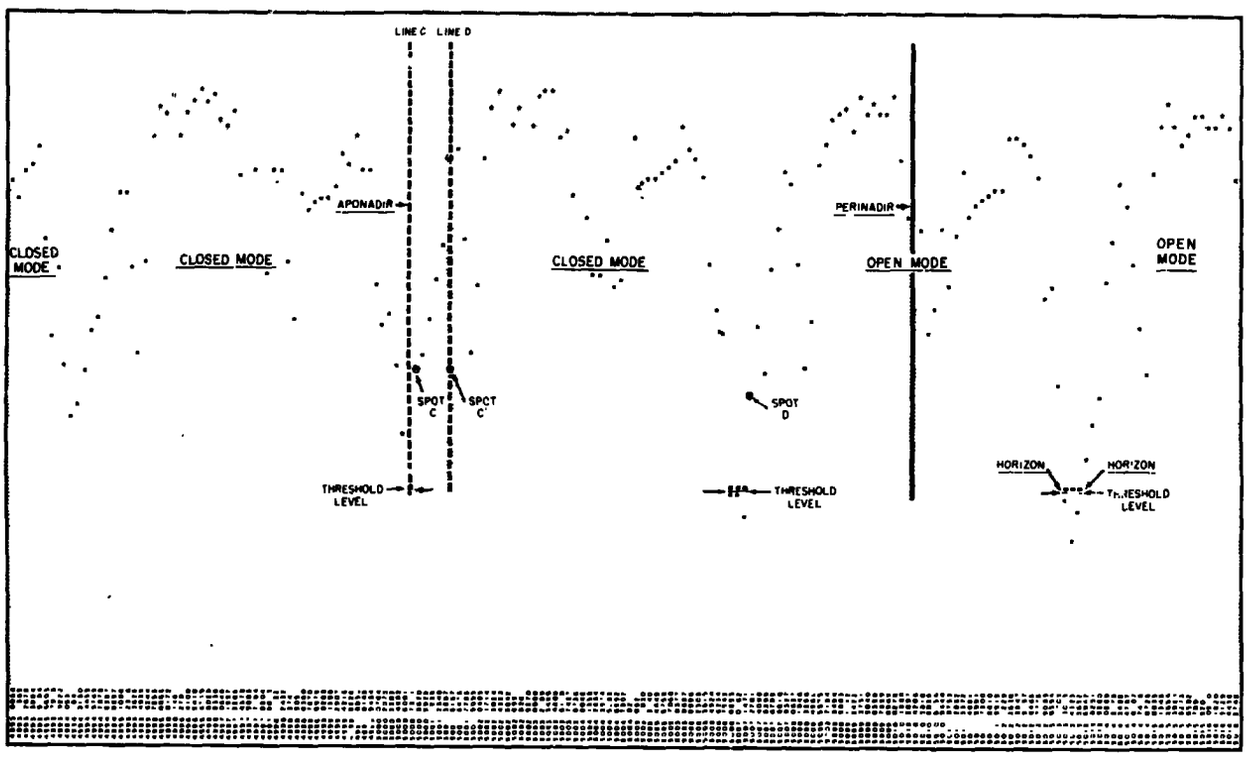

FIGURE 12.—Digitized form of the analog signal from Channel 2 during the transition from closed to single open scanning modes. The numbers along the bottom indicate the minutes and seconds from the beginning of the data. The ordinate is the radiometer output on a relative scale.

sun pulses and is assumed to be constant throughout the closed mode. For a spin rate determination error of 0.01°/sec (or 1 part in 6000), the spin angle error at the end of 10 minutes would be 6°, or about equal to one scan spot.[9]

The computer program is such that the first scan spot (Spot B) after the last open mode swath is positioned on the aponadir (Spot B'), a shift backward of 2½ scan points or about 15° of the spin angle.

All succeeding scan spots in the swath are shifted proportionally which results in a shift of the radiation data by 2½ scan spots (approx. 200 km). Figure 13 illustrates this mislocation in relation to geographic position, giving, however, examples for points close to the centers of the swaths. The measurement at point H of the first closed mode swath, which should be contiguous to that of point G within the last open mode swath, will be mislocated by the computer and appears in the wrong position H'. Comparing the last closed with the first open mode swath, point I should be contiguous to the measurement at point J; in this instance however, it was mislocated by the computer and shifted into the wrong location I'.

The 1½ to 2½ scan spot shift that occurs at the beginning of the closed mode is always counter to the rotation of the swath. If the spin rate used in the computer program is less than the actual rate, the mislocation of successive scan spots will be counter to the scan rotation. If the assumed spin rate is greater than the actual, the mislocation will be in the direction of the scan rotation.

The spin rate used for the 7 orbits in this study were all less than the actual rate, so that by the end of the closed mode, the mislocation averaged six data points or about 36° of the spin angle counter to the direction of scan rotation. Therefore, all scan spots were shifted backwards so that by the end, they were 6 spots too far in back of the true position. Thus, for example, spot C′ was erroneously located on the aponadir, (Figure 12) instead of on its correct position which should have been 6 spots ahead of the aponadir.

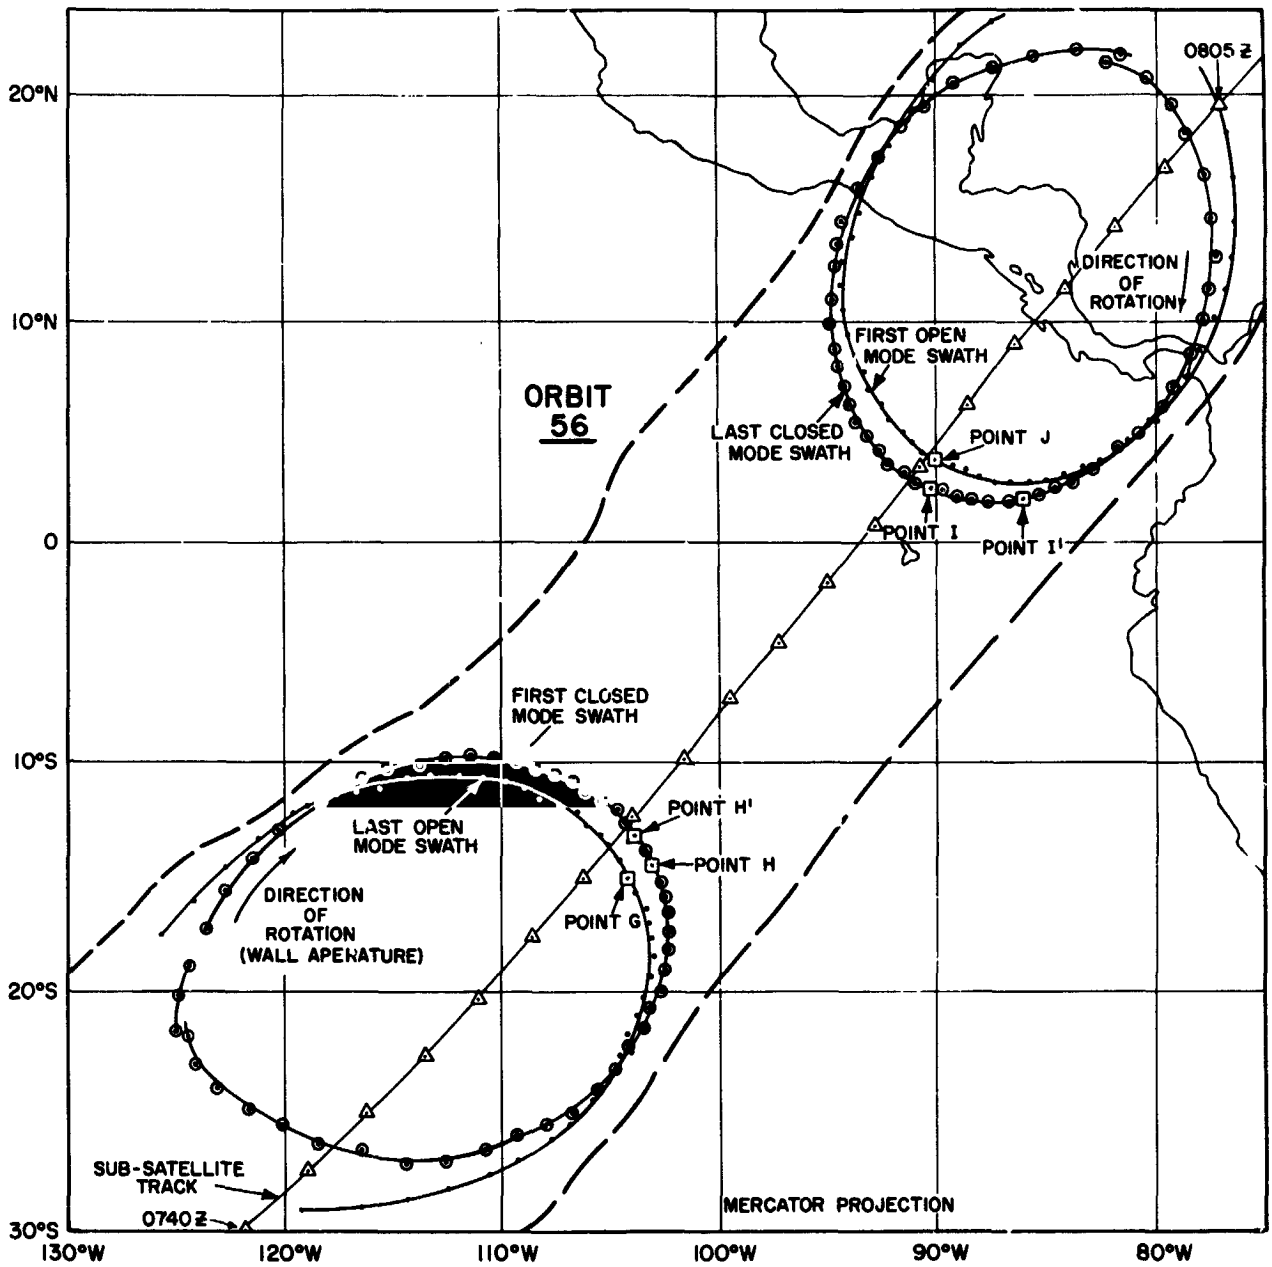

FIGURE 13.—An example of the scan spot shift at the entrance and exit from the closed scanning mode due to computer program techniques and inaccuracy in spin rate determination.

In order to improve the accuracy of location of the closed mode data, steps have been initiated to calculate the psuedo-spin rate values which should be individually applied to each closed mode sequence in the automatic reduction of the data.

2.5 Measurements Falling Below the Space-earth Discriminant

For the reasonable interpretation of the recorded radiometer signals it is necessary to distinguish very carefully between earth-scanned data and space-viewed or space-contaminated data. Therefore, the computer logic was set to make the distinction by means of an arbitrarily defined threshold value below which the data should be defined as "space viewed". Theoretically, this space-earth discriminant should be identical with the space viewed level and be located far from all atmospheric data. Practically, however, it is necessary to define the threshold value above the noise level of the radiometer system. Normally, there is no interference with

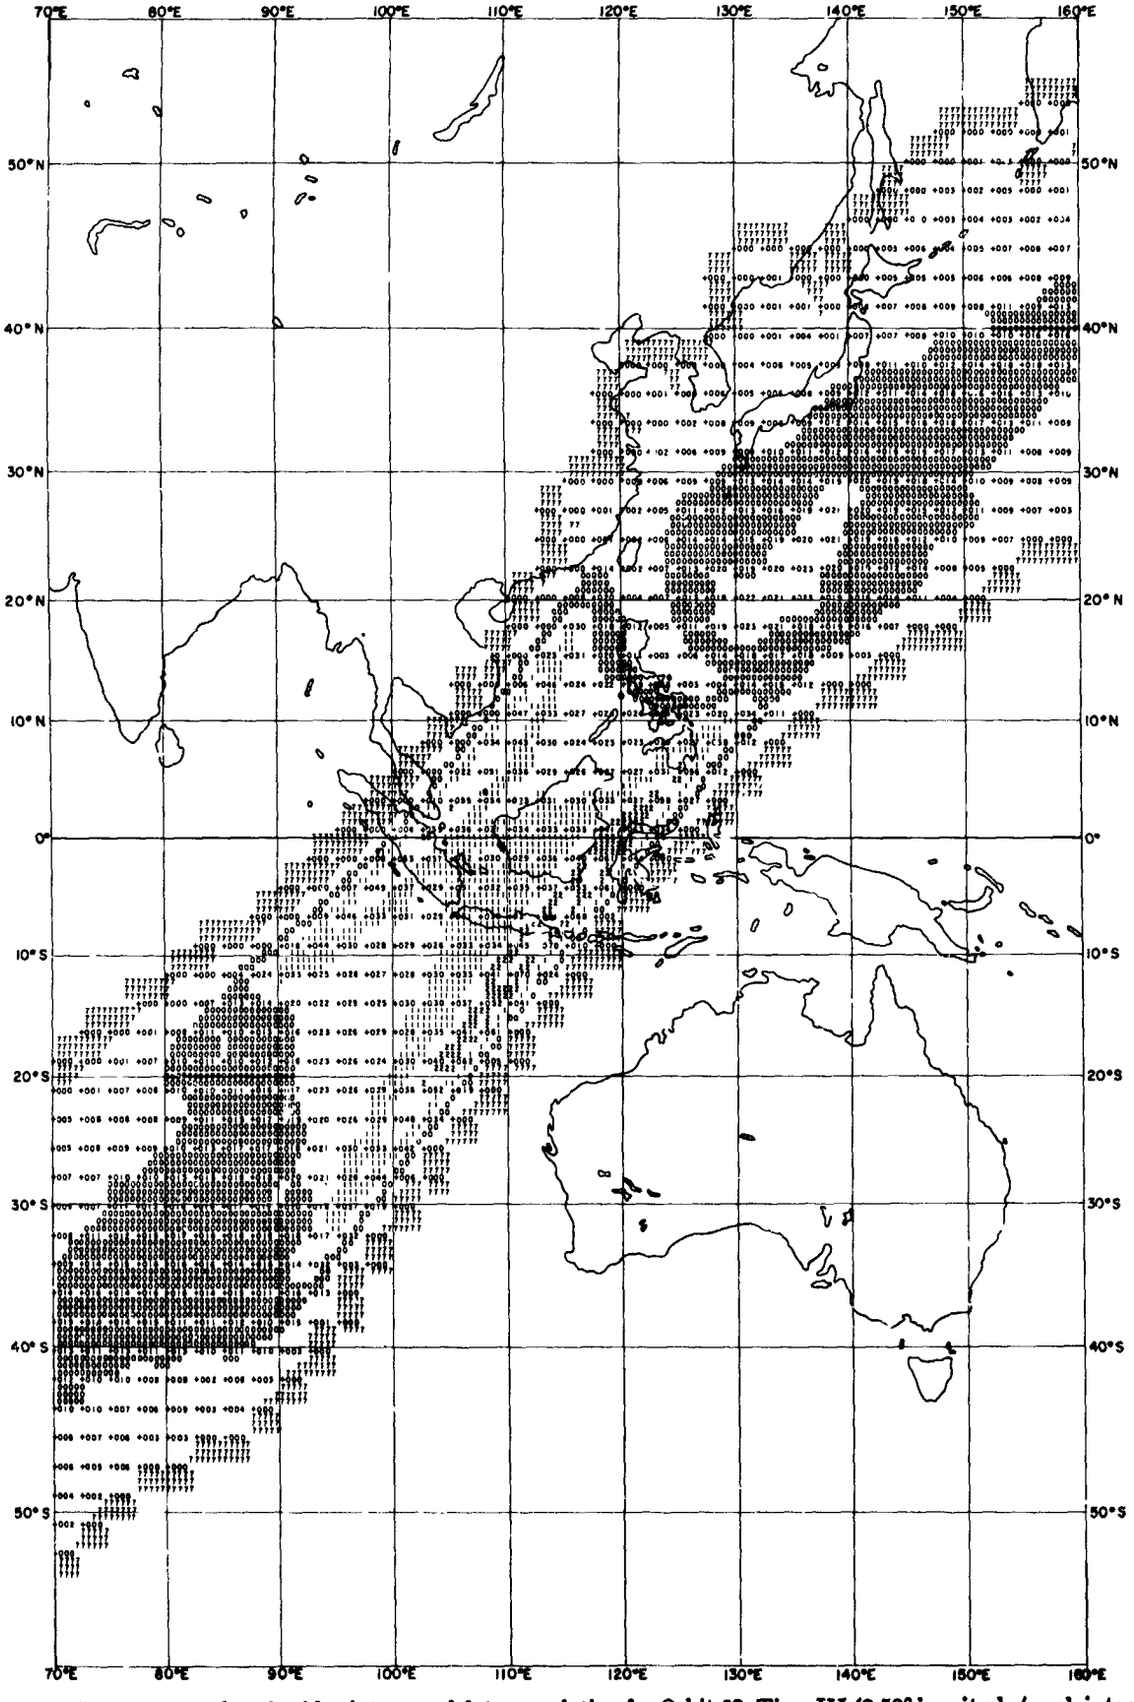

FIGURE 14.—Computer-produced grid print map of data population for Orbit 62, Tiros III (2.50° longitude/mesh interval).

real atmospheric measurements. But in the case of very low radiation intensities the actual equivalent blackbody temperatures may be lower than the threshold value. This occurs mainly over areas of very high opaque cloud systems such as tropical storms.

If a measurement appears below the space-earth discriminant, according to the TIROS III Radiation Data Users' Manual[1], it will be flagged by a minus sign on the FMR Tape and in the computer listings. Three or more consecutive values below the threshold will be assumed to define the end of a swath by the computer logic. Also, all data making up the terminal swath of the closed mode are flagged with minus signs for diagnostic purposes. This means that over large high-cloud areas or when an unusually high noise level occurs just in the transition between closed and open scanning modes, the computer logic may not be able to distinguish properly between real earth-scanned and space-viewed data, resulting in a large number of measurements being flagged with minus signs.

Generally, the computer will be ordered to reject all data flagged by a minus sign in order to avoid the use of questionable data. The com-

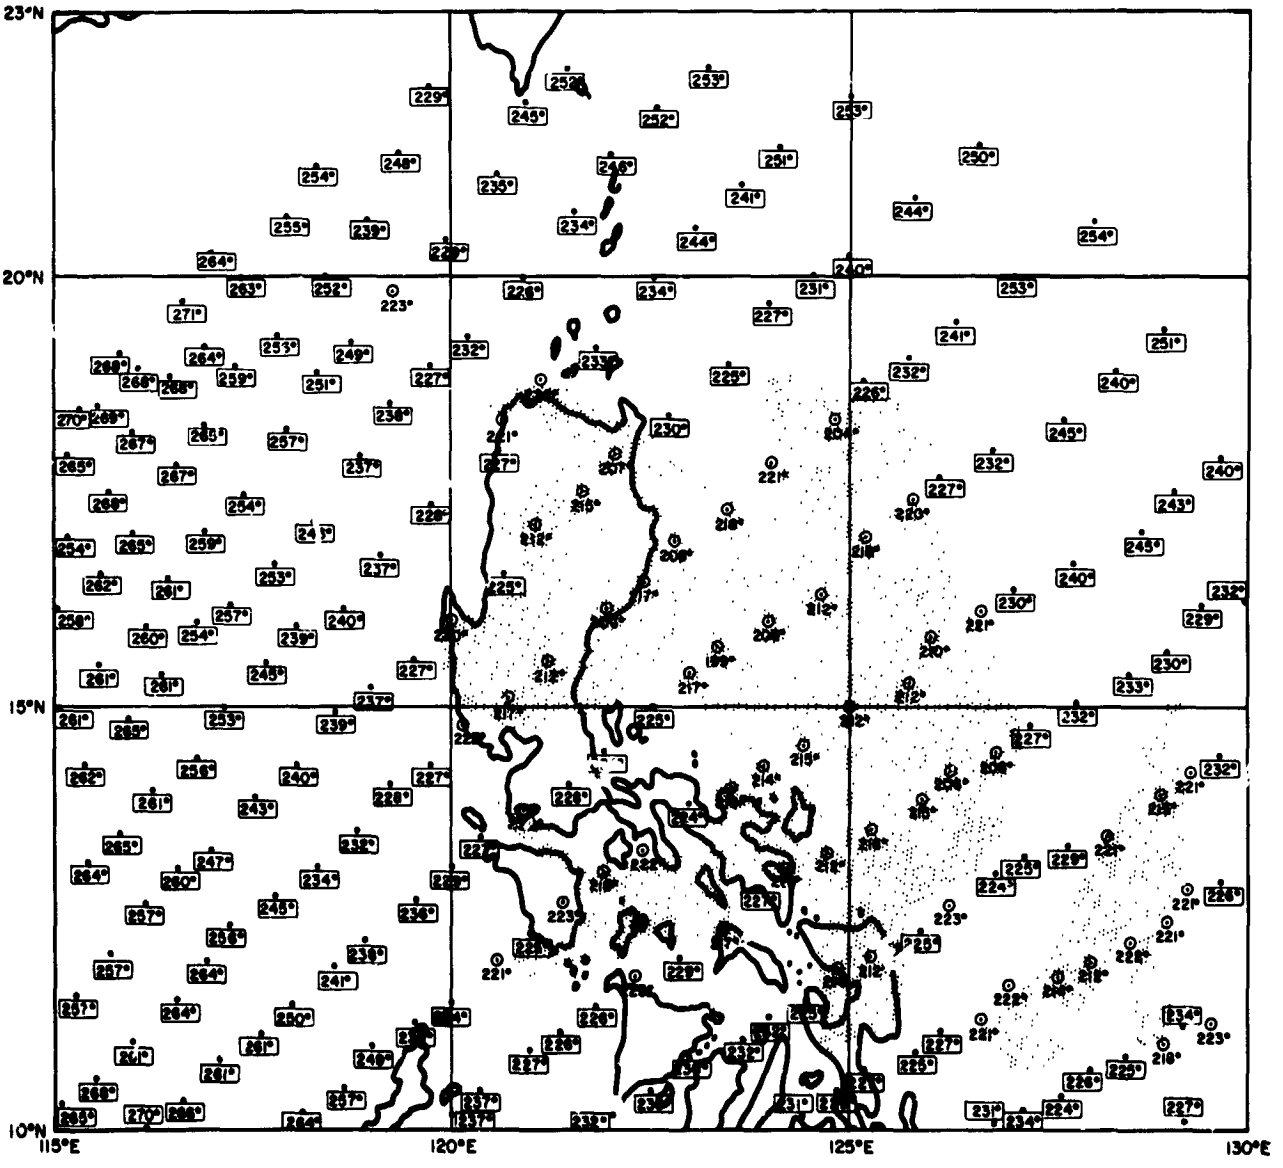

FIGURE 15.—Location of scan spots over a tropical disturbance close to the Philippines, based upon computer listings. (Encircled data in the shaded area were rejected by computer logic in producing the grid print maps).

puter has, however, an option to accept these data for grid print maps. Therefore, a careful check of the FMR Tape data is necessary under such circumstances to permit the analyst in advance to select the areas where the flagged data are meaningful for mapping.

An example of such an occurrence is given in Figure 14. By inspecting the population count, which shows how many data points are contributing to each grid point in the computer produced grid print map, for orbit 62 an irregularity is noted over the Philippine Islands. Approximately 20 data points were rejected by the computer in every grid square in this area. Figure 15 shows all the single data points taken from the computer listings. All data accepted by the computer mapping program are marked by a rectangle, while the rejected "flagged" data points are encircled. The final (Figure 16) analysis of this radiation field shows that just the most interesting low radiation temperature data (very high reaching dense cloud system) over Tropical Storm Flossie had been rejected. Thus, the effect of the artificially defined space-earth discriminate on the composition of radiation data over certain meteorologically significant areas

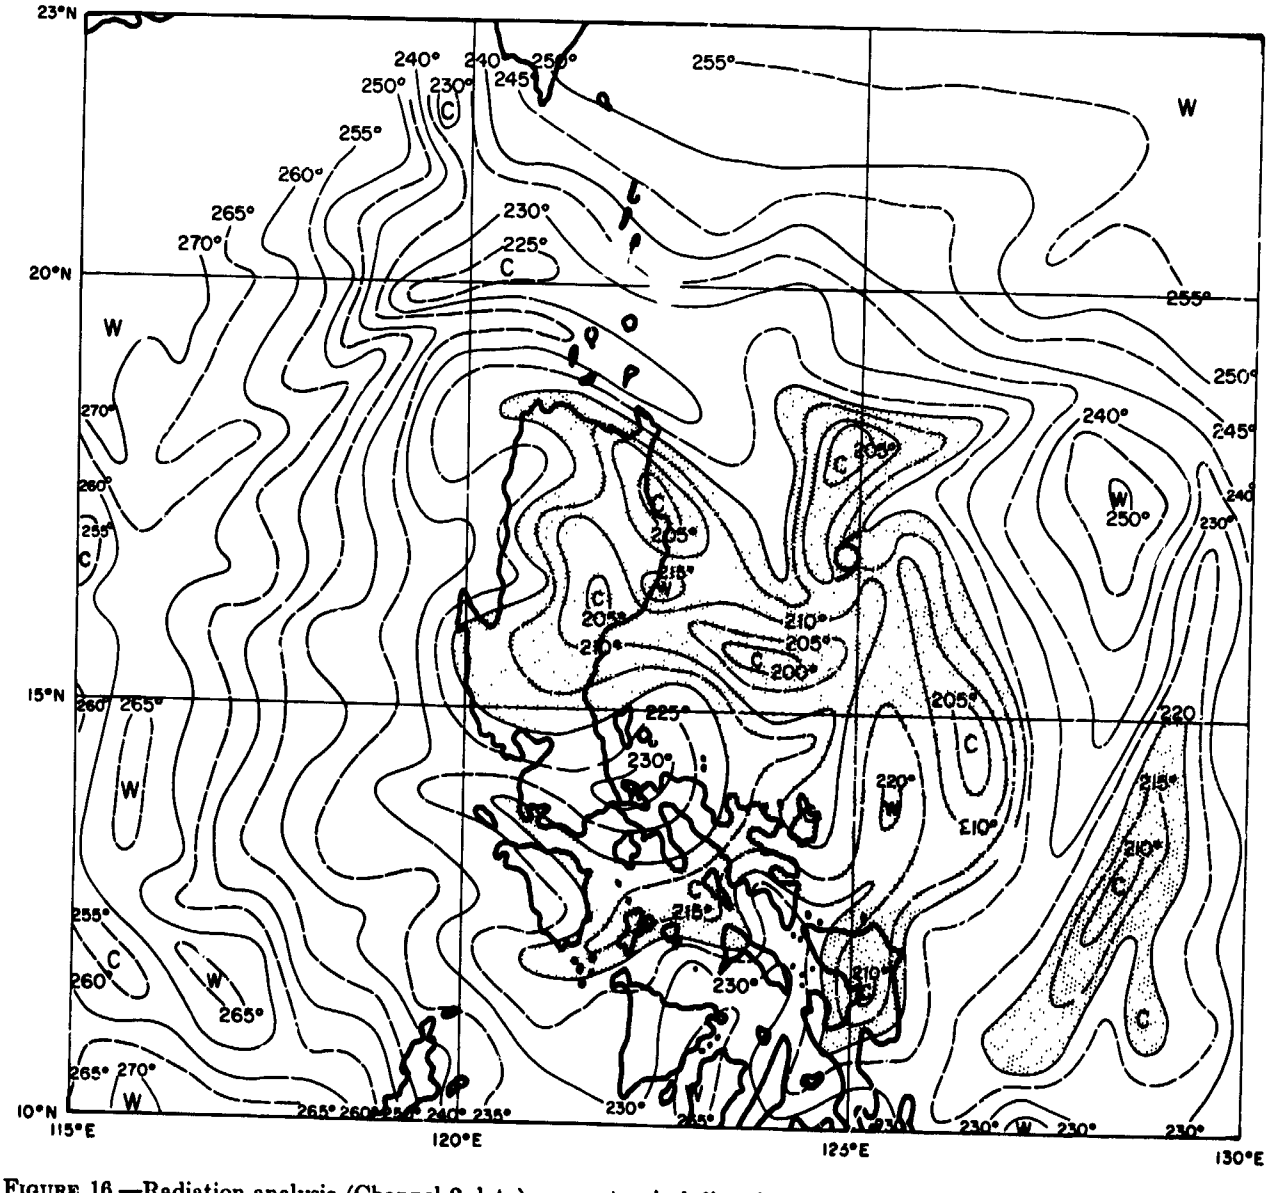

FIGURE 16.—Radiation analysis (Channel 2 data) over a tropical disturbance close to the Philippines, based upon computer listings. (Data within the grey shaded area were rejected by computer logic in producing the grid print maps.)

should always be accounted for in detailed studies. In certain cases, perhaps, the space-earth discriminant could be set somewhat lower, but this depends on such conditions, as signal-to-noise ratio, radiometer housing temperatures, etc. which are discussed in Reference 10.

3. CONCLUSIONS

This paper has attempted to review briefly the satellite radiation experiment and to discuss the current TIROS radiation data reduction processes. With improvement and modification of the computer processing procedures, it will become possible to reduce the location (closed mode) uncertainties of the data and also to accept low but real measurements so that these data could be used in operational weather analyses.

SYMMETRIC EULER ANGLE DECOMPOSITION OF THE TWO-ELECTRON FIXED-NUCLEUS PROBLEM*

A. K. BHATIA† AND A. TEMKIN

1. INTRODUCTION

The decomposition of the Laplacian operator,

$$\nabla^2=\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right)+\frac{1}{r^2}\left(\frac{1}{\sin\vartheta}\frac{\partial}{\partial\vartheta}\sin\vartheta\frac{\partial}{\partial\vartheta}+\frac{1}{\sin^2\vartheta}\frac{\partial^2}{\partial\varphi^2}\right),$$

where the coefficient of the second term is proportional to the square of the angular momentum operator, is the basic relation between kinetic energy and angular momentum in the quantum mechanics of the one body problem (or the relative motion of two particles). When acting on a wave function which is an eigenfunction of total angular momentum ℓ, the Laplacian simplifies to

$$\nabla^2=\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right)-\frac{\ell(\ell+1)}{r^2},$$

in which form it is clear that the effect of this decomposition is to reduce the Schödinger equation with a spherically symmetric potential from a three dimensional partial differential equation to a one dimensional (ordinary) differential equation. As such this relation is of fundamental mathematical importance and is familiar to everyone who utilizes quantum mechanics at all.

The analogous procedure when more than one particle is involved, in particular two identical particles in an external force field, although known, is not as well known, nor is it as well developed. When the external field is that of a fixed nucleus the wave function is expanded in eigenfunctions of the total angular momentum of the two particles multiplied by functions of the three remaining independent variables. The total angular momentum eigenfunctions are functions of the three Euler angles only. These angles are not unique, but in some way they must describe the orientation of the instantaneous plane formed by the two particles and the center of coordinates (nucleus) in space. The remaining three coordinates then describe the positions of the particles in this plane, and the functions of these variables are the generalized radial functions. Hylleraas' original papers[1] in effect contained the reduced or radial equations for total S states in terms of the residual coordinates r_1, r_2, r_{12}. In this case, the total orbital angular momentum is a constant function, and hence the reduction of a six-dimensional to a three-dimensional partial differential equation is independent of how one defines the Euler angles.

The standard treatment of the general problem is due to Breit.[2,3] He used the Euler angles that Hylleraas [1] originally introduced: namely the two spherical angles of one of the particles in the space fixed coordinate system and a second azimuthal angle between the r_1–z plane and the r_2–r_1 plane. Breit's remaining coordinates were chosen as r_1, r_2, and θ_{12}, the latter being the angle between $\mathbf{r}_1$ and $\mathbf{r}_2$. If, however, one wants to describe two electron atoms or ions in the approximation that the nuclei are fixed, then one has an additional requirement of which there is no analogue in the one-body problem. And that is the Pauli principal: the requirement that the spatial function be either symmetric or antisymmetric under the exchange of the particle coordinates. It is clear that the Hylleraas-Breit choice of Euler angles (which we hereinafter refer to as the Hylleraas-Breit angles), being quite unsymmetrical with respect to the two particles, is not optimum in this respect.[4] In fact the construction the linear combinations of angular momentum functions with the appropriate exchange properties is a very difficult task which

*Published as *Goddard Space Flight Center Document X-640-64-68*, March 1964.

†National Academy of Sciences—National Research Council Resident Research Associate.

depends not only on the Euler angles but on θ_{12} as well. It is not surprising, therefore, that Breit's original work[2] was limited to P-states, and work thereafter has always been limited to specific angular momentum states.[5]

However, a treatment by Holmberg[6] using a symmetrical choice of Euler angles (which we shall call Holmberg's angles) has in the interim been carried out. With these angles the description of exhange as well as parity (which latter property is also simply describably with th *II-B* angles) is simple (although these properties are only alluded to in Holmberg's paper). One of the purposes of the present paper is to examine these properties and relate them more clearly to the construction of the total wave function and further clarify other aspects of Holmberg's important paper. Consequently, we shall be enabled to derive the general radial equations for arbitrary angular momentum (ℓ) for the case of two identical particles in the field of a fixed nucleus. Holmberg's treatment applies to three particles of the same mass.

It is clear that in treating three particles of equal mass Holmberg had in mind the three nucleon problem whereas we are interested in two-electron atoms, ions, and diatomic molecules. The application of this formalism to two electron atoms and ions is clear, and the decomposition amounts to a rigorous reduction of the Schrödinger equation. It should only be remarked here that the scattering of electrons from one electron atoms and ions is also a special class of these problems. We have therefore worked out the connection between the boundary conditions for electron-atom scattering and Holmberg's angles (Section VIII).

Inasmuch as Holmberg's paper refers to the three nucleon problem, reference should also be made to the papers of Derrick and Blatt.[7] These papers deal much more realistically with the three nucleon problem in that full account is taken of an internucleon potential which is considerably more complicated than a central potential. As regards the actual choice of coordinates, Derrick and Blatt define axes along the moments of inertia of the three-body system. As such th[e] will depend on the lengths of the interparticle distances and therefore are quite different fr[o]m Holmberg's angles (Section II).

II. HOLMBERG'S ANGLES

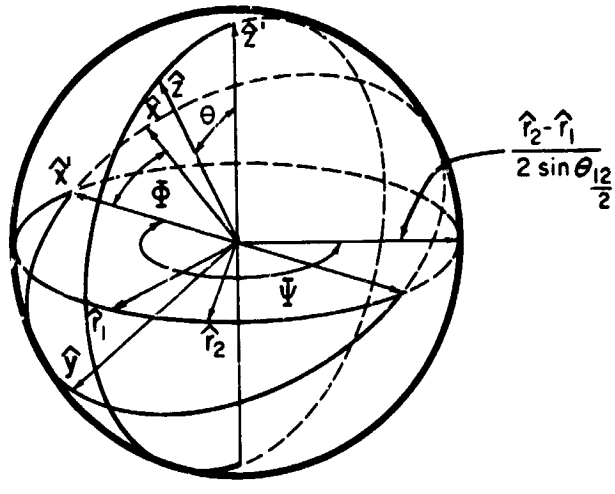

FIGURE 1.—Perspective drawing of (Holmberg's) Euler angles and the unit vectors of the problem.

Figure 1 contains a perspective drawing of Homberg's angles which define the particle plane with respect to the space fixed x, y, and z axes. The rotated axes x', y', z' are then defined by

$$\hat{\mathbf{z}}' = \frac{\hat{\mathbf{r}}_1 \times \hat{\mathbf{r}}_2}{|\mathbf{r}_1 \times \mathbf{r}_2|} \tag{1}$$

$$\hat{\mathbf{x}}' = \frac{\hat{\mathbf{z}}' \times \hat{\mathbf{z}}'}{|\mathbf{z} \times \mathbf{z}'|} \tag{2}$$

$$\hat{\mathbf{y}}' = \hat{\mathbf{z}}' \times \hat{\mathbf{x}} \tag{3}$$

The Holmberg Euler angles are then

$$\theta \equiv \text{angle between } \hat{\mathbf{z}} \text{ and } \hat{\mathbf{z}}' \tag{4}$$

$$\Phi \equiv \text{angle between } \hat{\mathbf{x}}' \text{ and } \hat{\mathbf{x}} \tag{5}$$

$$\Psi \equiv \text{angle between } \hat{\mathbf{x}}' \text{ and } (\hat{\mathbf{r}}_2 - \hat{\mathbf{r}}_1) \tag{6}$$

The ranges and planes of these angles are:

$0 \leq \theta \leq \pi$	in z–z' plane
$0 \leq \Phi \leq 2\pi$	in x–y plane
$0 \leq \Psi \leq 2\pi$	in x'–y' plane

As is usual a cap on a vector is used to represent a unit vector in the given direction. In particular $\hat{\mathbf{i}}$, $\hat{\mathbf{j}}$, $\hat{\mathbf{k}}$ are the three unit vectors along the (space fixed), x, y, and z axes respectively, and thus are synonymous with $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, and $\hat{\mathbf{z}}$. Similarly $\hat{\mathbf{i}}'$, $\hat{\mathbf{j}}'$, $\hat{\mathbf{k}}'$ and $\hat{\mathbf{x}}'$, $\hat{\mathbf{y}}'$, $\hat{\mathbf{z}}'$ are identical.

It is clear from the figure that $\hat{x}$, being in the x–y plane has components:

$$\hat{x}' = \hat{i}\cos\Phi + \hat{j}\sin\Phi \tag{7}$$

Since $\hat{x}'$ is perpendicular to the z–z' plane, it is perpendicular to every line in that plane going through the origin. This includes specifically the line of intersection of the z–z' plane with the x–y plane. However, the azimuthal angle of that intersecting line is the azimuth of $\hat{z}'$ itself, and since $\hat{x}'$ has azimuth Φ, $\hat{z}'$ has azimuth $\frac{3\pi}{2}+\Phi$ (cf. Figure 1). The polar angle of $\hat{z}'$ is clearly θ, therefore we have the important relation:

$$\hat{z}' = \hat{i}\sin\theta\sin\Phi - \hat{j}\sin\theta\cos\Phi + \hat{k}\cos\theta \tag{8}$$

The relations between Holmberg's angles and the spherical angles of the individual particles are obtained by substituting Eqs. (7) and (8) into the *lhs* of Eqs. (1) and (2) and using the ordinary decomposition of $\mathbf{r}_1$ and $\mathbf{r}_2$ in the *rhs*:

$$\hat{r}_1 = \hat{i}\sin\vartheta_1\cos\varphi_1 + \hat{j}\sin\vartheta_1\sin\varphi_1 + \hat{k}\cos\vartheta_1$$

$$\hat{r}_2 = \hat{i}\sin\vartheta_2\cos\varphi_2 + \hat{j}\sin\vartheta_2\sin\varphi_2 + \hat{k}\cos\vartheta_2$$

One obtains

$$\sin\theta_{12}\cos\theta = \sin\theta_1\sin\vartheta_2\sin(\varphi_1-\varphi_1) \tag{9}$$

$$\sin\theta_{12}\sin\theta\sin\Phi = \sin\vartheta_1\sin\varphi_1\cos\theta_2 - \cos\vartheta_1\sin\vartheta_2\sin\varphi_2 \tag{10}$$

$$\sin\theta_{12}\sin\theta\cos\Phi = \sin\vartheta_1\cos\varphi_1\cos\vartheta_2 - \cos\vartheta_1\sin\vartheta_2\cos\varphi_2 \tag{11}$$

$$2\sin(\tfrac{1}{2}\theta_{12})\cos\psi = \sin\varphi_2\cos(\varphi_2-\Phi) - \sin\vartheta_1\cos(\varphi_1-\Phi) \tag{12}$$

$$2\sin(\tfrac{1}{2}\theta_{12})\sin\psi = (\cos\vartheta_2-\cos\vartheta_1)\sin\theta - \sin\theta_1\sin(\varphi_1-\Phi) + \sin\vartheta_2\sin(\varphi_2-\Phi) \tag{13}$$

$$\cos\theta_{12} = \cos\vartheta_1\cos\vartheta_2 + \sin\vartheta_1\sin\vartheta_2\cos(\varphi_1-\varphi_2) \tag{14}$$

The latter relation is, of course, the well known expansion for the angle between two vectors.

It is also of interest to give the vectors $\hat{r}_1$ and $\hat{r}_2$ in the particle plane: (primed co-ordinate system):

$$\hat{r}_1 = \hat{i}'\sin(\psi-\tfrac{1}{2}\theta_{12}) - \hat{j}'\cos(\psi-\tfrac{1}{2}\theta_{12}) \tag{15}$$

$$\hat{r}_2 = \hat{i}'\sin(\psi+\tfrac{1}{2}\theta_{12}) - \hat{j}'\cos(\psi+\tfrac{1}{2}\theta_{12}) \tag{16}$$

$$\hat{z} = \hat{j}'\sin\theta + \hat{k}'\cos\theta \tag{17}$$

$$\hat{y} = \hat{i}'\sin\Phi + \hat{j}'\cos\theta\cos\Phi - \hat{k}'\sin\theta\cos\Phi \tag{18}$$

$$\hat{x} = \hat{i}'\cos\Phi - \hat{j}'\cos\theta\sin\Phi + \hat{k}'\sin\theta\cos\Phi \tag{19}$$

The following relations which are also very useful can now simply be derived by computing $(\hat{r}_1\cdot\hat{z})$, $(\hat{r}_2\cdot\hat{z})$ etc. in the primed system.

$$\cos\vartheta_1 = -\sin\theta\cos(\psi-\tfrac{1}{2}\theta_{12}) \tag{20a}$$

$$\cos\vartheta_2 = -\sin\theta\cos(\psi+\tfrac{1}{2}\theta_{12}) \tag{20b}$$

$$\sin\vartheta_1\cos\varphi_1 = \cos\Phi\sin(\psi-\tfrac{1}{2}\theta_{12}) + \cos\theta\sin\Phi\cos(\psi-\tfrac{1}{2}\theta_{12}) \tag{21a}$$

$$\sin\vartheta_2\cos\varphi_2 = \cos\Phi\sin(\psi+\tfrac{1}{2}\theta_{12}) + \cos\theta\sin\Phi\cos(\psi+\tfrac{1}{2}\theta_{12}) \tag{21b}$$

$$\sin\theta_1\sin\varphi_1 = \sin\Phi\sin(\psi-\tfrac{1}{2}\theta_{12}) - \cos\theta\cos\Phi\cos(\psi-\tfrac{1}{2}\theta_{12}) \tag{22a}$$

$$\sin\vartheta_2\sin\varphi_2 = \sin\Phi\sin(\psi+\tfrac{1}{2}\theta_{12}) - \cos\theta\cos\Phi\cos(\psi+\tfrac{1}{2}\theta_{12}) \tag{22b}$$

III. PROPERTIES UNDER PARITY AND EXCHANGE

The operation of parity corresponds to the simultaneous inversion of both particles' coordinates: $\mathbf{r}_1 \rightarrow -\mathbf{r}_1$, $\mathbf{r}_2 \rightarrow -\mathbf{r}_2$. It can be seen from figure 1 that this places $\mathbf{r}_1$ and $\mathbf{r}_2$ facing the opposite direction, but the cross product and hence $\hat{z}'$ will not change as a result of this operation. Thus the z–z' plane will not change and $\hat{x}'$ will not change. On the other hand $(\hat{r}_2-\hat{r}_1)$ goes into the negative of itself, so that ψ gets increased by π. In other words under *parity*

$$\begin{aligned}\theta &\rightarrow \theta\\ \Phi &\rightarrow \Phi\\ \psi &\rightarrow \psi+\pi\end{aligned} \tag{23}$$

Exchange corresponds to the transformation $\mathbf{r}_1 \rightleftarrows \mathbf{r}_2$. From the analytical definitions $\hat{z}'$ and $\hat{x}'$, Eqs. (1) and (2), the new primed axes will go into the negative of themselves. Also $(\hat{r}_2-\hat{r}_1)$ goes into negative of itself. Clearly the inversion of the z'

axis corresponds to the transformation $\theta\to\pi-\theta$. Noting that Φ is the angle in the x–y plane and measured as positive with respect to the z axis, which is fixed, we see that $\Phi\to\pi+\Phi$. The simultaneous inversion of $\hat{\mathbf{x}}'$ and $(\mathbf{r}_2-\mathbf{r}_1)$ means that the modulus of the angle ψ remains the same. However, since ψ is an angle in the x'–y' plane, it is measured as positive with respect to the z' axis. Since the latter goes into the negative of itself, it becomes clear that $\psi\to2\pi+\psi$. Thus we have under *exchange*

$$\begin{aligned}\theta&\to\pi-\theta\\ \Phi&\to\Phi+\pi\\ \psi&\to2\pi+\psi\end{aligned}\tag{24}$$

The significance of these transformations relates to the transformation properties of the vector spherical harmonics under the same operation. These functions, which are the eigenfunctions of the angular momentum (next section), are the basic functions in terms of which the complete wave function is expanded. They can be written

$$D_l^{m,k}(\theta,\Phi,\psi)=\frac{\sqrt{2(2l+1)}}{4\pi}e^{i(m\Phi+k\psi)}d_l^{m,k}(\theta)\tag{25}$$

where the normalization has been so chosen that the function is identical with what is given in Section IV and the $d_l^{mk}(\theta)$ agree with those given by Wigner.[8] Only the dependence on θ is nontrivial:

$$d_l^{m,k}(\theta)=(-1)^{\frac{1}{2}(|k-m|+k-m)}\sqrt{\frac{4\pi}{2(2l+1)}}N_{lmk}\sin^{|k-m|}\frac{\theta}{2}\times$$
$$\times\cos^{|k+m|}\frac{\theta}{2}F\left(-l-\frac{\beta}{2}-1,\ l+\frac{\beta}{2},\ 1+|k-m|,\ \sin^2\frac{\theta}{2}\right),\tag{26}$$

where β and N_{lmk} are defined in Eqs. (45) and (46). $F(a,b;c;z)$ is the hypergeometric function in the notation of Magnus and Oberhettinger.[9] The important property of $d_l^{mk}(\theta)$, proved in Wigner's book,[8] is:

$$d_l^{m,k}(\pi-\theta)=(-1)^{l-m}d_l^{m,-k}(\theta)\tag{27}$$

The phase in (26) is such that this relation holds for all values of m and k.

Letting P and E_{12} represent parity and exchange, we have from (23) and (24):

$$PD_l^{m,k}(\theta,\Phi,\psi)=D_l^{m,k}(\theta,\Phi,\pi+\psi)$$

$$E_{12}D_l^{m,k}(\theta,\Phi,\psi)=D_l^{m,k}(\pi+\vartheta,\pi+\Phi,2\pi-\psi)$$

which using (27) reduce to

$$PD_l^{m,k}(\theta,\Phi,\psi)=(-1)^kD_l^{m,k}(\theta,\Phi,\psi)\tag{28}$$

$$E_{12}D_l^{m,k}(\theta,\Phi,\psi)=(-1)^lD_l^{m,-k}(\theta,\Phi,\psi)\tag{29}$$

The simplicity of Eq. (29) is the essential feature which recommends Holmberg's angles to the description of the two electron problem.

IV. ANGULAR MOMENTUM

The components of the total angular momentum are readily expressed in terms of the particles spherical angles. Thus, for example

$$\frac{-i}{\hbar}M_z=\sin\varphi_1\frac{\partial}{\partial\theta_1}+\cot\vartheta_1\cos\varphi_1\frac{\partial}{\partial\varphi_1}+\sin\varphi_2\frac{\partial}{\partial\vartheta_2}$$
$$+\cot\vartheta_2\cos\varphi_2\frac{\partial}{\partial\varphi_2}\tag{30}$$

The particles' angles ϑ_1, φ_1, ϑ_2, φ_2 via (9)–(14) are implicit functions of the four angles θ, Φ, ψ, θ_{12}. Thus the problem of finding M_z in these angles is a straightforward problem of partial differentiation. We can write

$$\frac{-i}{\hbar}M_z=A_\theta\frac{\partial}{\partial\theta}+A_\Phi\frac{\partial}{\partial\Phi}+A_\psi\frac{\partial}{\partial\psi}+A_{\theta12}\frac{\partial}{\partial\theta_{12}}$$

where

$$A_\varkappa=\sin\varphi_1\frac{\partial x}{\partial\vartheta_1}+\sin\varphi_2\frac{\partial x}{\partial\vartheta_2}+\cot\vartheta_1\cos\varphi_1\frac{\partial x}{\partial\varphi_1}$$
$$+\cot\vartheta_2\cos\varphi_2\frac{\partial x}{\partial\varphi_2}\tag{31}$$

and $\varkappa$ can be any one of the angles θ, Φ, ψ, or θ_{12}.

Using then Eqs. (9)–(14), one finds that the following relations fall out quite easily:

$$A_{\theta 12}=0 \tag{32}$$

$$A_\theta=-\cos\Phi \tag{33}$$

$$A_\Phi=\sin\Phi\cot\theta \tag{34}$$

$$A_\psi=-\frac{\sin\Phi}{\sin\theta} \tag{35}$$

Thus

$$M_x=\hbar/i\left[\cos\Phi\frac{\partial}{\partial\theta}-\sin\Phi\cot\theta\frac{\partial}{\partial\Phi}+\frac{\sin\Phi}{\sin\theta}\frac{\partial}{\partial\psi}\right] \tag{36}$$

One can, of course, proceed in a completely analogous way to get the remaining components of the angular momentum, however, let us note from Eqs. (20) that

$$\frac{\partial\vartheta_1}{\partial\Phi}=\frac{\partial\vartheta_2}{\partial\Phi}=0 \tag{37}$$

and from (10) and (11)

$$\frac{\partial\varphi_1}{\partial\Phi}=\frac{\partial\varphi_2}{\partial\Phi}=1 \tag{38}$$

Since

$$\frac{\partial}{\partial\Phi}=\sum_{j=1}^{2}\left(\frac{\partial\varphi_j}{\partial\Phi}\cdot\frac{\partial}{\partial\varphi_j}+\frac{\partial\vartheta_j}{\partial\Phi}\cdot\frac{\partial}{\partial\vartheta_j}\right)$$

substitution of (37) and (38) yields

$$\frac{\partial}{\partial\Phi}=\frac{\partial}{\partial\varphi_1}+\frac{\partial}{\partial\varphi_2}$$

However, since

$$M_z=\frac{\hbar}{i}\left(\frac{\partial}{\partial\varphi_1}+\frac{\partial}{\partial\varphi_2}\right)$$

we therefore have the z-component of $\mathbf{M}$:

$$M_z=\frac{\hbar}{i}\frac{\partial}{\partial\Phi} \tag{39}$$

The remaining component of the angular momentum may be derived from the commutation relation $[M_z, M_x]=i\hbar M_y$
Straightforward substitution yields:

$$M_y=\frac{\hbar}{i}\left[\sin\Phi\frac{\partial}{\partial\theta}+\cos\Phi\cot\theta\frac{\partial}{\partial\Phi}-\frac{\cos\Phi}{\sin\theta}\cdot\frac{\partial}{\partial\psi}\right] \tag{40}$$

These relations are independent of θ_{12} corresponding to the statement that the angular momentum only depends on the (three) Euler angles θ, Φ, ψ. The forms of the three operators is the same as one gets with the Hylleraas-Breit angles.[3] The square of the angular momentum is likewise the same. One finds directly from the sum of the squares that

$$\mathbf{M}^2=-\hbar^2\left[\frac{\partial^2}{\partial\theta^2}+\frac{1}{\sin^2\theta}\left(\frac{\partial^2}{\partial\Phi^2}+\frac{\partial^2}{\partial\psi^2}\right)+\cot\theta\frac{\partial}{\partial\theta}-\frac{2\cot\theta}{\sin\theta}\frac{\partial^2}{\partial\Phi\partial\psi}\right] \tag{41}$$

The vector spherical harmonics, which have been given for the restricted range $m\geq k\geq 0$ in Eq. (25), are the simultaneous eigenfunctions of $\mathbf{M}^2$ with eigenvalue $\hbar^2\ell(\ell+1)$ and $\hbar m$

$$\mathbf{M}^2 D_\ell^{m,k}(\theta,\Phi,\psi)=\hbar^2\,\ell(\ell+1)\,D_\ell^{m,k}(\theta,\Phi,\psi)$$

$$\mathbf{M}_z D_\ell^{m,k}(\theta,\Phi,\psi)=\hbar m\,D_\ell^{m,k}(\theta,\Phi,\psi) \tag{43}$$

They are given in a completely general, normalized form in Pauling and Wilson.[10] With our phase [8] they are explicity

$$D_\ell^{m,k}(\theta,\Phi,\psi)=(-1)^{\frac{1}{2}[|k-m|+k-m]}N_{\ell mk}\sin^{|k-m|}\frac{\theta}{2}\cos^{|k+m|}\frac{\theta}{2}\times e^{i(m\Phi-k\psi)}F\left(-\ell+\frac{1}{2}\beta-1,\ \ell+\beta/2,\ 1+|k-m|,\ \sin^2\frac{\theta}{2}\right) \tag{44}$$

where

$$\beta=|k+m|+|k-m|+2 \tag{45}$$

and the normalization constant is

$$N_{\ell mk}=\left[\frac{(2\ell+1)(\ell+\frac{1}{2}|k+m|+\frac{1}{2}|k-m|)!(\ell-\frac{1}{2}|k+m|+\frac{1}{2}|k-m|)!}{8\pi_2(\ell-\frac{1}{2}|k+m|-\frac{1}{2}|k-m|)!(\ell+\frac{1}{2}|k+m|-\frac{1}{2}|k-m|)!}\right]^{\frac{1}{2}}\times\frac{1}{|k-m|!} \tag{46}$$

In addition to the usual magnetic quantum number m, the vector spherical harmonics depend on the quantum number k, an integer whose range of values is the same as m: $-\ell\leq m,\ k\leq\ell$.

The physical significance of k derives from the fact that the $D_l^{m,k}$ are the eigenfunctions of the spherical top (for which (42) is the Schrödinger equation), and k is the angular momentum quantum number about the body-fixed axis of rotation. With regard to the applications that we contemplate here, k can be considered a degeneracy label which must be adjusted such that other requirements are fulfilled.

V. CONSTRUCTION OF THE TOTAL WAVE FUNCTION

We shall confine ourselves here strictly to the atomic problem which implies that the potential energy as well as the kinetic energy commutes with the total angular momentum. In this case the total wave function for a given l must be a linear superposition of the degenerate $D_l^{m,k}$. In addition, m will be fixed for a given magnetic substate and the "radial" equations will be independent of m (cf. Appendix II).

Considering, for the moment, the residual coordinates as r_1, r_2, θ_{12}, we can therefore expand the total wave function in the form:

$$\psi lm(\mathbf{r}_1, \mathbf{r}_2) = \sum_{k=-l}^{l} g^k(r_1, r_2, \theta_{12}) D_l^{m,k}(\theta, \Phi, \psi) \tag{47}$$

The parity operations, Eq. (23), only effects the Euler angles, and from Eq. (28) it only multiplies the $D_l^{m,k}$ function by $(-1)^k$. Therefore by restricting the sum to even and odd values of k, we guarantee that the superpositions have even and odd parity respectively:

$$\Psi_{lm}^{\text{even}}(\mathbf{r}_1, \mathbf{r}_2) = \sum_{k \text{ even}}'' g_l^k(r_1, r_2, \theta_{12}) D_l^{m,k}(\theta, \Phi, \psi) \tag{48a}$$

$$\Psi_{lm}^{\text{odd}}(\mathbf{r}_1, \mathbf{r}_2) = \sum_{k \text{ odd}}'' g_l^k(r_1, r_2, \theta_{12}) D_l^{m,k}(\theta, \Phi, \psi) \tag{48b}$$

where the double prime on the summation emphasizes that the sum goes over every other value of k.

In deriving the radial equations (next section) we shall exploit the invariance of the radial equations with respect to m, by choosing $m=0$. When the Hamiltonian is written in terms of the Euler angles and the remaining variables, there will occur terms involving $\frac{\partial}{\partial\Phi}$ and $\frac{\partial}{\partial\psi}$. By virtue of $m=0$, the former terms vanish, but the latter terms would bring down the imaginery coefficient ik. In order to avoid complex equations, it is therefore convenient to construct real angular momentum functions. Let

$$D_l^{\varkappa+} = \frac{1}{\sqrt{2}} \frac{(D_l^{0,\varkappa} + D_l^{0,-\varkappa})}{(1+\delta_{0\varkappa}(\sqrt{2}-1))} = \frac{\sqrt{2l+1}}{2\pi} \frac{\cos \varkappa\psi}{(1+\delta_{0\varkappa}(\sqrt{2}-1))} d_l^{0,\varkappa}(\theta) \tag{49a}$$

$$D_l^{\varkappa-} = \frac{1}{\sqrt{2}i}(D_l^{0,\varkappa} - D_l^{0,-\varkappa}) = \frac{\sqrt{2l+1}}{2\pi} \cdot \sin \varkappa\psi d_l^{0,\varkappa}(\theta) \tag{49b}$$

for $\varkappa > 0$, where

$$\varkappa = |k|, \tag{50}$$

The important property of these linear combinations is that they are eigenfunctions of exchange:

$$E_{12} D_l^{\varkappa\pm} = \pm(-1)^l D_l^{\varkappa\pm} \tag{49c}$$

This then constitutes a set of real, orthonormal vector spherical harmonics. These real vector spherical harmonics are still eigenfunctions of parity with eigenvalue $(-1)^\varkappa$.

The property of exchange is a mite more complicated than parity in the sense that it affects not only the Euler angles, but the residual coordinates as well. The beauty and importance of Holmberg's angles, however, is that there is no mixing, and independent of whether we consider the residual variables r_1, r_2, θ_{12} or r_1, r_2, r_{12}, the effect of exchange on the residual coordinates is simply $r_1 \rightleftarrows r_2$.

Finally then, if we construct

$$\Psi_{l0}(\mathbf{r}_1, \mathbf{r}_2) = \sum_{\varkappa}'' [f_l^{\varkappa+}(r_1, r_2, \theta_{12}) \cdot D_l^{\varkappa+}(\theta, \Phi, \psi) + f_l^{\varkappa-}(r_1, r_2, \theta_{12}) D_l^{\varkappa-}(\theta, \Phi, \psi)], \tag{51}$$

the operation of exchange on this sum then gives, with the use of (49c),

$$E_{12}\psi_{l0}(\mathbf{r}_1, \mathbf{r}_2) = \psi_{l0}(\mathbf{r}_2, \mathbf{r}_1) = \sum_{\varkappa}'' [f_l^{\varkappa+}(\mathbf{r}_2, \mathbf{r}_1, \theta_{12})(-1)^l D_l^{\varkappa+}(\theta, \Phi, \psi) + f_l^{\varkappa-}(\mathbf{r}_2, \mathbf{r}_1, \theta_{12})(-1)^{l+1} D_l^{\varkappa-}(\theta, \Phi, \psi)]$$

Thus if

$$f_l^{\varkappa+}(r_2, r_1, \theta_{12}) = \pm(-1)^l f_l^{\varkappa+}(r_1, r_2, \theta_{12}) \quad (52a)$$

$$f_l^{\varkappa-}(r_2, r_1, \theta_{12}) = \pm(-1)^{l+1} f_l^{\varkappa-}(r_1, r_2, \theta_{12}), \quad (52b)$$

the function $\Psi_{\ell 0}$ of Eq. (51) is a real, space symmetric (upper sign) or space antisymmetric (lower sign), eigenfunction of $\mathbf{M}^2$ and M_z corresponding to the quantum numbers ℓ and m with $m=0$. The space symmetric and antisymmetric solutions correspond to singlet and triplet spin states respectively. Furthermore the restriction to $m=0$ is sufficient for deriving the radial equations.

We have shown that the $m=0$ function can be written in manifestly real form, Eq. (51). However, in that form, it is not obvious what the generalization is to arbitrary m states. The generalization is nevertheless simply obtained.

Let

$$g_l^{\varkappa} = \frac{1}{\sqrt{2}}(f_l^{\varkappa+} - i f_l^{\varkappa-}) \quad \varkappa > 0 \quad (53)$$

and

$$g_l^{-\varkappa} = \frac{1}{\sqrt{2}}(f_l^{\varkappa+} + i f_l^{\varkappa-})$$

then the form (51) reduces to that of Eq. (47) for $m=0$. For arbitrary m one then need only replace the $D_l^{0,k}$ functions by the appropriate $D_l^{m,k}$ functions, the radial g_l^k functions remaining the same.

Alternatively one can define generalizations of the $D_l^{\varkappa\pm}$, Eq. (49), for arbitrary m.

$$D_l^{(m,\varkappa)+} \equiv [\sqrt{2} + \delta_{0\varkappa}(2-\sqrt{2})]^{-1}(D_l^{m,\varkappa} + D_l^{m,-\varkappa}) \quad m \neq 0$$

$$D_l^{(m,\varkappa)-} \equiv [\sqrt{2}i]^{-1}(D_l^{m,\varkappa} - D_l^{m,-\varkappa}) \quad (54)$$

with $D^{(0,\varkappa)\pm} \equiv D_l^{\varkappa\pm}$ for $m=0$. Note for $m \neq 0$ that the modified spherical harmonics, $D_l^{(m\varkappa)\pm}$ are no longer real.

The complete function for arbitrary m can then be written

$$\psi_{\ell m}(\mathbf{r}_1, \mathbf{r}_2) = \sum' [f_l^{\varkappa+} D_l^{(m,\varkappa)+} + f_l^{\varkappa-} D_l^{(m,\varkappa)-}] \quad (55)$$

Note that by virtue of the action of the raising and lowering operators (Appendix II), the phase of the individual terms except possibly for an overall minus sign, is correct as it stands.

VI. THE KINETIC ENERGY

Just as in the case of the angular momentum, the kinetic energy can be obtained by a straightforward process of partial differentiation. In this case, however, since second partial derivatives are involved, the differentiation is a much longer job, and, as we shall see, the partial derivatives involving θ_{12} no longer cancel out.

We start then with the kinetic energy in spherical coordinates

$$\nabla_1^2 + \nabla_2^2 = \frac{1}{r_1}\frac{\partial^2}{\partial r_1^2} r_1 + \frac{1}{r_2}\frac{\partial^2}{\partial r_2^2} r_2 + \frac{1}{r_1^2}\left[\frac{1}{\sin\vartheta_1}\frac{\partial}{\partial\theta_1}\sin\vartheta_1\frac{\partial}{\partial\vartheta_1} + \frac{1}{\sin^2\vartheta_1}\frac{\partial^2}{\partial\varphi_1^2}\right] + \frac{1}{r_2^2}\left[\frac{1}{\sin\vartheta_2}\frac{\partial}{\partial\vartheta_2}\sin\vartheta_2\frac{\partial}{\partial\vartheta_2} + \frac{1}{\sin^2\vartheta_2}\frac{\partial^2}{\partial\varphi_2^2}\right] \quad (56)$$

The first two terms are, of course, unaffected by the transformation. The angular differentiations then involve the transformation from the variables ϑ, φ_1, ϑ_2, φ_2 to θ, Φ, ψ and θ_{12}.

Consider the coefficient of the r_1^{-2} term. After some regrouping, we can write

$$\frac{1}{\sin\vartheta_1}\frac{\partial}{\partial\vartheta_1}\sin\vartheta_1\frac{\partial}{\partial\vartheta_1} + \frac{1}{\sin^2\vartheta_1}\frac{\partial^2}{\partial\varphi^2} = \sum_{\alpha=1}^{\psi_1}\left[\left(\frac{\partial\varkappa_\alpha}{\partial\vartheta_1}\right)^2 + \frac{1}{\sin^2\vartheta_1}\left(\frac{\partial\varkappa_\alpha}{\partial\varphi_1}\right)^2\right]\frac{\partial^2}{\partial\varkappa_\alpha^2} + \sum_\alpha\left[\frac{\partial^2\varkappa_\alpha}{\partial\vartheta_1^2} + \frac{1}{\sin^2\vartheta_1}\frac{\partial^2\varkappa_\alpha}{\partial\varphi_1^2} + \cot\vartheta_1\frac{\partial\varkappa_\alpha}{\partial\vartheta_1}\right]\frac{\partial}{\partial\varkappa_\alpha} + 2\sum_{\alpha>}\sum_{\beta=1}\left[\frac{\partial\varkappa_\alpha}{\partial\vartheta_1}\frac{\partial\varkappa_\beta}{\partial\vartheta_1} + \frac{1}{\sin^2\vartheta_1}\frac{\partial\varkappa_\alpha}{\partial\varphi_1}\frac{\partial\varkappa_\beta}{\partial\varphi_1}\right]\frac{\partial^2}{\partial\varkappa_\alpha\partial\varkappa_\beta} \quad (57)$$

where for $\alpha=1, 2, 3, 4$, $\varkappa_\alpha$ refers to θ, Φ, ψ, θ_{12}. The problem thus reduces to finding each of the square brackets separately in terms of the Euler angles and θ_{12}. The results are given in Table 1.

The kinetic energy thus becomes

$$\nabla_1^2 + \nabla_2^2 = \left\{\frac{1}{r_1}\frac{\partial^2}{\partial r_1^2} r_1 + \frac{1}{r_2}\frac{\partial^2}{\partial r_2^2} r_2 + \left(\frac{1}{r_1^2} + \frac{1}{r_2^2}\right)\frac{1}{\sin\theta_{12}}\frac{\partial}{\partial\theta_{12}}\sin\theta_{12}\frac{\partial}{\partial\theta_{12}}\right\} + \frac{F_1}{r_1^2} + \frac{F_2}{r_2^2} \quad (58)$$

where

$$F_1=\frac{1}{\sin^2\theta_{12}}\Big[\sin^2\Big(\psi+\frac{1}{2}\theta_{12}\Big)\frac{\partial^2}{\partial\theta^2}+\cos^2\Big(\psi+\frac{1}{2}\theta_{12}\Big)\cot\theta\frac{\partial}{\partial\theta}+\cos^2\Big(\psi+\frac{1}{2}\theta_{12}\Big)\frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\Phi^2}$$
$$+\sin(2\psi+\theta_{12})\frac{\cot\theta}{\sin\theta}\frac{\partial}{\partial\Phi}-\sin(2\psi+\theta_{12})\frac{1}{\sin\theta}\frac{\partial^2}{\partial\theta\partial\Phi}+\sin(2\psi+\theta_{12})\cot\theta\frac{\partial^2}{\partial\psi\partial\theta}$$
$$-2\cos^2\Big(\psi+\frac{1}{2}\theta_{12}\Big)\frac{\cot\theta}{\sin\theta}\frac{\partial^2}{\partial\psi\partial\Phi}\Big]-\frac{\partial^2}{\partial\psi\partial\theta_{12}}+A_1\frac{\partial^2}{\partial\psi^2}+B_1\frac{\partial}{\partial\psi} \quad (59)$$

and

$$A_1=\frac{1}{\psi}+\frac{\cot^2\theta}{\sin^2\theta_{12}}\cos^2\Big(\psi+\frac{1}{2}\theta_{12}\Big) \quad (60)$$

$$B_1=-\frac{\cos\psi\sin(\psi+\theta_{12})}{\sin^2\theta_{12}}-\frac{\cot^2\theta}{\sin^2\theta_{12}}\sin(2\psi+\theta_{12})$$
$$+\frac{\cos\theta_{12}}{2\sin\Big(\frac{\theta_{12}}{2}\Big)}\Bigg(1-\frac{1}{\cos\Big(\frac{1}{2}\theta_{12}\Big)}\Bigg) \quad (61)$$

The expressions for F_2, A_2 and B_2 can be obtained by replacing θ_{12} by $-\theta_{12}$ in the above formulae (including the appropriate partial derivatives). This is equivalent to operating with E_{12}.

$$F_2(\theta,\Phi,\psi,\theta_{12})=F_1(\theta,\Phi,\psi,-\theta_{12}) \quad (62)$$

It is clear, since all the coefficients are independent of Φ, that M_z commutes with the kinetic energy. We have also explicitly verified that $[M_z,\triangle 1^2+\triangle 2^2]=0$.

Note that the partial derivative involving θ_{12} and no other angles has been placed in the curly brackets with the radial derivatives. This is because this term, as the radial derivatives themselves, do not affect the orbital angular momentum, and are the terms which act on total S states[1,2,3]

In fact; in the action of the remaining terms on the angular momentum eigenfunction rests the bulk of the reduction of the Schrödinger equation to its 3-dimensional "radial" form. With this reduction in mind (cf. next section), it is convenient to write F_1 in terms of operators whose effect on the angular momentum eigenfunctions is particularly simple. One can show

$$F_1=\frac{1}{2}\sin^2\theta_{12}\Big[-\frac{1}{\hbar^2}\mathbf{M}^2+\cos\theta_{12}(\sin 2\psi\Lambda_2$$
$$-\cos 2\psi\Lambda_1)+\sin\theta_{12}(\sin 2\psi\Lambda_1+\cos 2\psi\Lambda_2)\Big]$$
$$-\frac{\partial^2}{\partial\theta_{12}\partial\psi}+\Big(\frac{1}{\psi}-\frac{1}{2\sin^2\theta_{12}}\Big)\frac{\partial^2}{\partial\psi^2}$$
$$+\Bigg(\frac{\cos\theta_{12}}{2\sin\Big(\frac{1}{2}\theta_{12}\Big)}-\cot\theta_{12}-\frac{1}{2\sin\theta_{12}}\Bigg)\frac{\partial}{\partial\psi} \quad (63)$$

where

$$\Lambda_1=2\frac{\partial^2}{\partial\theta_2}+\frac{\partial^2}{\partial\psi^2}+\frac{1}{\hbar^2}\mathbf{M}^2$$
$$\Lambda_2=2\frac{\cot\theta}{\sin\theta}\frac{\partial}{\partial\Phi}-(1+2\cot^2\theta)\frac{\partial}{\partial\psi}$$
$$-\frac{2}{\sin\theta}\frac{\partial^2}{\partial\theta\partial\Phi}+2\cot\theta\frac{\partial^2}{\partial\theta\partial\psi} \quad (64)$$

and $\mathbf{M}^2$ is the total angular momentum squared operator given in Eq. (41). F_2 is again derivable from F_1 by replacing θ_{12} by $-\theta_{12}$.

VII. THE REDUCED OR RADIAL EQUATIONS, ATOMIC CASE

The essential properties of the combinations of the operators appearing in F_1 and F_2, Eq. (62) are the following (cf. Appendix I):

$$(\sin 2\psi\Lambda_2-\cos 2\psi\Lambda_1)D_l^{\varkappa+}=-2\varkappa(\varkappa-1)B_{l\varkappa}(1-\delta_{0\varkappa})D_l^{(\varkappa-2)+}+\delta_{1\varkappa}(1-2A_\varkappa^l)D_l^{\varkappa+}$$
$$-\frac{(1+3\delta_{0\varkappa})}{(1+\delta_{0\varkappa}(\sqrt{2}-1))}\frac{A_\varkappa^l A_{\varkappa+1}^l}{2B_{l,\varkappa+2}}D_l^{(\varkappa+2)+} \quad (65a)$$

$$(\sin 2\psi\Lambda_1+\cos 2\psi\Lambda_2)D_l^{\varkappa+}=-2\varkappa(\varkappa-1)B_{l\varkappa}(1-\delta_{2\varkappa})(1-\delta_{0\varkappa})D_l^{(\varkappa-2)-}-\delta_{1\varkappa}(1-2A_\varkappa^l)D_l^{\varkappa-}$$
$$+\frac{1+3\delta_{0\varkappa}}{(1+\delta_{0\varkappa}(\sqrt{2}-1))}\frac{A_\varkappa^l A_{\varkappa+1}^l}{2B_{l,\varkappa+2}}D_l^{(\varkappa+2)-} \quad (65b)$$

$$(\sin 2\psi\Lambda_2-\cos 2\psi\Lambda_1)D_\ell^{\varkappa-}=-2\varkappa(\varkappa-1)B_{\ell\varkappa}(1-\delta_{2\varkappa})(1-\delta_{0\varkappa})D_\ell^{(\varkappa-2)-}-\delta_{1\varkappa}(1-2A_\varkappa^\ell)D_\ell^{\varkappa-}$$
$$-\frac{(1-\delta_{0\varkappa})}{(1+\delta_{0\chi}(\sqrt{2}-1))}\frac{A_\varkappa^\ell A_{\varkappa+1}^\ell}{2B_{\ell,\varkappa+2}}D_\ell^{(\varkappa+2)-} \quad (66a)$$

$$(\sin 2\psi\Lambda_1+\cos 2\psi\Lambda_2)D_\ell^{\varkappa-}=2\varkappa(\varkappa-1)B_{\ell\varkappa}(1-\delta_{0\varkappa})D_\ell^{(\varkappa-2)+}-\delta_{1\varkappa}(1-2A_\varkappa^\ell)D_\ell^{\varkappa+}$$
$$-\frac{(1-\delta_{0\varkappa})}{(1+\delta_{0\varkappa}(\sqrt{2}-1))}\frac{A_\varkappa^\ell A_{\varkappa+1}^\ell}{2B_{\ell\,\varkappa+2}}D_\ell^{(\varkappa+2)+} \quad (66b)$$

where

$$A_\varkappa^\ell=\frac{(\varkappa-\ell)(\varkappa+\ell+1)}{2(\varkappa+1)} \quad (67)$$

and

$$B_{\ell\varkappa}=\frac{[(\ell-\varkappa+1)(\ell-\varkappa+2)(\ell+\varkappa)(\ell+\varkappa-1)]^{\frac{1}{2}}}{4\varkappa(\varkappa-1)} \quad (68)$$

Recall that $\varkappa$ is the absolute value of k, Eq. (50).

We have proved in Appendix II that these relationships are not altered if one replaces the $D_\ell^{\varkappa\pm}$ functions by the $D_\ell^{(m,\varkappa)\pm}$ functions of Eq. (54). As such it becomes quite simple to derive the reduced equations from the original Schrödinger equation

$$H\psi_{\ell m}=E\psi_{\ell m} \quad (69)$$

for any m, and to see that the radial equations are independent of m. One obtains

$$\left[L_{\theta 12}+\frac{2m}{\hbar^2}(E-V)\right]f_\ell^{\varkappa+}-\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\left[\left\{\frac{\ell(\ell+1)-\varkappa^2}{2\sin^2\theta_{12}}+\frac{\varkappa^2}{4}-\frac{\cot\theta_{12}}{2\sin\theta_{12}}\delta_{1\varkappa}(1-2A_\varkappa^\ell)\right\}f_\ell^{\varkappa+}\right.$$
$$+\frac{\cot\theta_{12}}{\sin\theta_{12}}(\varkappa+1)(\varkappa+2)B_{\ell,\varkappa+2}f_\ell^{(\varkappa+2)+}+\frac{\cot\theta_{12}}{4\sin\theta_{12}}\frac{(1+3\delta_{0,\varkappa-2})}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1))}\frac{A_{\varkappa-1}^\ell A_{\varkappa-2}^\ell}{B_{\ell\varkappa}}f_\ell^{(\varkappa-2)+}\Big]$$
$$+\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)\left[\varkappa\left(\frac{\cos\theta_{12}}{2\sin\theta_{12}}-\cot\theta_{12}-\frac{1}{2\sin\theta_{12}}\right)f_\ell^{\varkappa-}-\varkappa\frac{\partial f_\ell^{\varkappa-}}{\partial\theta_{12}}-\frac{\delta_{1\varkappa}(1-2A_\varkappa^\ell)}{2\sin\theta_{12}}f_\ell^{\varkappa-}\right.$$
$$\left.+\frac{(\varkappa+1)(\varkappa+2)}{\sin\theta_{12}}B_{\ell,\varkappa+2}f_\ell^{(\varkappa+2)-}-\frac{1}{4\sin\theta_{12}}\frac{(1-\delta_{0,\varkappa-2})}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1))}\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{B_{\ell\varkappa}}f_\ell^{(\varkappa-2)-}\right]=0 \quad (70a)$$

$$\left[L_{\theta 12}+\frac{2m}{\hbar^2}(E-V)\right]f_\ell^{\varkappa-}-\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\left[\left\{\frac{\ell(\ell+1)-\varkappa^2}{2\sin^2\theta_{12}}+\frac{\varkappa^2}{4}+\frac{\cot\theta_{12}}{2\sin\theta_{12}}\delta_{1\varkappa}(1-2A_\varkappa^\ell)\right\}f_\ell^{\varkappa-}\right.$$
$$+\frac{\cot\theta_{12}}{\sin\theta_{12}}(1-\delta_{2,\varkappa+2})(\varkappa+1)(\varkappa+2)B_{\ell,\varkappa+2}f_\ell^{(\varkappa+2)-}+\frac{\cot\theta_{12}}{4\sin\theta_{12}}\frac{(1-\delta_{0,\varkappa-2})}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1))}\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{B_{\ell\varkappa}}f_\ell^{(\varkappa-2)-}\Big]$$
$$+\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)\left[-\varkappa\left(\frac{\cos\theta_{12}}{2\sin\left(\frac{\theta_{12}}{2}\right)}-\cot\theta_{12}-\frac{1}{2\sin\theta_{12}}\right)f_\ell^{\varkappa+}+\varkappa\frac{\partial f_\ell^{\varkappa+}}{\partial\theta_{12}}-\frac{\delta_{1\varkappa}(1-2A_\varkappa^\ell)}{2\sin\theta_{12}}f_\ell^{\varkappa+}\right.$$
$$\left.-\frac{(1-\delta_{2,\varkappa+2})}{\sin\theta_{12}}(\varkappa+1)(\varkappa+2)B_{\ell,\varkappa+2}f_\ell^{(\varkappa+2)+}+\frac{1}{4\sin\theta_{12}}\frac{(1+3\delta_{0,\varkappa-2})}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1))}\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{B_{\ell\varkappa}}f_\ell^{(\varkappa-2)+}\right]=0 \quad (70b)$$

$L_{\theta 12}$ is the S wave part of the kinetic energy, and only the term containing it survives in the description of S states:[1,2,3]

$$L_{\theta 12}=\frac{1}{r_1}\frac{\partial^2}{\partial r_1^2}r_1+\frac{1}{r_2}\frac{\partial^2}{\partial r_2^2}r_2$$
$$+\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\frac{1}{\sin\theta_{12}}\frac{\partial}{\partial\theta_{12}}\left(\sin\theta_{12}\frac{\partial}{\partial\theta_{12}}\right) \quad (71)$$

Eqs. (70) are the "radial" equations, which it has been our purpose to derive. They pertain to both types of parity and exchange states. Parity is determined by the evenness or oddness of $\varkappa$. If, for example, ℓ is even, and we want to describe a state of even parity, Eqs. (70) couple the functions $f_\ell^{\varkappa+}$ and $f_\ell^{\varkappa-}$ for $\varkappa=0,2,4\ldots\ell$. This involves $\ell/2$ pairs plus one function (for $\varkappa=0$, D_ℓ^{0-} is zero hence f_ℓ^{0-} can be taken to be zero)

or $\ell+1$ functions. The odd parity equations for the same ℓ correspond to the coupling of the function with $\varkappa=1,3,\ldots,\ell-1$. This relates $\ell/2$ pairs or ℓ functions to each other. Both even and odd parity together therefore involve $(2\ell+1)$ functions corresponding to the $(2\ell+1)$ degeneracy of the vector spherical harmonics for a given m. For ℓ odd, there are ℓ functions involved in the even parity equations and $\ell+1$ functions in the odd parity equations.

For a given parity and ℓ, both singlet and triplet (space symmetric and antisymmetric) states are described by the same set of equations. The differences in the solutions devolve from the different boundary conditions which must be applied, Eqs. (52). One of the key virtues of the functions $f_\ell^{\varkappa\pm}(r_1, r_2, \theta_{12})$ is that they are either symmetric or antisymmetric; thus they may be confined to the region, say, $r_1\geq r_2$. If, for example, the exchange character of $f_\ell^{\varkappa+}$ is symmetric (which, according to (52), implies that $f_\ell^{\varkappa-}$ is antisymmetric), then these properties may be embodied in the boundary conditions [11]:

$$\left[\frac{\partial}{\partial n} f_\ell^{\varkappa+}(r_1, r_2, \theta_{12})\right]_{r_1=r_2}=0 \tag{72}$$

where $\frac{\partial}{\partial n}$ represents the normal derivative, and

$$[f_\ell^{\varkappa-}(r_1, r_2, \theta_{12})]_{r_1=r_2}=0 \tag{73}$$

and the solution from there on involves only the region $r_1>r_2\geq 0$. Such equations have distinct advantages from the point of view of numerical solutions.[12]

One can define, however, an asymmetric function in terms of which the radial equations can be more simply written. Letting

$$F_\ell^{\varkappa}(r_1,r_2,\theta_{12})\equiv f_\ell^{\varkappa+}(r_1,r_2,\theta_{12})+f_\ell^{\varkappa-}(r_1,r_2,\theta_{12}) \tag{74}$$

and

$$\tilde{F}_\ell^{\varkappa}(r_1, r_2, \theta_{12})\equiv f_\ell^{\varkappa+}(r_1, r_2, \theta_{12})-f_\ell^{\varkappa-}(r_1, r_2, \theta_{12}) \tag{75}$$

so that, from eq. (74),

$$\tilde{F}_\ell^{\varkappa}(r_2, r_1, \theta_{12})=\pm(-1)^\ell F_\ell^{\varkappa}(r_1, r_2, \theta_{12}) \tag{76}$$

for singlet (upper sign) and triplet (lower sign) cases.

one obtains by adding (70a) and (70b):

$$\begin{aligned}
&\left[L_{\theta 12}+\frac{2m}{\hbar^2}(E-V)\right]F_\ell^{\varkappa}-\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\left[\left(\frac{\ell(\ell+1)-\varkappa^2}{2\sin^2\theta_{12}}+\frac{\varkappa^2}{4}\right)F_\ell^{\varkappa}-\frac{\cot\theta_{12}}{2\sin\theta_{12}}\delta_{1\varkappa}(1-2A_\varkappa^\ell)\tilde{F}_\ell^{\varkappa}\right.\\
&+\frac{\cot\theta_{12}}{\sin\theta_{12}}(\varkappa+1)(\varkappa+2)B_{\ell,\varkappa+2}\left\{F_\ell^{\varkappa+2}-\frac{\delta_{2,\varkappa+2}}{2}(F_\ell^{\varkappa+2}-\tilde{F}_\ell^{\varkappa+2})\right\}+\frac{\cot\theta_{12}}{4\sin\theta_{12}}\frac{1}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1)}\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{B_{\ell\varkappa}}\{F_\ell^{\varkappa-2}\\
&\left.+\delta_{0,\varkappa-2}(2\tilde{F}_\ell^{\varkappa-2}+F_\ell^{\varkappa-2})\}\right]+\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)\left[-\varkappa\left(\frac{\cos\theta_{12}}{2\sin\left(\frac{\theta_{12}}{2}\right)}-\cot\theta_{12}-\frac{1}{2\sin\theta_{12}}\right)\tilde{F}_\ell^{\varkappa}+\varkappa\frac{\partial\tilde{F}_\ell^{\varkappa}}{\partial\theta_{12}}\right.\\
&-\frac{\delta_{1\varkappa}(1-2A_\varkappa^\ell)}{2\sin\theta_{12}}F_\ell^{\varkappa}+\frac{(\varkappa+1)(\varkappa+2)}{\sin\theta_{12}}B_{\ell,\varkappa+2}\left\{-\tilde{F}_\ell^{\varkappa+2}+\frac{1}{2}\delta_{2,\varkappa+2}(F_\ell^{\varkappa+2}+\tilde{F}_\ell^{\varkappa+2})\right\}\\
&\left.\left.+\frac{1}{4\sin\theta_{12}}\frac{1}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1))}\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{B_{\ell\varkappa}}\left\{\tilde{F}_\ell^{\varkappa-2}+\delta_{0,\varkappa-2}(2F_\ell^{\varkappa-2}+\tilde{F}_\ell^{\varkappa-2})\right\}\right]=0
\end{aligned} \tag{77}$$

These equations, depending as they do on F_ℓ and $\tilde{F}_\ell$, are more analogous to the form of the P-wave equation of Breit.[2] The question may arise in connection with these as well as Breit's equations, of whether they are well-defined, since they involve two functions $F_\ell^{\varkappa}$ and $F_\ell^{\varkappa}$ and yet there is only one equation (for a given $\varkappa$). This question, in fact would appear to be particularly relevant as the previous form of our equations, (70) do constitute a coupled set for a given $\varkappa$. To see that both situations are meaningful and in particular that (77) is well-defined, consider a numerical solution of (77). In that case the space of the independent variables is divided into a grid of points, and $F_\ell^{\varkappa}$ is the collection of numbers associated with these grid points. $F_\ell^{\varkappa}$ can

therefore be considered a vector with as many components as there are grid points. The differential equation is replaced by a matrix which operates on the vector $F_l^\varkappa$. Now everytime an $\tilde{F}_l^\varkappa$ occurs in the equation, it is completely clear what has to be done: namely one must let the matrix counterpart of its coefficient in the differential equation operate on that component of $F_l^\varkappa$ which is its reflection point defined by (76). This is a completely unambiguous prescription which is tantamount to saying that the set (77) is well-defined by itself. The reason that (70) is composed of two equations for each $\varkappa$ whereas (77) is not is due to the fact that the functions $F_l^\varkappa$ are asymmetric and therefore must be solved for in the whole r_1, r_2, θ_{12} space. On the other hand the $f_l^{\varkappa\pm}$ functions are either symmetric or antisymmetric, and therefore they are restricted to the $r_1 \geq r_2$, θ_{12} (or equivalently to the $r_1 \leq r_2$, θ_{12}) space. Since this is only half the independent variable space, it is necessary that there be double the number of functions to recover the same information. This is again to say that (70) and (77) are completely equivalent. (Nevertheless a redundant equation with $F_l^\varkappa$ and $\tilde{F}_l^\varkappa$ interchanged may readily be derived.)

We have stated that (70) has certain advantages from the point of view of numerical integration. However, it should also be stated that the form (77) will probably be more advantageous for ordinary variational calculations. This is because if one adopts a specific analytic form of $F_l^\varkappa$, one need only interchange r_1 and r_2 in the expression to obtain $\tilde{F}_l^\varkappa$.

The differences in the $f_l^{\varkappa\pm}$ description from that of $F_l^\varkappa$ gives rise to characteristic differences in the formulation of boundary conditions for scattering problems (cf. the next section).

The restriction of these equations to the atomic case (two identical particles in a fixed central field) has implicitly been made by assuming that the potential is a function of the residual coordinates,

$$V = V(r_1, r_2, r_{12}), \tag{78}$$

so that V commutes with the angular momentum and therefore appears as an additional diagonal term in the radial equations. The inter-particle distance r_{12} is related to the independent radial coordinates that we have thus far considered, r_1, r_2, θ_{12} via the law of cosines:

$$r_{12}^2 = r_1^2 + r_2^2 - 2r_1 r_2 \cos \theta_{12}.$$

Alternatively, however, one can consider r_1, r_2, and r_{12} as the independent coordinates and derive radial equations involving them. Those coordinates, in fact, have certain advantages since the three singularities in the potential occur at their null points. As such they can describe the wave function in the region of close interaction very well. These variables, therefore, are particularly suited to calculation of lowlying bound states of two-electron atoms (where on the whole the electrons are quite close to each other and to the nucleus) and such successful calculations have been done ever since the early work of Hylleraas.[1]

When one considers the equation in the form we have previously given them, involving θ_{12}, one is naturally led to expand the "radial" wave function in terms of Legendre polynomials of cos θ_{12}[11]. The expansion is then truncated after some P_n (cos θ_{12}) and convergence is sought as a function of n. In these classes of two electron problems, this constitutes the idea of configuration interaction in its most general form. Recently this idea has come under some criticism [13,14,15] principally because such a relative partial wave expansion necessarily converges slowly where the electron-electron interaction is large (r_{12} small). The argument has some validity for the above-mentioned low-lying bound states. However, the argument can easily get distorted and exaggerated, for instance when applied to the low-energy scattering of electrons from hydrogen.[14] The point there is that the long-range correlation coming from the induced potential in the atom is at least as important as the short range correlations [16] and yet is only poorly approximated by the conventional Hylleraas type of expansion. This situation has been discussed elsewhere.[12]

These reservations notwithstanding, however, it is nevertheless true that the most accurate three body calculations have been made using the r_1, r_2, r_{12} coordinates, or linear combinations of them,[17] on the low-lying states of helium [18] and its isoelectronic ions.[17] We therefore give below the radial equations in terms of r_1, r_2, r_{12}. The equations are in their asymmetric form corres-

ponding to Eq. (77), since it is assumed that they will be utilized in connection with variational calculations with analytic expansions of the radial wave functions.

$$\left[L_{r12}+\frac{2m}{\hbar^2}(E-V)\right]F_\ell^\varkappa-\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\Bigg[\left\{\frac{(\ell(\ell+1)-\varkappa^2)}{\zeta^2}2r_1^2r_2^2+\frac{\varkappa^2}{4}\right\}F_\ell^\varkappa-\delta_{1\varkappa}(1-2A_\varkappa^\ell)(r_1^2+r_2^2-r_{12}^2)\frac{r_1r_2}{\zeta^2}\tilde{F}_\ell^\varkappa$$

$$+(\varkappa+1)(\varkappa+2)B_{\ell,\varkappa+2}(r_1^2+r_2^2-r_{12}^2)\frac{2r_1r_2}{\zeta^2}\left\{F_\ell^{\varkappa+2}-\frac{\delta_{2,\varkappa+2}}{2}(F_\ell^{\varkappa+2}-\tilde{F}_\ell^{\varkappa+2})\right\}$$

$$+\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell(r_1^2+r_2^2-r_{12}^2)}{2B_{\ell\varkappa}[1+\delta_{0,\varkappa-2}(\sqrt{2}-1)]}\frac{r_1r_2}{\zeta^2}\{F_\ell^{\varkappa-2}+\delta_{0,\varkappa-2}(2\tilde{F}_\ell^{\varkappa-2}+F_\ell^{\varkappa-2})\}\Bigg]+\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)\Bigg[-\varkappa\Bigg\{\frac{1}{2}\frac{r_1^2+r_2^2-r_{12}^2}{\sqrt{r_1r_2[r_{12}^2-(r_1-r_2)^2]}}$$

$$-\frac{r_1^2+r_2^2-r_{12}^2+r_1r_2}{\zeta}\Bigg\}\tilde{F}_\ell^\varkappa+\frac{\varkappa\zeta}{2r_{12}}\frac{\partial\tilde{F}_\ell^\varkappa}{\partial r_{12}}+(\varkappa+1)(\varkappa+2)B_{\ell,\varkappa+2}\frac{2r_1r_2}{\zeta}\left\{-\tilde{F}_\ell^{\varkappa+2}+\frac{1}{2}\delta_{2,\varkappa+2}(F_\ell^{\varkappa+2}+\tilde{F}_\ell^{\varkappa+2})\right\}$$

$$+\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{2B_{\ell\varkappa}}\frac{r_1r_2}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1))}\frac{1}{\zeta}\{\tilde{F}_\ell^{\varkappa-2}+\delta_{0,\varkappa-2}(2F_\ell^{\varkappa-2}+\tilde{F}_\ell^{\varkappa-2})\}-\delta_{1\varkappa}(1-2A_\varkappa^\ell)\frac{r_1r_2}{\zeta}\tilde{F}_\ell^\varkappa\Bigg]=0 \quad (79)$$

Here

$$\zeta=+[r_{12}^4-(r_1^2-r_2^2)^2+2r_{12}^2(r_1^2+r_2^2)]^{\frac{1}{2}} \quad (80)$$

The quantity whose square root ζ is can easily be shown to be positive definite. In the equation (79) the $F_\ell^\varkappa$ is understood to be a function of r_1, r_2, r_{12}:

$$F_\ell^\varkappa=F_\ell^\varkappa(r_1, r_2, r_{12})$$

In addition L_{r12} is the kinetic energy counterpart of the S-wave $L_{\theta 12}$ in terms of r_1, r_2, r_{12}:

$$L_{r12}=\frac{1}{r_1}\frac{\partial^2}{\partial r_1^2}r_1+\frac{1}{r_2}\frac{\partial^2}{\partial r_2^2}r_2+\frac{2}{r_{12}}\frac{\partial^2}{\partial r_{12}^2}r_{12}$$

$$+(r_1^2+r_{12}^2-r_2^2)\frac{1}{r_1r_2}\frac{\partial^2}{\partial r_1\partial r_{12}}$$

$$+(r_2^2+r_{12}^2-r_1^2)\frac{1}{r_1r_2}\frac{\partial^2}{\partial r_2\partial r_{12}} \quad (81)$$

The equations (79) can readily be put in the form of coupled equations for a given $\varkappa$. In that form they would be closest to the form originally given by Holmberg,[6] (although as we have stated his equations apply to three equal mass particles). One salient difference between the two sets of equations, however, is that the present ones are manifestly real, whereas one term in Holmberg's equations is imaginary.[6] It is clear that the equations as well as the solutions must be reducible to completely real form for any given angular momentum state. The accomplishment of this in the present case comes from the explicit construction of real vector spherical harmonics, Eq. (49).

VIII. BOUNDARY CONDITIONS FOR SCATTERING

In this section we derive the asymptotic forms of the radial functions corresponding to the scattering of an electron from a one electron atom in its ground state. The Coulomb modifications when the target system is an ion instead of an atom can readily be made and will have no effect on the angular integrations with which we are here concerned.

As we have seen in the foregoing sections culminating in the last section, the selection of a symmetric choice of Euler angles (Holmberg's angles) has allowed for a completely general derivation of the radial equations. From the point of view of a scattering problem, however, a symmetric choice of angles is not the most advantageous since here we are concerned with an intrinsically asymmetric situation. Thus if we consider that region of configuration space where r_1 is large and r_2 small, corresponding to electron 1 being scattered from the atom to which electron 2 is bound, the wave function *in this region alone* will not be symmetric. However, in terms of the Hylleraas-Breit angles, the spherical angles of one of the particles being defined as two of the Euler angles. the wave function in this asymmetric region is easier to describe. Nevertheless this is a complication of detail only, since all the

angular integrations may readily be performed as we shall now show.

We start with the statement that the complete wave function must have the asymptotic form:

$$\lim_{r_1\to\infty}\psi_{\ell 0}(\mathbf{r}_1,\mathbf{r}_2)=\frac{1}{r_1}\sin\left(kr_1+\delta\ell-\frac{\ell\pi}{2}\right)Y_{\ell 0}(\Omega_1)\frac{R_{1s}}{r_2}(r_2)Y_{00}(\Omega_2) \quad (82)$$

where $(R_{1s}(r_2)/r_2)\,Y_{00}(\Omega_2)$ is the ground state of the one-electron atom (hydrogen). On the other hand, from Eq. (51).

$$\lim_{r_1\to\infty}\psi_{\ell 0}(\mathbf{r}_1,\mathbf{r}_2)=\frac{1}{r_1}\sin\left(kr_1+\delta\ell-\frac{\ell\pi}{2}\right)\frac{R_{1s}(r_2)}{r_2}\times \times\sum_{\varkappa}''[\alpha_\ell^{\varkappa+}(\theta_{12})D_\ell^{\varkappa+}(\theta,\Phi,\psi)+\alpha_\ell^{\varkappa-}(\theta_{12})D_\ell^{\varkappa-}(\theta,\Phi,\psi)] \quad (83)$$

where

$$\alpha_\ell^{\varkappa\pm}(\theta_{12})=Y_{00}\int_0^\pi\int_0^{2\pi}\int_0^{2\pi}D_\ell^{\varkappa\pm}(\theta,\Phi,\psi)Y_{\ell 0}(\vartheta_1)\sin\theta d\theta\,d\Phi\,d\psi \quad (84)$$

It should be noted that (82) refers to the state of parity $(-1)^\ell$ as long as we are considering elastic scattering from the ground (1s) state. This then defines the evenness of oddness of the values over which $\varkappa$ goes in the summation in Eq. (83).

The quadrature in (84) can readily be performed by recalling from Section II that ϑ_1 is the angle between $\hat{\mathbf{z}}$ and $\hat{\mathbf{r}}_1$ whose spherical angles in the primed coordinate systems are given in Eq. (20). One can then use these spherical angles to expand $P_\ell(\cos\vartheta_1)$ via the addition theorems for spherical harmonics.

In its real form [9] this gives in the present case

$$P_\ell(\vartheta_1)=P_\ell(\pi/2)P_\ell(0)+2\sum_{m=1}^{\ell}(-1)^m\frac{(\ell-m)!}{(\ell+m)!}P_\ell^m(\pi/2)P_\ell^m(\theta)\cos m\left(\psi-\frac{1}{2}\theta_{12}\right) \quad (85)$$

In (85) we have written both the Legendre and associated Legendre polynomials as functions of the angle but what we mean in all cases is that the angle is to be substituted into the transcendental form of the function. For example $P_1(\beta)=\cos\beta$ and *not* $P_1(\beta)=\beta$. The sign of the P_ℓ^m is that of Magnus and Oberhettinger [9] (which differs by $(-1)^m$ from that of Morse and Feshbach [3]). To complete the quadrature in (84) we note that

$$d_\ell^{0,\varkappa}(\theta)=\left[\frac{(\ell-\varkappa)!}{(\ell+\varkappa)!}\right]^{\frac{1}{2}}P_\ell^\varkappa(\theta) \quad (86)$$

Substitution into (84) now yields the desired result:

$$\alpha_\ell^{\varkappa+}(\theta_{12})=(-1)^\varkappa P_\ell^\varkappa\left(\frac{\pi}{2}\right)\left[\frac{(\ell-\varkappa)!}{(\ell+\varkappa)!}\right]^{\frac{1}{2}}\left\{\frac{\delta_{0\varkappa}}{\sqrt{2}}+(1-\delta_{0\varkappa})\cos\left(\varkappa\frac{\theta}{2}12\right)\right\} \quad (87a)$$

$$\alpha_\ell^{\varkappa-}(\theta_{12})=(-1)^\varkappa P_\ell^\varkappa\left(\frac{\pi}{2}\right)\left[\frac{(\ell-\varkappa)!}{(\ell+\varkappa)!}\right]^{\frac{1}{2}}\sin\left(\varkappa\frac{\theta}{2}12\right) \quad (87b)$$

The radial function themselves thus approach

$$\lim_{r_1\to\infty}f_\ell^{\varkappa\pm}(r_1,r_2,\theta_{12})=\frac{1}{r_1}\sin\left(kr_1+\delta_\ell-\ell\frac{\pi}{2}\right)\frac{R_{1s}(r_2)}{r_2}\alpha_\ell^{\varkappa\pm}(\theta_{12}) \quad (88)$$

in which form we see that r_1, r_2 dependence of all the $f_\ell^{\varkappa\pm}$ functions is independent of $\varkappa$, so that none of them vanishes in the asymptotic region. Since in all cases the θ_{12} dependence is trivial, it may be worthwhile to define new functions whose asymptotic behaviour is strictly the r_1, r_2 dependence in (88).

For bound state problems, it is clear that all the radial functions must vanish in all asymptotic regions.

IX. OTHER APPLICATIONS

In addition to two electron atomic or ionic systems the present equations apply to double *mu* or *pi* mesic atoms, although as the mass of the identical particles get heavier, the correction for the center of mass becomes more important. Also for the spinless bosons (*pi* mesons) only the space symmetric solutions will presumably be relevant.

The equations can also be applied to two different particles of the same mass (positron-hydrogen scattering, for example). In this case, the potential, V will no longer be symmetric hence the solutions will not be symmetric which implies that boundary conditions like (72) must be

changed to matching conditions of the asymmetric solutions along the line $r_1 = r_2$.[19] This has the effect of giving one solution where formerly there were two, in accord with the distinguishability of the particles.

The major further application of this approach is to two-electron diatomic molecules. In this case, the extension from one [20] to two electrons is non-trivial. However, the analysis has been completed and will be published elsewhere.[21]

TABLE 1.—*Coefficients of the Angular Derivatives in the Kinetic Energy.*[a] *Cf. Eq. (49)*

Coefficient	Derivative	Coefficient	Derivative
$\dfrac{\sin^2\left(\psi \mp \frac{\theta_{12}}{2}\right)}{\sin^2 \theta_{12}}$	$\dfrac{\partial^2}{\partial\theta^2}$	$\cot \theta_{12}$	$\dfrac{\partial}{\partial\theta_{12}}$
$\dfrac{\cos^2\left(\psi + \frac{\theta_{12}}{2}\right)}{\sin^2 \theta_{12} \sin^2\theta}$	$\dfrac{\partial^2}{\partial\Phi^2}$	$\dfrac{-\sin (2\psi + \theta_{12})}{\sin^2 \theta_{12} \sin \theta}$	$\dfrac{\partial^2}{\partial\theta\partial\Phi}$
A_1	$\dfrac{\partial^2}{\partial\psi^2}$	$\dfrac{\cot \theta \sin (2\psi + \theta_{12})}{\sin_2 \theta_{12}}$	$\dfrac{\partial^2}{\partial\theta\partial\psi}$
1	$\dfrac{\partial^2}{\partial\theta_{12}^2}$	0	$\dfrac{\partial^2}{\partial\theta\partial\theta_{12}}$
$\dfrac{\cot \theta \cos^2\left(\psi + \frac{\theta_{12}}{2}\right)}{\sin^2 \theta_{12}}$	$\dfrac{\partial}{\partial\theta}$	$\dfrac{-2 \cos \theta \cos^2\left(\psi + \frac{\theta_{12}}{2}\right)}{\sin^2 \theta_{12} \sin^2\theta}$	$\dfrac{\partial^2}{\partial\Phi\partial\psi}$
$\dfrac{\cos \theta \sin (2\psi + \theta_{12})}{\sin^2 \theta \sin^2 \theta^{12}}$	$\dfrac{\partial}{\partial\Phi}$	0	$\dfrac{\partial^2}{\partial\Phi\partial\theta_{12}}$
B_1	$\dfrac{\partial}{\partial\psi}$	-1	$\dfrac{\partial^2}{\partial\psi\partial\theta_{12}}$

[a] A_1 and B_1 are given in Eqs. (60) and (61).

APPENDIX I

In this appendix, we prove the Eqs. (65) and (66). For $m=0$, $\frac{\partial}{\partial\Phi}$ terms give zero. Therefore, we can write

$$\Lambda_1 \rightarrow \frac{\partial^2}{\partial\theta^2} - \cot\theta\frac{\partial}{\partial\theta} - \cot^2\theta\frac{\partial^2}{\partial\psi^2} \tag{I-1}$$

$$\Lambda_2 \rightarrow 2\cot\theta\frac{\partial^2}{\partial\psi\partial\theta} - \frac{\partial}{\partial\psi} - 2\cot^2\theta\frac{\partial}{\partial\psi} \tag{I-2}$$

and

$$D_\ell^{\varkappa+} = N_{\ell\varkappa}\cos\varkappa\psi\sin^\varkappa\theta F_\varkappa \tag{I-3}$$

$$D_\ell^{\varkappa-} = N_{\ell\varkappa}\sin\varkappa\psi\sin^\varkappa\theta F_\varkappa \tag{I-4}$$

where

$$N_{\ell\varkappa} = \sqrt{\frac{2\ell+1}{8\pi^2}\frac{(\ell+\varkappa)!}{(\ell-\varkappa)!}}\frac{1}{\varkappa!}\frac{1}{2^\varkappa} \tag{I-5}$$

and

$$F_\varkappa = F\left(\varkappa-\ell,\ \varkappa+\ell+1,\ 1+\varkappa,\ \sin^2\frac{\theta}{2}\right) \tag{I-6}$$

Now

$$\begin{aligned}\Lambda_1 D_\ell^{\varkappa+} = N_{\ell\varkappa}\cos\varkappa\psi[&2\varkappa(\varkappa-1)\sin^{\varkappa-2}\theta\cos^2\theta F_\varkappa \\ &-\varkappa\sin^\varkappa\theta F_\varkappa + 2\varkappa\sin^\varkappa\theta\cos\theta A_\varkappa^\ell F_{\varkappa+1} \\ &+\sin^{\varkappa+2}\theta A_\varkappa^\ell A_{\varkappa+1}^\ell F_{\varkappa+2}]\end{aligned} \tag{I-7}$$

where we have used the well known relations for the derivatives of hypergeometric functions:

$$\frac{dF_\varkappa}{d\theta} = A_\varkappa^\ell\sin\theta F_{\varkappa+1} \tag{I-8}$$

$$\frac{d^2}{d\theta^2}F_\varkappa = A_\varkappa^\ell\cos\theta F_{\varkappa+1} + A_\varkappa^\ell A_{\varkappa+1}^\ell\sin^2\theta F_{\varkappa+2} \tag{I-9}$$

A relation between $F_\varkappa$, $F_{\varkappa+2}$ can be obtained from the differential equation satisfied by the hypergeometric function

$$\cos\theta F_{\varkappa+1} = F_\varkappa - \sin^2\theta\frac{A_{\varkappa+1}^\ell}{2(\varkappa+1)}F_{\varkappa+2} \tag{I-10}$$

Using (I-10) in (I-7), we find

$$\begin{aligned}\Lambda_1 D_\ell^{\varkappa+} = N_{\ell\varkappa}\cos\varkappa\psi\Big[&2\varkappa(\varkappa-1)\sin^{\varkappa-2}\theta\cos^2\theta F_\varkappa \\ &-\varkappa\sin^\varkappa\theta F_\varkappa + 2\varkappa\sin^\varkappa\theta A_\varkappa^\ell F_\varkappa \\ &+\left(1-\frac{\varkappa}{\varkappa+1}\right)\sin^{\varkappa+2}\theta A_\varkappa^\ell A_{\varkappa+1}^\ell F_{\varkappa+2}\Big]\end{aligned} \tag{I-11}$$

Similarly,

$$\begin{aligned}\Lambda_2 D_\ell^{\varkappa+} = -N_{\ell\varkappa}\sin\varkappa\psi\Big[&2\varkappa(\varkappa-1)\sin^{\varkappa-2}\theta\cos^2\theta F_\varkappa \\ &-\varkappa\sin^\varkappa\theta F_\varkappa + 2\varkappa A_\varkappa^\ell\sin^\varkappa\theta F_\varkappa \\ &-\frac{\varkappa}{\varkappa+1}\sin^{\varkappa+2}\theta A_\varkappa^\ell A_{\varkappa+1}^\ell F_{\varkappa+2}\Big]\end{aligned} \tag{I-12}$$

Multiply (I-12) by $\sin 2\psi$ and (I-11) by $\cos 2\psi$ and subtract to get

$$\begin{aligned}(\sin 2\psi\Lambda_2 - \cos 2\psi\Lambda_1)D_\ell^{\varkappa+} = &-N_{\ell\varkappa}\cos(\varkappa-2)\psi G \\ &-\frac{N_{\ell\varkappa}}{N_{\ell\varkappa+2}}A_\varkappa^\ell A_{\varkappa+1}^\ell D_\ell^{(\varkappa+2)+}\end{aligned} \tag{I-13}$$

where

$$\begin{aligned}G = [&2\varkappa(\varkappa-1)\sin^{\varkappa-2}\theta\cos^2\theta - \varkappa\sin^\varkappa\theta \\ &+2\varkappa A_\varkappa^\ell\sin^\varkappa\theta]F_\varkappa \\ &+\frac{1-\varkappa}{2(1+)\varkappa}\sin^{\varkappa+2}\theta A_\varkappa^\ell A_{\varkappa+1}^\ell F_{\varkappa+2}\end{aligned} \tag{I-14}$$

Let $\varkappa\rightarrow\varkappa+1$ in (I-10), then

$$\cos\theta F_{\varkappa+2} = F_{\varkappa+1} - \frac{\sin^2\theta}{2(\varkappa+2)}A_{\varkappa+2}^\ell F_{\varkappa+3}$$

Substituting in the above for $F_{\varkappa+1}$ and $F_{\varkappa+3}$ by using (I-10) we get after some rearrangement

$$\begin{aligned}\Big[\cos^2\theta\frac{(\varkappa+2)}{(\varkappa+1)} + &\frac{\varkappa+2}{2(\varkappa+1)^2}\sin^2\theta A_{\varkappa+1}^\ell \\ &+\frac{\sin^2\theta A_{\varkappa+2}^\ell}{2(\varkappa+1)}\Big]F_{\varkappa+2} \\ &-\sin^4\theta\frac{A_{\varkappa+2}^\ell A_{\varkappa+3}^\ell}{4(\varkappa+1)(\varkappa+3)}F_{\varkappa+4} = \frac{\varkappa+2}{\varkappa+1}F_\varkappa\end{aligned}$$

Letting $\varkappa \to \varkappa - 2$ multiplying by $2(\varkappa-1)^2 \sin^2\theta$ and rearranging we have for $\varkappa \geq 2$

$$G = 2\varkappa(\varkappa-1)\sin^{\varkappa-2}\theta F_{\varkappa-2} \qquad \text{(I-15)}$$

Also we find directly from (I-11) and (I-12)

$$G = \tfrac{1}{2}\sin^2\theta A_0^{\ell} A_1^{\ell} F_2 \quad \varkappa = 0 \qquad \text{(I-16)}$$

$$G = -(1-2A_{\varkappa}^{\ell})\sin\theta F_1 \quad \varkappa = 1 \qquad \text{(I-17)}$$

Finally then with the substitution of the above in (I-13) we obtain for $\varkappa \geq 2$

$$(\sin 2\psi\Lambda_2 - \cos 2\psi\Lambda_1) D_{\ell}^{\varkappa+} = -2\varkappa(\varkappa-1) B_{\ell\varkappa} D_{\ell}^{(\varkappa-2)+} - \frac{A_{\varkappa}^{\ell} A_{\varkappa+1}^{\ell}}{2B_{\ell,\varkappa+2}} D_{\ell}^{(\varkappa+2)+} \qquad \text{(I-18)}$$

where $B_{\ell\varkappa}$ has already been defined in Eq. (68).

The special cases $\varkappa = 0$, 1 can be determined from (I-13), (I-16), (I-17). With proper normalization

$$(\sin 2\psi\Lambda_2 - \cos 2\psi\Lambda_1) D_{\ell}^{0+} = -\sqrt{2}\frac{A_0^{\ell} A_1^{\ell}}{B_{\ell 2}} D_{\ell}^{2+} \qquad \text{(I-19)}$$

and

$$(\sin 2\psi\Lambda_2 - \cos 2\psi\Lambda_1) D_{\ell}^{1+} = (1-2A_1^{\ell}) D_{\ell}^{1+} - \frac{A_1^{\ell} A_2^{\ell}}{2B_{\ell 3}} D_{\ell}^{3+} \qquad \text{(I-20)}$$

We can combine (I-18, I-19, I-20) to get Eq. (65)a. If $\ell - \varkappa$ is odd, one can show that the + and − superscripts become reversed as is implicit in (65a)

Similarly, we can prove (65b), (66a), (66b).

APPENDIX II

We can form the raising and lowering operators $M_{\pm}=M_x\pm iM_y$ by using Eqs. (36) and (37). It can be proved easily

$$\frac{i}{\hbar}M+D_l^{m,k}=-\sqrt{(l-m)(l+m+1)}D_l^{m+1,k} \quad \text{(II-1)}$$

$$\frac{i}{\hbar}M-D_l^{m,k}=\sqrt{(l-m)(l-m+1)}D_l^{m-1,k} \quad \text{(II-2)}$$

It is well known that $M_{\pm}$ commutes with H, and in particular with the kinetic energy. One can show explicitly that they commute with the relevant part of the kinetic energy given below:

$$[\sin 2\psi\Lambda_2-\cos 2\psi\Lambda_1,\ M_{\pm}]=0 \quad \text{(II-3)}$$

$$[\sin 2\psi\Lambda_1+\cos 2\psi\Lambda_2,\ M_{\pm}]=0 \quad \text{(II-4)}$$

It may be useful to give the following relations

$$[\Lambda_1,\ M_{\pm}]=\pm\frac{2\hbar}{\sin\theta}e^{\pm i\Phi}\Lambda_2 \quad \text{(II-5)}$$

$$[\Lambda_2,\ M_{\pm}]=\mp\frac{2\hbar}{\sin\theta}e^{\pm i\Phi}\Lambda_1 \quad \text{(II-6)}$$

Below we give the results of the raising and lowering operators on the exchange vector spherical harmonics. These results may be derived from Eqs. (II 1), (II 2) and the definition (54).

$$\frac{i}{\hbar}M_+D_l^{(m,\kappa)\pm}=-\sqrt{(l-m)(l+m+1)}D_l^{(m+1,\kappa)\pm} \quad \text{(II-7)}$$

$$\frac{i}{\hbar}M_-D_l^{(m,\kappa)\pm}=\sqrt{(l+m)(l-m+1)}D_l^{(m-1,\kappa)\pm} \quad \text{(II-8)}$$

Operating $M\pm$ on Eqs. (65a), we find

$$\begin{aligned}M_+&(\sin 2\psi\Lambda_2-\cos 2\psi\Lambda_1)D_l^{\kappa+}\\&=-2\kappa(\kappa-1)B_{l\kappa}(1-\delta_{0\kappa})M_+D_l^{(\kappa-2)+}\\&\quad+\delta_{1\kappa}(1-2A_\kappa^l)M_+D_l^{\kappa+}\\&\quad-\frac{-1+3\delta_{0\kappa}}{(1+\delta_{0\kappa}(\sqrt{2}-1))}\frac{A_\kappa^lA_{\kappa+1}^l}{2B_{l,\kappa+2}}\times M_+D_l^{(\kappa+2)+}\end{aligned} \quad \text{(II-9)}$$

Using Eqs. (II 3) and (II 7), we get

$$\begin{aligned}(\sin 2\psi\Lambda_2&-\cos 2\psi\Lambda_1)D_l^{(1,\kappa)+}\\&=-2\kappa(\kappa-1)B_{l\kappa}(1-\delta_{0\kappa})D_l^{(1,\kappa-2)+}\\&\quad+\delta_{1\kappa}(1-2A_\kappa^l)D_l^{(1,\kappa)+}\\&\quad+\frac{(1+3\delta_{0\kappa})}{(1+\delta_{0\kappa}(\sqrt{2}-1))}\frac{A_\kappa^lA_{\kappa+1}^l}{2B_{l,\kappa+2}}D_l^{(1,\kappa+2)+}\end{aligned} \quad \text{(II-10)}$$

With repeated operation of M_+, it follows by induction that the above relation is true for any m. Similarly we can obtain Eqs. (65b), (66a) and (66b) for any m. Thus the radial equations are independent of m.

It can also be shown that

$$\psi_{l-m}=(-1)^{\kappa-m}\psi_{lm}^* \quad \text{(II-11)}$$

In order to show this, it is only necessary to state the easily derivable relation

$$[D_l^{(m,\kappa)\pm}]^*=(-1)^{\kappa-m}D_l^{(-m,\kappa)\pm} \quad \text{(II-12)}$$

SPACE: HIGHLIGHTS OF RECENT RESEARCH*

ROBERT JASTROW AND A. G. W. CAMERON

Space science is the collection of scientific problems to which space vehicles can make some specific contributions not achievable by ground-based experiments. At present this field includes broad segments of the traditional disciplines of the earth sciences, physics, and astronomy. In future years the biological sciences will join this group in an important role, as our explorations of the moon and planets provide us with opportunities for studying the conditions under which physical life may have developed. This article reviews some highlights of recent space research in the physical sciences.

GEODESY

Important results have been achieved in determining the internal structure of our own planet with the aid of near earth satellites. A satellite's orbit is determined by the distribution of mass within the earth. If the earth were a perfect sphere, under the attraction of the mass point at the earth's center of gravity the satellite would move in an ellipse whose plane would have a constant orientation in space.

Actually, the plane of a satellite's orbit rotates slowly in space, due to the additional force of attraction exerted by the equatorial bulge. Studies of the orbital rotation rates of a number of satellites have yielded a very precise value for the height of the equatorial bulge. These indicate a discrepancy between the observed value for the flattening and the value expected on the basis of an assumption of hydrostatic equilibrium. It has been suggested by Munk and MacDonald that these results imply that the interior of the earth is not in hydrostatic equilibrium but has a mechanical strength sufficient to maintain the earth's shape in spite of the stresses at the base of the mantle.

There are other departures of the geoid from the shape expected in the case of hydrostatic equilibrium, in addition to the discrepancy in the flattening. These departures are of very great significance because they represent variations in gravity which depend on the entire distribution of mass within the planet, which are more significant for the gross structure of the planet than the simple topographical variations—for example, mountains—which represent the distribution of the mass at the surface alone.

Detailed analysis of these gravitational variations yields a figure of the earth having a positive anomaly, or a lump, in the region of the western Pacific, near Indonesia and the Philippines, a large depression or negative anomaly in the Indian Ocean, and a negative anomaly in the Antarctic (Fig. 1).

Although these depressions and elevations are relatively minute, they are exceedingly significant because they represent variations in the force of gravity, or in the amount of matter per square centimeter, in the regions in question. For example, the depression in the Indian Ocean is only 60 meters deep, but it signifies that the force of gravity there is, relatively, so weak that the waters of the sea are not drawn together to the depth that one would expect if the whole earth were subject to a uniform gravitational force.

These anomalies are correlated with the rate at which heat flows through the body of the earth to the surface. The correlation is such that, where the geoid is anomalously high, the heat flow is anomalously low. On the average, the flow of heat outward through the crust of the earth is 60 erg cm^{-2} sec^{-1}. In the depression of the geoid near India, the flow of heat is substantially higher, 80 erg cm^{-2} sec^{-1}. At the elevation of the geoid in the western Pacific, the flow of heat is substantially lower, about 40 erg cm^{-2} sec^{-1}.

We expect this kind of correlation if there is a

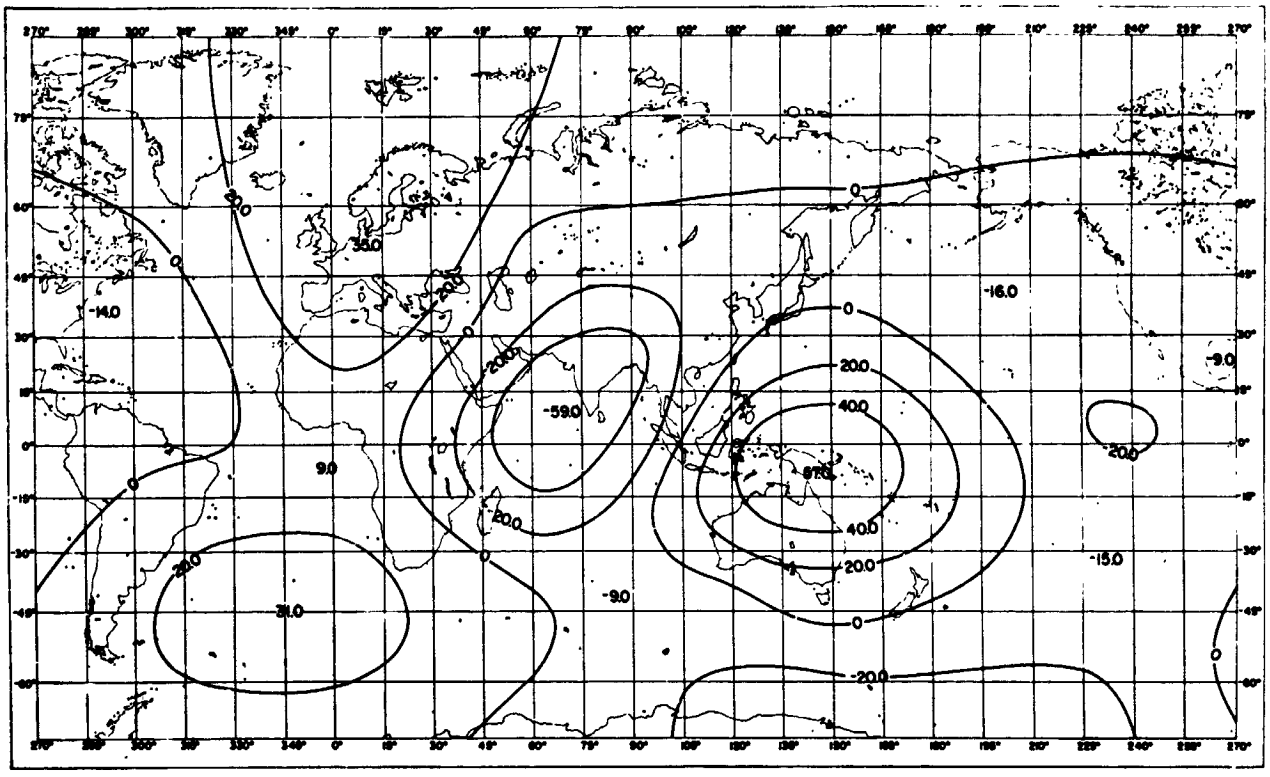

FIGURE 1.—Geoid heights (in meters) relative to an ellipsoid with a flattening of 1/298.3. The major features include a negative anomaly in the Indian Ocean and a positive anomaly centered near Indonesia and the Philippines. [From G. J. F. MacDonald, *Science* 143, 921 (1964)].

mass transport, or convection of matter, from the deep interior of the earth to the surface in these regions. If there were an upward motion through the interior of the earth which carried relatively warm material from below to the surface, this upward-moving column would have a lower density than its surroundings, and therefore the mass per square centimeter in the column, and the gravitational force on the surface of the earth about it, would be lower than the average. At the same time, the heat which the warm column transports upward would add to the normal release of radioactive heat throughout the mantle and crust, so that above the same upward-moving column there would be an exceptionally high rate of heat flow through the surface. The converse would hold for a descending column, which would carry a relatively dense, and therefore relatively cold, material from the surface layer to the interior of the earth. Above the cold and dense column the gravitational force would be relatively great, and a bump would appear in the sea level there. This may be the cause of the elevation in the western Pacific.

METEOROLOGY

In geocentric order, the next major area of investigation in space science concerns the atmosphere and the control exerted over it by the sun. This field of research includes questions related to the circulation of the winds in the lower atmosphere and to the vertical structure of the atmosphere at higher altitudes.

Eight Tiros satellites have been launched in the past 4 years, all carrying vidicon cameras for the global study of the cloud cover; Tiros II, III, IV, and VII carried, in addition, a set of infrared detectors for measuring the intensity of infrared radiation emitted from the earth-atmosphere system.

The cloud-cover photographs have already yielded results that are of great interest when correlated with ground observations, and they indicate that use of satellites may lead to a substantial improvement in weather forecasting by providing global and nearly continuous coverage of regions of weather activity. The matter of global coverage is critically important, because the success of weather forecasting has been found

to increase rapidly with the size of the region covered by the observations; yet at present large parts of the globe are very poorly covered. These are regions in which weather activity can develop and grow without detection before moving out into the inhabited areas. They include the polar regions, the major deserts, and the southern oceans. Satellite coverage will greatly strengthen the hand of the meteorologist by filling in these blank portions of the global weather map, and it may be expected to have important consequences for the economies of this country and the world.

The cloud photographs may also be important for the basic objectives of long-range forecasting and the understanding of the causes of weather activity, because clouds have a strong influence on both the amount of solar energy admitted to the earth-atmosphere system and the amount of energy returned to space from the surface.

The energy balance of the earth-atmosphere system is the difference between the incoming solar radiation, mostly in the visible region of the spectrum, and the outgoing terrestrial radiation, in the infrared. The latitudinal variation of the energy balance shows an excess of incoming solar radiation over outgoing radiation near the equator, and a deficiency at the poles. It is this variation of the energy balance with latitude that drives the atmospheric heat engine.

That part of the visible radiation from the sun which is not reflected by clouds or scattered in the atmosphere reaches the surface of the earth and is absorbed, heating the ground to a temperature in the neighborhood of 235°K. For a glowing body at a temperature of 235°K, most of the energy is radiated at wavelengths in the far infrared. This infrared radiation is strongly absorbed by several constituents of the atmosphere, including water, carbon dioxide, and ozone. The absorption of infrared radiation from the ground by these molecules heats the lower atmosphere, which reradiates the absorbed energy, partly upward to outer space and partly downward, providing additional heating of the surface.

The additional heating of the surface by the return of infrared radiation from the atmosphere is analogous to the action of the glass panes of a greenhouse, and is called the "greenhouse effect." It is sufficient to raise the temperature of the surface of the earth by about 55°K, so that the average temperature of the surface of our planet becomes 290°K.

Clouds are strong absorbers of infrared radiation and influence the infrared transmission and the local greenhouse effect. (This is in addition to the primary effect of clouds as reflectors of incident visible solar radiation.)

Thus, the cloud cover has an important effect on the deposition of energy in the atmosphere because it influences both the inflow and the outflow of energy through the atmosphere. Thus far the characteristics of clouds—amount, types, and approximate heights—have all been measured by ground-based observers. Satellite observation by television cameras introduces the possibility of obtaining extensive data on global cloud cover in relatively short periods.

A. Arking, of the Goddard Institute for Space Studies and New York University, has recently carried out the first statistical analysis of Tiros cloud-cover data, using a digitizing technique applied to Tiros III photographs. The Tiros III results are compared in Fig. 2 with a climatological mean cloudiness for the Northern Hemisphere that was compiled by K. Telegadas and J. London, then at New York University, from ground observations extending over a 50-year period. The Southern Hemisphere data of Fig. 2 were compiled by H. Landsberg of the U.S. Weather Bureau.

The results in Fig. 2 show that the cloud cover in middle latitudes is the same in the Northern and Southern hemispheres. However, in tropical latitudes there is an asymmetry, with a local maximum of the cloud cover in the tropics centered at 10° N. This is the average position of the "thermal equator" during the period 12 July to 30 September.

These results are preliminary, but the approach seems promising, and it is hoped that improved techniques will make it possible to detect fine-scale temporal and geographical variations in the distribution of the energy balance.

UPPER ATMOSPHERE

The physical processes which control the upper atmosphere are determined largely by the absorption of solar ultraviolet radiation by the atoms and molecules existing at great heights. Although the ultraviolet component of the solar radiation

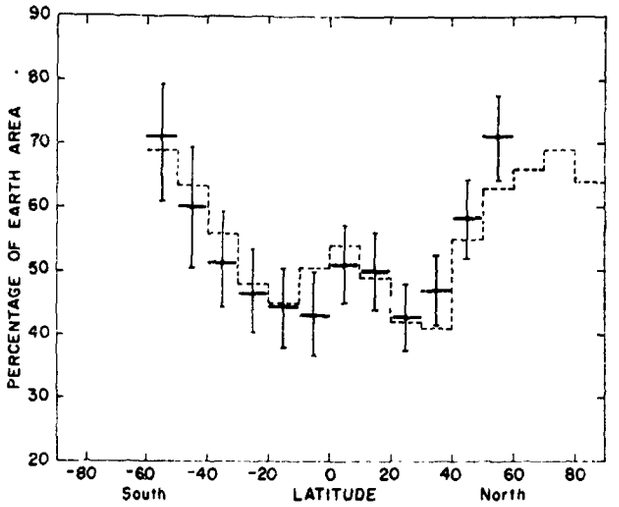

FIGURE 2.—The latitudinal distribution of cloud cover. (Solid horizontal bars.) Results derived from Tiros III photographs taken from 12 July to 30 September 1961; (vertical lines) estimated uncertainty in the Tiros derived data; (dashed histogram) climatological mean cloud cover derived from ground observations, as compiled by Telegadas and London for the Northern Hemisphere and by Landsberg for the Southern Hemisphere. The broad features of the latitudinal distribution are consistent with the known pattern of the general circulation. The air rising at the thermal equator produces a relative maximum in the cloud cover, while, on the average, there is downward motion of cool, dry air at latitudes 30° north and south of the thermal equator, which explains the realtive minimum of cloudiness. (From A. Arking, *Science* 143, 569 1964)

is only a small fraction of the total flux of solar energy, the absorption cross sections in the far ultraviolet are so large that radiation at these wavelengths has been effectively removed from the incident spectrum by the time the incident flux has penetrated to a height of 100 kilometers. The ultraviolet radiation is the principal source of heating of the thin upper air and the major determining factor in its structure.

At lower altitudes the air is composed of oxygen and nitrogen, and we can measure the proportions of these rather accurately. At the highest altitudes these gases have partially settled out of the air through diffusion. The lighter gases dominate the composition of the air at sufficiently high altitudes. Of these gases hydrogen is the lightest, and for this reason it was once believed to be the dominant constituent of the air above the oxygen-nitrogen layer. The emergence of the hydrogen atmosphere was thought to come at an altitude of about 1200 kilometers. However, in July 1961, Marcel Nicolet of Belgium suggested, on the basis of an initial examination of the density data of Echo I, that between the oxygen-nitrogen atmosphere and the hydrogen atmosphere there lies a layer of helium. The helium layer was discovered experimentally a short time later by R. Bourdeau, of the NASA Goddard Space Flight Center, and the finding has since been confirmed in other experiments (Fig. 3).

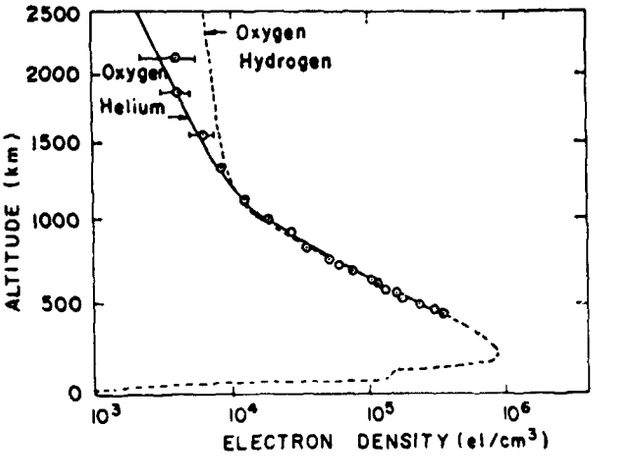

FIGURE 3.—Electron density profile measured by a Scout rocket, and providing evidence for a helium layer in the upper atmosphere. (Dotted line) Density distribution for a scale height derived from an oxygen-hydrogen mixture; (solid line) calculated density distribution for an oxygen-hydrogen mixture. [From S. J. Bauer and J. E. Jackson, J. Geophys. Res. 67, 1676 (1962)]

Our knowledge of properties of the atmosphere at altitudes above 200 kilometers is mainly derived from measurements of atmospheric drag on satellites. The period of revolution of a satellite decreases steadily at a rate proportional to the drag force exerted by the atmosphere, which is, in turn, proportional to air density; a measurement of the rate of change of period therefore gives the value of the air density suitably averaged around the orbit.

Data on satellite drag have been a very valuable source of information on atmospheric properties. L. G. Jacchia of the Smithsonian Astrophysical Observatory was the first to discover, by careful analysis of time variations in the drag, that the upper atmosphere is extremely responsive to solar control, deviating in density from the mean by as

much as a factor of 100 and deviating in temperature by hundreds of degrees at times of solar activity.

The significance of the correlation between solar activity and the properties of the earth's upper atmosphere can be described as follows. The surface of the sun is the scene of great activity, especially during the maximum of the sunspot cycle, when it is marked by sunspots and by hot, dense regions with temperatures of some millions of degrees, which are located in the solar corona above the sunspot areas. When such an active region faces toward the earth in the course of the sun's rotation, extreme ultraviolet radiation emitted from these active regions is absorbed in the upper atmosphere. The precise correlation between solar activity and density was discovered by Jacchia and by W. Priester of Bonn University Observatory and the Goddard Institute for Space Studies. Their results suggest that the amount of energy transferred to the earth is sufficient to heat the atmosphere appreciably, causing an upward expansion and a large increase in the density of the exceedingly thin air at high altitudes. This discovery provided the first direct evidence of the influence of solar surface activity on atmospheric properties.

The continuing analysis of the correlation has given us a rather full picture of solar control over the upper atmosphere. It indicates that the atmosphere is appreciably heated by the ultraviolet radiation emitted at times of general solar surface activity, and is further heated by interaction of the earth with the clouds of solar particles which are emitted from the sun following solar surface eruptions. The arrival of the clouds of particles at the earth is signified by the onset of geomagnetic disturbances or "magnetic storms." It is found that increases in the temperature of the atmosphere occur shortly after the commencement of the magnetic storms. Thus, it appears that both ultraviolet radiation and corpuscular streams are sources of energy for the upper atmosphere (Figs. 4 and 5). The question of the energy sources for the upper atmosphere is the most important single problem for upper-atmosphere physics at this time. The continuing investigation of this matter and, in particular, of the roles played by particle and radiation sources, respectively, will be one of the main areas of ex-

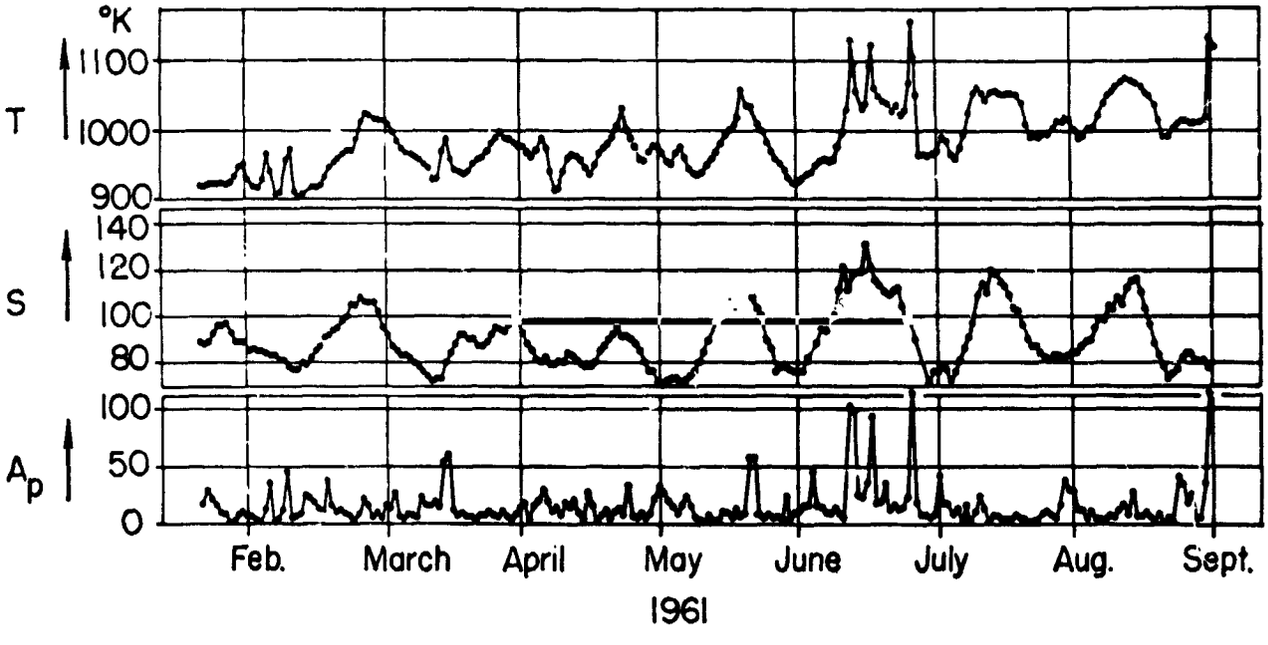

FIGURE 4.—Temperature variation correlated with solar radio emission and geomagnetic indices for the interval from February through September 1961. (Upper curve) Exospheric densities and temperatures, derived from Explorer IX drag measurements by L. G. Jacchia and J. Slowey (1962); (middle curve) flux of the solar radiation at 20-centimeter wavelengths, an indicator of solar activity measured at the Heinrick Hertz Institut in Berlin; (lower curve) geomagnetic activity index (A_p). FIGURE 5.—Density variations at 250 kilometers above sea level as a function of local time t, determined by L. G. Jacchia and J. Slowey (1963) of the satellite Injun III from 15 December 1962 through 29 June 1963. During this time the geographic latitude of the perigee cover the range from $+70°$ to $-60°$, as indicated by the numbers on the density curve. (Solid curve) The Harris-Priester model for the proper level of solar activity; (histogram at top) daily geomagnetic indices A_p; (open circles) densities during magnetic storms; (solid circles) densities during magnetically quiet days ($A_p<2$). The response of the atmosphere to solar activity, as indicated by violent solar storms, is much greater within the auroral zone than outside it. [Adapted from L. G. Jacchia and J. Slowey, *J. Geophys. Res.* 69, 905 (1964)].

perimental and theoretical effort in the next several years.

MAGNETOSPHERE

The evidence cited suggests that corpuscular streams from the sun transfer appreciable amounts of energy to the atmosphere. How does the transfer of energy in the atmosphere occur?

The general answer seems to be connected with the properties of the outermost layer of the atmosphere. The density of the upper air merges into the density of the interplanetary gas at an altitude of about 100,000 kilometers, marking the boundary of the atmosphere. Early in 1958, however, J. A. Van Allen of the State University of Iowa discovered, by analyzing Geiger-counter data from Explorer I, that there was an additional layer of energetic charged particles in the upper atmosphere. These charged particles are trapped in the atmosphere by the earth's magnetic field, and the atmospheric layer which they constitute is therefore called the magnetosphere.

During the last few years three important developments have substantially changed our earlier impressions about the character of the magnetically trapped particles and their geophysical effects.

First, B. O'Brien, also of the State University of Iowa, using measurements from the Injun I satellite, discovered that the flux of charged particles coming down from the trapped-particle region was so large that, if this flux consisted of previously trapped particles which had just been dislodged by solar disturbances, it would drain the whole magnetosphere in about an hour. He also found that when a solar disturbance occurred, both the flux of untrapped descending particles and the number of trapped particles increased. Thus he concluded that the leakage of trapped particles from the Van Allen belts cannot be the principal source of the electrons which pass down through the atmosphere. He decided that, while a few charged particles are trapped during or after a solar disturbance, most pass directly into the atmosphere without spending an appreciable amount of time in the trapped-particle region.

Apparently, the charged particles which are observed in auroral displays and other atmospheric phenomena are those which come directly down the lines of force into the atmosphere.

Second, a large population of low-energy protons, having a range from 100,000 to several million electron volts, was discovered by A. H. Davis and J. M. Williamson of the Goddard Space Flight Center. The concentration of these protons reaches a maximum at a distance of 3.5 earth radii. At that distance their density is about one per cubic centimeter. This value for density of the trapped protons has interesting implications. As a result of the magnetic field gradient and curvature effects, the trapped protons drift westward in the magnetic field, with an associated electric current that produces magnetic effects. These effects have been calculated by S. Akasofu of the University of Alaska, S. Chapman of the universities of Colorado and Alaska, and (in unpublished work) R. A. Hoffman of the Goddard Space Flight Center. They find that the changes in the intensities of these trapped protons produce magnetic perturbations large enough to explain most magnetic storms observed on the earth, and also the very large perturbations of the geomagnetic field in space in the neighborhood of the proton belt. The relation between the trapped-proton drift current and the geomagnetic storms was suggested by S. F. Singer of the University of Maryland in 1956.

The third development was the discovery of a substantial flux of electrons with very high energies (in the neighborhood of 1 million volts) at a distance of 3 or 4 earth radii, presumably produced by beta decay of albedo neutrons resulting from cosmic ray interactions in the atmosphere. These electrons penetrate the Geiger counters with high efficiency, and when allowance is made for their presence, the estimate of the total flux of electrons is reduced from the earlier estimated value of 10^{10} cm^{-2} sec^{-1} srad^{-1} to the currently accepted value of 10^{8} cm^{-2} sec^{-1} srad^{-1}.

THE MAGNETOPAUSE

The connection between the magnetosphere and the transfer of corpuscular energy to the atmosphere is probably to be found in the properties of the atmosphere near the magnetopause, the boundary separating the interplanetary medium from the region around the earth, in which the geomagnetic field is dominant. The sharply defined surface of the magnetopause marks the termination of both the trapped-particle region and the geomagnetic field. Satellite measurements of the geomagnetic field by L. J. Cahill of the National Aeronautics and Space Administration and of the University of New Hampshire show that the magnetopause has a thickness on the order of 100 kilometers and occurs at a distance of 8 to 10 earth radii on the sunlit side of the earth.

The sharpness of the magnetospheric boundary is illustrated by Figs. 6 and 7. Figure 6 represents the magnetic-field measurements obtained by Cahill and P. G. Amazeen of the University of New Hampshire, using a three-component magnetometer flown on Explorer XII. At the magnetopause a sudden drop occurs and outside the magnetosphere the magnetic field is highly variable in magnitude and direction. Figure 7 shows the counting rates of charged particle detectors flown on Explorer XIV by Van Allen, L. A. Frank, and E. Macagno of the State University of Iowa.

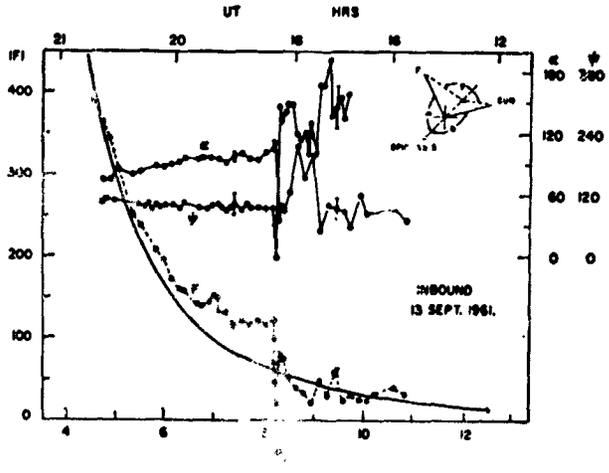

FIGURE 6.—Explorer XII measurements showing the abrupt termination of the geomagnetic field at the magnetopause. F is the magnitude of the magnetic field and α and β refer to its direction. Within the magnetosphere the field is closely described by the high-altitude extrapolation of the earth's approximately dipole field, shown as the solid curve. Outside the magnetopause, which occurred at 8.2 earth radii (R_E) during this flight, the field varies in magnitude and direction. [From L. J. Cahill and P. G. Amazeen, *J. Geophys. Res.* 68, 1841 (1963)].

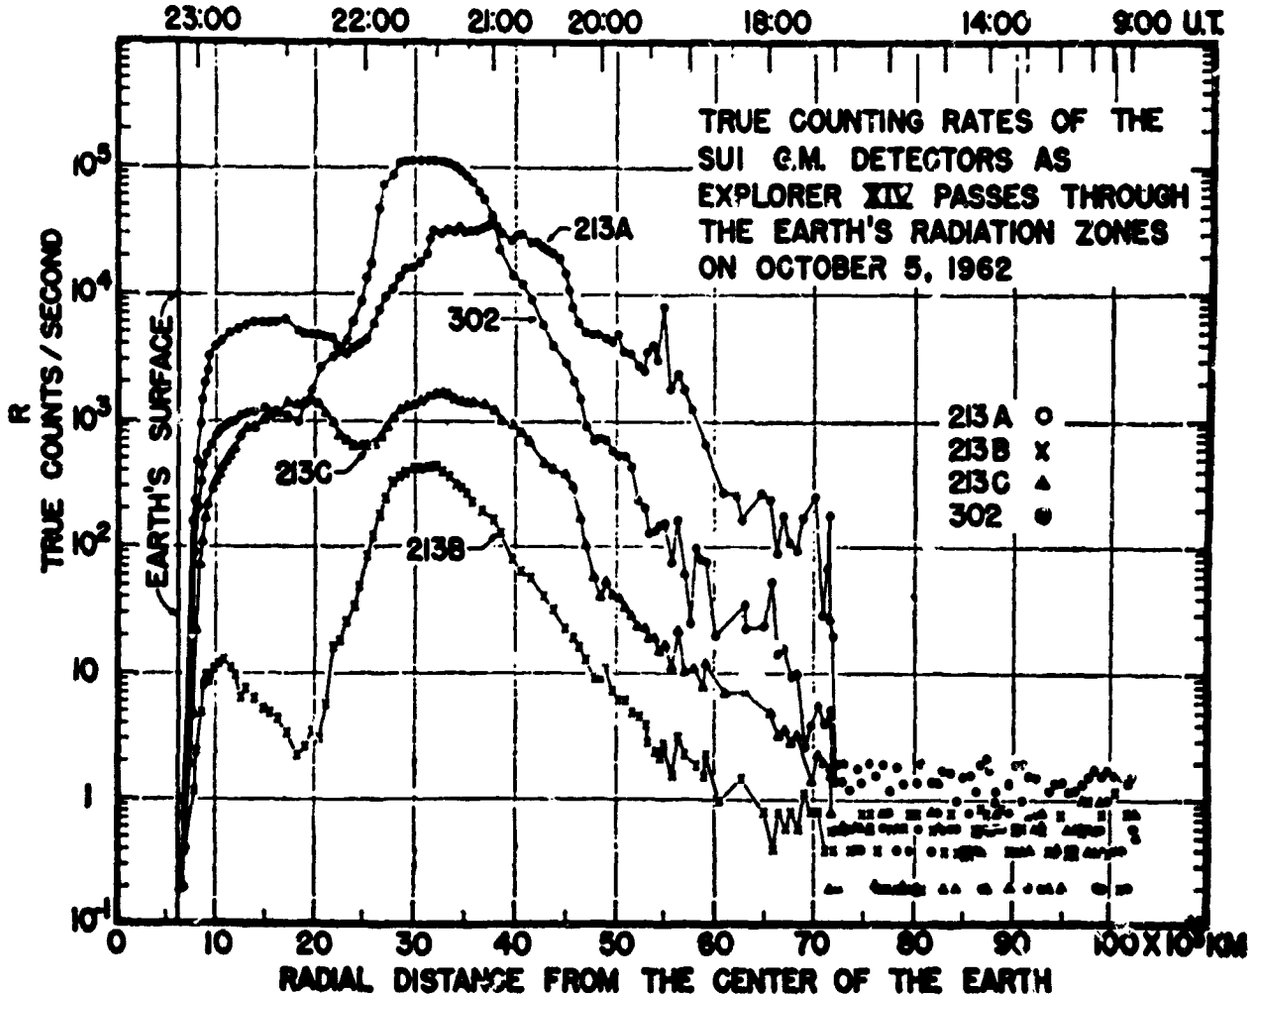

FIGURE 7.—Explorer XIV data showing the abrupt termination of the magnetically trapped particle belts at the magnetopause. The detector labeled 213A accepts the particles of lowest energy; it records principally 50-kev electrons. Its counting rate drops sharply at a radius of 72,000 kilometers, or 12.5 R_E, which corresponds to the location of the magnetopause during this flight. [From L. A. Frank, J. A. Van Allen, E. Macagno, *J. Geophys. Res.* 68, 3545 (1963).]

The detector which accepts the particles of lowest energy is labeled 213A, and its counting rate reflects principally the flux of 50-kev electrons. At the magnetopause the counting rate of this detector drops, by a factor of approximately 20, to a value which is approximately independent of altitude and is produced by the cosmic ray background in space.

Within the magnetopause there are no substantial fluxes of energetic particles other than those of the magnetically trapped particles illustrated in Fig. 8. Detectors flown on Mariner II indicate that the sun is the source of a particle stream which flows through interplanetary space continually, although with variable velocity and intensity. The Mariner II detectors, and also the plasma probe flown on Explorer X by B. Rossi, H. S. Bridge, A. J. Lazarus, A. Bonetti, and F. Scherb of the Massachusetts Institute of Technology, have shown that these particles move radially outward from the sun at velocities varying from 300 to 600 kilometers per second and at an average flux of 10^8 sec^{-1} outside the magnetopause. The interplanetary stream of solar particles, called the solar wind, cannot penetrate the magnetic field of the earth but divides and flows around it as the waters of a stream divide around a boulder (Fig. 8). The closest distance of approach of the solar wind to the earth is about 10 earth radii.

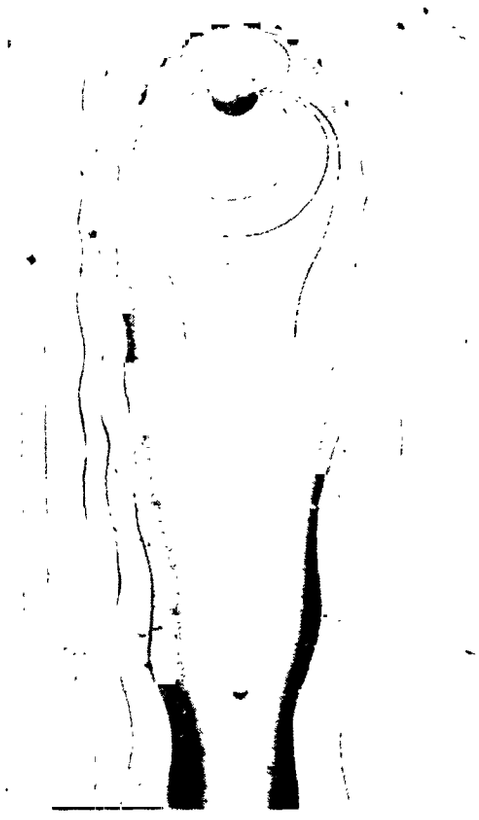

FIGURE 8.—The geomagnetic cavity in the solar wind.

The shadow or cavity carved by the magnetic field of the earth in the solar wind should, in principle, extend back indefinitely far into the solar system behind the earth. However, because the particles of the stream have appreciable transverse velocities associated with their thermal motions, we expect these particles to diffuse together eventually in the shadow of the earth. The ratio of mean transverse to radial velocities is about ¼, hence we expect the geomagnetic cavity to be filled in at a distance of 4 times the diameter of the cavity, or, roughly, the distance of the moon from the earth, as suggested in Fig. 8.

The amount of energy transferred from the solar wind to the atmosphere within the cavity is difficult to estimate. The variable magnetic fields in the solar plasma are believed to glue the particles together and give their motion the properties of fluid flow, in spite of the low density; thus turbulence would be expected at the region of impact of the solar wind on the magnetopause. The bufleting of the magnetospheric boundary associated with this turbulent impact may generate disturbances in the field just within the magnetopause. These disturbances propagate hydromagnetically down or across the field lines into the atmosphere, where they transfer energy which may appear as atmospheric heating, ionization, auroral disturbances, and magnetic storms —that is, the whole complex of disturbances produced in the atmosphere at high geomagnetic latitudes at times of solar activity.

The interaction of the solar plasma with the magnetosphere also leads to the expectation that a "shock wave" will be formed some distance beyond the actual magnetopause. This expectation arises from the fact that the flow of the plasma is supersonic and must become subsonic in the vicinity of the earth. Such a transition would set up a shock wave which would stand off some distance from the magnetopause and would have a thickness determined by the ability of the magnetic field to change the bulk motion of the plasma particles. Evidence of the perturbed magnetic fields corresponding to the shock wave and the intervening transition region has been detected by N. F. Ness of the Goddard Space Center with magnetometers flown on the Interplanetary Monitoring Platform (IMP) spacecraft launched on 27 November 1963.

ATMOSPHERE OF VENUS

Venus is the third brightest object in the sky, the planet nearest the earth, and the planet most closely resembling the earth in size and mass. It has been studied with the telescope since Galileo's time, and yet it remains an enigma, because its surface is permanently shrouded by a layer of clouds. In this state of ignorance, hope has flourished that Venus offers a hospital environment for the development of advanced forms of life.

Some information regarding the surface of the planet has been obtained in recent years through study of the microwave radiation emitted in the longwave region of its thermal spectrum. This radiation, with wavelengths in the region of 1 to 10 centimeters, penetrates the clouds without significant attenuation; its intensity is proportional to the temperature of the emitting surface.

The first attempts to measure the microwave radiation from Venus were made in 1956 with the Naval Research Laboratory radio telescope. The

temperature inferred from the measured radiation intensity was approximately 600°K (700°F)—certainly too high to permit any terrestrial forms of life. Repeated measurements have confirmed the Naval Research Laboratory results and have a revision of our ideas regarding the surface and lower atmosphere of Venus.

It is difficult to understand why the temperature of Venus should be so much higher than that of the earth. The path to an explanation would seem to lie in the assumption of an extremely dense atmosphere which absorbs strongly in the infrared region of the spectrum but is transparent with respect to visible radiation. The part of the incident sunlight which is not reflected back by the clouds will therefore penetrate through the atmosphere and heat the surface of the planet. But when the surface layers reradiate this energy at infrared wavelengths, the radiation is absorbed by the atmosphere and returned in large measure to the surface, thus giving an additional flux of energy into the ground and raising its temperature. This atmospheric phenomenon is the greenhouse effect described earlier.

The clouds of Venus reflect three-quarters of the incident sunlight; the remaining quarter of the incident radiation would bring the surface of the planet to a temperature of 235°K if there were no atmospheric greenhouse effect. If the greenhouse effect is to raise the ground temperature to 600°K, the optical thickness of the atmosphere must be 50 mean free paths throughout the far-infrared region. In an atmosphere with this degree of opacity, only one photon in 10^{21} escapes directly, without absorption. This condition is so severe that alternative suggestions have been made, among them the hypothesis that the apparently high radio temperature of Venus is the result of microwave emission from its ionosphere rather than from the surface.

The Mariner II Venus flyby launched on 27 August 1962 included experiments designed to test this hypothesis. This spacecraft passed Venus at a distance of 33,440 kilometers (20,900 miles) on 14 December 1962, and made crucial measurements of the temperature across the disc. The spacecraft was equipped with two sets of radiation detectors, one in the infrared and one in the microwave region. Measurements of the radiation emitted by the planet in the microwave region included measurements of radiation of 19-millimeter wavelength, which passes through the atmosphere with little attenuation and hence provides a measure of the temperature at the ground, provided there is no additional emission from the ionosphere.

A modest degree of atmospheric attenuation is, however, to be expected, and in the scan of Mariner II across the disc of the planet this slight degree of attenuation should show up as a lower intensity of measured radiation at the edge or limb of Venus, where the thickness of the intervening atmosphere is greater. However, if the high microwave intensities and apparent temperatures result from emission by electrons in the atmosphere of Venus, then the readings at the limb should indicate an enhancement or brightening because of the greater thickness of the ionosphere in the line of sight.

The Mariner II results showed a conclusive darkening of the limb of Venus at 19 millimeter wavelength, thus eliminating the possibility of ionospheric emission and confirming the supposition that the measured radio temperature of 600°K is associated with the surface of the planet.

EXPLORATION OF THE MOON

The moon is a uniquely important body in the study of the history of the solar system because its surface has preserved the record of its history remarkably well. The moon has a negligible atmosphere and no oceans. It is, therefore, unchanged by the processes of erosion which erase the history of the earth's surface in a relatively short time—between 10 and 30 million years.

This is evidenced, in part, by the tens of thousands of craters on the lunar surface, produced by the impact of meteorites which, presumably, have been colliding with the moon since its formation. This is perhaps the only physical record which we have of events in the development of the solar system going back to that early time.

Because of the antiquity of the moon's surface, there is another remarkable record preserved—a layer of cosmic dust which is believed to have rained on it from the solar system since its formation. This dust may be as much as 30 centimeters or more in depth and may contain organic molecules and the precursors of life on earth.

The most important measurements of lunar properties from spacecraft have resulted from flights of the Russian Lunik II and Lunik III. From the Lunik II magnetometer data Soviet scientists concluded that an upper limit of approxmately 100 gammas could be placed on the moon's magnetic field. In future flights, refinement of this limiting value for the moon's magnetic field may provide information on the presence or absence of a liquid core within that body (on the earth the magnetic field is supposed to be associated with currents in the liquid core of the planet). This in turn could have a bearing on our understanding of the formation of the moon and of similar bodies in the solar system.

Lunik III has provided us with the first pictures of the remote side of the moon. In spite of some blurring, the photographs are of great interest, for it is possible to distinguish a large number of features resembling the craters and maria on the front face. Perhaps the most interesting feature is the Soviet Mountain Range, a chain extending across the center of the moon's hidden face. It resembles the great ranges on the earth and is unlike the mountain formations characteristic of the moon's front face, which seem to be circular crater walls and deposits of debris formed by the impact of large meteorites on the lunar surface.

According to our present ideas, terrestrial mountains result from the combined effects of erosion and wrinkling of the earth's crust, but such mountain-building forces have been much less effective on the moon. In the photograph, the markings designated the Soviet Mountain Range could have resulted from the running together of several obscured but independent markings. However, if these features continue to appear as a single range in later, more detailed pictures, we may have to revise our theories of lunar structure.

SOLAR PHYSICS

One of the most interesting questions in solar physics concerns the manner in which energy is transported above the surface of the sun to heat the chromosphere and corona.

We know that near the center of the sun, where the temperature is approximately 15 million degrees Kelvin, hydrogen is converted into helium by a variety of nuclear reactions. We also know that the sun is a self-adjusting system which expands or contracts in order to maintain a precise balance between the energy generation at the center and the energy emission from the surface.

All regular mechanisms of energy transport can carry heat only from a region of high temperature to a region of low temperature. Therefore, in order for the heat generated by nuclear reactions to be carried away from the center of the sun, the temperature must fall continuously from the center to the edge. This is in fact the case; the temperature falls from 15 million degrees at the center of the sun to 5800 degrees at the visible edge.

However, above the visible edge, which is called the photosphere, there lies a relatively tenuous region of gas which constitutes the atmosphere of the sun. This region is divided into the chromosphere and, above that, the corona.

The puzzling fact is that the temperature of the sun *rises* again above the photosphere, reaching a value of 1.5 to 2 million degrees in the corona. One of the burning questions of solar physics is what constitutes the source of the energy which produces the very high temperatures in the solar corona. Also, what is the mechanism of energy transport by which energy can be carried without appreciable losses through the dense gases of the photosphere and yet undergo great losses in the tenuous regions of the corona?

A current belief is that a wave motion—either a sound wave, a hydromagnetic wave, or a gravity wave—carries energy upward from the photosphere and deposits it in the corona. When a sound wave propagates into a region of decreasing density, its amplitude increases and it steepens into a shock wave. This is a mechanism in which considerable dissipation of energy takes place. It appears that hydromagnetic waves are rapidly damped out below the photosphere, but if they could be generated in the region of the chromosphere, then they would tend not to be dissipated until the waves had reached the corona. Magnetic disturbances above the photosphere may be particularly effective in generating these waves. Gravity waves consist of a kind of rolling motion similar to the waves on the surface of the ocean. These may, like sound waves, be generated by the motions of convecting material in the transition layer; they would have a vertical component of

propagation and would be dissipated in the corona.

It may be that all three of these mechanisms are operating in the heating of the chromosphere and corona. If this is the case, there may be a steady heating of the corona upon which is superimposed a localized heating associated with magnetic activity. Thus, the heating of the corona is expected to depend upon the magnetic structure in the outer layers of the sun. This dependence is observed in many phenomena. In particular, in sunspot regions where the strengths of the magnetic field are higher than is normal on the sun's surface, both the chromosphere and the corona have a higher than normal temperature.

The behavior of the chromosphere and the corona is most easily observed by studying the ultraviolet emission from the sun, since in the ultraviolet region the amount of light emitted from the photosphere greatly decreases, whereas the higher temperatures in the chromosphere and corona are responsible for the presence of large numbers of emission lines. The most important emission lines are attributable to hydrogen and helium. In order to understand solar-surface physics in more detail, it is essential to obtain observations of the time variations of these emission lines as indicators of the time variations of behavior in the chromosphere and corona.

The first experiments in this direction were very successfully accomplished by the flight of the first Orbiting Solar Observatory, which was launched on 7 March 1962. It gave data over several months, continuously monitoring a number of different wavelength regions for emission from the sun.

Particularly interesting are the data for the interval 11 through 22 March 1962. At the beginning of this period the sun was in an exceptionally quiet condition, but as the period progressed the sun became more and more active, until on 22 March there was a flare of intensity 3. Experiments revealed that the Lyman alpha line of helium II at 304 angstroms increased in intensity by some 33 percent during the interval, and during the flare itself the intensity of the line increased by an additional 14 percent. The lines of iron XV at 284 angstroms and iron XVI at 335 angstroms also increased in intensity by a factor of 4. At longer wavelengths the Lyman alpha line of hydrogen was observed to increase in intensity by 6.8 percent during the flare.

Very interesting results were also obtained in the x-ray region, 1 to 10 angstroms. During the quiet period a flux was observed which was 360 times the theoretical background radiation which would be obtained from a corona at a temperature of 1.8×10^6 degrees Kelvin. This indicates that nonthermal processes are present and important in the corona under even the quietest solar conditions.

A continuing series of Orbiting Solar Observatories is planned in which these interesting phenomena can be monitored continuously during future years.

X-RAYS AND GAMMA RAYS

The space research program is not confined to the discovery of new facts about the solar system. It also gives the astrophysicist an important opportunity to extend his knowledge of more distant parts of space through observations at wavelengths for which photons do not penetrate through the atmosphere. The principal regions involved are the x-ray and gamma ray region, the ultraviolet, the infrared, and long-wavelength radio waves. The early rocket and satellite measurements of x-rays and gamma rays have been particularly interesting to physicists because they suggest several possible new types of phenomena in space.

X-rays and gamma rays can be produced by a variety of high-energy processes. These processes include collisions between high-energy nucleons, which can create neutral pions, which in turn decay to give gamma rays exceeding 50 Mev in energy. Fast electrons can produce X-rays of bremsstrahlung when they pass close to a nucleus. Fast electrons can also collide with photons of visible starlight and increase the energy of the photons up to the x-ray and gamma ray regions. If radioactive nuclei are produced and dispersed in space between the stars, then some of them should emit characteristic gamma ray energies which might be detected. If positrons are produced in dense regions of matter, such as stellar surfaces, then, upon being slowed down and annihilated, they will emit the characteristic gamma rays of 0.51-Mev energy. If neutrons are produced near stellar surfaces and are slowed down

and captured by the overwhelmingly abundant hydrogen that is present, then these will provide characteristic capture gamma rays with an energy of 2.31 Mev. Finally, if objects should exist in space with surface temperatures of some millions of degrees Kelvin, then photons in the x-ray region would be emitted by thermal processes from their surfaces.

Preliminary measurements now exist of the fluxes of x-rays and gamma rays in a number of different energy intervals. A general background of x-rays of energy of a few thousand electron volts was observed in a rocket flight by R. Giacconi, H. Gursky, and F. R. Paolini, of American Science and Engineering, Inc., and by B. B. Rossi of the Massachusetts Institute of Technology. A general background radiation of gamma rays in the region near 1-Mev energy was measured in the Ranger III flight by J. R. Arnold of the University of California (La Jolla), A. E. Metzger, of the California Institute of Technology, and E. C. Anderson and M. A. Van Dilla, of Los Alamos. A small but still significant flux of gamma rays with energies exceeding 50 Mev was observed with the Explorer XI satellite by W. L. Kraushaar and G. W. Clark of the Massachusetts Institute of Technology.

A number of attempts have been made to explain the presence of these background x-rays and gamma rays. Most mechanisms thus far examined appear quantitatively inadequate to explain the observed fluxes. One promising explanation was proposed by J. E. Felten and P. Morrison of Cornell University, who suggested the importance of the inverse Compton effect in which the high-energy electrons present in the cosmic rays collide with photons with energies of the order of 1 electron volt which are emitted from stars. Following such a collision, the energies of the photons can easily be raised to the observed x-ray or gamma ray energies, depending upon the energies of the electrons with which they collide. Calculations by Felten and Morrison were based on this effect (Fig. 9). A flux will be emitted by the outer halo region of our galaxy if the observed flux of high-energy electrons at the earth exists throughout this large outer region of the galaxy. Electrons in the halo fail to account for the observed x-ray and gamma ray fluxes by some 2½ orders of magnitude. However, if the flux of high-energy electrons is the same throughout space as near the earth, then a background radiation some 30,000 times that which would be produced within the galactic halo would be observed. Evidently, such high fluxes of electrons cannot exist throughout space. One percent of such a flux of electrons can be expected to give a background of x-rays and gamma rays which fits the observations very nicely.

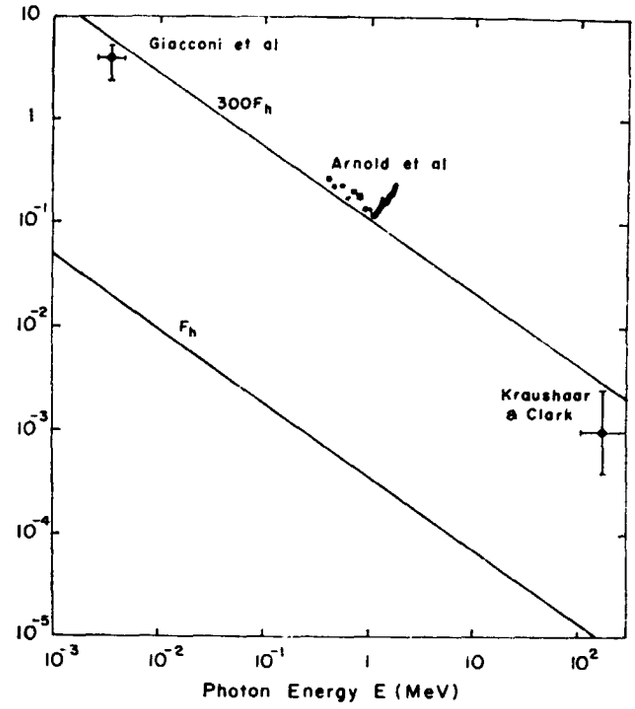

FIGURE 9.—Data on hard photon fluxes in space, compared with theoretical recoil spectra. The data points are as plotted by Felton and Morrison. F_h is the expected contribution from scattering in our galactic halo. The upper curve shows a flux 300 times greater, but still less by two orders of magnitude than the flux that would be obtained if the electrons in our galactic halo extended throughout intergalactic space. [From J. E. Felten and P. Morrison, *Phys. Rev. Letters* 10, 455 (1963)].

Perhaps the most interesting questions concerning the celestial x-rays have been raised through the discovery of discrete sources by Rossi and his colleagues and by H. Friedman. S. Bowyer, T. A. Chubb, and E. T. Byram of the Naval Research Laboratory. Both groups have observed a strong x-ray source in Scorpius which is not coincident with any conspicuous object. Friedman has suggested that this object is a neutron star having a surface temperature of several million degrees, and that the x-rays are due to

thermal emission from the surface layers. Rossi and his colleagues have determined from atmospheric absorption measurements that if the Scorpius source has a thermal spectrum its temperature is approximately 8×10^6 degrees Kelvin. Friedman and his colleagues have also observed x-rays from the direction of the Crab Nebula, the remnant of the supernova explosion of A.D. 1054 (Fig. 10).

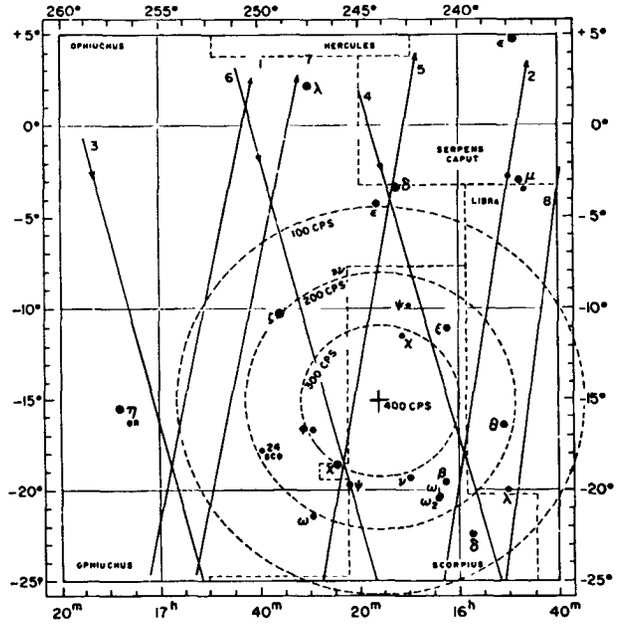

FIGURE 10.—Tracks of eight scans across the Scorpius region. The numbers along the tracks are counts per 0.09-second interval. The dashed circles are best fits to equal-intensity contours and indicate a central intensity peak of 400 count/sec at $\alpha = 16$ hours 15 minutes, $\delta = -15°$. [From S. Bowyer, E. T. Bryam, T. A. Chubb, H Friedman, *Nature* 201, 1307 (1964)].

Neutron stars are hypothetical objects which form one class of degenerate stars, the other class being the degenerate white dwarf stars, which are observed. A typical density for matter in a white dwarf star is 10^6 g/cm^3, and the electrons form a degenerate gas which exerts sufficient pressure to maintain the stars against further contraction. If mass were to be added to such a star, the central region would have to become denser in order to supply the additional pressure required to support the additional mass. There is a relativistic upper limit to the mass of white dwarf stars, but before this limit is reached, the energies of the degenerate electrons have become so high that the nuclei are forced to undergo multiple electron capture reactions, and the nuclei dissolve mainly into neutrons, with only enough protons and electrons left to prevent the neutrons from undergoing their usual mode of decay into electrons and protons.

At 10^{15} g/cm^3 or more, densities comparable to those in the atomic nucleus, this neutron-rich nuclear matter itself becomes degenerate, and it is expected that stable stars could be constructed of it. Such stars may be formed in the central regions of more massive stars when these stars undergo supernova explosions and blow off most of their mass. Recent work by D. Morton of Princeton, E. E. Salpeter of Cornell, and H. Y. Chiu, S. Tsuruta, and A. G. W. Cameron of the Goddard Institute for Space Studies indicates that the surface temperature of a neutron star is likely to lie below its central temperature by between one and two orders of magnitude. Thus, if such stars are formed with central temperatures over 10^9 degrees Kelvin, such as would probably be produced in a supernova explosion, then their surface temperatures are likely to be many millions of degrees for several thousand years.

g_J OF THE $(5s5p)\ ^3P_1$ LEVEL OF Cd AND THE $(6s6p)\ ^3P_1$ LEVEL OF Hg BY HIGH-FIELD DOUBLE RESONANCE*

R. KOHLER† AND P. THADDEUS

An optical double resonance experiment at high magnetic fields has determined g_J for the $(5s5p)\ ^3P_1$ level of the even cadmium isotopes to be 1.499846(13), and g_J for the $(6s6p)\ ^3P_1$ level of the even mercury isotopes to be 1.486094(8). Resonance was observed in all cases at a frequency of exactly 24 Gc/sec, and magnetic fields near 11 430 G. At these high fields the Zeeman energy is of the order of 10^{-3} of the fine structure separations of the triplet terms of the $(nsnp)$ configuration, and the $\Delta m = \pm 1$ transitions are split by 9.51(7) G for Cd, and by 2.99(7) G for Hg. This splitting represents several linewidths in the case of Hg, and many linewidths in that of Cd. The average field of the two $\Delta m = \pm 1$ transitions, however, determines g_J to high precision independent of second-order corrections.

I. INTRODUCTION

The double resonance[1,2] and level crossing techniques[3,4] have been used in extensive studies of hyperfine structure (hfs) in the lowest lying $(nsnp)\ ^3P_1$ level of mercury,[5–11] cadmium,[12–17] and zinc.[18–20] Sufficient sensitivity has been obtained to allow the determination of the hfs, and consequently the nuclear moments, of radioactive isotopes with half-lives as short as a few hours.[15,16]

While the level crossing method has the great advantage in practice of doing away with all radio-frequency and microwave apparatus, aside from nuclear magnetic resonance (NMR) magnetometers, it allows a determination of only the ratio of the hyperfine interaction constants to g_J, and an independent measurement of g_J must therefore be made to determine these constants to high precision.[16] While g_J can of course be measured by double resonance in the odd isotopes at various fields, or by observing both double resonance and level crossings,[9,13] it is most directly found from double resonance in the even isotopes of the element.

In principle, the higher the frequency and the greater the magnetic field, the more accurate the determination of g_J. In a series of experiments designed to measure g_J of the lowest lying $^3P_1$ level of zinc, cadmium, and mercury to high precision (it is $\frac{3}{2}$ on the basis of LS coupling), we therefore chose to work at a frequency of 24 Gc/sec, and a field near 11 400 G—approaching the limit attainable with the available 12-in. electromagnet when operating with a gap of 2 in.

The $\Delta m = \pm 1$ transitions for these states coincide at low magnetic fields, but at high fields interaction with the neighboring fine structure terms of the configuration (and to a negligible degree with levels of other configurations) splits the resonances into two well-resolved components, as shown in Fig. 1. Precise measurement of the splitting of the two resonances therefore serves also as a check on the theory of the second-order fine structure interactions.

II. THEORY

Signal Strengths

It is well known that double resonance can be observed between hyperfine or Zeeman states excited by resonance radiation in a variety of ways. Population differences can be produced by resonance radiation that is polarized, nonisotropic, or confined to a narrow wavelength interval,

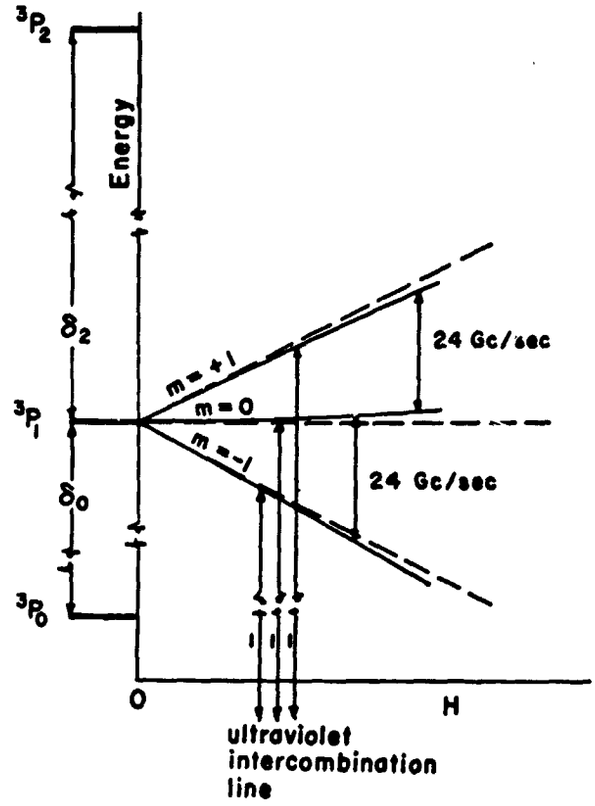

FIGURE 1.—Zeeman effect of the $^3P_1$ state of the even isotopes of zinc, cadmium and mercury, showing the effect of second-order interaction with the other fine structure levels of the configuration.

and all of these methods have been put to practical use.[1,2,6]

To dispense with ultraviolet polarizers, we relied on the latter two effects and used the exeprimental geometry shown in Fig. 2. Only lamps containing the natural metal were used. In the case of cadmium, the Zeeman shift of the $m=\pm 1$ states at 11 400 G is somewhat greater than the isotope shifts and the hyperfine splittings of the natural cadmium isotopes (and the optical Doppler width),[14] and only the $m=0$ state is therefore illuminated. It is then readily calculated in terms of the transition probabilities that at double resonance the resonance fluorescence at 90° is reduced by a factor of $\frac{1}{4}$.

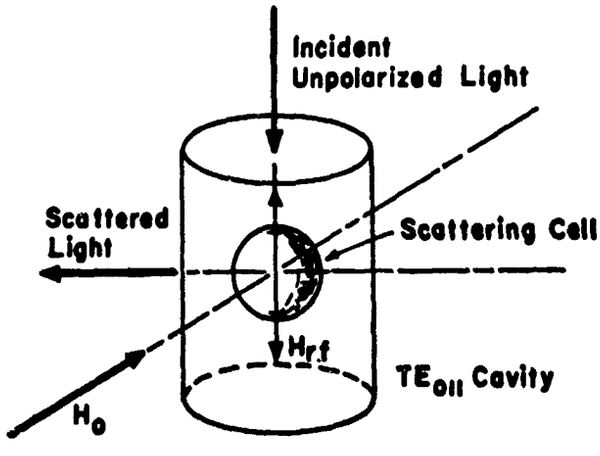

FIGURE 2.—Geometry of the experiment.

For mercury, on the other hand, the isotope shifts and hyperfine splittings are comparable to the Zeeman shift of the $\Delta m=\pm 1$ states,[21] and we must rely mainly on the nonisotropic nature of the resonance radiation. In the least favorable case, on the assumption that all three states are equally illuminated, it is calculated that the resonance fluorescence at 90° is reduced by a factor of 1/12 at double resonance.

Linewidths

Several effects determine the linewidth and shape of the double resonance effect, and have all been considered in detail elsewhere. Most fundamentally, the natural lifetime τ of the state gives a Lorentzian line shape with full width at half-maximum of $g_J\mu_0\Delta H_n=\Delta\nu_n=1/\pi\tau$.[1,6] The natural linewidths for zinc, cadmium, and mercury calculated from the lifetimes in Table I are listed in Table II.

If the rf magnetic field is strong enough to induce many transitions during the lifetime τ, the resonance will be power broadened.[1,6] In practice the rf power is always attenuated to the point where this effect is small, and it will therefore not be considered further.

Double resonance owes its high resolution to the fact that Doppler broadening is determined by the radio rather than the optical frequency. At microwave frequencies, however, the Doppler linewidth $\Delta\nu_d=(\nu/c)\times(8NkT\ \ln 2/M)^{1/2}$, where N is Avogadro's number and M is the molecular weight, may not be altogether negligible, as is shown in Table II.

Inhomogeneity of the magnetic field over the scattering sample contributes a linewidth ΔH_m that can often be reduced by careful alignment of the pole pieces. We found, however, that as our magnetic field approached 11 400 G, its homogeneity fell off rapidly due presumably to uneven

saturation. We estimate that $\Delta H_m = 50$ mG over a 5-mm sample.

Collisions with the walls of the scattering cell effectively shorten the lifetime of the excited state, and contribute a wall-quenching linewidth $\Delta\nu_w$ which depends mainly on the size of the cell. We have made estimates of $\Delta\nu_w$ in Table II on the assumption that $\Delta\nu_w = 1/\pi\tau_w = (3NkT/M)^{1/2}/\pi a$, where τ_w is the time for an atom at the temperature of the optimum vapor pressure to travel the radius a of the scattering cell.

Collisions between the scattering atoms will broaden the resonance at high vapor densities, while multiple scattering of the optical photons may actually decrease the linewidth (coherence narrowing).[22,23] Both of these effects may be avoided by working at low enough temperatures.

Quenching by atomic or molecular contaminants in the scattering cell, on the other hand, may contribute a linewidth $\Delta\nu_c$ which cannot be easily estimated in advance, and cannot be reduced once the cell is made. We shall see that possibly except for zinc we found no evidence of quenching of this kind.

Zeeman Effect

Interaction with the two neighboring triplet levels of the ($nsnp$) configuration contributes a term which is of the order of the (Zeeman energy)^2/(fine structure energy) $\approx 10^{-3}\times$(Zeeman energy) to the energy of the $m=\pm1$, 0 states. More precisely, from perturbation theory,[24]

$$W_{+1} = g_J\mu_0 H - \frac{\alpha^2(g_S-g_L)^2\mu_0^2H^2}{4\delta_2}, \qquad (1a)$$

$$W_0 = \alpha^2(g_S-g_L)^2\mu_0^2H^2\left(\frac{2}{3\delta_0}-\frac{1}{3\delta_2}\right), \qquad (1b)$$

$$W_{-1} = -g_J\mu_0 H - \frac{\alpha^2(g_S-g_L)^2\mu_0^2H^2}{4\delta_2}, \qquad (1c)$$

where μ_0 is the Bohr magneton, α is the mixing coefficient which indicates the departure from Russell-Saunders coupling, and δ_0 and δ_2 are the magnitude of the fine structure separations. We adopt the convention that g_J is positive. Interaction with the singlet term of the configuration, and with terms of other configurations, contributes less than one part in 10^6 to the energy, and third-order terms vanish.

For double resonance at a fixed frequency ν_{dr}, the field H^+, for which $m=0\rightarrow+1$, is greater than H^-, for which $m=0\rightarrow-1$. To within one part in 10^6 we find from Eq. (1) that in terms of the average field $\bar{H}=(H^++H^-)/2$

$$g_J = h\nu_{dr}/\mu_0\bar{H}. \qquad (2a)$$

This becomes

$$g_J = g_p(\nu_{dr}/\nu_p), \qquad (2b)$$

if the field is measured in terms of the NMR frequency ν_p of protons. g_p is defined such that the proton magnetic dipole-moment operator is $\mathbf{u}_p = g_p \mu_0 \mathbf{I}_p$. For protons in mineral oil we will take $g_p = 3.041978(3) \times 10^{-3}$, from the average of the measurements of g_s/g_p for protons in mineral oil of Koenig, Prodell, and Kusch,[25] and Beringer and Heald,[26] and the recent measurement of g_s of Wilkinson and Crane.[27]

For the separation of the two resonances we find that

$$\Delta H = H^+ - H^- = \frac{\alpha^2 (g_S - g_L)^2 \mu_0 H^2}{g_J} \left(\frac{4}{3\delta_0} - \frac{1}{6\delta_2} \right), \quad (3a)$$

where δ_0 and δ_2 are in ergs. When the field is measured in terms of the proton frequency,

$$\Delta \nu_p = \frac{\alpha^2 (g_S - g_L)^2 \bar{\nu}_p^2}{c g_p g_J} \left(\frac{4}{3\delta_0} - \frac{1}{6\delta_2} \right), \quad (3b)$$

where δ_0 and δ_2 are in cm^{-1}.

III. EXPERIMENT

A schematic illustration of the experiment is shown in Fig. 3. Resonance radiation from an rf lamp was focused with a quartz condensing lens onto a small cell containing cadmium or mercury vapor. The cell was located within a microwave cavity between the poles of a 12-in. electromagnet. This cavity in the case of cadmium also served as an oven to control the vapor density in the scattering cell.

Resonance fluorescence of the atomic vapor was observed with a photomultiplier at an angle of 90°. A light pipe allowed the photomultiplier to be removed from the magnetic field without loss of solid angle. A glass color filter effectively removed all scattered light except the resonance radiation.

The microwave cavity was tuned to resonance with a klystron kept at a frequency of exactly 24 Gc/sec, the field being modulated at a low audio frequency, typically 37 cps, by small rectangular coils attached to the pole faces. At resonance, the light scattered at 90° changed in intensity, and the signal from the photomultiplier was displayed on an oscilloscope.

Field measurements were made with an NMR magnetometer, whose small mineral-oil probe was located as close to the scattering cell as possible. The offset correction was measured with a second probe and oscillator.

Optics

The cadmium lamp used consisted of a small quartz cylinder, 1.5 cm diameter and 2.5 cm long, carefully baked out, purged with an rf discharge in argon and then filled with a small amount of distilled natural cadmium and about 1 torr of spectroscopically pure argon. It was identical to the lamps previously used in this laboratory for several level crossing and double resonance experiments.[13,14] It was excited by being placed, without cooling, in the tank coil of a Hartley oscillator operating in the vicinity of 30 Mc/sec. Experience has shown that these lamps furnish about 1 W (total output over 4π solid angle) in the 3261-Å intercombination line.

For mercury an Osram lamp was used that had the outer jacket removed, and was cooled with a gentle air stream to eliminate self-reversal. It too was excited with a radiofrequency oscillator operating near 30 Mc/sec and was run at the same

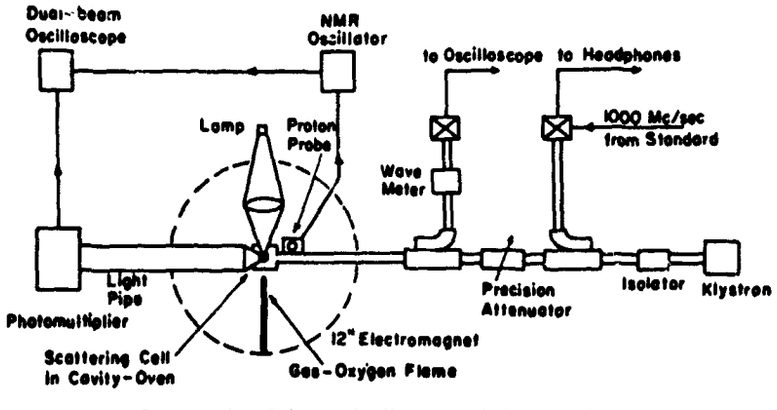

FIGURE 3.—Schematic diagram of the experiment.

current specified by the manufacturer for operation at 60 cps.

The scattering cells were designed to have as small an effect as possible on the electrical properties of the microwave cavity. They were very thin walled quartz bubbles, 5 mm in diameter, blown at the end of a length of 2 mm outer diameter quartz tubing, which, when cut off at a length of 5 cm, served as the tail of the cell. These cells were baked out at 1000°C for a day or longer, purged with a Tessla coil for several minutes, and filled with a small quantity of distilled metal, all under very high vacuum (less than 10^{-8} Torr for the last stage). The light pipe used to remove the RCA-1P28 photomultiplier from the vicinity of the magnet was a glass tube aluminized on the inside, 1 in. in diameter, and about 2½ ft. long. To pass the 3261-Å line of cadmium, or the 2537-Å line of mercury, and exclude other scattered light, a Schott UG-11 or UG-5 colored glass filter was cemented to the end of the light pipe.

Microwave Cavity and Oven

The TE_{011} cylindrical aluminum cavity oven used for cadmium is shown in Fig. 4. It had an internal diameter of 1.4 cm, a Q of about 4000 when loaded with the cell, and was coupled about 50 percent to the microwave line. A hole 6 mm in diameter at the top of the cavity, below cutoff at 24 Gc/sec, allowed illumination of the scattering cell. Small slits in the side of the cavity, also below cutoff, allowed the light scattered at 90° to be observed.

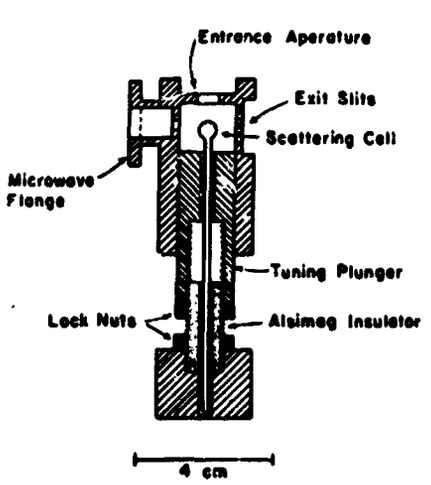

FIGURE 4.—The cavity oven used for cadmium.

The waveguide connecting the cavity to the microwave line was thinned to provide thermal insulation. The cavity was heated with a small gas-oxygen flame, the temperature being monitored by a small copper-constantin thermocouple. Thermal regulation was provided by a Honeywell R7086A thermocouple-activated regulator that played a stream of cool air against the cavity when the thermocouple voltage exceeded a preset figure.

The long tail of the scattering cell passed through an aluminum tuning plunger, and an insulating refractory section, and terminated in the aluminum cylinder shown in the bottom of Fig. 4. This cylinder was heated with another gas-oxygen flame, and its temperature regulated with a separate regulator unit. It was always kept at least 40°C cooler than the oven, and consequently determined the cadmium vapor pressure.

For mercury, in an attempt to gain a higher Q, a thin-walled copper cavity was used that was kept at room temperature. With a brass tuning plunger, a loaded cavity Q of about 8000 was obtained. The tail of the cell was usually kept at room temperature, but could also be cooled in an ice bath.

Microwave Measurements

The Varian VA-98E klystron used in this experiment is an extremely stable tube that oscillates only over the region from 23.6 to 24.4 Gc/sec, with an average output of about 30 mW. To achieve maximum stability, we used batteries for both the heater and repeller voltages, and a well-regulated power supply for the beam voltage. No electronic stabilization of the tube was employed. During a run it was kept manually to within an audiobeat not of the 24th harmonic of the 1000 Mc/sec output of the laboratory's frequency standard. This represents a stability of about one part in 10^6, and is therefore quite adequate for the purpose of this experiment.

Field Measurements

The proton probe of the NMR magnetometer used for field measurements consisted of a small spherical cavity filled with mineral oil drilled in the center of a teflon spool. The inductance for a transistorized marginal oscillator was wound on the spool which was then placed in a brass or copper shield. It was located as close as possible

to the scattering cell (about 4 cm away), and the output signal of the marginal oscillator was displayed with the double resonance signal on a dual beam oscilloscope. The NMR frequency, near 48 Mc/sec, was measured with a Hewlett-Packard direct reading frequency counter whose reference frequency was taken from the laboratory standard. The offset correction was measured by removing the oven, placing a second probe driven by another identical oscillator at the scattering cell location, and measuring the beat frequency (≈ 4 kc/sec) of the two oscillators with the frequency counter. A pentode mixer gave the difference frequency without excessive cross coupling of the two oscillators.

The offset correction was found to depend on the field history, and a correction was therefore made after each field measurement.

IV. RESULTS

For cadmium the onset of power broadening was observed when about 5 mW of microwave power were incident on the cavity, in rough accord with our preliminary estimates based on the lifetime of the $(5s5p)\ ^3P_1$ level, and the electrical properties of the cavity. With oscilloscope display giving a detector bandwidth of about 1 kc/sec we succeeded in obtaining a signal-to-noise ratio of about 30 for both the $\Delta m = \pm 1$ double resonance transitions [Fig. 5(a)]. The observed linewidth (Table II) shows no evidence of contamination broadening.

The shorter lifetime of the $(6s6p)\ ^3P_1$ level of mercury was found to require for maximum signal strength somewhat higher rf fields than the VA-98E klystron and aluminum cavity could provide. A higher Q copper cavity subsequently used for mercury just allowed the level of power broadening to be reached. The observed resonances [Fig. 5(b)] had a signal-to-noise ratio of about 5. It should be recalled that because of the illumination of the $m = \pm 1$ states the mercury signals are expected to be about 3 times weaker than those of cadmium. The additional discrepancy in signal strength can be attributed to the somewhat weaker output of the mercury lamp. The linewidth was in agreement with expectations (Table II).

We had originally hoped to extend our measurements to the $(4s4p)\ ^3P_1$ level of the even zinc isotopes, although we were aware that the long lifetime of this level would produce serious quenching of the excited state atoms against the wall of the scattering cell. We, in fact, made several runs using narrow-band phase-sensitive detection with time constants as long as 5 sec, but failed to detect either double resonance or fluorescence. Beyond the quenching and broadening mechanisms listed in Table II, we are inclined to attribute this to contaminants produced by the high cell temperatures required for zinc.

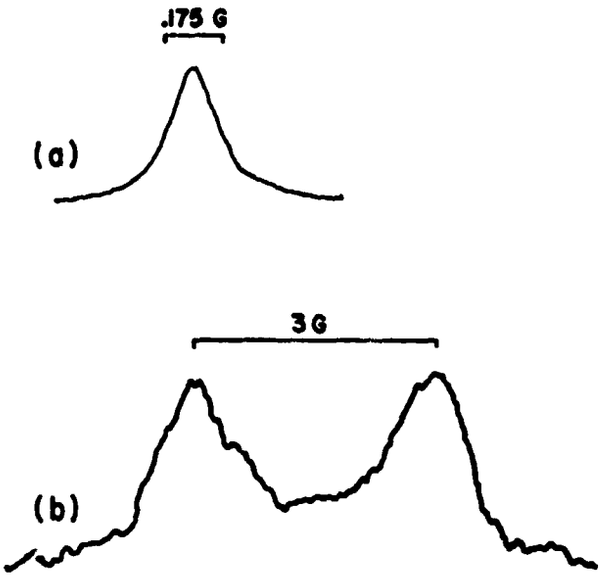

FIGURE 5.—Oscilloscope traces of the double resonance signals: (a) is one of the $\Delta m = \pm 1$ cadmium transitions, (b) is the sum of these two transitions for mercury, split by the second-order interactions.

The magnetic fields at which double resonance was observed for cadmium and mercury are listed in Table III. From Eq. (2) we then find for the $(5s5p)\ ^3P_1$ level of cadmium that

$$g_J = 1.499846(13) = \tfrac{3}{2} - 154(13) \times 10^{-6},$$

in good agreement with the values $g_J^{111} = \frac{3}{2} - 171(9) \times 10^{-6}$ and $g_J^{113} = \frac{3}{2} - 157(9) \times 10^{-6}$ found for the odd isotopes from level crossings[13] and zero-field double resonance[12] (we have here recalculated g_J^{111} and g_J^{113} taking $g_p = 3.041978 \times 10^{-3}$).

Likewise, we find for the $(6s6p)\ ^3P_1$ level of mercury that

$$g_J = 1.486094(8) = \tfrac{3}{2} - 13\ 906(8) \times 10^{-6}.$$

This is in reasonably good agreement with a recent preliminary value of $g_J^{199} = 1.486118(16)$ found by

Smith,[28] who considered both his own level-crossing study of Hg^{199}, and the results of low-field double resonance.[11] It is also in agreement with the less precise value 1.486350(300) found by Dodd[29] from double resonance in the even isotopes. It is in disagreement, however, with the self-consistent values $g_J^{199}=1.486147(10)$ and $g_J^{201}=1.486156(18)$ calculated by Kaul in his thesis[9] from his study of level crossings, and the low-field double resonance results.[6,11]

For cadmium the known lifetimes of the $^3P_1$ and $^1P_1$ levels allow α to be calculated directly from the relation

$$\frac{\beta^2}{\alpha^2}=\frac{\tau(^1P_1)\lambda^3(^3P_1)}{\tau(^3P_1)\lambda^3(^1P_1)}, \tag{4}$$

and the normalization condition $\alpha^2+\beta^2=1$. Using the lifetimes and wavelengths of Table I we find that $\alpha=0.99900(5)$ and $\beta=-0.0448(11)$. The phase convention of Condon and Shortley is used to determine the sign of β.[24] From Eq. (3) the splitting of the resonances is then calculated to be $\Delta\nu_p=40.245(4)$ kc/sec, or $\Delta H=9.452(1)$ G. This is seen from Table III to be 0.255 kc/sec lower than the experimental value, but just within the experimental uncertainty.

Knowing α and β independently from the lifetimes, we are in a position to determine the sum of the relativistic and diamagnetic corrections to g_J. Theoretically

$$g_J=\tfrac{1}{2}\alpha^2(g_L+g_S)+\beta^2 g_L+\Delta g_{\rm rel}+\Delta g_{\rm diam}. \tag{5}$$

Taking $g_L=1$,[30] and $g_S=2.002319$,[27] we find that[31]

$$\Delta g_{\rm rel}+\Delta g_{\rm diam}=-318(40)\times 10^{-6}.$$

Since for mercury the lifetime of the $^1P_1$ level is poorly known, the sum of the relativistic and diamagnetic corrections cannot be found. Instead, however, we may use Eq. (5) neglecting these corrections to obtain $\alpha=0.9849(4)$ and $\beta=-0.1733(24)$. We then calculate from Eq. (3) the splitting of the mercury resonances be to $\Delta\nu_p=12.468(8)$ kc/sec or $\Delta H=2.928(2)$ G. It is interesting to note that this is lower than the experimental value by 0.252 kc/sec, nearly the same as in the case of cadmium. Since the measurement of the splitting ΔH is not susceptible to the same systematic errors as the absolute field measurements, the uncertainties in ΔH given in Table III must be considered quite conservative, and this discrepancy may be significant.

V. DISCUSSION

While an accuracy of about one part in 10^5 has been attained in the field measurements reported in this experiment, for cadmium this represents an uncertainty of one linewidth, and can certainly be improved upon. In retrospect we believe that higher precision could have been realized at somewhat lower frequencies and fields. Most of our uncertainty can be ascribed to the inhomogeneities which crept in as the field approached 11 400 G. Had we worked at half the present field and frequency, for example, the field would have been

TABLE III.—*Measured fields for double resonance in cadmium and mercury, in terms of the NMR frequency of protons in mineral oil, and in G, taking for $1/2\pi\times$ the gyromagnetic ratio 4.25760(4) kc/sec-G.*[a] *A series of runs were made for each atom, care being taken to randomize systematic errors from run to run by slightly relocating the cell and probe within the field, reversing the polarity of the magnet, varying the modulation frequency, changing the vapor pressure, reassembling the optics, etc. The uncertainties quoted are 3 times the standard deviation of the means of the individual runs.*

[a] R. L. Driscoll and P. L. Bender, Phys. Rev. Letters 1, 413 (1958).

considerably more uniform, the scattering cell would have been twice as large (and easier to construct and more durable), the Doppler and wall collision linewidths halved, and the exit and entrance apertures increased in area by four. It is probable that under these circumstances we would have had sufficient signal strength to observe double resonance in zinc, and that the cadmium resonance could have been measured to a small fraction of its width.

ACKNOWLEDGMENTS

We wish to express our thanks to the staff of the Columbia Radiation Laboratory for their invaluable assistance, and to Professor R. Novick for his advice and support. We would like especially to acknowledge the assistance of H. Feldman, who collaborated with us during a part of the cadmium experiment. Finally, Raymond Eisenstark assisted us liberally during all phases of this work as data taker and calculator, and T. Psaropulos kindly prepared the drawings.

ORIGIN OF DIAMONDS IN THE URELITES*

MICHAEL E. LIPSCHUTZ†

Diamonds in two of the three diamantiferous stony meteorites (ureilites) show a pronounced crystallographic orientation. This suggests that the diamonds were produced by shock during breakup of the meteorite's parent body rather than by high gravitational pressure.

In previous papers (*1*, *2*) on the origin of meteoritic diamonds (Table 1) I concluded that the diamonds in the Canyon Diablo iron were formed by conversion of graphite as a result of the shock of impact of the meteoroid with the earth. The subsequent finding of coesite and stishovite (*3*) in the sandstone around the Canyon Diablo crater indicates shock pressures of at least 100 kbar. The successful shock-induced conversion of graphite to diamond in the laboratory (*4*) also lends strong support to the shock origin of Canyon Diablo diamonds.

Diamonds also occur in a rare type of stony meteorite, the ureilites (*5*). These meteorites, however, are too small (Table 1) to have hit the earth at speeds much greater than terminal velocity, and this implies that the diamonds could not have been formed during the impact of the ureilites with the earth. I therefore suggested (*1*) that the diamonds in these meteorites were formed by some preterrestrial shock—probably the one occurring during catastrophic breakup of the ureilites' parent body. In this paper I report on an x-ray study of meteoritic and synthetic diamonds which was undertaken to examine this suggestion.

The direct conversion of graphite to diamond is not a complex one. It is necessary only to increase the interatomic distance within individual carbon planes by 0.12 Å (Fig. 1) and to decrease the interplanar spacing (*c*-axis) by about 1.86 Å. If a randomly oriented infinite distribution of graphite crystallites is assumed, it should be possible to determine whether a given diamond aggregate was produced by shock, inasmuch as only those graphite crystallites with *c*-axes parallel to the direction of motion of the shock will be converted to diamond (*6*). The resulting diamonds should exhibit a preferred crystallographic orientation. Diamonds formed by hydrostatic (gravitational) compression, on the other hand, will show no such structure since hydrostatic pressure acts isotropically in a medium. In fact, the situation may not be quite so simple because of

complicating effects due to secondary and rarefaction (reflection) waves. Therefore, a preferred orientation should be apparent in at least some instances of diamonds formed by shock. The absence of such an orientation, however, cannot rule out the formation of diamonds by shock.

Specimens from all three ureilites were prepared for x-ray analysis by carefully carving or chipping them out so as not to affect the possible orientation of the crystallites within each fragment. The specimens, each of which weighed less than about 0.1 mg, were then examined by previously described diffraction techniques and equipment (*2*) to determine their composition. Fortunately the other phases in the specimens did not possess diffraction lines which would interfere with those of diamond.

After verification of the presence of diamond in the fragment, the specimen was studied with a Unicam model S.25 single crystal goniometer (*7*). In this experimental arrangement, a polycrystalline aggregate would be indicated by uniform ellipses centered on the x-ray outlet port, while preferred orientation would be evidenced by enhancement of segments of these ellipses. Large single crystals would be indicated by single spots, while deformed single crystals would be evidenced by asterism of these spots in directions approximately perpendicular to the ellipses.

Stationary x-ray photographs were taken every 10° with iron-filtered CoKα [for the (111) diamond planes] and zirconium-filtered MoKα [for the (220) and (311) planes of Goalpara diamond]. The angles ρ and Φ, corresponding to the ends of the preferred orientation zones in each set of normals to the reflecting planes, were measured (*8*) and then plotted on a polar stereographic net graduated in 2° increments (*9*).

The composition and sizes of the diamonds in the ureilites vary. All of the discrete diamond grains that I have analyzed are polycrystalline aggregates consisting of diamond, randomly oriented polycrystalline graphite, and other phases (Table 1).

The α^1–α^2 doublet of the diamond (331) plane provides a useful measure of the average crystallite size. From the lack of resolution of this doublet in Goalpara, Zachariasen (*10*) has estimated that the diamonds are about 100 Å. The diamonds from Dyalpur and Novo Urei on the other hand

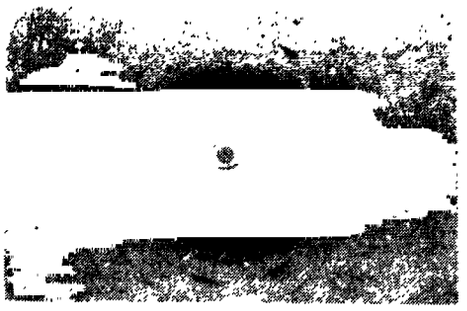

FIGURE 2.—Zirconium-filtered MoKα x-ray pattern of nonrotated diamond grain from Goalpara (×2). The graphite [002] plane shows that the graphite is polycrystalline and randomly oriented. The diamond [111], [220], [311], [400], and [331], on the other hand, shows preferred orientation.

are relatively large; those from Dyalpur are very much larger than 300 Å.

The diffraction pattern of a Goalpara diamond is shown in Fig. 2. The diamond reflections indicate pronounced preferred orientation whereas the graphite is randomly oriented. Stereographic projections of the diamond [111], [220], and [311] directions (Fig. 3 *a*, *b*, and *c*) reveal very striking patterns. The angles listed on each projection are those which that simple cubic plane makes with its (311) plane while the roman numerals indicate the multiplicity of these angles (*11*). Agreement is quite good and indicates that the oriented planes in the diamond are probably those parallel to (311).

It is important to note that the preferred orientation of diamond, which is indicative of formation by an anisotropic process, is present in Goalpara and (as will be demonstrated) also in Novo Urei. Natural terrestrial diamonds have never been reported to contain preferred orientation and in an extensive monograph (*12*) on these structures in terrestrial rocks and minerals there is no mention of this "fabric" in diamond.

Previous x-ray studies of hydrostatically produced synthetic diamond (*13*) do not indicate preferred orientation. The two samples which I studied do not show such orientation.

Synthetic diamonds produced by the anisotropic application of temperature or pressure or both, that is by flash-heating (*14*) or by a 300-kbar shock (Fig. 4), have oriented structures. The stereographic projections of these data show a grouping at about $\rho = 70°$ for the former and a

single "node" (compare with Fig. 5) at about 40° for the latter. Diamonds produced by shock at pressures significantly lower than 300 kbar are very polycrystalline and thus do not have detectable orientation. Thus, in accord with theory, the only diamonds that exhibit preferred orientation were produced by some anisotropic process.

The x-ray pattern of a diamond from Novo Urei (Fig. 6) is similar to that of a diamond produced

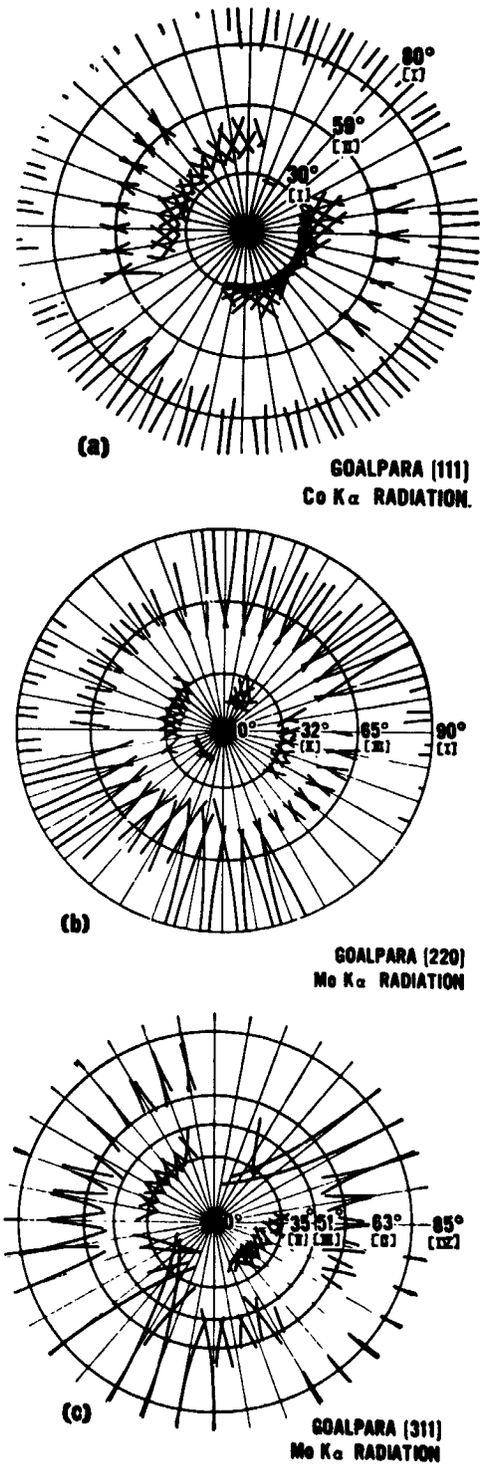

FIGURE 3.—Stereographic projections of Goalpara diamond (a) [111], (b) [220], and (c) [311]. The theoretical angles shown between each direction and the [311] are in agreement with the observed groupings.

FIGURE 4.—Iron filtered *CoKα* x-ray pattern of graphite partly converted to diamond by a 300-kbar shock. While the graphite is polycrystalline and randomly oriented, the diamond shows preferred orientation.

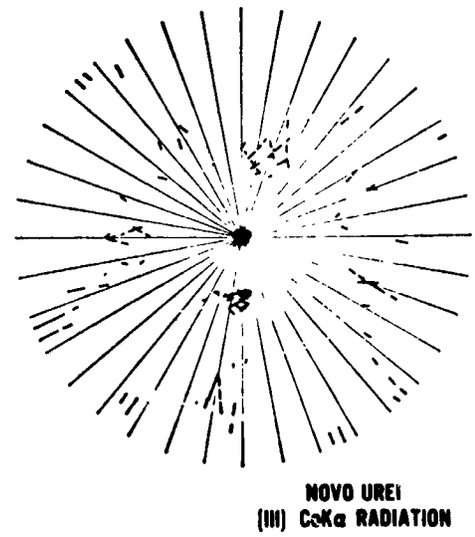

FIGURE 5.—Stereographic projection of Novo Urei diamond [111] directions. Although a pattern is evident, it is somewhat different in nature from that in Figure 3a.

FIGURE 6.—X-ray pattern (iron-filtered *CoKα*) of Novo Urei diamond. The diamond crystalline orientation is similar to that shown in Figure 4.

by a 300-kbar shock (Fig. 4). The stereographic projection of the Novo Urei data (Fig. 5) is different in character from that of Goalpara (Fig. 3*a*), possibly arising from a different alignment of the Novo Urei diamond relative to the x-ray beam or from actual differences in their pressure history.

Other phases in these two meteorites can yield information on the ureilites' pressure-temperature history. Olivine grains from Novo Urei (Fig. 7*a*) still appear to be reasonably good single crystals, although fractured to some extent. Goalpara olivine, on the other hand, is heavily fractured (Fig. 7*b*) and in some regions shows signs of recrystallization along grain boundaries, indicating excursion into temperatures well above its melting point. Since the only known natural process that can give rise to significant short-term anisotropic pressure is shock, it appears reasonable that the diamonds in at least these two ureilites were formed in this manner. It does not seem too extreme to suppose that the diamond formation and recrystallization of the olivine in Goalpara were contemporaneous. The data of Hughes and McQueen (*15*) on shocked olivine (dunite) indicate that even at the maximum pressure studied (700 kbar), the temperature reached only 720°. At pressures of 400 kbar, which is well in the diamond-forming region, the temperature rises to less than 200°. Thus, Goalpara, which was shocked more severely than Novo Urei, was probably exposed to pressures considerably in excess of 700 kbar.

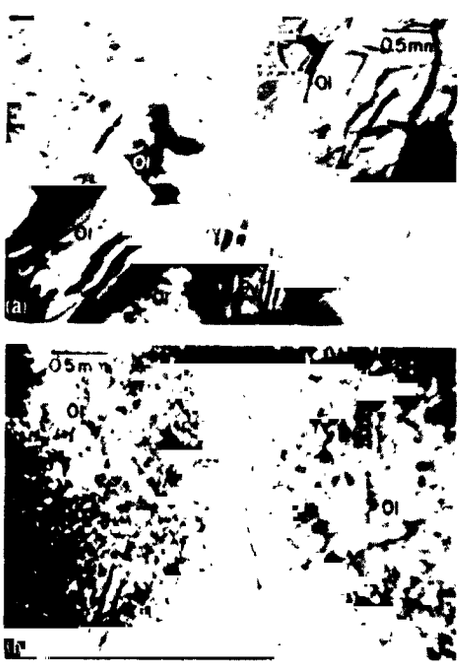

FIGURE 7.—Thin section of (a) Novo Urei ureilite and (b) Goalpara ureilite (both × 50). In (a), olivine (*Ol*) apparently still exists as single crystals although somewhat fractured. The clinopyroxene (*Py*) grains show cleavages. The opaque material is a graphite-diamond-kamacite mixture. In (b), the clinopyroxene grains are still apparently single crystals although some show an undulatory character under polarized light. Olivine grains (*Ol*) are badly shattered and in some locations are apparently recrystallized.

Diamond from Dyalpur shows no preferred orientation. One could suggest that the diamonds in this meteorite were formed by gravitational pressure rather than by shock as in Goalpara and Novo Urei. However, Dyalpur's textural similarity to the other two ureilites (particularly to Novo Urei (*16*) would argue against different modes of diamond formation by Occam's principle (see *17*).

Figure 3 (*a*, *b*, and *c*) shows certain features which may have bearing on the details of shock formation of diamond in Goalpara. First, some degree of symmetry seems evident in the distribution of groupings in each set of normals. Second, there are two "nodes" in the [220] that occur at about 20°. The former effect may be explained by lattice distortion of the diamond crystallites while the latter may be due to the presence of some diamonds formed by rarefaction waves or by secondary shocks. Another feature which may be of significance is that there appear to be only a few groupings at about 51°. These angles occur three times within the crystal (multiplicity III) and should be more prominent than the 63° angle which occurs twice (multiplicity II). This effect may only be an apparent one inasmuch as the zones in the Goalpara [311] are quite extended and markedly overlap the 51° line. The only other reasonable match for the groupings would be by planes parallel to the (220). Were these the oriented planes, however, we would not expect the group at about 30° in the [220] or at about 60° in the [111]. It is possible that the observed distribution of axes is due to some combination of oriented (110) and (311) planes, although the available evidence favors the interpretation of the oriented planes being parallel to (311) only.

From an examination of meteoritic and artificially shock-produced diamonds some sugges-

tions can be made concerning the mechanism of conversion of graphite to diamond by shock. At pressures well below 300 kbar, polycrystalline fine-grained diamond is apparently formed from polycrystalline graphite, possibly by the compression of rhombohedral graphite only (*4*). From pressures of about 300 kbar to well above 700 kbar the solid-state reaction involves conversion of the basal (001) plane of graphite to diamond (311), or possibly some combination of (311) and (110). Only at very high pressures may the conversion involve the hypothetical "metallic carbon" postulated by Libby (*18*) or possibly formation from shock-melted graphite.

The simultaneous presence of graphite, diamond, and kamacite in all of the ureilitic "diamonds" that I have investigated shows that these grains are not equilibrium assemblages. This raises the question of whether they represented an arrested stage in the conversion of graphite to diamond, or vice versa. Studies at 0 kbar (*19*) and 100 kbar (*20*) show that graphite formed from diamond shows preferred orientation. In at least two meteorites, however, it is the diamonds which are oriented, and in all diamantiferous meteorites the graphite is polycrystalline and randomly oriented. Thus, the graphite cannot have been formed from diamond. On the other hand, the theory predicts that, under favorable circumstances, shock-formed diamond would show preferential orientation. It thus appears that all meteoritic diamonds were formed by shock rather than by gravitational compression of graphite.

THE BACKWARD RECURRENCE METHOD FOR COMPUTING THE REGULAR BESSEL FUNCTION*

THOMAS E. MICHELS

The Backward Recurrence Method (suggested by Dr. J. C. P. Miller) for computing the regular Bessel function is investigated for real, imaginary, and complex arguments. From this, one can obtain the functions $J_n(z)$, $I_n(z)$, $ber_n(z)$, and $bei_n(z)$. A section has also been devoted to show the behavior of the functions for all arguments, and graphs are presented which show the magnitudes of the functions for all orders and real arguments between 0 and 6000.

INTRODUCTION

Bessel's Equation is a second order differential equation with a singular point at $z=0$ and is of the form

$$\frac{d^2y}{dz^2} + \frac{1}{z}\frac{dy}{dz} + \left(1 - \frac{n^2}{z^2}\right)y = 0 .$$

Its two independent solutions are referred to as the regular and irregular Bessel functions (see Appendix A). Computation of the irregular function, $Y_n(z)$, is fairly easy, since one can use a straightforward recurrence relationship once he has two starting values (Reference 1) and obtain good accuracy for all n and z values. However, this method cannot be used to compute the regular function, $J_n(z)$, due to error accumulation in the recurrence. For large order and argument, asymptotic formulas prove to be too cumbersome; and in computer computation they are also inaccurate. But a method was devised by Dr. J. C. P. Miller (Reference 2) whereby an ingenious use of the recurrence relationship yields good values for all orders and arguments which fall within the limits of any particular computer.

It is the purpose of this report to explain the method and the need for it, as well as give details on the behavior and use of the recurrence formula and the accuracies obtained. (Hopefully it will also give insight into the behavior of the functions themselves.) This has been done for the argument z real, imaginary, and complex. In order to keep to this primary purpose, not much will be said about the irregular function. In general, however, the irregular functions behave just oppositely to the regular function in the range where $J_n(z)$ decreases or increases exponentially, while they behave similarly in the rest of the range. That is, if the magnitude of $J_n(z)$ *decreases exponentially*, the irregular function *increases;* and when $J_n(z)$ oscillates, the irregular function does the same.

It should be noted that the recurrence formula computes a sequence of Bessel functions as a function of n, the order, rather than the usual tabulations which are a function of z. Throughout this discussion, where the order is referred to as n in $J_n(z)$, it should be taken to mean any value of n (integer, half orders, one-third orders, etc.), unless otherwise specified. Also m is always greater than n, and $z(=x+iy)$ is regarded as a complex number. If just the real numbers are being referred to, x will be used, and for the imaginary iy will be used.

Reference is made from time to time to single and double precision. All tests were made on an IBM 7090 computer which has a word length of 36 binary bits. In the floating point mode, single precision arithmetic is done with 9 decimal digits and double precision with 18 decimal digits. This is implied throughout.

EXPLANATION OF THE METHOD FOR COMPUTING THE REGULAR BESSEL FUNCTION

Importance of the Backward Recurrence

It is well known that both the regular $J_n(z)$ and the irregular $Y_n(z)$, Bessel functions (see Appen-

*Published in *NASA Technical Note* D 2141, March 1964.

dix A) obey the recurrence relationship

$$F_{n+1}(z) + F_{n-1}(z) = \frac{2n}{z} F_n(z) .$$

If the recurrence is started with either $J_0(z)$, $J_1(z)$ or $Y_0(z)$, $Y_1(z)$, in the computer where there are a fixed number of digits, good accuracy is obtained from $n \leq z$ for both functions. This accuracy continues for the irregular function since $Y_n(z)$ *increases exponentially* for $n > z$, and the number of accurate digits is maintained or increased; but for the regular function at this point accuracy is lost very rapidly, since $J_n(z)$ *decreases* exponentially for $n > z$.

Actually, throughout the recurrence, by recurring in either direction, we obtain numbers which represent solutions to Bessel's equation, but they are linear combinations of the regular and irregular solution. Therefore, the error introduced in recurring for the regular function is actually some constant times the irregular function.

In using the formula for recurring Bessel functions, and recurring in the direction of increasing n, the number of digits of accuracy is lost very rapidly. This is not even taking into account loss of accuracy due to round off.

Let us take an extreme case and look at it this way: Assume we are in a computer which produces 8 significant digits and we are using the recurrence formula below with a small error in each term on the right, say in the last decimal place. We ask what the error ϵ_{n+1} is in our new term F_{n+1}:

$$F_{n+1}(z) + \epsilon_{n+1} = \frac{2n}{z} \left[F_n(z) + \epsilon_n\right] - \left[F_{n-1}(z) + \epsilon_{n-1}\right] .$$

Let us assume reasonable values—say for the second term on the right $F_{n-1}(z) \approx 10^{-1}$—and make the error the best we could have, and therefore in the last significant digit, or $\epsilon_{n-1} \approx 10^{-8}$. Let the magnitude of $F_n(z)$ be smaller, say 10^{-2}, again with the error being in the last place, or $\epsilon_n \approx 10^{-9}$. Now we recur to a smaller number $F_{n+1}(z)$, say of the magnitude 10^{-3}. Still, there was an error at 10^{-8}, and therefore $\epsilon_{n+1} \approx 10^{-8}$. The $(n-1)$ term had 7 accurate digits and two terms away, at $(n+1)$, the number of accurate digits is reduced by two and our error is now in the sixth significant digit.

A similar argument can be made to show that when we recur to numbers of increasing magnitude, the number of significant digits of accuracy is actually increased, or at least stays equal to the maximum number of digits available in the computer. Therefore, the use of the foregoing recurrence formula to compute the regular Bessel functions in the region where they decrease in magnitude is not acceptable as it stands.

Statement of Method

Miller's Method

A scheme was devised by Miller (Reference 2) whereby the recurrence formula could be used and accuracy still maintained throughout the whole range of n values. We start at some m, with

$$F_{m+1}(z) = 0 ,$$

$$F_m(z) = a ,$$

where a is any constant, and use the recurrence formula, but in *decreasing* magnitude in n (where we are recurring to larger numbers and therefore increasing accuracy) and generate a series of functions $F_n(z)$, $F_{n-1}(z), \cdots F_0(z)$ at some $n < m$, by

$$F_{n-1}(z) = \frac{2n}{z} F_n(z) - F_{n+1}(z)$$

which are all a constant multiple of the regular Bessel function. That is,

$$F_n(z) = \alpha J_n(z) .$$

Proof

Since the recurrence formula follows for both the regular and irregular function, we can say that it follows for a linear combination of them also, or

$$F_n(z) = \alpha J_n(z) + \beta Y_n(z) .$$

Since

$$F_{m+1}(z) = 0 = \alpha J_{m+1}(z) + \beta Y_{m+1}(z) .$$

we have

$$F_n(z) = \alpha \left[J_n(z) - J_{m+1}(z) \frac{Y_n(z)}{Y_{m+1}(z)} \right] .$$

Therefore at some $n < m$

$$J_{m+1}(z) \frac{Y_n(z)}{Y_{m+1}(z)} \approx 0$$

and hence

$$F_n(z) = \alpha J_n(z)$$

to any desired degree of accuracy. Therefore all that remains to obtain the regular Bessel function is to determine α.

Determination of α

There are a number of ways in which α can be determined. One method is to use an addition formula such as the following (Reference 3):

$$2^{\nu} \sum_{k=0}^{\infty} (\nu + 2k) J_{\nu+2k}(z) z^{-\nu} \frac{\Gamma(\nu + k)}{k!} = 1 .$$

which, of course, for integral orders or $\nu = 0$, becomes

$$J_0(z) + 2 \sum_{k=1}^{\infty} J_{2k}(z) = 1 .$$

or, for $F_k(z) = \alpha J_k(z)$,

$$F_0(z) + 2 \sum_{k=1}^{\infty} F_{2k}(z) = \alpha .$$

The summation can be carried out to $k = n$ and will give α the particular accuracy desired. Here n implies the number of the term $< m$ where $F_n(z) = \alpha J_n = \alpha J_n(z)$ (see page 1251).

Of course, if an expression is known for a particular $J_n(z)$ value, say

$$J_{1/2}(z) = \left(\frac{2}{\pi z}\right)^{1/2} \sin z .$$

then α is more easily determined by

$$\alpha = \frac{F_{1/2}(z)}{J_{1/2}(z)} .$$

For z real, the foregoing addition formula proves to be fairly accurate in the determination of α; however, for z complex or imaginary, using the addition formula in the comput r proves to be inaccurate (see page 1252).

The value of the Bessel function is only as accurate as α, since each term is divided by α; therefore the computation of α is extremely critical.

Error Introduced from Additional Formulas for Complex or Imaginary Argument

In looking at the regular Bessel function of complex or imaginary argument, we observe that

$$|J_0(z)| \approx 0.1 e^{y}$$

and

$$\lim_{n \to \infty} J_n(z) = 0 .$$

As n increases, $J_n(x+iy)$ decreases at an exponential rate almost immediately for $|z| < 10$, and for larger z it takes a few more terms before the exponential decrease. It is almost a logarithmic spiraling into the origin of the complex plane.

With this in mind, assume we are performing the addition formula for integral orders. We want to investigate the error that will exist in the determination of α, assuming an error in some $F_n(z)$.

In our downward recurrence we have the following:

$$F_0(z) + \epsilon_0 + 2 \sum_{n=1}^{\infty} \left(F_{2n}(z) + \epsilon_{2n} \right) = (1 + \epsilon) \alpha .$$

Assume the error to be in the last digit in all $F_n(z)$, which of course is the best we could expect in the

computer. Upon factoring out α, we have

$$\alpha(J_0(z) + \epsilon_0) + 2\alpha \sum_{n=1}^{\infty} (J_{2n}(z) + \epsilon_{2n}) = \alpha(1 + \epsilon) ;$$

and since

$$J_0(z) + 2 \sum_{n=1}^{\infty} J_{2n}(z) = 1 ,$$

we have

$$\epsilon_0 + 2 \sum_{n=1}^{\infty} \epsilon_{2n} = \epsilon ,$$

where ϵ is now the error we introduce in computing the number 1.

Since the errors decrease at an exponential rate as n increases,

$$\epsilon \approx \epsilon_0 ,$$

which says the error we introduce in computing the digit 1 is of the order of the error in $J_0(z)$. Therefore α will be in error by this factor. It can be seen that if $J_0(z)$ had five figure accuracy and was of the order of magnitude 10^7, the summation would actually become meaningless.

Thus, to determine α one of the Bessel function values must be computed. This can be done by an asymptotic formula which simplifies for $J_0(z)$, or the following integral relationship can be used:

$$J_n(z) = \frac{1}{\pi} \int_0^{\pi} \cos(n\theta - z \sin\theta)\, d\theta ,$$

or

$$J_0(z) = \frac{1}{\pi} \int_0^{\pi} \cos(z \sin\theta)\, d\theta .$$

Integration of the expression for $J_0(z)$ by the trapezoidal rule generally yields sufficient accuracy, especially for large z values for which the slopes of the functions become large. For larger z values, of course, $\Delta\theta$ must be decreased. Integration performed by using the trapezoidal rule on various $|z|$ values (less than 75) and with $\Delta\theta = \pi/1000$ gave accuracy in the seventh and eighth digit.

When using the recurrence formula for $I_n(y)$

$$G_{n-1}(y) - G_{n+1}(y) = \frac{2n}{y} G_n(y) ,$$

the summation

$$e^y = I_0(y) + 2 \sum_{n=1}^{\infty} I_n(y)$$

can be used to determine α. This formula is of course used in the same manner as are the $F_n(z)$ functions. That is,

$$G_{m+1}(y) = 0 ,$$

$$G_m(y) = a ,$$

and, at the same n,

$$G_n(y) = aI_n(y)$$

to any desired degree of accuracy, and

$$ae^y = G_0(y) + \sum_{n=1}^{\infty} G_n(y).$$

No tests were made with this recurrence formula.

Determination of n versus m Values

We cannot give a definite value to the number of terms necessary in the recurrence to obtain good values for $J_n(z)$. It depends, of course, on z as well as the value given to a in $F_m(z) = a$, and also upon the particular accuracy desired.

The following empirical formulas will give values for m which generate a sequence $J_0(z), \cdots, J_n(z)$, where $J_n(z)$ is of the magnitude 10^{-21}, that have the accuracies described in a later section. This is assuming computation is done in single

precision and $a = 10^{-20}$.

$$m = 5.0\,|z| + 15 \quad \text{for} \quad 0.1 \le |z| < 10 ; \tag{1}$$

$$m = 1.48\,|z| + 48 \quad \text{for} \quad 10 \le |z| < 150 ; \tag{2}$$

$$m = 1.05\,|z| + 112 \quad \text{for} \quad 150 \le |z| \le 6000 . \tag{3}$$

It is felt that Equation 3 can be extended indefinitely for all values of $z \ge 150$; however, tests did not go beyond the range given.

For all values of z and n the following general rule can be employed: *For single precision accuracy, a safe* m *vs* n *is obtained when the following condition is met:*

$$\frac{J_m(z)}{J_n(z)} < 10^{-5} .$$

Table 1 gives various n vs m values for real arguments in the range from 0.01 to 6000.

Details on Accuracy

z Real

It has been said that accuracy is gained in the downward recurrence until the point where oscillations begin to occur. If the correct n vs m has been used for a particular x, then at this n value $F_n(x) = \alpha J_n(x)$ to any desired degree of accuracy. From here down to $J_0(x)$, accuracy loss is due only to round off and truncation in the computer. But, in this region, the functions oscillate usually between +0.3 and the number of accurate digits

Table 1

The integral order n of the regular Bessel function having a particular magnitude in the range where $n > x$ is given for various x values, and the recurrence term m which will yield eight place accuracy for all orders from zero to n. Also tabulated is the value of m which yields overflow in the computer for the downward recurrence at $F_0(x)$. These values were obtained using double precision with $F_m(x) = 10^{-20}$.

Argument x	Magnitude of $J_n(x)$, where $n > x$, for particular orders n and recurrence terms m										m value yielding overflow

becomes more or less as the recurrence goes from larger to smaller numbers. Therefore, accuracy loss due to round off is not quite as bad as it might seem. In fact, when recurring for $x=6000$, and $m=6400$, the error only crept over to the fifth significant digit; this was using single precision in the computer.

Particular values were checked in already existing tables (References 3, 4) for $0.05 \leq x \leq 100$ and $0 \leq n \leq 100$. Values having greater x and n were checked against values obtained using the recurrence in double precision. The accuracies obtained were the following:

Argument	Accuracy
	within a few figures
$0.05 < x \leq 30$	in the 8th digit
$30 < x \leq 100$	at least 7 digits
$100 < x \leq 1000$	at least 5 digits
$1000 < x \leq 6000$	at least 4 digits

These accuracies are the worst obtained over the whole range of orders out to where $J_n(x) \approx 10^{-38}$.

Using double precision, of course, would give approximately eight more digits of accuracy for all arguments tabulated. It seemed unnecessary to check the recurrence for real arguments greater than 6000, in view of their sparse usage.

The accuracy stated above is obtained only if α in

$$F_n(x) = \alpha J_n(x)$$

is computed to at least the number of digits stated. Of course, if α is only good to a few digits then the Bessel function can be no better.

z Complex or Imaginary

In the downward recurrence for imaginary and complex argument $(x+iy)$, where $|y/x|$ is not small, the magnitudes of the numbers increase over the whole range of n values. Therefore, accuracy is gained or maintained over the whole range. These functions were checked in tables of Thomson functions for ber(x) and bei(x) and in formulas for $J_{1/2}(z)$, $J_{3/2}(z)$, $J_{5/2}(z)$. These all proved to be accurate to seven digits for various $|z|$ values ranging from .05 to 100.

For argument $(x+iy)$ where $|y/x|$ is small, approximately, less than 0.1) the function behaves similarly to the real function in that the magnitudes oscillate and then continually decrease when n becomes greater than z. In general the accuracies should behave similarly to the accuracies of the real function.

Details on Use of the Recurrence
Choosing the Value for α

When using the above method for computing the regular Bessel function, the value we give to a is completely arbitrary. In other words the method "works" for any value of a. However, as a general rule, we should use as small a value, in magnitude, as is practical for the computer. This enables us to start out farther in the downward recurrence or use a larger m value and thereby obtaining higher order Bessel functions—and, of course, with less chance of overflow in recurring to numbers which are too large for the particular computer.

Consider a sequence of functions, say for real z,

$$J_0(x),\ J_1(x) \cdots J_n(x),\ J_{n+1}(x)\ .$$

The magnitudes of the functions may vary from approximately 0.1 for $J_0(x)$ down to say 10^{-38} for $J_n(x)$. That is, the values cover a range equal to approximately 10^{38}. Since the same range would be covered in our downward recurrence, the magnitude of $F_0(x)$ depends completely on the value of a at any particular m. If $a=10^{-12}$, then $F_0(x)$ would be 38 orders of magnitude away or 10^{25}, and so on. Therefore, to compute larger order Bessel functions, a smaller value for

$$F_m(x) = a\ ,$$

should be used. It should be noted that the value given to a will not increase or decrease accuracy.

z Real

As has been stated, $J_0(x)$ does not become greater than 1 for all x, and

$$\lim_{n \to \infty} J_n(x) = 0\ ,$$

the values oscillate usually between ± 0.3 until n becomes greater than x, then they stay positive

and begin to decrease at exponential rate to zero at $n = \infty$. The recurrence must start beyond this point for the method to succeed.

As a general rule, for all x, recurrence can begin at an m value for a particular order n where

$$\frac{F_m(x)}{F_n(x)} = \frac{J_m(x)}{J_n(x)} < 10^{-s} ,$$

and still obtain eight figure accuracy for $J_n(x)$.

z Complex

In contrast to the function of real argument,

$$|J_0(z)| \approx 0.1\, e^{y} ,$$

but still

$$\lim_{n\to\infty} J_n(x) = 0 ,$$

and the magnitude of the complex function decreases continually, slowly at first for low orders

Table 2

Values obtained for $J_n(10)$ from the forward recurrence in double and single precision and the backward recurrence in double precision.

until, approximately when n becomes greater than x/2, they decrease at an exponential rate. The role that x plays will be discussed in a later section. Therefore the downward recurrence can begin anywhere in the range of n values as long as the condition

$$\frac{F_m(z)}{F_n(z)} < 10^{-5} ,$$

is met to give eight figure accuracy in $J_n(z)$.

z Imaginary

The function of imaginary argument behaves similarly to the function of complex argument in that they continually decrease in magnitude and, approximately at z/2, they decrease exponentially. For integral orders, the functions oscillate between being pure real and pure imaginary; but for orders that are not integral, $J_n(iy)$ possess both real and imaginary parts. The integral orders are usually multiplied by $e-in\ \pi/2$ to give the real function, $I_n(y)$, which is widely used. That is,

$$I_n(y) = e^{-in\pi/2} J_n(iy) .$$

More will be discussed on the function $I_n(y)$ in the next section. An example of the method will be found in Table 2, which gives $J_n(10)$ by the forward recurrence technique in both single and double precision, and by the backward recurrence technique in double precision.

NUMERICAL BEHAVIOR OF THE REGULAR BESSEL FUNCTION

In seeking to present a complete picture of the regular solutions to Bessel's equation

$$y'' + \frac{1}{z} y' + \left(1 - \frac{n^2}{z^2}\right) y = 0$$

it seemed that a better understanding of the solutions was brought about when first they were observed as functions of n, and then as functions z. Then they could be brought together and a better picture could be visualized for all n and z.

z Real

Two-dimensional graphs have been drawn (Appendix B) showing various lines of constant magnitude for all real z and n for $0<x\leq6000$. These can be extended to larger x, since the lines are fairly linear.

It n be seen from a plot of $J_n(x)$ vs. n (Figure 1) that the functions oscillate between ±1, with

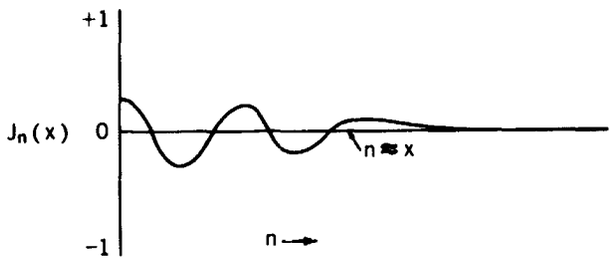

FIGURE 1.—Plot of $J_n(x)$ vs. n, n continuous.

the oscillations dampening in the range $0\leq n\leq x$. Then for $n\geq x$ the values stay positive and begin to decrease very rapidly (here is where forward recurrence begins to fail), until at $n=\infty$, $J_n(x)=0$. This is true for all values of x with the exception $J_n(0)=0$, and $J_0(0)=1$. Let us now consider the function more closely.

For $5<x<n$, $J_n(x)$ oscillates between ±0.3 and for $0<x\leq5$, $n\leq3$, $J_n(x)$ oscillates between ±0.2 and for all n, $J_n(n)\leq\cdot1$. It can be seen that dampening of the oscillations takes longer for larger x, since it takes more terms for n to become similar to x.

On the other hand, it can be seen from a plot of $J_n(x)$ vs. x (Figure 2) that the functions start

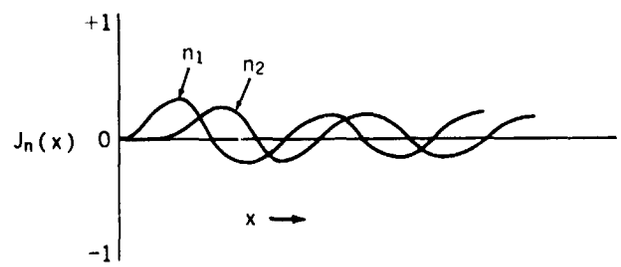

FIGURE 2.—Plot of $J_n(x)$ vs. x, $n_1<n_2$.

at $x=0$, (except that $J_0(0)=1$) and increase very slowly; the larger the n value the slower it increases, staying positive and never exceeding 0.1 until $n\approx x$. At this point they continue to increase, but as x increases oscillations begin. For $n>3$ and all x, the oscillations are between ±0.3.

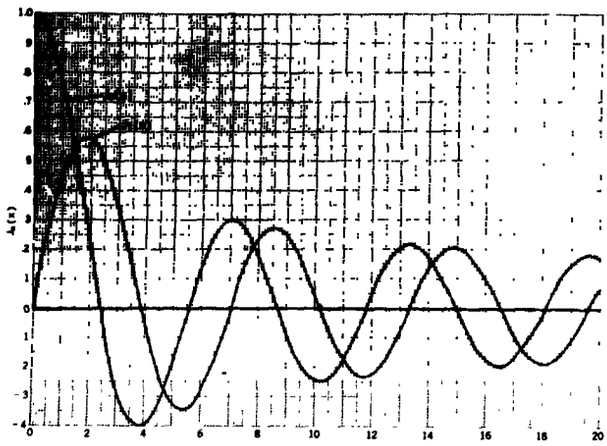

FIGURE 3.—Detailed plot of $J_0(x)$ and $J_1(x)$ vs. x, $0 \leq x \leq 20$.

Figure 3 shows a detailed plot of $J_0(x)$ and $J_1(x)$ versus x.

z Complex

The magnitude of the function for complex argument $z = x+iy$ begins at

$$|J_0(x+iy)| \approx 0.1\, e^y$$

for any z and, where $|y/x|$ is not small (see page 9)

$$\lim_{n\to\infty} J_n(x+iy) = 0 .$$

The functions continually decrease in magnitude as n becomes larger and, at approximately where $n > |z|/2$, they decrease at an exponential rate.

If we plot the modulus of $J_n(z)$ vs. n, we get the exponential curve shown in Figure 4. The

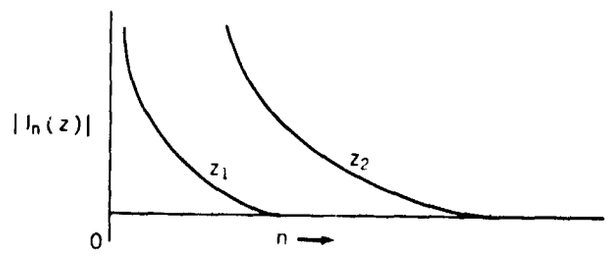

FIGURE 4.—Plot of $|J_n(x+iy)|$ vs. n.

effect of x in the argument is that for larger x, the gradient of the slope becomes less.

In considering a picture of the function of complex argument, it seems that the easiest and perhaps the best approach is set

$$J_n(x+iy) = u+iv$$

and plot the functions in both planes.

In Figure 5, the spiral is started at $J_0(x+iy)$, and as n increases the function spirals into the

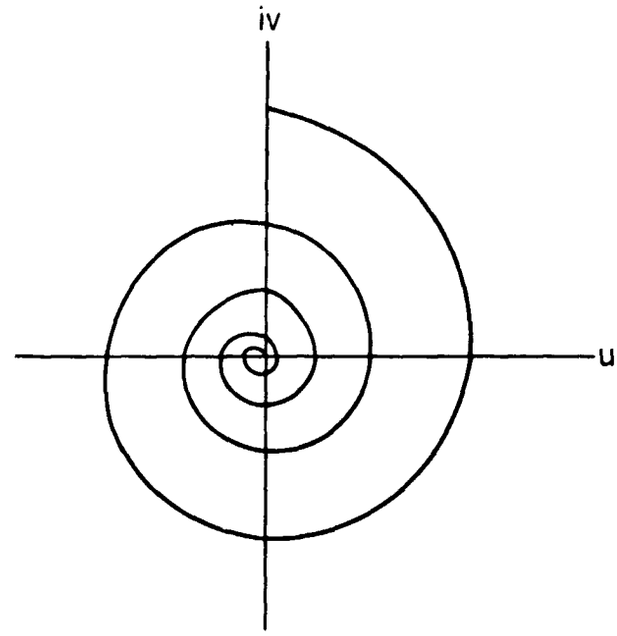

FIGURE 5.—Projection of $J_n(x+iy)$ on the u, iv plane as a function of n, n continuous.

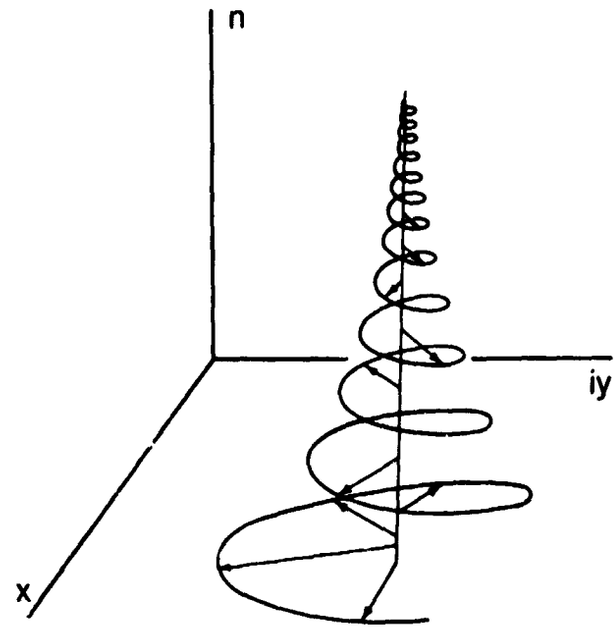

FIGURE 6.—Plot of $J_n(x+iy)$ in the x, iy, n space as function of n, n continuous.

origin as a limit. Figure 6 is again a plot of $J_n(x+iy)$ as a function of n but now it is the three dimensional picture in x, iy, and n.

If the spiral is moved around in the x, iy plane, the base of the spiral becomes larger as y increases, and becomes more spread out or flatter as x increases. If movement was directed along one of the 45 degree lines, the slope and the width would change at approximately the same rate. It should be noted that for movement along the 45 degree lines the plot would be of the Thomson Functions, $ber_n(z)$, $bei_n(z)$.

The direction of the spiraling is not significant, for it changes direction as the argument of z changes. The functions of arguments (x+iy) and (x−iy) would spiral into the origin in opposite directions.

If a three dimensional plot is made of $J_n(x+iy)$ in the x, iy plane, contour lines of constant magnitude would give the effect of a crater (Reference 5, page 127).

For argument (x+iy) where |y/x| is small, the modulus of $J_n(x+iy)$ oscillates until n becomes greater than z and at this point, it stays in the first quadrant of the u, iv plane, continually decreasing to the origin at $n = \infty$.

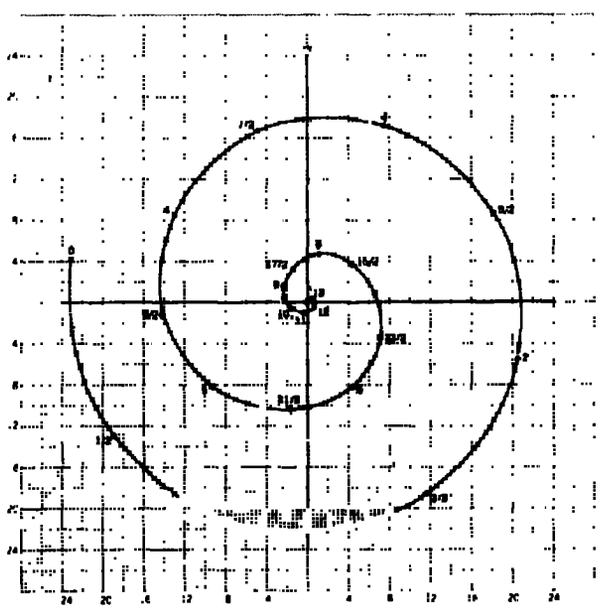

FIGURE 7.—Detailed plot of the projection of $J_n(10+i10)$ on the u,iv plane as a function of n.

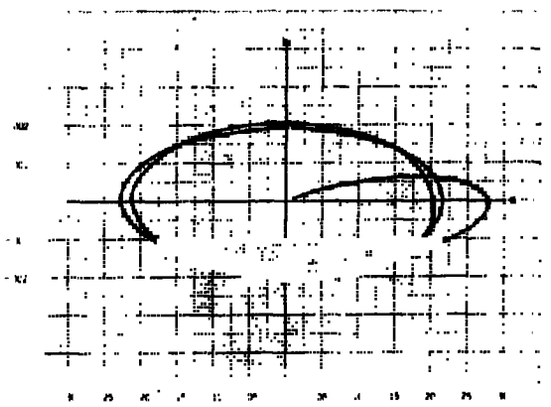

FIGURE 8.—Detailed plot of the projection of $J_n(15+6.01)$ on the u,iv plane vs. n.

z Imaginary

The regular Bessel function of imaginary argument $J_n(iy)$ behaves similarly to the function of complex argument. $|J_0(iy)|$ is of the order of magnitude $0.1e^y$ with

$$\lim_{n\to\infty} J_n(iy) = 0 ,$$

and the function spirals in toward the origin of the u, iv plane. The figures for imaginary argument would be similar to the complex argument with the integral orders lying on the axis and half orders displaced by an angle $\pi/4$, etc. In the u, iv plane they would appear as in Figure 9. Here again the direction of the spiral is determined by the argument of z, or $\pm\pi/2$. These functions

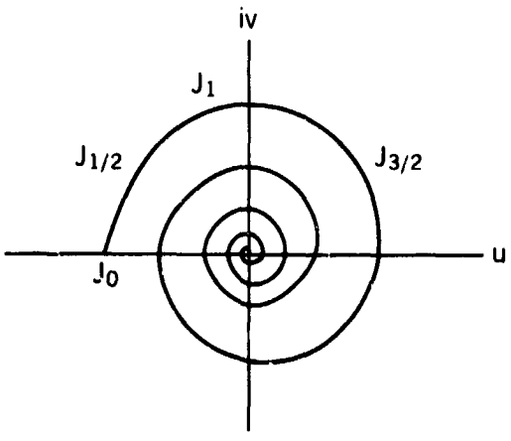

FIGURE 9.—Projection of $J_n(iy)$ on the u,iv plane.

are really solutions of the equation

$$y'' + \frac{1}{z} y' - \left(1 + \frac{n^2}{z^2}\right) y = 0 ,$$

which occurs frequently in problems of mathematical physics; however, it is usually desirable to express the solutions in real form.

The solutions $J_n(iy)$, $Y_n(iy)$ are not always real, as was shown for the regular function; however the function $e^{-in\pi/2}J_n(iy)$ is always real and is a solution of the equation. In effect the imaginary values are rotated thru an angle of $\pi/2$. These functions are the $I_n(y)$ functions and are defined by

$$I_n(y) = e^{-in\pi/2} J_n(iy) ;$$

they obey the recurrence formula

$$I_{n-1}(y) - I_{n+1}(y) = \frac{2n}{y} I_n(y)$$

the use of which was discussed in a previous section.

CONCLUDING REMARKS

It has been shown that the backwa.d recurrence is an accurate and especially easy method for computing the regular Bessel Function. Indirectly, this report came about through a need for and investigation of computing the 1/2 order Bessel functions for the intensity functions of light scattering by spherical particles. Since the calculations required the Bessel functions varying in the order, the recurrence was especially suitable. The backward recurrence method should be a very useful tool to those requiring Bessel functions of any order or argument:

The magnitude graphs (Appendix B, Figures B2, B3, B4) are significant in that they give an overall picture of the functions varying in both the order and the argument. This could be useful in many computations, e.g., an integral of the type

$$A = \int_a^b J_n(x)\,dx .$$

Insight might be obtained as to the range of x that would add to the value of the integral and so on.

SOLUTIONS OF BESSEL'S DIFFERENTIAL EQUATION

If α is any real constant, Bessel's equation of order α is

$$y'' + \frac{1}{x} y' + \left(1 - \frac{\alpha^2}{x^2}\right) y = 0 .$$

This is a linear differential equation of second order, and therefore has two and only two independent solutions. If these two solutions are $y_1(x)$ and $y_2(x)$, then there cannot exist two non-zero constants c_1 and c_2 such that

$$c_1 y_1(x) + c_2 y_2(x) = 0 .$$

That is to say that any other solution, say $y_3(x)$, is a linear combination of the two independent solutions, or

$$y_3(x) = c_1 y_1(x) + c_2 y_2(x) .$$

Note that Bessel's equation has a singular point at $x=0$, but a solution can be obtained by the method of Frobenius. That is, assume a solution of the type

$$y = \sum_{k=0}^{\infty} C_k x^{k+\alpha}$$

and it turns out that the two solution types are completely dependent upon α. They are referred to by order α and argument x. If α is an integer, the two independent solutions are $J_\alpha(x)$ and $Y_\alpha(x)$, α = integer. If α is not an integer the two solutions are $J_\alpha(x)$ and $J_{-\alpha}(x)$, $\alpha \neq$ integer. If α is half an odd integer they are usually referred to as the *plus and minus half orders*. $J_\alpha(x)$ is the regular solution; and $J_{-\alpha}(x)$, α not an integer, and $Y_\alpha(x)$, α = integer, are the irregular solutions. The two solutions are also referred to as Bessel functions of the first and second kind respectively.

If the argument x is purely imaginary, the solution is referred to as

$$I_\alpha(x) \quad \text{and} \quad K_\alpha(x) .$$

$I_\alpha(x)$ is analogous to the regular Bessel function and $K_\alpha(x)$ to the irregular Bessel function.

$H_\alpha^{(1)}(x)$ and $H_\alpha^{(2)}(x)$ are known as Bessel functions of the third kind, or first and second Hankel Functions respectively. They are defined as

$$H_\alpha^{(1)}(x) = J_\alpha(x) + i Y_\alpha(x) . \qquad (A1)$$

$$H_\alpha^{(2)}(x) = J_\alpha(x) - i Y_\alpha(x) . \qquad (A2)$$

These are obtained from

$$F_\alpha(x) = A J_\alpha(x) + B Y_\alpha(x)$$

with $A=1$ and $B=\pm i$. If we add and subtract Equations A1 and A2, we arrive at other identities which are sometimes useful:

$$J_\alpha(x) = \frac{1}{2}\left(H_\alpha^{(1)}(x) + H_\alpha^{(2)}(x)\right) .$$

$$Y_\alpha(x) = \frac{-i}{2}\left(H_\alpha^{(1)}(x) - H_\alpha^{(2)}(x)\right) .$$

For complex argument $i^{3/2}x$, one obtains the Thomson function $ber_\alpha(x)$, $bei_\alpha(x)$:

$$J_\alpha\left(i^{3/2}x\right) = ber_\alpha(x) + i\, bei_\alpha(x) .$$

If $\alpha = 0$ the subscripts are usually omitted. Listed below are the two general types of differential equations and their associated functions as

solutions:

$$y'' + \frac{1}{x} y' + k^2 y = 0 \qquad \left\{ \begin{array}{l} y = AJ_0(kx) + BY_0(kx) \\ y = AH_0^{(1)}(kx) + BH_0^{(2)}(kx) \end{array} \right\};$$

$$y'' + \frac{1}{x} y' + \left(k^2 - \frac{\alpha^2}{x^2}\right) y = 0 \qquad \left\{ \begin{array}{l} y = AJ_\alpha(kx) + BY_\alpha(kx) \\ y = AJ_\alpha(kx) + BJ_{-\alpha}(kx) \\ y = AH_\alpha^{(1)}(kx) + BH_\alpha^{(2)}(kx) \end{array} \right\};$$

$$y'' + \frac{1}{x} y' - k^2 y = 0 \qquad \left\{ y = AI_0(kx) + BK_0(kx) \right\};$$

$$y'' + \frac{1}{x} y' - \left(k^2 - \frac{\alpha^2}{x^2}\right) y = 0 \qquad \left\{ \begin{array}{l} y = AI_\alpha(kx) + BK_\alpha(kx) \\ y = AI_\alpha(kx) + BI_{-\alpha}(kx) \end{array} \right\}.$$

Appendix B

THE MAGNITUDE GRAPHS

The Magnitude graphs are plots of constant $J_n(x)$ in the x, n plane. The plot of $J_n(x)$ is continuous in this plane both as a function of n and as a function of x. It is a rolling surface and slopes down into the surface of the graph as x and n become larger. Between the zeros, lines of constant magnitude can be drawn, of which there would be two of the same value that connect at some larger x and n value; however, it was felt these would be superfluous here and they were left out. Since the surface is continuous, peak values either plus or minus would fall between two zeros and the magnitude of the function would decrease as we go toward the zero. All lines below the 10^{-2} line represent the approximate n and x value for the zeros of the Bessel function with the sign of the function indicated between the zeros.

In looking at the magnitude graphs that follow, pick a particular case, say $J_n(x)$ varying in n for $x=40$; it can be seen that $J_0(40)$ is positive and there are six oscillations before the functions stay positive. It can be seen that

$$-0.3 \leq J_n(x) \leq 0.3 \quad , \qquad 0 \leq n \leq 46 \quad ,$$

$$0 < J_n(x) < 10^{-2} \quad , \qquad n > 46 \quad ,$$

$$0 \leq J_n(x) \leq 10^{-16} \quad , \qquad n > 79 \quad ,$$

and so on. A graph of $J_n(40)$ versus n would appear as in Figure B1.

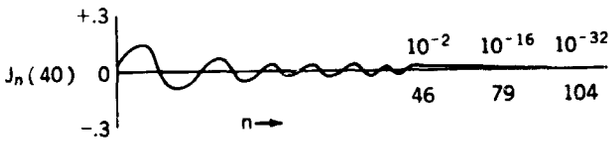

FIGURE B1.—Plot of $J_n(40)$ vs. n.

On the other hand, looking at $J_n(x)$ varying in x, say for $n=50$, the function increases from 0 to 10^{-32} for x ranging from 0 to approximately 8.8, and oscillations do not begin until x is approximately 55. It can be seen that

$$J_{50}(x) < 10^{-32} \quad , \qquad 0 \leq x < 8.8 \quad ,$$

$$10^{-32} \leq J_{50}(x) < 10^{-2} \quad , \qquad 8.8 \leq x \leq 44 \quad ,$$

$$-0.3 \leq J_{50}(x) \leq 0.3 \quad , \qquad x > 44 \quad .$$

Therefore, an idea of how the function behaves can be obtained for any order or argument within the limits of the graph.

THEORY OF THE 2s AND 2p EXCITATION OF THE HYDROGEN ATOM INDUCED BY ELECTRON IMPACT*

KAZEM OMIDVAR

A numerical calculation has been carried out to evaluate the 3×3 cross-section matrix involved in the electron impact excitation of the ground state of H atom to the 2s and 2p levels. The method of solution is that of atomic eigenstates expansion. In this paper, instead of the iterative technique used by other authors, the definite integral terms in the coupled radial differential equations are eliminated through some linear transformation of the radial functions, thus avoiding iteration of these equations. The accuracy of the numerical integration is tested by satisfying the equation of reciprocity and the equation of continuity of currents with an error-to-value ratio less than 1 per 1000 on the average; and the maximum of this ratio, except for a few cases, has been kept below 5 percent. The results are in agreement with the results of an iterative technique.

To evaluate the effect of the long-range and the centrifugal potential, a simple perturbation theory is developed. The six cross sections 1s→2s, 1s→2p, 1s→1s, 2s→2s, 2s→2p, and 2p→2p are tabulated. The 2p→2p cross section requires the solution of the sets of differential equations with different parities. With the validity of the eigenstates expansion assumed, it is found by comparison with the eigenstates expansion calculation that the Born approximation, despite its simplicity, gives meaningful results for low and close-to-the-threshold energies of the bombarding electrons. The effect of the exchange potentials on the cross sections is also investigated. Finally, an interesting structure of the 1s→2s excitation cross section above threshold is found.

INTRODUCTION

Calculation of the excitation cross sections in atomic hydrogen by electron impact corresponds to the solution of the problem of three interacting bodies: one proton, and two electrons. By taking the position of the proton as the center of mass, the problem will reduce to the task of finding the nonseparable wave function of the system of the two electrons with an attractive center of force. Such a solution has not been found. However, if this wave function is expanded in terms of the eigenstates of the hydrogen atom, the coefficients of the expansion, which are functions of the position vector of the free electron, can be found through numerical integration. When an infinite number of terms is included in the expansion, the solution to the problem is exact. Furthermore, the expansion has the advantage that the asymptotic form of its coefficients is automatically the asymptotic form of the free electron wave function scattered from different atomic states, which are simply related to the excitation cross sections.

In this paper, atomic states 1s, 2s, 2p are included in the expansion and, by antisymmetrizing the two electron wave functions according to the exclusion principle, some contribution from the continuum in the expansion is also taken into account. The first calculation of this type was performed by Marriot (Reference 1), whose expansion consisted of the 1s and 2s states in order to calculate the 1s→2s transition cross section. This calculation was extended by Smith (Reference 2) to higher total orbital angular momenta of the system. Percival and Seaton (Reference 3) have formulated the eigenstate expansion technique in general and have tabulated the coefficients of the integro-differential equations for s, p, and d atomic electrons. Burge, Smith, and Schey (References 4 and 5†), using the equations of Percival and Seaton for the three states 1s, 2s, 2p, have inte-

*Published as *NASA Technical Note D-2145*, June 1964. This work has also appeared in a condensed form in the *Physical Review*, 133, February 17, 1964.

†A similar calculation has been performed by R. Damburg and R. Peterkop; this will appear in the *USSR Journal of Experimental and Theoretical Physics*. A different method to calculate the 1s–2s electron impact transition cross section in hydrogen is being considered by L. Kyle and A. Temkin, adopting the nonadiabatic theory of electron scattering developed by A. Temkin (see References 21, 22); the calculation is in progress.

IN D-

grated the resulting integro-differential equations. In this paper we solve the same differential equations by a linear transformation of the differential equations in order to avoid the need for iteration of these equations (Reference 6).*

The numerical integrations were carried out for all partial waves, while in higher partial waves the Born approximation was used. The transition between the eigenstates expansion calculation and the Born approximation takes place when the results of the two calculations agree closely.

FORMULATION

Derivation of the Differential Equations

Since spin orbit interaction of the electrons is neglected, the total orbital angular momentum L and the total spin angular momentum S are separately conserved. We can then divide the interactions into antiparallel spin states, where $S=0$, and parallel spin states, where $S=1$. We deal with spatial wave functions of the electrons only, and for brevity we call the orbital angular momentum the *angular momentum.*

Neglecting the motion of the proton of the hydrogen atom and taking its position as the origin of the coordinate system, the Schroedinger equation for the system can be written

$$[H-E]\,\psi(\mathbf{r}_1, \mathbf{r}_2) = 0 \,. \tag{1}$$

where $\mathbf{r}_1$ and $\mathbf{r}_2$ are the position vectors of the bound and free electrons; and in atomic units

$$H - E = -\frac{1}{2}\nabla_1^2 - \frac{1}{2}\nabla_2^2 - \frac{1}{r_1} - \frac{1}{r_2} + \frac{1}{r_{12}} - E \,, \tag{2}$$

where E is the total energy of the system and r_{12} is the distance between the two electrons. We expand the total wave function $\psi(\mathbf{r}_1, \mathbf{r}_2)$ in terms of the eigenfunctions of the total angular momentum L,

$$\psi(\mathbf{r}_1, \mathbf{r}_2) = \sum_{L=0}^{\infty} \psi_L(\mathbf{r}_1, \mathbf{r}_2) \,. \tag{3}$$

Since these eigenfunctions are orthogonal and distinct, substitution of Equation 3 in Equation 1 gives

$$[H-E]\,\psi_L(\mathbf{r}_1, \mathbf{r}_2) = 0 \tag{4}$$

The explicit form of $\psi_L(\mathbf{r}_1, \mathbf{r}_2)$ is given by

$$\psi_L(\mathbf{r}_1, \mathbf{r}_2) = (1+\beta P_{12}) \sum_{n_1 \ell_1 \ell_2} \sum_{m_1 m_2} C^{\ell_1 \ell_2 L}_{m_1 m_2 M}\, \phi(n_1 \ell_1 m_1, \mathbf{r}_1)$$

$$\times\, r_2^{-1}\, u(k_{n_1} \ell_2, r_2)\, Y_{\ell_2 m_2}(\Omega_2) \,, \tag{5}$$

$$\phi(n_1 \ell_1 m_1, \mathbf{r}_1) = r_1^{-1} P(n_1 \ell_1, r_1)\, Y_{\ell_1 m_1}(\Omega_1) \,. \tag{6}$$

Here $\phi(n_1\, \ell_1\, m_1, \mathbf{r}_1)$ is the hydrogen atom wave function with radial part $r_1^{-1}P(n_1\, \ell_1, r_1)$ and angular part $Y_{\ell_1 m_1}(\Omega_1)$ and quantum numbers $n\ell_1\, m_1$; $r_2^{-1}u(k_{n_1}\, \ell_2, r_2)$ is the radial part and $Y_{\ell_2 m_2}(\Omega_2)$ is the angular part of the free electron wave function with quantum numbers $k_{n_1}\, \ell_2\, m_2$. The relation between the wave number k_{n_1} and n_1 is given by

$$k_{n_1}^2 = 2\left(E + \frac{1}{2n_1^2}\right) \,. \tag{7}$$

Finally the constants $C^{\ell_1 \ell_2 L}_{m_1 m_2 M} = (\ell_1\, \ell_2\, m_1\, m_2 | LM)$, with M representing the total magnetic quantum number, are vector coupling coefficients which make the linear combination of the products of the one electron wave function in Equation 5 the eigenfunction of L. In the problem under consideration, $n_1 = 1, 2$; $\ell_1 = 0, 1$; $\ell_2 = |L-\ell_1|, \cdots, |L+\ell_1|$; $m_1 = -\ell_1, \cdots, \ell_1$; and $m_2 = -\ell_2, \cdots, \ell_2$. To make the total wave function symmetric for antiparallel spins or antisymmetric for parallel spins, the operator P_{12} interchanges $\mathbf{r}_1$ and $\mathbf{r}_2$ while β is $+1$ for the first case and is -1 for the second.

*A similar calculation has been carried out in Reference 6. Here the L=0,1 cases have been solved by noniterative, and all other cases by iterative, methods.

By taking **L** perpendicular to the z-axis, $M = 0$ and $m_2 = m_1$. Equation 5 can then be written

$$\psi_L(\mathbf{r}_1, \mathbf{r}_2) = (1 + \beta P_{12}) \sum_{n_1 \ell_1 \ell_2} \sum_{m_1} C^{\ell_1 \ell_2 L}_{m_1 - m_1 0} \phi(n_1 \ell_1 m_1, \mathbf{r}_1) \times r_2^{-1} u(k_{n_1 \ell_2}, r_2) Y_{\ell_2 m_2}(\Omega_2) . \quad (8)$$

In order that $\psi(\mathbf{r}_1, \mathbf{r}_2)$ closely approximates the exact wave function, we minimize the expectation value of the energy operator with respect to the radial parts of the free electron wave functions,

$$\delta \int \psi_L^*(\mathbf{r}_1, \mathbf{r}_2) [H - E] \psi_L(\mathbf{r}_1, \mathbf{r}_2) d^3 r_1 d^3 r_2 = 0 . \quad (9)$$

It has been shown by Kohn (Reference 7) that the differences between the scattering amplitudes obtained from these equations and the exact scattering amplitudes are quadratic in the difference between $\psi_L(\mathbf{r}_1, \mathbf{r}_2)$ and the exact wave function. When the variation is carried out inside the integral, we obtain

$$\sum_{m_1} C^{\ell_1 \ell_2 L}_{m_1 - m_1 0} \int \phi^*(n_1 \ell_1 m_1, \mathbf{r}_1) Y^*_{\ell_2 m_2}(\Omega_2) [H - E] \psi_L(\mathbf{r}_1, \mathbf{r}_2) d^3 r_1 d\Omega_2 = 0 . \quad (10)$$

By means of Equations 2 and 8, the Schroedinger equation for the hydrogen atom,

$$\left[\nabla_1^2 + \frac{2}{r_1}\right] \phi(n_1 \ell_1 m_1, \mathbf{r}_1) = \frac{1}{n_1^2} \phi(n_1 \ell_1 m_1, \mathbf{r}_1) , \quad (11)$$

and Equation 7, Equation 10 reduces to

$$\sum_{m_1} \sum_{n_1' \ell_1' \ell_2'} \sum_{m_1'} C^{\ell_1 \ell_2 L}_{m_1 - m_1 0} C^{\ell_1' \ell_2' L}_{m_1' - m_1' 0} \int \phi^*(n_1 \ell_1 m_1, \mathbf{r}_1) Y^*_{\ell_2 m_2}(\Omega_2) (1 + \beta P_{12}) \times \left[\nabla^2_{r_2} - \frac{\ell_2'(\ell_2' + 1)}{r_2^2} + k^2_{n_1'} + 2\left(\frac{1}{r_2} - \frac{1}{r_{12}}\right)\right] \phi(n_1' \ell_1' m_1', \mathbf{r}_1) \times r_2^{-1} u(k_{n_1'} \ell_2', r_2) Y_{\ell_2' m_2'}(\Omega_2) d^3 r_1 d\Omega_2 = 0 , \quad (12)$$

where ∇^2_{r2} is the radial part of ∇_2^2. By orthogonality of the hydrogen atom and spherical harmonics wave functions, the relation (Reference 8)

$$\sum_{m_1} \left[C^{\ell_1 \ell_2 L}_{m_1 - m_1 0}\right]^2 = 1 , \quad (13)$$

the integration by parts of the exchange terms, and the relation*

$$C^{\ell_2 \ell_1 L}_{-m_1 m_1 0} = (-)^{L - \ell_1 - \ell_2} C^{\ell_1 \ell_2 L}_{m_1 - m_1 0} . \quad (14)$$

*Reference 8, Equation 3.16b.

Equation 12 leads to

$$\left[\nabla^2_{r_2} - \frac{l_2(l_2+1)}{r_2^2} + k_{n_1}^2 + \frac{2}{r_2}\right]\frac{u(k_{n_1} l_2, r_2)}{r_2} - 2\sum_{m_1}\sum_{n_1' l_1' l_2'}\sum_{m_1'} C^{l_1 l_2 L}_{m_1 - m_1' 0}\, C^{l_1' l_2' L}_{m_1 - m_1' 0}$$

$$\int \frac{\phi^*(n_1 l_1 m_1, r_1)\, Y^*_{l_2 m_2}(\Omega_2)}{r_{12}} \times \left[\phi(n_1' l_1' m_1', r_1)\frac{u(k_{n_1'} l_2', r_2)}{r_2} Y_{l_2' m_2'}(\Omega_2)\right.$$

$$\left. + \beta\phi(n_1' l_1' m_1', r_2) \times \frac{u(k_{n_1'} l_2', r_1)}{r_1} Y_{l_2' m_2'}(\Omega_1)\right] d^3 r_1\, d\Omega_2$$

$$+ \beta \sum_{n_1' l_1' l_2'} (-)^{L - l_1 - l_2}\, \delta(l_1' l_2', l_2 l_1)\left(\frac{1}{n_1^2} + k_{n_1'}^2\right)$$

$$\int_0^\infty P(n_1 l_1, r_1)\, r_2^{-1} P(n_1' l_1', r_2) \times u(k_{n_1'} l_2', r_1)\, dr_1 = 0. \qquad (15)$$

If $1/r_{12}$ is expanded in terms of the Legendre polynomials and use is made of the addition theorem,* we obtain

$$\frac{1}{r_{12}} = \sum_{\lambda=0}^{\infty} \frac{r_<^\lambda}{r_>^{\lambda+1}} P_\lambda(\cos\theta_{12})$$

$$= \sum_{\lambda=0}^{\infty}\sum_{\mu=-\lambda}^{+\lambda} \frac{4\pi}{2\lambda+1}\frac{r_<^\lambda}{r_>^{\lambda+1}} Y_{\lambda\mu}(\Omega_1)\, Y^*_{\lambda\mu}(\Omega_2). \qquad (16)$$

In this expression θ_{12} is the angle between the position vectors $\mathbf{r}_1$ and $\mathbf{r}_2$ at the origin, and $r<$ is the smaller and $r>$ is the larger of $|\mathbf{r}_1|$ and $|\mathbf{r}_2|$. We also introduce

$$y_\lambda(n l\, n' l', r_2) = r_2^{-(\lambda+1)} \int_0^{r_2} P(n l, r_1)\, P(n' l', r_1)\, r_1^\lambda\, dr_1$$

$$+ r_2^\lambda \int_{r_2}^\infty P(n l, r_1)\, P(n' l', r_1)\, r_1^{-(\lambda+1)}\, dr_1. \qquad (17)$$

Then it follows that

$$\int_0^\infty \frac{P(n l, r_1)\, P(n' l', r_1)}{r_{12}}\, dr_1 = \sum_{\lambda=0}^{\infty}\sum_{m=-\lambda}^{+\lambda} Y_{\lambda\mu}(\Omega_1)\, Y^*_{\lambda\mu}(\Omega_2)\, y_\lambda(n l\, n' l', r_2). \qquad (18)$$

*Reference 8, Equation 4.28.

By means of Equation 18, the relation*

$$\int Y^*_{\ell_3 m_3} Y_{\ell_2 m_2} Y_{\ell_1 m_1} d\Omega = \left[\frac{(2\ell_1+1)(2\ell_2+1)}{4\pi(2\ell_3+1)}\right]^{1/2} C^{\ell_1\ell_2\ell_3}_{m_1 m_2 m_3} C^{\ell_1\ell_2\ell_3}_{000} , \tag{19}$$

and the definition

$$\left(n\ell | k_{n_1}\ell'\right) = \int_0^\infty P(n\ell, r)\, u\left(k_{n_1}\ell', r\right) dr , \tag{20}$$

Equation 15 when multiplied by r_2 gives

$$\left[\frac{d^2}{dr_2^2} - \frac{\ell_2(\ell_2+1)}{r_2^2} + k_{n_1}^2 + \frac{2}{r_2}\right] u\left(k_{n_1}\ell_2, r_2\right)$$

$$- 2\left(\frac{2\ell_2+1}{2\ell_1+1}\right)^{1/2} \sum_{n_1'\ell_1'\ell_2'} \sum_{m_1 m_1'} \sum_{\lambda=0}^{\infty} \sum_{\mu=-\lambda}^{+\lambda} C^{\ell_1\ell_2 L}_{m_1 - m_1 0} C^{\ell_1'\ell_2' L}_{m_1' - m_1' 0}$$

$$\times \left\{ \left(\frac{2\ell_1'+1}{2\ell_2'+1}\right)^{1/2} C^{\lambda\ell_1'\ell_1}_{\mu m_1' m_1} C^{\lambda\ell_1'\ell_1}_{000} C^{\lambda\ell_2\ell_2'}_{\mu m_2 m_2'} C^{\lambda\ell_2\ell_2'}_{000} g_\lambda\left(n_1\ell_1 n_1'\ell_1', r_2\right) u\left(k_{n_1'}\ell_2', r_2\right) \right.$$

$$\left. + \beta\left(\frac{2\ell_2'+1}{2\ell_1'+1}\right)^{1/2} C^{\lambda\ell_2'\ell_1}_{\mu m_2 m_1} C^{\lambda\ell_2'\ell_1}_{000} C^{\lambda\ell_2\ell_1'}_{\mu m_2 m_1'} C^{\lambda\ell_2\ell_1'}_{000} P\left(n_1'\ell_1', r_2\right) g_\lambda\left(n_1\ell_1 k_{n_1'}\ell_2', r_2\right) \right\}$$

$$+ \beta \sum_{n_1'\ell_1'\ell_2'} (-)^{L-\ell_1-\ell_2} \delta\left(\ell_1'\ell_2', \ell_2\ell_1\right)\left(\frac{1}{n_1^2} + k_{n_1'}^2\right) P\left(n_1'\ell_1', r_2\right)\left(n_1\ell_1 | k_{n_1'}\ell_2'\right) = 0 . \tag{21}$$

In the exchange integrals above we have defined $P(k_{n_1}\ell_2, r)$ as $u(k_{n_1}\ell_2, r)$.

The vectorial equations

$$\mathbf{L} = \boldsymbol{\ell}_1 + \boldsymbol{\ell}_2 , \tag{22}$$

where $\mathbf{L}$ is constant but $\boldsymbol{\ell}_1$ and $\boldsymbol{\ell}_2$ take the values given before, can be divided into two groups, one with $L-\ell_1-\ell_2$ even and the other with $L-\ell_1-\ell_2$ odd. Since the total spatial wave function has the parity of $\ell_1+\ell_2$, in the first group the wave function has the parity of L and in the second a parity opposite to L. By conservation of parity we have two distinct groups of interactions. In this problem, where 1s, 2s, and 2p states of atomic hydrogen are taken into account, it is easy to see that, when $L-\ell_1-\ell_2$ is even, the set of quantum numbers $k_{n_1}\ell_2$ has four values: one for each of the 1s and 2s states, and two for the 2p state. When $L-\ell_1-\ell_2$ is odd, $k_{n_1}\ell_2$ has one value which corresponds to the elastic scattering of electrons by the 2p state of the hydrogen atom. Equation 21 is evaluated for these cases, and the resulting differential equations are listed in Appendix A. In evaluating Equation 21, it should be noted that the $C^{\ell_1\ell_2\ell_3}_{m_1 m_2 m_3}$ coefficients are subject to the condition that $\ell_1\ \ell_2\ \ell_3$ form a closed triangle and $m_3 = m_1 + m_2$.† This limits the summation over λ and μ considerably to few terms only. Summation over m_1, m_1', λ, and μ is carried out using the numerical values of the C coefficients given by Condon and Shortley (Reference 9).

*Reference 8, Equation 4.34.

†Reference 8, Equation 3.14.

Percival and Seaton (Reference 3) have derived the same differential equations for the scattering of free electrons by atomic s, p, and d electrons in the hydrogen atom using the theory of irreducible tensor operators to evaluate the interaction terms between the two electrons in the differential equations. The calculation becomes considerably simpler in this way. The results of the two methods are identical.

In the rest of the paper, except the section on page 14, we discuss the solutions to the four coupled differential equations given in Appendix A and which arise when $L-\ell_1-\ell_2$ is even. The single differential equations for $L-l_1-l_2$ odd are derived in the excepted section (page 14). Its numerical integration can be treated as a special case of the four coupled differential equations.

When the integrals representing the direct potentials in the four differential equations are evaluated and some change is made in the limits of the exchange potential integrals, these equations can be written in the following matrix form:

$$\left[\frac{d^2}{dr^2} + k_n^2 - \frac{l_n(l_n+1)}{r^2}\right] u(k_n l_n, r) = 2V u(k_n l_n, r) . \tag{23}$$

The four components of **u** are the four radial functions of the free electron. **V** is a 4x4 symmetric matrix that is the sum of three matrices,

$$\left.\begin{aligned} V_{ij} &= D_{ij} + E_{ij} , \\ E_{ij} &= F_{ij} + \sum_{\nu=1}^{\sigma} g_{ij}^{\nu} \int_0^{\infty} h_{ij}^{\nu}\, dr , \end{aligned}\right\} \tag{24}$$

where D_{ij} is the direct potential, E_{ij} is the exchange potential, and where both are functions of r. The matrix E_{ij} contains in addition integrals with respect to r, and for the purpose of numerical integration it can be written as the sum of two matrices. The explicit forms of D_{ij}, F_{ij}, g_{ij}^{ν}, and h_{ij}^{ν} are given in Appendix B. The value of σ is 2 for i=j=3 and i=j=4, and is 1 for all other values of i and j. It is understood that for the exchange terms the components of u on the right-hand side of Equation 23 are inside the integrals of the exchange terms.

Derivation of the Transmission Matrix from Solutions of the Differential Equations

The method is similar to that used by Bransden and McKee (Reference 10), and by Marriot (Reference 1). Equation 23 constitutes a set of four coupled second-order differential equations. Three components of **u** can be eliminated from these equations, resulting in an 8th order differential equation for the remaining component. Therefore there are eight sets of solutions to Equation 23. However, only half of these solutions are regular at the origin. Each of the four regular solutions corresponds to a definite vector **u**. The four vectors can properly be represented by a 4x4 matrix u_{nj}, n, j=1, 2, 3, 4, where n corresponds to the particular component and j corresponds to the particular solution of **u**. The four solutions are carried out numerically in the next section.

From the explicit form of **V** it can be seen that **V** vanishes at infinity. The asymptotic solution of **u** as given by Equation 23 is therefore

$$u_{nj}(r) \approx a_{nj} \sin\left(k_n r - \frac{l_n \pi}{2} + \delta_{nj}\right) \quad (n, j = 1, 2, 3, 4) , \tag{25}$$

where a_{nj} is the amplitude and δ_{nj} is the phase shift of the j^{th} solution of the n^{th} component of **u**.

Corresponding to the four components of **u**, there are 4 channels open to the reaction. If the incident wave is in the m^{th} channel (m=1, 2, 3, 4), the traveling wave in the n^{th} channel will be given by

$$u_n(r) \approx \exp\left[-i\left(k_n r - \tfrac{1}{2} l_n \pi\right)\right] \delta(m, n) - S_{mn} \exp\left[i\left(k_n r - \tfrac{1}{2} l_n \pi\right)\right] \quad (n = 1, 2, 3, 4) . \tag{26}$$

The constants S_{mn} are the amplitudes of the scattered waves. Since Equation 26 is also the asymptotic solution of Equation 23, they must be equal to linear combinations of Equation 25. If we call the coefficients of the linear combinations P_j, we must have

$$\sum_{j=1}^{4} P_j a_{nj} \sin\left(k_n r - \frac{l_n \pi}{2} + \delta_{nj}\right) =$$

$$(k_n)^{-1/2}\left\{\exp\left[-i\left(k_n r - \frac{1}{2} l_n \pi\right)\right]\delta(m, n) - S_{mn}\exp\left[i\left(k_n r - \frac{1}{2} l_n \pi\right)\right]\right\}$$

$$(n, m = 1, 2, 3, 4) . \quad (27)$$

On the right-hand side, we have used the normalization of Blatt and Weisskopf (Reference 11). If we equate the coefficients of $\exp[-i(k_n r - 1/2 l_n \pi)]$ and $\exp[i(k_n r - 1/2 l_n \pi)]$ in Equation 27, we obtain

$$\left.\begin{aligned} \sum_{j=1}^{4} P_j a_{nj} \exp - [i\delta_{nj}] &= \frac{-2i}{\sqrt{k_n}}\delta(m, n) . \\ \sum_{j=1}^{4} P_j a_{nj} \exp [i\delta_{nj}] &= \frac{-2i}{\sqrt{k_n}} S_{mn} . \end{aligned}\right\} \quad (28)$$

Separation of Equations 28 into real and imaginary parts gives

$$\left.\begin{aligned} \sum_{j=1}^{4}\left[(\Re P_j)\sin\delta_{nj} - (\Im P_j)\cos\delta_{nj}\right] a_{nj} &= \frac{2}{\sqrt{k_n}}\delta(m, n) , \\ \sum_{j=1}^{4}\left[(\Re P_j)\cos\delta_{nj} + (\Im P_j)\sin\delta_{nj}\right] a_{nj} &= 0 , \\ \sum_{j=1}^{4}\left[(\Re P_j)\sin\delta_{nj} + (\Im P_j)\cos\delta_{nj}\right] a_{nj} &= \frac{-2}{\sqrt{k_n}}\Re S_{mn} , \\ \sum_{j=1}^{4}\left[(\Re P_j)\cos\delta_{nj} - (\Im P_j)\sin\delta_{nj}\right] a_{nj} &= \frac{2}{\sqrt{k_n}}\Im S_{mn} . \end{aligned}\right\} \quad (29)$$

In the above R or I represent the real or the imaginary part of the quantity that follows them. Equations 29 are a set of 16 linear equations for 16 unknowns RP_j, IP_j, RS_{mn} and IS_{mn}. Once these unknowns are found,* the magnitude of S_{mn} will be given by

$$|S_{mn}|^2 = (RS_{mn})^2 + (IS_{mn})^2 . \quad (30)$$

The cross section is obtained by asymptotic expansion in spherical harmonics of the incident plane wave†

$$\exp[ikz] \approx \frac{\pi^{1/2}}{kr} \sum_{l=0}^{\infty} (2l+1)^{1/2} i^{l+1} \left\{ \exp\left[-i\left(kr - \frac{1}{2} l\pi\right)\right] - \exp\left[i\left(kr - \frac{1}{2} l\pi\right)\right] \right\} Y_{l,0} . \quad (31)$$

The magnitude of the ingoing wave on the right-hand side of Equation 27 for $n=m$ is $[k_m/\pi(2l_m+1)]^{1/2}$ times the magnitude of the partial wave of the expansion of $r \exp[ik_m z]$. The plane wave has a flux of v which, in atomic units, is equal to k. The ingoing flux of the right-hand side of Equation 27 is therefore $k_m^2/[\pi(2l_m+1)]$. The outgoing flux in the channel $n \neq m$ is $|S_{mn}|^2$. The cross section is obtained when we average the ratio of the outgoing flux to the ingoing flux over the initial states and sum over the final states. For a particular spin state of the two electrons, unpolarized electron beam, and unoriented atoms, the multiplicity of the initial states is $(2l_1+1)(2l_2+1)$, where l_1 and l_2 are the angular momentum of the bound and free electrons. For a polarized beam, $m_2 = 0$, where m_2 is the magnetic quantum number of the free electron. Then $m_1 = M$, where m_1 and M are the bound electron and the total magnetic quantum numbers. Since M is constant, there is only one initial state for a polarized beam. The multiplicity of the final states is $2L+1$, where L is the total orbital angular momentum. Since $\ell_m = \ell_2$, the cross section for $m \neq n$ is

$$Q_{mn} = \frac{\pi(2L+1)}{k_m^2(2l_1+1)} |S_{mn}|^2 \quad (m \neq n) . \quad (32)$$

The outgoing partial wave in the incident channel m consists of the scattered wave plus the outgoing wave given in the expansion of the plane wave. Then, according to Equation 27 for $n=m$, the magnitude of the amplitude of the scattered wave is $|1-S_{mn}|$. The elastic scattering cross section is therefore given by

$$Q_{mm} = \frac{\pi(2L+1)}{k_m^2(2l_1+1)} |1-S_{mm}|^2 . \quad (33)$$

If we define a matrix T by the relation

$$T = 1 - S , \quad (34)$$

Equations 32 and 33 can then be combined into a single equation,

$$Q_{mn} = \frac{\pi(2L+1)}{k_m^2(2l_1+1)} |T_{mn}|^2 . \quad (35)$$

T_{mn} is the transmitted amplitude in the n^{th} channel due to an incident wave in the m^{th} channel. The elements of T_{mn} constitute the transmission matrix.

The matrix S has two properties that are useful as tests on the accuracy of numerical integration. From Equation 26 it can be seen that S transforms the ingoing wave into the outgoing waves. The continuity of the electronic current requires that S be a unitary matrix.

$$\sum_{n=1}^{4} |S_{mn}|^2 = 1 \quad (m = 1, 2, 3, 4) . \quad (36)$$

Furthermore, since the Hamiltonian is Hermetian,

*Equations 29 with their present form and without further simplifications are solvable by the computer.

†Reference 11, Ch. VIII, Equation 2.7.

S must be symmetric (Reference 11):

$$S_{mn} = S_{nm} . \tag{37}$$

Equations 36 and 37 are used as tests on the accuracy of numerical integration.

A Useful Relation

A relation based on the symmetry of the interaction potentials, which serves as another test on the accuracy of the solutions, can be derived. The l^{th} and the k^{th} solutions of the i^{th} component of $\mathbf{u}$ by Equation 23 are given by

$$\left.\begin{aligned}\left[\frac{d^2}{dr^2} + k_i^2 - l_i \frac{(l_i+1)}{r^2}\right] u_{il} &= \sum_j V_{ij} u_{jl} ,\\ \left[\frac{d^2}{dr^2} + k_i^2 - l_i \frac{(l_i+1)}{r^2}\right] u_{ik} &= \sum_j V_{ij} u_{jk} .\end{aligned}\right\} \tag{38}$$

Multiplying the first by u_{ik} and the second by u_{il}, subtracting the two expressions, and summing over i gives

$$\sum_i \left[u_{ik} \frac{d^2}{dr^2} u_{il} - u_{il} \frac{d^2}{dr^2} u_{ik}\right] = \sum_{i,j} V_{ij} \left[u_{ik} u_{jl} - u_{il} u_{jk}\right] . \tag{39}$$

Since $V_{ij} = V_{ji}$, the interchange of the summation indices changes the sign on the right-hand side of the equation; the right-hand side must therefore be zero. Integrating the left-hand side from zero to infinity, we obtain

$$\sum_i \int_0^\infty \left[u_{ik} \frac{d^2}{dr^2} u_{il} - u_{il} \frac{d^2}{dr^2} u_{ik}\right] dr = 0 . \tag{40}$$

Integrating the above equation by parts, and applying Equation 25, we obtain

$$\sum_{i=1}^{4} k_i a_{ik} a_{il} \sin(\delta_{ik} - \delta_{il}) = 0 \qquad (k, l = 1, 2, 3, 4, k \neq l) . \tag{41}$$

Although the terms containing the exchange potentials do not cancel out on the right-hand side of Equation 39, the cancellation does take place after the integration is carried out in Equation 40.

Transmission Matrix According to Born Approximation

The Born approximation consists of neglecting the exchange potential terms appearing in the V matrix of Equation 23, and also of neglecting all the direct potential terms in this matrix except those terms that connect the incident channel to all other channels (Reference 12). Equation 23, when the incident wave is in the m^{th} channel, reduces to

$$\left[\frac{d^2}{dr^2} + k_n^2 - \frac{l_n (l_n+1)}{r^2}\right] u_n = 2 D_{nm} u_m \qquad (n = 1, 2, 3, 4) ; \tag{42}$$

u_m and u_n are given asymptotically by

$$u_m \approx k_m^{-1/2} \sin\left(k_m r - l_m \frac{\pi}{2}\right) , \tag{43}$$

$$u_n \approx k_n^{-1/2} B_{nm} \cos\left(k_n r - l_n \frac{\pi}{2}\right) . \tag{44}$$

We have chosen the constants of proportionality of u_m and u_n such that B_{nm} is the Born approximation of the reactance matrix R (Reference 13).* Equation 43 shows that u_m must have the following

*Also Reference 11, Ch. V, Sec. 4.

form (Reference 14):

$$u_m = k_m^{1/2} r j_{l_m}(k_m r) , \qquad (45)$$

where $jl_m(k_m r)$ are spherical Bessel functions. Furthermore, if y_n represents the homogenous solution of Equation 42, it must have the following forms:

$$y_n = a_n k_n r j_{l_n}(k_n r) , \qquad (46)$$

$$y_n \approx a_n \sin\left(k_n r - l_n \frac{\pi}{2}\right) , \qquad (47)$$

with a_n some unknown constant. Multiplying Equation 42 on the left by y_n and integrating the result from zero to infinity, we obtain by partial integration

$$2\int_0^\infty y_n D_{nm} u_m \, dr = \int_0^\infty y_n \left[\frac{d^2}{dr^2} + k_n^2 - \frac{l_n(l_n+1)}{r^2}\right] u_n \, dr$$

$$= \left[y_n \frac{d}{dr} u_n - u_n \frac{d}{dr} y_n\right]_0^\infty$$

$$= -k_n^{1/2} a_n B_{nm} .$$

The last equality has been obtained by noticing that y_n and u_n vanish at the origin, and by using their asymptotic forms as given by Equations 44 and 47. We therefore have

$$B_{nm} = -2(k_n k_m)^{1/2} \int_0^\infty j_{l_n}(k_n r) D_{nm} j_{l_m}(k_m r) r^2 \, dr . \qquad (48)$$

This is identical to the expression given for B by Seaton.*

The transmission and the reactance matrices are related by $\mathbf{T} = -2i\mathbf{R}/(1-i\mathbf{R})$. Since in the Born approximation $\mathbf{R} = \mathbf{B} \ll 1$, the transmission matrix according to the Born approximation is given by

$$T_{nm}^B = 4i(k_n k_m)^{1/2} \int_0^\infty j_{l_n}(k_n r) D_{nm} j_{l_m}(k_m r) r^2 \, dr . \qquad (49)$$

Substitution of Equation 49 into 35 would give the cross section according to the Born approximation. It should be noted that the symmetry of T insures Equation 37 to be satisfied while Equation 36 is no longer satisfied.

Elastic Scattering of Electrons by the 2p States of the Hydrogen Atom

The angular momentum of the free electron l_2 in the 2p channel has the values L−1, L, L+1, where L is the total angular momentum of the system. The first and the last values were considered in previous sections. The case $l_2 = L$ corresponds to a wave function in the 2p channel with a parity different from all channel wave functions considered previously. It therefore corresponds to elastic scattering. The wave function

*Reference 13, Equation 3.10.

in this case is given by

$$\psi_L(r_1, r_2) = (1 + \beta P_{12}) \sum_{m_1=-1}^{+1} C^{1LL}_{m_1 - m_1 0}\, \phi_{2p m_1}(r_1)\, \frac{u(k_2 L, r_2)}{r_2}\, Y_{L-m_1}(\Omega_2) \quad (50)$$

When Equation 9 is formed with this wave function, and minimized with respect to $u(k_2L, r_2)$, treatment which led to the derivation of the four differential equations will give the following differential equation:

$$\left[\frac{d^2}{dr^2} + k_2^2 - \frac{L(L+1)}{r^2} + \frac{2}{r}\right] u_L(r)$$

$$- \beta\left(\frac{1}{4} + k_2^2\right) \delta(L, 1)\, r\, R_{21}(r)\, \left(2p | k_2 L\right)$$

$$+ 2\left[y_0(2p\,2p, r) - \frac{1}{5} y_2(2p\,2p, r)\right] u_L(r)$$

$$+ 2\beta r R_{21}(r)\left[-\frac{3y_{L-1}(2p k_2 L, r)}{(2L+1)(2L-1)} + \frac{3y_{L+1}(2p k_2 L, r)}{(2L+1)(2L+3)}\right] = 0 . \quad (51)$$

The asymptotic solution of this equation is given by

$$u_L \approx a_L \sin(k_2 r - L\pi/2 + \delta_L) . \quad (52)$$

If the scattering amplitude is designated by T_{55}, it can be shown from the section on page 8 that for a particular L

$$T_{55} = 1 - \exp 2i\delta = -2i \exp(i\delta) \sin\delta , \quad (53)$$

where for simplicity we have suppressed the subscript L. The cross section, according to Equation 35, is given by

$$Q_{55} = \frac{4\pi(2L+1)}{3k_2^2} \sin^2\delta . \quad (54)$$

The total elastic scattering cross section by the 2p states is the sum of this cross section and the cross section corresponding to $l_2 = L-1$ and $l_2 = L+1$ (which were considered previously).

The Born amplitude, Equation 48, in this case is given by

$$B_{55} = -2k_2 \int_0^\infty j_L(k_2 r)\, D_{55}\, j_L(k_2 r)\, r^2\, dr , \quad (55)$$

where, by Equation 51,

$$D_{55} = -\frac{1}{r} + y_0(2p\,2p, r) - \frac{1}{5} y_2(2p\,2p, r) . \quad (56)$$

NUMERICAL INTERGRATION

Decomposition of the Differential Equations

If it were not for the definite integrals appearing in the potential matrix **V**, the set of the four coupled differential equations (23) could be integrated by any standard technique. The presence of these unknown constants whose integrand involves the unknown functions makes it necessary to solve these equations by iteration or by transformation of **u** into other vectors, whose differential equations do not contain definite integrals. Since the terms containing definite integrals are small as compared with the direct potentials, the iteration method can be used by assuming that the values of these integrals are zero. The differential equations are then integrated, the values of the definite integrals that are subsequently obtained are substituted in the differential equations, and the integration is repeated. The process is repeated

until sufficiently consistent values of these integrals are obtained. This method is useful if the convergences of the constants are fast enough, and the cross section is not very sensitive to the values of these constants.

In the second method, the transformation of **u** fixes the values of the constants and thus avoids iteration, whereby the computation is reduced considerably. The description of the method will be given here (Reference 15).*

By making use of Equations 24, Equation 23 can be written

$$\left[\frac{d^2}{dr^2} + k_i^2 - \frac{l_i(l_i+1)}{r^2}\right] u_i = 2\sum_{j=1}^{4}\left[(D_{ij}+F_{ij})\,u_j + \sum_{\mu=1}^{\sigma} g_{ij}^{\mu} C_{ij}^{\mu}\right], \tag{57}$$

where

$$C_{ij}^{\mu} = \int_0^{\infty} h_{ij}^{\mu}(r)\,u_j(r)\,dr . \tag{58}$$

We introduce the functions v_i and u_i^{kl} that are solutions of the following differential equations:

$$\left[\frac{d^2}{dr^2} + k_i^2 - \frac{l_i(l_i+1)}{r^2}\right] v_i = 2\sum_{j=1}^{4}\left[D_{ij}+F_{ij}\right] v_j , \tag{59}$$

$$\left[\frac{d^2}{dr^2} + k_i^2 - \frac{l_i(l_i+1)}{r^2}\right] u_i^{kl} = 2\sum_{j=1}^{4}\left[D_{ij}+F_{ij}\right] u_j^{kl} + 2\delta(i,k)\,g_{kl}^{\nu} . \tag{60}$$

Then u_i is given by the following expression:

$$u_i = v_i + \sum_{k=1}^{4}\sum_{l=1}^{4}\sum_{\nu=1}^{\sigma} C_{kl}^{\nu}\,u_i^{kl} . \tag{61}$$

Equation 61 can be verified by multiplying Equation 60 by C_{kl}^{ν}; summing over k, l, and ν; and adding to Equation 59—whereupon Equation 57 results. Substitution of Equation 61 in Equation 58 gives.

$$\sum_{k=1}^{4}\sum_{l=1}^{4}\sum_{\nu=1}^{\sigma}\left[\delta(ij\mu, kl\nu) - A_{ij}^{\mu kl}\right] C_{kl}^{\nu} = B_{ij}^{\mu}$$

$$(i, j = 1, 2, 3, 4;\ \mu = 1, 2 \text{ for } i = j = 3 \text{ and } i = j = 4;\ \mu = 1 \text{ otherwise}) , \tag{62}$$

where $A_{ij}^{\mu kl}$ and B_{ij}^{μ} are defined by

$$\left.\begin{aligned} A_{ij}^{\mu kl} &= \int_0^{\infty} h_{ij}^{\mu}\,u_j^{kl}\,dr , \\ B_{ij}^{\mu} &= \int_0^{\infty} h_{ij}^{\mu}\,v_j\,dr . \end{aligned}\right\} \tag{63}$$

The numerical integration is carried out by integrating Equations 59 and 60 by any standard method, calculating $A_{ij}^{\mu kl}$ and B_{ij}^{μ} by Equations 63

*Also, Reference 1. This description differs from the description of Reference 15 and the present paper. In Reference 1, v_i, in Equation 61 is set to 0; this makes $B_{ij}^{\mu}=0$. Equations 62 then reduce to a set of homogeneous equations whose determinant must be 0. Since the amplitude of any of the four components of **u** can be left arbitrary, one of the C_{kl} is set equal to 1 and the rest of the constants are found subsequently.

and, finally, solving the system of 18 algebraic equations given by Equation 62 to find C_{kl}^{ν}. With the known values of these constants the integration of Equation 57 is straightforward.

The determinant of Equation 62 becomes singular for L = 0 and 1. This is shown in Appendix C. To remove the singularity, some of the C_{kl}^{ν} are chosen arbitrarily, and the rest of the C_{kl}^{ν} are found in terms of the chosen ones.

Solution at the Origin

In order that the four solutions of **u** be independent of each other, we must have

$$\sum_{j=1}^{4} C_j u_{ij} \neq 0 \quad (i = 1, 2, 3, 4) , \tag{64}$$

where C_j are some constants. A necessary condition for this to be satisfied is that the determinant of Equation 64 be nonzero:

$$||u_{ij}|| \neq 0 . \tag{65}$$

It is not difficult to see that this also is a sufficient condition. At the origin the solution u_{ij} can be expressed as power series in r,

$$u_{ij} = \sum_{\nu=0}^{\infty} a_{ij}^{\nu} r^{s_i+\nu} , \tag{66}$$

where a_{ij}^{ν} are the coefficients of expansion, and s_i are given integers for each component of **u** and are fixed by the behavior of Equation 23 at the origin. We can satisfy Equation 65 at the origin by having

$$||a_{ij}^{0}|| \neq 0 . \tag{67}$$

By choosing suitable values of a_{ij}^{0}, subject to the restriction of Equation 67, four independent solutions are obtained.

Solution at Large r

With given initial values, the solution of Equation 23 can be extended from origin to any desired value of r. To obtain the asymptotic amplitudes and the phase shifts, the presence of the centrifugal and long-range potentials makes it necessary to extend the solutions to infinity. This is undesirable because of the time consumption on the computer, and the accumulated error due to the long-range integration. Seaton (Reference 13) has solved the problem of r^{-2} long-range potentials occurring in the off-diagonal terms of the potential matrix **V** by diagonalizing the asymptotic form of the differential Equation 23 and the corresponding S-matrix. By an inverse transformation the elements of the original S-matrix are found.

Instead, we develop here a perturbation theory which is based on the method described by Mott and Massey (Reference 16). The error in the resulting solution is inversely proportional to the square of the distance from the origin.

Equation 23 for large distances of r can be written

$$\left[\frac{d^2}{dr^2} + k_n^2\right] u(k_n l_n, r) = 2\mathbf{U}u(k_n l_n, r) , \tag{68}$$

where **U** is the sum of the centrifugal potential matrix and the asymptotic form of the **V** matrix. The elements of **U** are given in Appendix D. A component of Equation 68 is of the following form:

$$\left.\begin{aligned} \left[\frac{d^2}{dr^2} + k^2\right] u(r) &= g(r) , \\ g(r) &\ll k^2 u(r) \quad (g(r) \to 0 \text{ as } r \to \infty) . \end{aligned}\right\} \tag{69}$$

The perturbation theory is applied between some large distance R and infinity. Suppose u vanishes at R; then we have the following boundary condition:

$$u(R) = 0 . \tag{70}$$

If we represent the solution of the homogenous equation by y (r), at infinity, we must have

$$\left.\begin{aligned} y(r) &= a \sin(kr - kR) , \\ u(r) &= (a + \Delta a) \sin(kr - kR + \eta) , \end{aligned}\right\} \tag{71}$$

where a is the amplitude of u(r) if g(r) were identically zero and ΔA and η are generated by g(r). Since g(r) is small, we can write

$$u = y(1+\zeta) , \tag{72}$$

where ζ is a small function. Substitution of Equation 72 in Equation 69 gives

$$\frac{d}{dr}\left(y^2 \frac{d\zeta}{dr}\right) = g(r)\, y , \tag{73}$$

where, upon double integration, we obtain

$$\zeta = \int_R^r \frac{dr}{y^2} \int_R^r g(r')\, y\, dr' . \tag{74}$$

The constants of integrations are fixed by the condition (70) and the fact that $u'(R) = y'(R)$.

We now integrate Equation 74 by parts,

$$\zeta = \left[\int_R^r g(r)\, y\, dr\right]\left[\int_R^r \frac{dr}{y^2}\right] - \int_R^r g(r)\, y\, dr \int_R^r \frac{dr}{y^2} . \tag{75}$$

When the integration with respect to y is carried out, and the result is substituted in Equation 73, we obtain

$$u(r) = \sin(kr - kR)\left[a + \frac{1}{k}\int_R^r g(r)\cos(kr - kR)\, dr\right] + \cos(kr - kR)\left[-\frac{1}{k}\int_R^r g(r)\sin(kr - kR)\, dr\right] . \tag{76}$$

Comparison of the second of Equations 71 and 76 shows that

$$\left.\begin{aligned} \Delta a &= \frac{1}{k}\int_R^\infty g(r)\cos(kr - kR)\, dr , \\ \eta &= -\frac{1}{ak}\int_R^\infty g(r)\sin(kr - kR)\, dr \end{aligned}\right\} \tag{77}$$

to first order. The functions g(r) in the four differential Equations 68 are given by

$$g_i(r) = 2\sum_j U_{ij}\, u_j . \tag{78}$$

To first order this can be written by

$$g_i(r) = 2\sum_j a_j\, U_{ij} \sin\left(k_i\, r - k_j\, R_j\right) , \tag{79}$$

where R_j is the last zero of u_j with positive slope. Substitution of this equation in Equation 77 gives

$$\left.\begin{aligned} \Delta a_i &= -\sum_j \frac{a_j}{k_i}\int^{R_i} \cos\left(k_i\, r - k_i\, R_i\right) U_{ij} \sin\left(k_j\, r - k_j\, R_j\right) dr , \\ \eta_i &= \sum_j \frac{a_j}{a_i\, k_i}\int^{R_i} \sin\left(k_i\, r - k_i\, R_i\right) U_{ij} \sin\left(k_j\, r - k_j\, R_j\right) dr . \end{aligned}\right\} \tag{80}$$

Δa_i and η_i can easily be calculated by substituting the values of U_{ij} from Appendix D, integrating the resulting integrals by parts, and retaining the leading terms.

The asymptotic amplitudes and phase shifts are given by

$$\left.\begin{aligned} a_i(\infty) &= a_i(R_i) + \Delta a_i , \\ \delta_i(\infty) &= \delta_i(R_i) + \eta_i + \left[L - \delta(i,3) + \delta(i,4)\right]\frac{\pi}{2} , \end{aligned}\right\} \tag{81}$$

where $a_i(R_i)$ and $\delta_i(R_i)$ are the amplitudes and total phase shifts calculated at R_i by the machine, and where $\delta(i, 3)$ and $\delta(i, 4)$ are the δ functions.

Details of the Numerical Integration

Milne's (Reference 17) method with variable mesh size and Simpson's* rule were used for the integration of the differential equations and evaluations of the integrals respectively. As the solution advances from the origin, the differential equations become less sensitive to the size of the increment, and the error of integration falls below certain small number ϵ. At each value of r the value of the function is found, first with the given value of the increment, and second with the value of increment divided in half. The error of integration is defined as the difference between these two solutions. When the error becomes small, the increment is doubled until a maximum value is reached. At some distance R_1 all the exchange potentials and, similarly, all the direct potentials except those representing optically allowed transitions and the 2p−2p elastic scattering potential become vanishingly small (see Appendix D). At this distance the set of differential equations is replaced by the simpler set containing only these potentials. The integration is continued until some distance R_2, where the first-order solution of the rest of the range of integration is obtained by the method developed in the previous section. No attempt was made to solve any set of linear equations or any matrix equations, as these equations are solvable by the computer in their original form.

The values of the constants of the numerical integration are given below; h_i and h_f are the initial and the final increments of integration. In some exceptional cases, different values were used.

$$h_i = 1 \times 10^{-5}$$

$$h_f = 0.05$$

$$\epsilon = 1 \times 10^{-4}$$

$$R_1 = 30$$

$$R_2 = 200$$

(All quantities are in units of Bohr radius except ϵ, which is dimensionless.)

RESULTS AND DISCUSSION

The differential equations (23) with the known values of the elements of the potential matrix **V** as given in Appendix B were integrated numerically by the methods described in the last section. By choosing different values for the determinant (Equation 67) different sets of independent solutions can be generated. The cross sections reported in this paper have been obtained by averaging the cross sections obtained from two independent sets of solutions. To test the accuracy of the numerical integration, we define the three quantities D_{mn}, D'_{mn}, and D''_m given by

$$D_{mn} = \frac{\left|\sum_{i=1}^{4} k_i a_{im} a_{in} \sin(\delta_{im} - \delta_{in})\right|}{\sum_{i=1}^{4} k_i a_{im} a_{in} \left|\sin(\delta_{im} - \delta_{in})\right|} \quad (m, n = 1, 2, 3, 4, m \neq n), \tag{82}$$

$$D'_{mn} = \frac{|S_{mn} - S_{nm}|}{|S_{mn}| + |S_{nm}|} \quad (m, n = 1, 2, 3, 4, m \neq n), \tag{83}$$

$$D''_m = \frac{\left|\sum_{n=1}^{4} |S_{mn}|^2 - 1\right|}{\sum_{n=1}^{4} |S_{mn}|^2 + 1} \quad (m = 1, 2, 3, 4). \tag{84}$$

*Reference 17, Sec. 33.

Based on Equations 36, 37, and 41 in an exact solution of the four differential equations, the right-hand side of these equations would vanish; they can therefore be used to test the accuracy of the numerical integration. As an illustration the numerical values of D_{mn}, D'_{mn}, and D''_{m} for the case of $1s-2s-2p$ coupling, $\beta=+1$, $k_1=2.0$, and $L=3$, are given below:

$$D_{12} = 1.4 \times 10^{-3}, \quad D_{13} = 2.6 \times 10^{-4}, \quad D_{14} = 1.3 \times 10^{-3},$$

$$D_{23} = 5.1 \times 10^{-4}, \quad D_{24} = 2.2 \times 10^{-3}, \quad D_{34} = 1.8 \times 10^{-3},$$

$$D'_{12} = 7.6 \times 10^{-4}, \quad D'_{13} = 5.1 \times 10^{-3}, \quad D'_{14} = 5.6 \times 10^{-3},$$

$$D'_{23} = 5.4 \times 10^{-3}, \quad D'_{24} = 5.7 \times 10^{-3}, \quad D'_{34} = 1.3 \times 10^{-3},$$

$$D''_{1} = 1.8 \times 10^{-4}, \quad D''_{2} = 7.6 \times 10^{-5}, \quad D''_{3} = 2.5 \times 10^{-4}, \quad D''_{4} = 4.4 \times 10^{-6}.$$

To compare the results of the numerical integration by the noniterative method we have carried out here with those of the iterative method of References 2, 4, and 5, we have provided Table 1.* The $1s \rightarrow 2s$ excitation cross section is given by the two methods; I and II refer to the iterative and noniterative methods, respectively; and E_{max} is the maximum of the error to value ratios in the reciprocity relations (Equation 83). In the $1s-2s$ eigenstates coupling approximation the non-iterative method is far more accurate than the iterative method and, as is seen, the cross

*Author is indebted to Dr. K. Smith for sending some of the data used in Table 1.

sections by the two methods differ from each other sometimes in their first significant figure. In the 1s−2s−2p eigenstates coupling approximation, on the other hand, the results by the iterative method seems to be somewhat more accurate. The reason is contributed to the effect of the r^{-2} long-range potential, which appears in the differential equations when the 2p state is included in the eigenstates coupling approximation. Two different methods are used in References 4 and 5 and in the present paper to estimate the effect of this potential for large distances; and it may be that in References 4 and 5 this effect is better taken into account. Nevertheless the cross sections are the same in their first three decimal places.

In Figure 1 we present the theoretical and the experimental estimate of the 1s−2s excitation cross section. The calculated curves are Born, 1s—2s coupling, 1s−2s−2p coupling exchange neglected, and 1s−2s−2p coupling exchange included approximation. The first three of these curves are the same as References 4 and 5. The experimental curves are those of Lichten and Schultz (Reference 18) and Stebbings, Fite, and Hummer (Reference 19). The various calculated results agree better with the results of Lichten and Schultz. However, recent calculations of Taylor and Burke (Reference 20) have shown that, in an eigenstates expansion calculation where 1s, 2s, 2p, 3s, and 3p are included, the cross section at the peak of the 1s−2s−2p curve is reduced by 30 percent. This suggests that, within the eigenstates expansion approximation, more states should be included to insure that the convergence has been achieved; and the discrepancy between the two experimental results is still an unresolved problem. As another theoretical approach to the problem, H. L. Kyle and A. Temkin (Reference 21) have extended the nonadiabatic theory of scattering developed by A. Temkin (Reference 22) to the L=0, 1s→2s inelastic scattering of electrons by the hydrogen atom. They find a 30 percent decrease in the 1s→2s cross section as calculated by the 1s−2s close coupling approximation.

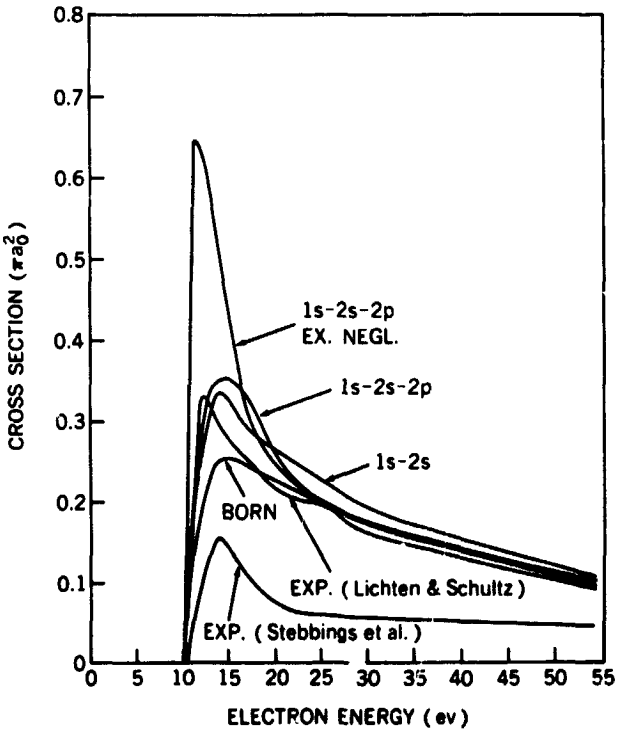

FIGURE 1.—1s→2s total excitation cross section. (1s–2s refers to 1s–2s eigenstates coupling approximation; 1s–2s–2p has similar meaning. EX.NEGL. refers to exchange neglected case, BORN is the Born approximation, and EXP. refers to experiment.)

Comparison of the exchange neglected and exchange included 1s−2s−2p coupling shows that exchange is mostly important at threshold, and its effect does not extend beyond 20 electron volts.

Table 2 gives the numerical values of the 1s→2s cross section in different approximations. The 1s→2s excitation cross section in the singlet state has an interesting behavior immediately above threshold. In Figure 2 this cross section for a range of 600 milli electron volts (mev) above threshold is plotted. In the 1s−2s coupling approximation a maximum appears at 34 mev, while in the 1s−2s−2p coupling approximation there are three maxima of approximately the same magnitudes at 17, 34, and 87 mev, respectively. In the singlet case the cross section rises sharply within a range of 17 mev above threshold to a value of about $0.04\pi a_0^2$; it then rises with an approximately constant and small slope. The contribution of the triplet case is seen to be almost negligible at the threshold, and it has no maximum in this region. It should be noted that the principal maximum in the 12→2s excitation cross section appears at about 3 ev with a value of about 0.35, and has a contribution from a higher angular momentum than L=0. Although no study has been made to relate the existence of the maxima above threshold to any physical phenom-

*k_2 is the wave number of the inelastically scattered wave, and E is the corresponding energy in mev; Q_1 and Q_2 are the cross sections according to the 1s - 2s and the 1s - 2s - 2p couplings, respectively.

ena, it may be said that, similar to resonances below threshold in the elastic scattering of electrons by the hydrogen atom, these maxima are due to formation of some unstable states of the negative hydrogen ion. The numerical values of the 1s→2s cross section at threshold are given in Table 3. Damburg and Peterkop (Reference 6), and Gailitis and Damburg (Reference 23) have made an extensive study of the behavior of different cross sections near threshold in the 1s−2s

*According to Gailitis and Damburg, when the energy difference between the 2s and 2p states is neglected in the 1s-2s-2p couplings, the 1s→2s excitation cross section does not go to zero at threshold (see Reference 23, and Figure 2). Figures 2 and 4 show that in the 1s-2s-2p couplings, if E_{n-1} and E_n represent the energy with respect to the threshold of the two neighboring maxima or minima then $E_n/E_{n-1} \approx$ constant. This may be attributed to the r^{-4} potential, which is due to the coupling between the 2s and the 2p states. For further details, see Reference 23.

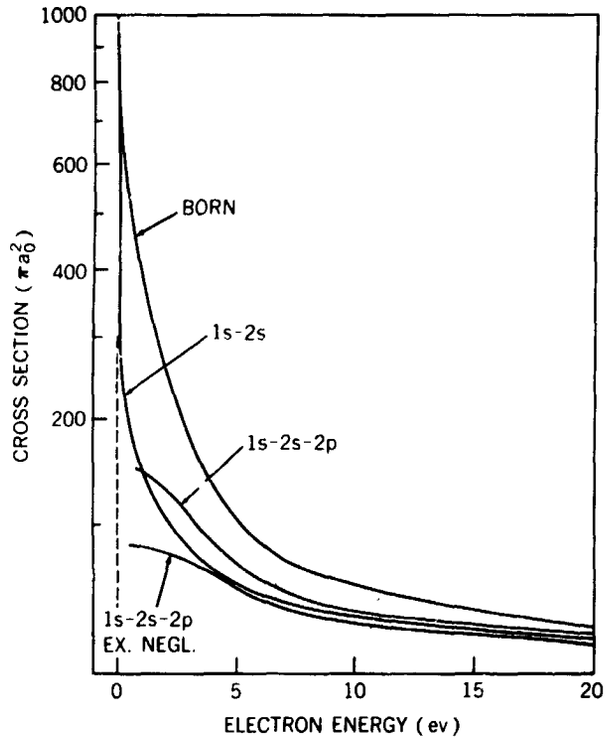

FIGURE 3.—2s→2s total elastic cross section. (Curves are designated as in Figure 1).

and the 1s−2s−2p eigenstates coupling approximations.

In Figure 3 we have shown the 2s→2s elastic cross section. The 1s−2s coupling approximation gives a value of $944\pi\ a_0^2$ at zero incident energy, while the corresponding value in the Born approximation is $768\pi\ a_0^2$. The high value of this cross section at zero energy is in sharp contrast with its geometrical cross section. The zero energy 2s→2s cross section in the 1s−2s−2p coupling approximation, because of the r^{-2} potential, is difficult to find. The 2s→2s cross section has certain maxima and minima at low energy which are not found in the 1s→1s cross section. Figure 4 shows the L=0 singlet and triplet 2s→2s cross section in the two approximations. While there is one minimum in the 1s−2s coupling approximation, there are three minima in the 1s−2s−2p coupling approximation. It is thought that the existence of these minima is due to a wider potential range in the 2s→2s scattering, a case which does not exist in the 1s→1s scattering. In Table 4 we have listed the numerical

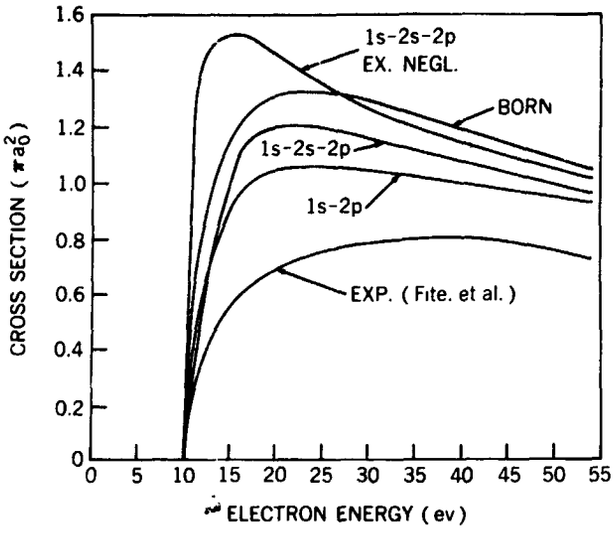

FIGURE 5.—1s→2p total excitation cross section. (1s–2p refers to 1s–2p eigenstates coupling approximation; 1s–2s–2p has similar meaning. EX.NEGL. refers to exchange case, BORN is the Born approximation, and EXP. refers to experiment.

values of the 2s→2s cross section in different approximations.

In Figure 5 the four calculated curves for the 1s→2p excitation cross section are compared with the measurement of Fite, Stebbings, and Brackmann (References 24 and 25). The 1s−2s−2p and the Born curves are the same as in References 4 and 5, but the 1s−2s−2p exchange neglected and the 1s−2p curves are not calculated in these references. As concluded before, the calculated curves are higher than the experimental. Moreover, we notice that, similar to the 1s→2s excitation cross section, the inclusion of the exchange lowers the value of the cross section at threshold. Table 5 gives the numerical values of the 1s→2p cross section in different approximations.

The calculation of the 2p→2p elastic cross section is more complicated than the cases so far considered. For a given total angular momentum L, the angular momentum of the partial wave which is scattered from the 2p state may be L−1, L, and L+1. The first and the third values correspond to a wave function which has the same parity as the wave functions in the 1s and the 2s channels; in this case, $L-\ell_1-\ell_2$ is even. The second value corresponds to a wave function with a different parity, and the only process that occurs with this parity is the 2p elastic scattering; in this case, $L-\ell_1-\ell_2$ is odd. We have calculated the

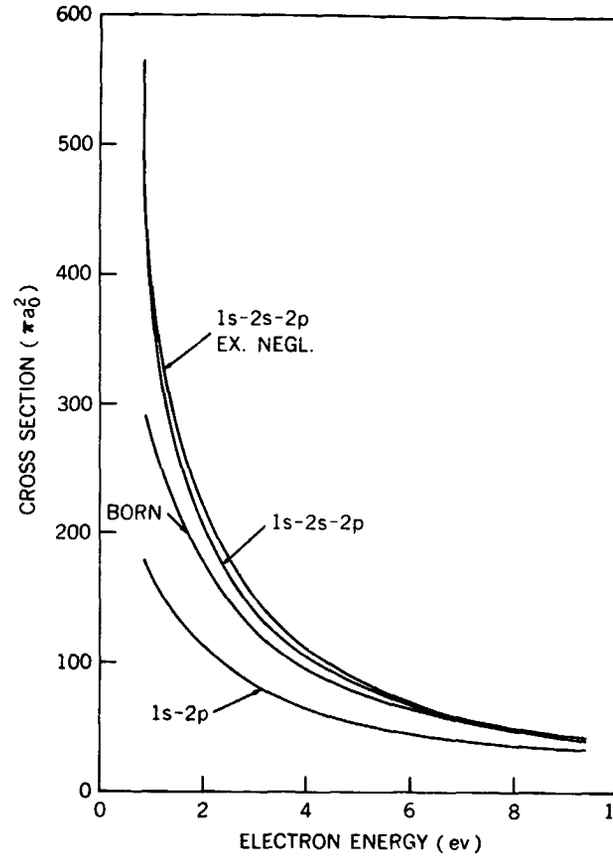

FIGURE 6.—2p→2p total elastic cross sections. (Curves are designated as in Figure 5. The cross section at zero energy is finite but is not found here.)

2p→2p cross sections for the two cases, and they are listed in Table 6. The total cross section is shown in Figure 6 (on page 33). Because of the r^{-2} potential it is difficult to find the zero energy value of this cross section.

The 2s→2p transition cross section has application in some plasma and stellar atmosphere calculations. The total cross section using the Born approximation is given by Seaton (Reference 26). In Table 7 (on page 32) we list the partial cross section using the close coupling approximation. This table may be found useful in problems in which plasma shielding occurs, where only electrons with an impact parameter with a given range can induce the 2s→2p transition.

It may be noted that the cross sections for the inverse processes 2s→1s, 2p→1s, and 2p→2s may be calculated by Equation 35 and the symmetry of the T-matrix.

In all the tables listed here, k_1 is the wave number in the 1s, and k_2 is the wave number in

Table 5
1s → 2p Excitation Cross Section.

the 2s or the 2p channels. The energy, in electron volts, of the incident electron in each channel is given by $E = 13.6\ k^2$, where k could be k_1 or k_2. All cross sections are in units of πa_0^2. In the different tables, Σ is the sum of the partial cross sections calculated. The total cross section Q_T is obtained by adding the contribution of higher partial waves than those calculated using the regular Born approximation; this could easily be done with the help of the table of the Born approximation.

CONCLUSION

The noniterative technique employed here can be applied to a large class of problems containing exchange integrals. The method is particularly useful when the exchange potential is comparable to the direct potential, in which case the convergence of iteration is slow.

ACKNOWLEDGMENTS

The programming of the numerical integration of the radial differential equations on the IBM 7090 computer has been performed by Mr. Edward Sullivan; through his meticulous and systematic programming the solution of the present problem has become available.

I am indebted to Dr. A. Temkin for many fruitful and illuminating discussions. I also wish to thank Prof. Myers of the University of Maryland for a clarifying discussion.

$$g_{43} = g_{34} .$$

In the F_{ij} matrix the interchange of the functions R_{10}, R_{20}, and R_{21} accompanies the interchange of their arguments too.

Appendix C

REMOVAL OF THE SINGULARITY IN THE DETERMINANT OF THE COEFFICIENTS OF THE LINEAR TRANSFORMATION FOR L=0, 1

Case I: L=0

By using the definition of D_{ij} and F_{ij} and Equations 63 in the text, the following relation can be derived from Equation 59 (text):

$$\int_0^\infty \left[rR_{20}\left(\frac{d^2}{dr^2} + k_1^2\right) v_1 - \beta\, rR_{10}\left(\frac{d^2}{dr^2} + k_2^2\right) v_2 \right] dr = -\frac{2}{\sqrt{3}} \left[a_{13}\, B_{24} - \beta\, a_{23}\, B_{14} \right] , \tag{C1}$$

where the superscript μ is suppressed when there is only one value for μ, and

$$a_{13} = \int_0^\infty R_{10}\, R_{21}\, r^3\, dr = \left[2^{15} \times 3^{-9} \right]^{1/2} ,$$

$$a_{23} = \int_0^\infty R_{20}\, R_{21}\, r^3\, dr = -3\sqrt{3} .$$

Integrating the left-hand side of Equation C1 by parts, and making use of Equations 11 and 63 (text), we obtain

$$\int_0^\infty \left[rR_{20}\left(\frac{d^2}{dr^2} + k_1^2\right) v_1 - \beta\, rR_{10}\left(-\frac{d^2}{dr^2} + k_2^2\right) v_2 \right] dr = -2 \left[B_{21} - \beta B_{12} \right] . \tag{C2}$$

We conclude that

$$B_{21} - \beta B_{12} = \frac{1}{\sqrt{3}} \left[a_{13} B_{24} - \beta\, a_{23} B_{14} \right] . \tag{C3}$$

Equation C3 connects the right-hand sides of the four equations of Equation 62 specified by ij = 21, 12, 24, 14. A similar relation should hold among the left-hand sides of these equations. This in fact is the case and, by making use of the first of Equations 63, it can be shown directly that equations similar to Equation C3 hold among the elements of each column k1ν of the left-hand side of Equation 62 specified by ij = 21, 12, 24, 14. We conclude that one equation of Equation 62 is linearly dependent on others and the determinant of Equation 62 is singular.

Case II: L = 1

Similar to the previous case, the following relation can be derived from Equation 59 in the text:

$$\int_0^\infty \left[rR_{21}\left(\frac{d^2}{dr^2} + k_1^2 - \frac{2}{r^2}\right) v_1 - \beta\, rR_{10}\left(\frac{d^2}{dr^2} + k_2^2\right) v_3 \right] dr$$

$$= -\frac{2}{3}\left[\beta a_{13} B_{11} + \beta a_{23} B_{12} - a_{13} B_{33}^1 + \sqrt{2}\left(a_{13} B_{34} - \frac{3}{5}\beta a_{33} B_{14}\right)\right] , \qquad \text{(C4)}$$

where

$$a_{33} = \int_0^\infty R_{21}^2\, r^4\, dr = 30 .$$

Integrating the left-hand side of Equation C4 by parts, and making use of Equations 11 and 63, we obtain

$$\int_0^\infty \left[rR_{21}\left(\frac{d^2}{dr^2} + k_1^2 - \frac{2}{r^2}\right) v_1 - \beta\, rR_{10}\left(\frac{d^2}{dr^2} + k_2^2\right) v_3 \right] dr = -2\left[B_{31} - \beta B_{13}\right] . \qquad \text{(C5)}$$

Combining Equations C4 and C5, we get

$$B_{31} - \beta B_{13} = \frac{1}{3}\left[\beta a_{13} B_{11} + \beta a_{23} B_{12} - a_{13} B_{33}^1 + \sqrt{2}\left(a_{13} B_{34} - \frac{3}{5}\beta a_{33} B_{14}\right)\right] . \qquad \text{(C6)}$$

Finally, Equation 59 (text) gives the following relation:

$$\int_0^\infty \left[rR_{21}\left(\frac{d^2}{dr^2} + k_2^2 - \frac{2}{r^2}\right) v_2 - \beta\, rR_{20}\left(\frac{d^2}{dr^2} + k_2^2\right) v_3 \right] dr$$

$$= -\frac{2}{3}\left[\beta a_{23} B_{22} + \beta a_{13} B_{21} - a_{23} B_{33}^1 + \sqrt{2}\left(a_{23} B_{34} - \frac{3}{5}\beta a_{33} B_{24}\right)\right] . \qquad \text{(C7)}$$

Integration by parts of the left-hand side gives, as before,

$$\int_0^\infty \left[rR_{21}\left(\frac{d^2}{dr^2} + k_2^2 - \frac{2}{r^2}\right) v_2 - \beta\, rR_{20}\left(\frac{d^2}{dr^2} + k_2^2\right) v_3 \right] dr = -2\left[B_{32} - \beta B_{23}\right] , \qquad \text{(C8)}$$

whereupon we get

$$B_{32} - \beta B_{23} = \frac{1}{3}\left[\beta a_{23} B_{22} + \beta a_{13} B_{21} - a_{23} B_{33}^{1} + \sqrt{2}\left(a_{23} B_{34} - \frac{3}{5}\beta a_{33} B_{24}\right)\right] \tag{C9}$$

Similar to the case L=0, Equations C6 and C9 indicate that two equations of Equation 62 are linearly dependent on others and the determinant of Equation 62 is singular.

To remove the singularity in the L=0 case, one of the C_{kl}^{ν} is chosen to be arbitrary; and a degenerate equation is removed from Equation 62(text). Similarly, in the L=1 case two of the C_{kl}^{ν} are chosen arbitrary; and two degenerate equations are removed from Equation 62.

EFFECTS OF NON-PHOTOCHEMICAL PROCESSES ON THE MERIDIONAL DISTRIBUTION AND TOTAL AMOUNT OF OZONE IN THE ATMOSPHERE*

CUDDAPAH PRABHAKARA

The photochemical equilibrium distribution of ozone below 41 km is computed for the solstices and equinoxes from recent rocket observations of the solar ultraviolet energy received at the top of the atmosphere.

In this study an attempt is made to investigate the important part played by the mean seasonal transport processes in distributing the ozone below 41 km in the stratosphere. To make such an investigation it is assumed that a steady state meridional distribution of ozone is produced when photochemical and transport processes are acting together. Relevant theory and numerical procedure to compute such a steady state meridional distribution of ozone have been developed.

In order to make a model of the transport processes that is needed for the calculation of the distribution of ozone, theoretical and observational information available at present on the various transport processes present in the stratosphere is reviewed. Further, in the calculations of ozone an attempt is made to combine the mean meridional motions and the large scale mixing processes within the limits acceptable to the current ideas on these transport processes.

The seasonal distribution of total ozone thus computed from the model of the transport processes and with an assumption of steady state condition shows a satisfactory agreement with the observed seasonal and latitudinal variation of total ozone. The mean annual total ozone variation with latitude deduced from the computed seasonal distribution of total ozone demonstrates the ability of the method developed here to account for the mean annual total ozone variation with latitude observed in the earth's atmosphere.

The model of the transport processes developed in this study to calculate the distribution of ozone in the atmosphere emphasizes the importance of the large scale eddy diffusion processes. The theoretical and observational findings from the spread of W^{185} (a radioactive isotope of tungsten introduced into the stratosphere by nuclear explosions) have been very useful in making this model of the transport processes.

INTRODUCTION

Our knowledge of the distribution of ozone in the atmosphere is derived largely from the observations of the vertical distribution of ozone at comparatively few and widely scattered stations on the earth.

The Umkehr method (Götz, Reference 1) of obtaining the distribution of ozone was widely used until recently. From the Umkehr method standard curves of the vertical distribution of ozone† at a given station for different amounts of total ozone contained in a vertical column of unit area were constructed. Then, using the observed total amount of ozone at the station for any given day, the vertical distribution of ozone for the day was read off these standard curves. Ramanathan and Kulkarni (Reference 2) have constructed the meridional distribution of ozone using such a technique on the data obtained at Kodaikanal, Poona, Mount Abu, Delhi, Srinagar, Tetano, Arosa, Tromsö, and College, Alaska. The models of the distribution of ozone given by Ramanathan and Kulkarni from the equator to 80°N latitude for November and July are combined as shown in Figure 1 to yield a distribution of ozone from one pole to the other.

Besides the Umkehr method there have been other methods developed to measure the vertical distribution of ozone. Regener (Reference 3), using an ozone-sonde based on the principle of

*Published as *NASA Technical Note D-2106*, June 1964. This work was also published in the *Monthly Weather Review*, 91(9):411-431, September 1963.

†Vertical distribution of ozone is usually expressed in Dobson Units: D.U. $=10^{-3}$cm of ozone at standard temperature and pressure. Also D.U. $=2.69\times10^{16}$ molecules of ozone/cm^2.

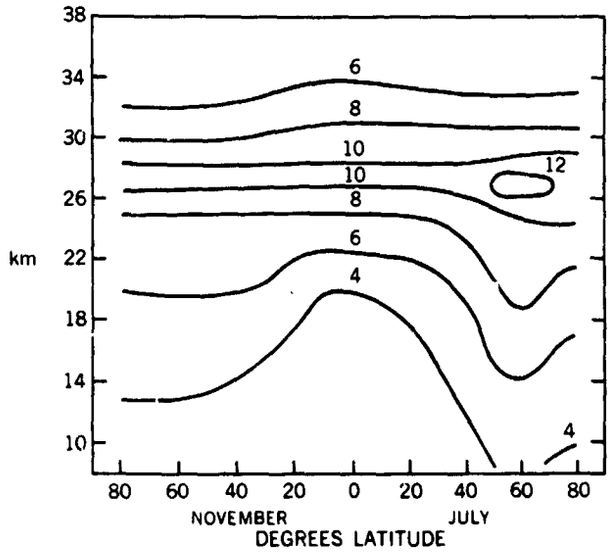

FIGURE 1.— Model of the "observed" meridional distribution of ozone (1.33xD.U./km), constructed after Ramanathan and Kulkarni (Reference 2).

photographic photometry, has measured the vertical distribution of ozone at Albuquerque. Using the observations of the emission and absorption of infrared radiation by ozone in the 9.6μ band, Epstein et al. (Reference 4) at Flagstaff, Arizona, and Goody and Roach (Reference 5) at Oxford, England, have derived the vertical distribution of ozone. Brewer (Reference 6) has made measurements of the vertical distribution of ozone at Liverpool and Malta with a chemical ozone-sonde. It is very difficult to put together such measurements obtained by different methods and to make a model of the meridional distribution of ozone.

Very recently Paetzold and Piscalar (Reference 7) using the observations of the vertical distribution of ozone made during the I.G.Y. with an optical radio ozone-sonde at four stations—Tromsö, Weissenau, Leopoldville, and Denver—have constructed a meridional distribution of ozone for spring and fall, which is presented here as Figure 2.

Both these models of the "observed" meridional distribution of ozone, the construction of which could not be attempted until recently, are still based on data collected from a few stations. Nevertheless, these models bring out the salient features of the atmospheric ozone.

Ozone is produced in the earth's atmosphere by the photochemical reactions induced by the solar ultraviolet radiation (Chapman, Reference 8). Although the photochemical reactions (referred to hereafter as photochemical theory) lead to the formation of ozone in the atmosphere, the observed global distribution of ozone cannot be completely explained on the basis of photochemical theory alone.

Total ozone computed from the photochemical theory is short of the observed total amounts at higher latitudes, and it is in excess of the amounts observed at the equatorial latitudes (Craig, Reference 9). Photochemical theory would lead to summer maximum and winter minimum of total ozone at all latitudes, while the observations show a maximum in spring and a minimum in autumn at high latitudes as shown in Figure 3 (London, Reference 10). Small seasonal variations are observed at the equatorial latitudes (Ramanathan, Reference 11).

The vertical distribution of ozone concentration according to photochemical theory has a maximum at about 30 km height in the atmosphere, and the position of maximum is higher, the higher the latitude (Figure 12). On the contrary, observations on the vertical distribution of ozone show that the position of the maximum is usually lower when the latitude is higher, leading to a lowering of the center of gravity of the ozone layer with increase in latitude (Figure 4).

Photochemical studies made by previous investigators (see, e.g., Wulf and Deming, Reference

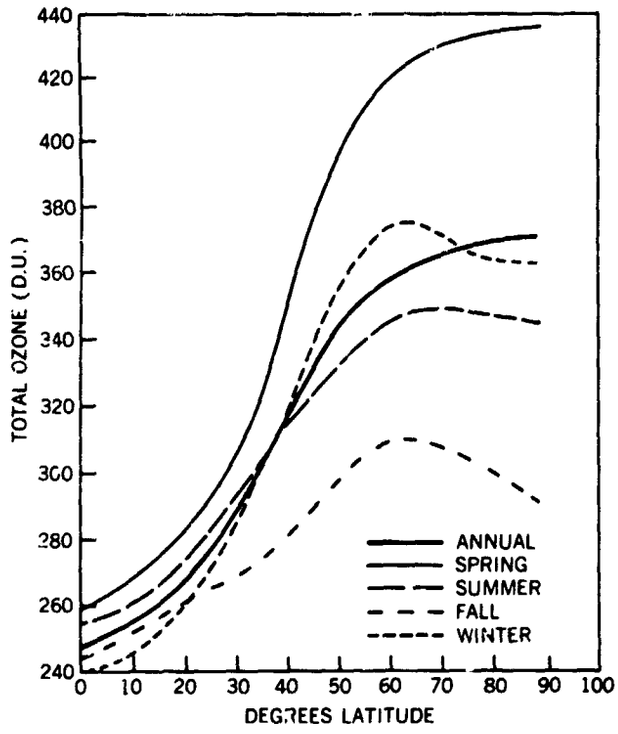

FIGURE 3.—Total ozone variation with latitude and season, after London (Reference 10).

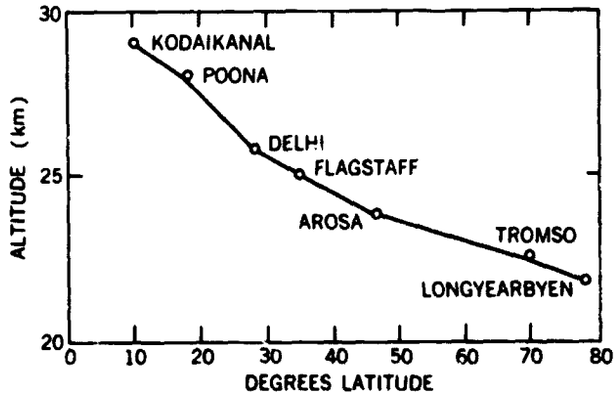

FIGURE 4.—Latitudinal variation of ozone center of gravity after Miller (Reference 12).

13; Craig, Reference 9; Dütsch, Reference 14) showed that the half-life of ozone was of the order of a day at heights above about 30 km, and that photochemical conditions could prevail above that level. However, below that level the production of ozone by solar ultraviolet rapidly decreased, and any departures from photochemical equilibrium conditions could persist for long periods of time. Arguing on such grounds to explain the seasonal and latitudinal variations of ozone, Craig suggested that there should be "some atmospheric process which transports ozone from regions where it can be quickly reformed (high levels or equatorial regions) to lower protected levels where it can persist." He further commented that"... this process must be most effective in middle and high latitudes in winter, when the total amount of ozone increases most rapidly."

Dütsch (Reference 15) first made an attempt to introduce changes of ozone due to Austausch and circulation and to obtain a seasonal variation of ozone as a function of latitude. Craig (Reference 9) remarked that the seasonal and latitudinal variations obtained by Dütsch were qualitatively similar to the observed ones, but of extremely small amplitude (about 20 percent of the observed latitudinal amplitude and about 5 to 10 percent of the observed seasonal amplitude at high latitudes).

Objective of the Present Study

From the earlier discussion it may be seen that transport by advection and diffusion on different space and time scales plays a significant role in producing the geographical distribution of ozone. At present it is difficult to consider elaborately the effects of small scale phenomena owing to the lack of information on nature of these transport processes on small space and time scales in the stratosphere.

In this study it is intended to compute the photochemical distribution of ozone, using the best available data needed for such computations, as a function of latitude and season. This is done as a basic step before proceeding to examine the influence of transport processes on the distribution of ozone.

The measurements of total ozone in the atmosphere show clearly an annual cycle of the ozone variation with the largest and the least amounts in spring and fall respectively. The striking contrast between the mean seasonal ozone amounts in the atmosphere has been demonstrated by Ramanthan (Reference 11) and London (Reference 10). Such mean seasonal features of total ozone suggest that the part played by the mean seasonal transport processes in distributing the ozone in the lower stratosphere, where the bulk of

ozone present is under weak solar control, could be of paramount importance. This influence of the mean seasonal transport processes on ozone in the lower stratosphere is probably capable of masking the direct influence of solar radiation, the ultimate source of ozone. Hence in this study it is intended to make an experiment on the calculation of the meridional distribution of ozone produced under steady state condition by transport processes and solar radiation. Further, it is intended to see if such an approach can explain the seasonal variation of ozone in the earth's atmosphere.

In this study an attempt is made to develop the equations necessary for calculating the distribution of ozone in the atmosphere under steady state conditions when photochemistry is coupled with local change of ozone due to mean seasonal meridional motions and large scale mixing processes. Further, the numerical procedure to solve such equations will be developed.

Posing the problem of atmospheric ozone as a steady state or boundary value problem has a unique advantage; namely, it is not necessary to specify the initial distribution of ozone in the atmosphere to get a steady state solution, so that the solution is not subject to the uncertainties of the initial distribution.

The mean seasonal transport processes in the stratosphere needed for this study will be deduced from the recent available observational and theoretical information.

THEORY

Basic Photochemistry of Ozone

The photochemical reactions involved in producing the ozone layer below 50 km are (see, e.g., Craig, Reference 9; Dütsch, Reference 14):

$$O_2 + h\nu \longrightarrow O_1 + O_1 , \tag{1}$$

(λ < 2400 A, oxygen absorption in Schumann-Runge bands and Herzberg continuum)

$$O_1 + O_2 + M \xrightarrow{K_2} O_3 + M , \tag{2}$$

$$O_3 + O_1 \xrightarrow{K_3} 2O_2 , \tag{3}$$

$$O_3 + h\nu \longrightarrow O_1 + O_2 , \tag{4}$$

(λ < 11,000 A, ozone absorption in Hartley, Huggins, and Chappuis bands)

where O_1, O_2, O_3, and M stand for number of atomic oxygen, molecular ozygen, ozone, and total number of molecules per cm³. Symbol h is the Planck's constant and ν, the frequency of radiation. K_2 (cm⁶ molec⁻² sec⁻¹) and K_3 (cm³ molec⁻¹ sec⁻¹) are the rate coefficients of the Reactions 2 and 3.

The above four reactions give the rate of growth of O_1 and O_3 as

$$\frac{\partial O_1}{\partial t} = 2f_2O_2 + f_3O_3 - K_2O_1O_2M - K_3O_1O_3 , \tag{5}$$

$$\frac{\partial O_3}{\partial t} = -f_3O_3 + K_2O_1O_2M - K_3O_1O_3 , \tag{6}$$

where f_2 and f_3 stand for the number of quanta of energy absorbed per second per molecule of oxygen and ozone.

Under equilibrium conditions

$$\frac{\partial O_1}{\partial t} = \frac{\partial O_3}{\partial t} = 0 . \tag{7}$$

With the above condition we have from Equation 5

$$O_1 = \frac{2f_2O_2 + f_3O_3}{K_2O_2M + K_3O_3} . \tag{8}$$

Substituting for O_1 from Equation 8 into (6) (and neglecting O_3 in comparison to (K_2/K_3)

(O_2M) we get the photochemical equilibrium ozone, O_{3e}:

$$O_{3e} = O_2\sqrt{\frac{K_2}{K_3}\frac{f_2}{f_3}M} . \quad (9)$$

Effects of Transport Processes

General Considerations

The photochemical equations are developed by considering only the solar radiation and its direct influence on the atmosphere. However, if transport processes such as advection and diffusion are present in the atmosphere, they tend to redistribute the ozone produced by solar radiation. In such a redistribution, regions of the atmosphere where photochemical production of ozone is rapid act like sources, and regions where the photochemical production is weak constitute sinks of ozone.

Before introducing the effects of transport processes into the growth equation for ozone, it is intended to develop basic ideas necessary for such a study by considering the influence on ozone of an external input at the rate of F molecules of O_3/cm^3–sec. The growth Equation 6 for ozone now becomes

$$\frac{\partial O_3}{\partial t} = -f_3O_3 + K_2O_2O_1M - K_3O_3O_1 + F . \quad (10)$$

Substituting for O_1 from 8 into 10, we have

$$\frac{\partial O_3}{\partial t} = -f_3O_3 + \{K_2O_2M - K_3O_3\}\frac{(2f_2O_2 + f_3O_3)}{(K_2O_2M + K_3O_3)} + F . \quad (11)$$

We divide the above equation by K_3O_3 and write N_3^* for K_2O_2M/K_3 and get

$$\frac{\partial O_3}{\partial t}\left[\frac{N_3^*}{O_3} + 1\right] = -2f_3O_3 + F\left[1 + \frac{N_3^*}{O_3}\right] + 2f_2O_2\left[\frac{N_3^*}{O_3} - 1\right] . \quad (12)$$

Now the external input at the rate of F molecules of O_3/cm^3–sec and the photochemical process tend to a new equilibrium of ozone O_{3E} given by 13, when $\partial O_3/\partial t = 0$:

$$2f_3O_{3E} - F\left\{1 + \frac{N_3^*}{O_{3E}}\right\} - 2f_2O_2\left\{\frac{N_3^*}{O_{3E}} - 1\right\} = 0. \quad (13)$$

Since $N_3^*/O_{3E} \gg 1$, as was stated in arriving at Equation 9, we can write Equation 13 as

$$2f_3O_{3E} - F\frac{N_3^*}{O_{3E}} - 2f_2O_2\frac{N_3^*}{O_{3E}} = 0 \quad (14)$$

or

$$O_{3E} = \sqrt{\frac{(F + 2f_2O_2)}{2f_3}N_3^*} . \quad (15)$$

Dütsch (Reference 15) first arrived at this equation. Equation 15 may be transformed with the help of Equation 9 as

$$O_{3E} = O_{3e}\sqrt{1 + \frac{F}{2f_2O_2}} . \quad (16)$$

Equation 16 shows that an input of F molecules of O_3/cm^3–sec does not indefinitely increase the amount of ozone, for solar radiation exerts a control on the growth of ozone so that a new equilibrium is reached which is related to the photochemical equilibrium O_{3e} and to the ratio $F/2f_2O_2$.

Similarly from 16 it may further be inferred that $O_{3E} < O_{3e}$ when F is negative. However, when F is negative, a scrutiny of Equation 16 shows that there is no real solution for O_{3E} if $(2f_2O_2 + F) < 0$. This condition can be overcome by the following physical considerations.

Until now F was considered only as a positive or negative rate of input for developing the basic equations. However, in the atmosphere local rate of change of ozone due to advective and diffusive processes results from the spatial distribution of ozone and the relative intensities of these transporting agencies. Thus, under equilibrium conditions, the spatial distribution assumed by ozone will be such that at each point in the field, flux convergence or divergence of ozone is in balance with the photochemical destruction or

production of ozone at that point. On physical grounds it becomes untenable to obtain a field of ozone under steady state that has flux divergence at any point in the field over and above photochemical production at that point.

Transport by Large Scale Diffusion and Mean Meridional Motions

We may now proceed to introduce the changes of ozone due to large scale diffusion and mean meridional motions in the growth Equation 12. However, to take into account the variation of density in the atmosphere we have to choose a property of ozone that is a function of the atmospheric density. Such a property of ozone is its mixing ratio

$$\chi = \frac{O_3 \text{ molecules, cm}^3}{\text{air molecules, cm}^3} .$$

Thus

$$O_3 = M\chi . \tag{17}$$

Now the rate at which ozone increases at any given point per unit volume per unit time, due to a velocity $\mathbb{V}$, is given by the equation of continuity for ozone:

$$\left[\frac{\partial (M\chi)}{\partial t}\right]_a = -\nabla \cdot (M\chi \mathbb{V}) . \tag{18}$$

The subscript a refers to air motions.

Now let u, v, and w be the components of $\mathbb{V}$ along x the east, y the north, and z the vertical direction. Expressing these velocity components and χ in terms of their mean and turbulent part we have

$$\begin{aligned} \chi &= \bar{\chi} + \chi' , \\ \mathbb{V} &= \bar{\mathbb{V}} + \mathbb{V}' , \\ u &= \bar{u} + u' , \\ v &= \bar{v} + v' , \\ w &= \bar{w} + w' , \end{aligned} \tag{19}$$

where the time averaged quantities $\bar{\chi}$, $\bar{\mathbb{V}}$, $\bar{u}$, $\bar{v}$, and $\bar{w}$ are defined as

$$\overline{(\quad)} = \frac{1}{\tau} \int_0^\tau (\quad)\, dt . \tag{20}$$

τ is a period comparable to the length of a season. Thus

$$\left[\frac{\partial (M\chi)}{\partial t}\right]_a = -\nabla \cdot \left[M(\bar{\chi} + \chi')(\bar{\mathbb{V}} + \mathbb{V}')\right] ; \tag{21}$$

that is,

$$\left[\frac{\partial (M\chi)}{\partial t}\right]_a = -\nabla \cdot (M\bar{\chi}\bar{\mathbb{V}}) - \nabla \cdot (M\bar{\chi}\mathbb{V}') - \nabla \cdot (M\chi'\bar{\mathbb{V}}) - \nabla \cdot (M\chi'\mathbb{V}') . \tag{22}$$

Let $\bar{M} = M$. Then averaging over time would give

$$\left[\frac{\partial (M\chi)}{\partial t}\right]_a = -\nabla \cdot (M\bar{\chi}\bar{\mathbb{V}}) - \nabla \cdot (M\bar{\chi}'\bar{\mathbb{V}}') = -\bar{\mathbb{V}} \cdot \nabla (M\bar{\chi}) - M\bar{\chi}\nabla \cdot \bar{\mathbb{V}} - \nabla \cdot (M\bar{\chi}'\bar{\mathbb{V}}') ; \tag{23}$$

therefore,

$$\left[M\frac{\partial \bar{\chi}}{\partial t} + \bar{\chi}\frac{\partial M}{\partial t}\right]_a = -M\bar{\mathbb{V}} \cdot \nabla\bar{\chi} - \bar{\chi}\bar{\mathbb{V}} \cdot \nabla M - M\bar{\chi}\nabla \cdot \bar{\mathbb{V}} - \nabla \cdot (M\bar{\chi}'\bar{\mathbb{V}}') . \tag{24}$$

Now, from the equation of continuity we have

$$\frac{1}{M}\frac{dM}{dt} = -\nabla \cdot \bar{\mathbb{V}} . \tag{25}$$

Therefore,

$$\bar{\chi}\left(\frac{\partial M}{\partial t} + \bar{\mathbb{V}} \cdot \nabla M\right) + M\bar{\chi}\nabla \cdot \bar{\mathbb{V}} = 0 ; \tag{26}$$

and so

$$\left[\frac{\partial \bar{\chi}}{\partial t}\right]_a = -\bar{\mathbb{V}} \cdot \nabla\bar{\chi} - \frac{1}{M}\nabla \cdot (M\bar{\chi}'\bar{\mathbb{V}}') . \tag{27}$$

When we expand $\bar{V}$ and $\bar{V}'$ into their components, we get

$$\left[\frac{\partial \bar{\chi}}{\partial t}\right]_a = -\left(\bar{u}\frac{\partial \bar{\chi}}{\partial x} + \bar{v}\frac{\partial \bar{\chi}}{\partial y} + \bar{w}\frac{\partial \bar{\chi}}{\partial z}\right) - \frac{1}{M}\left\{\frac{\partial}{\partial x} M\overline{\chi' u'} + \frac{\partial}{\partial y} M\overline{\chi' v'} + \frac{\partial}{\partial z} M\overline{\chi' w'}\right\} . \quad (28)$$

We further assume zonal symmetry of $\bar{\chi}$ and a steady zonal wind $\bar{u}$, and we can reduce Equation 28 to

$$\left[\frac{\partial \bar{\chi}}{\partial t}\right]_a = -\left(\bar{v}\frac{\partial \bar{\chi}}{\partial y} + \bar{w}\frac{\partial \bar{\chi}}{\partial z}\right) - \frac{1}{M}\left\{\frac{\partial}{\partial y} M\overline{\chi' v'} + \frac{\partial}{\partial z} M\overline{\chi' w'}\right\} . \quad (29)$$

The term $-\left(\bar{v}\frac{\partial \bar{\chi}}{\partial y} + w\frac{\partial \bar{\chi}}{\partial z}\right)$ in 29 expresses the local change of χ at any given point in the meridional plane due to mean meridional and vertical motions.

The terms $-\frac{\partial}{\partial y} M\overline{\chi' v'}$ and $-\frac{\partial}{\partial z} M\overline{\chi' w'}$ in 29 may be transformed with the help of the Austausch assumption (see, e.g., Haurwitz, Reference 16) of diffusion as

$$-\frac{\partial}{\partial y}\left(M\overline{\chi' v'}\right) = \frac{\partial}{\partial y}\left[Mk_y \frac{\partial \bar{\chi}}{\partial y}\right]$$

and

$$-\frac{\partial}{\partial z}\left(M\overline{\chi' w'}\right) = \frac{\partial}{\partial z}\left[Mk_z \frac{\partial \bar{\chi}}{\partial z}\right], \quad (30)$$

where K_Y and K_Z (cm^2/sec) are the eddy diffusion coefficients along the y and z directions. Upon neglecting the variation of density, M along y, the local change of ozone at a given point due to large scale diffusion and mean meridional motions may be obtained from 29, 30, and 17 as

$$\left[M\frac{\partial \bar{\chi}}{\partial t}\right]_a = -M\left(\bar{v}\frac{\partial \bar{\chi}}{\partial y} + \bar{w}\frac{\partial \bar{\chi}}{\partial z}\right) + M\left[K_y\frac{\partial^2 \bar{\chi}}{\partial y^2} + \frac{\partial K_y}{\partial y}\frac{\partial \bar{\chi}}{\partial y} + K_z\frac{\partial^2 \bar{\chi}}{\partial z^2} + \frac{\partial K_z}{\partial z}\frac{\partial \bar{\chi}}{\partial z} + K_z\frac{1}{M}\frac{\partial M}{\partial z}\frac{\partial \bar{\chi}}{\partial z}\right]. \quad (31)$$

If we substitute for F, in Equation 13, the local change of ozone $M\left[\frac{\partial \bar{\chi}}{\partial t}\right]_a$ from 31 and then divide by $\left(\frac{O_{3E}+N_3^*}{O_{3E}}\right)$, we obtain

$$-2f_3\frac{O_{3E}^2}{N_3^* + O_{3E}} + 2f_2 O_2\left[\frac{N_3^* - O_{3E}}{N_3^* + O_{3E}}\right] + \left[M\frac{\partial \bar{\chi}}{\partial t}\right]_a = 0 \quad (32)$$

or

$$-2\frac{f_3}{M}\frac{(M\bar{\chi})^2}{(N_3^* + M\bar{\chi})} + 2f_2\frac{O_2}{M}\left[\frac{N_3^* - M\bar{\chi}}{N_3^* + M\bar{\chi}}\right] + \left[\frac{\partial \bar{\chi}}{\partial t}\right]_a = 0 \quad (33)$$

Equation 33 describes the combined effects of the photochemical and transport processes under steady state conditions. By solving 33 for $\bar{\chi}$ as a function of latitude and height we can get the distribution of $\bar{\chi}$ and hence O_{3E} in the meridional plane.

The numerical methods and boundary conditions necessary to solve Equation 33 are discussed in the next section.

During the polar night in the winter hemisphere there is no discussion of oxygen or ozone by radiation. Hence the local change of ozone at any point under such conditions will be entirely due to transport processes. It is also possible that air motions could transport atomic oxygen into the polar night. Such transported atomic oxygen could form ozone in the polar night through Reaction 2. Kellogg (Reference 17) has demonstrated by his calculations the importance of such transported atomic oxygen in heating the layers of the atmosphere above 80 km. However, at lower levels below about 40km, it is reasonable

to assume, following Craig (Reference 9), that O_1 is used up in Reaction 2 in situ, so that the O_1 transport may be neglected.

PROCEDURE OF THE INVESTIGATION

Discussion of the Data Used

It is necessary to have data on the solar energy received at the top of the atmosphere, the absorption coefficients of oxygen and ozone, the temperature and density distribution in the atmosphere, and the reaction rate coefficients K_2 and K_3 in order to calculate the vertical distribution of ozone in the atmosphere.

From the most recent rocket measurements of the solar spectrum we have now very reliable estimates of the energy in the ultraviolet radiation received at the top of the atmosphere. The two measurements of the solar ultraviolet spectrum, one reported by Detwiler et al. (Reference 18) and the other by Hinteregger (Reference 19), agree with one another quite well. The value of the solar ultraviolet energy received at the top of the atmosphere from 1800 to 2600 A used in this study are taken from measurements of Detwiler et al. Above 2600 A the solar radiation received at the top of the atmosphere tabulated by Gast (Reference 20) is adopted. The solar spectrum thus constructed is shown in Figure 5.

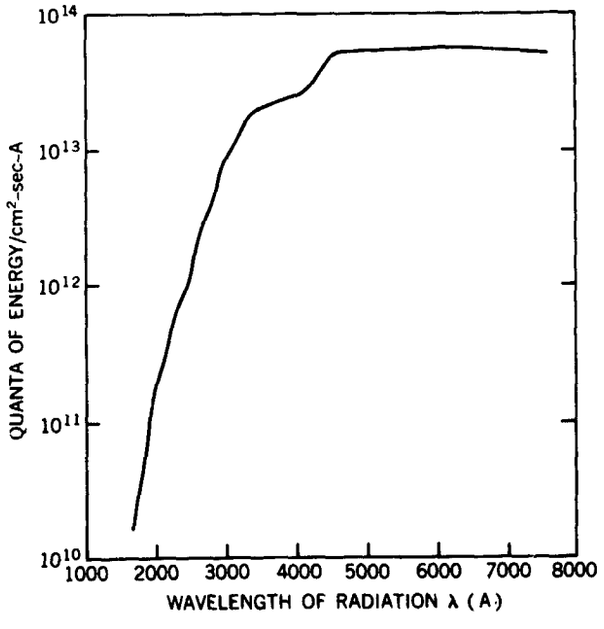

FIGURE 5.—Solar energy received at the top of the atmosphere.

Watanabe et al. (Reference 21), using vacuum ultraviolet technique, measured the absorption coefficients of oxygen between 1050 and 1900 A. The absorption coefficients of oxygen in the Schumann-Runge bands from 1800 to 1900 A are adopted from the measurements reported, independent of pressure, by these investigators. However, they point out that their results show a pressure variation of the coefficients by a factor of 4 to 5 in the absorption peaks, and 2 to 3 in the absorption minima. In view of the apparent pressure dependency of the "observed coefficients" reported by them, they remark that their "data were smoothed somewhat arbitrarily; that is, low pressure data were used for maxima, and high pressure data for minima" to obtain absorption coefficients of oxygen independent of pressure.

Heilpern (Reference 22) showed that the absorption coefficient of oxygen is pressure dependent in the region 2100 to 2400 A. In his measurements he used eight different pressures (between 50 and 127 kgm/cm²) to obtain the functional form of pressure dependency of the extinction coefficients for a mixture of oxygen and nitrogen having a composition similar to air. Samples of air gave the same results within the accuracy of his experimental values. He fitted his results for the entire region to an equation of the form

$$\epsilon_p = \epsilon_1 P_1 + \epsilon_2 P_2 + \epsilon_3 P_1 P_2 ,$$

where $\epsilon_p(cm^{-1})$ is the extinction coefficient, P_1 (kgm/cm²) is the partial pressure of oxygen, P_2(kgm/cm²) is the partial pressure of nitrogen, and ϵ_1, ϵ_2 and ϵ_3 are coefficients evaluated by fitting the data to the above equation.

Heilpern's investigation of the extinction coefficient of a similar mixture in the pressure range 0.2 to 130 kgm/cm² and at 2144 A agreed with the functional form obtained from the whole region 2100 A to 2400 A. On the strength of the observations at 2144 A, which were extended to the lower pressure range, this form of pressure dependency is accepted in this work to hold good at low pressure for the entire region 2100 to 2400 A. The absorption coefficients at pressures below 0.2 kgm/cm², encountered in the atmosphere, are obtained by extrapolating the experimental data with the help of the above functional form of pressure dependency.

The absorption coefficient of oxygen for the region 1900 to 2100 A, lying between the limits of the experimental studies of Watanabe et al. and Heilpern, were obtained by interpolation. The interpolation was made at each desired pressure in the atmosphere.

The absorption coefficient of oxygen thus obtained at sea level pressure is compared in Figure 6 with that of Craig (Reference 9).

Vassy (Reference 23) determined the absorption coefficients of ozone from 2020 A to 2170 A using ozonized oxygen and a photographic photometric method. However, she used Ny and Choong's (Reference 24) value of the absorption coefficient of ozone in the Huggins bands to measure the path length of ozone in her experiment.

Absorption coefficients of ozone in the region 1050 to 2200 A were measured by Tanaka et al. (Reference 25) using a vacuum ultraviolet technique. Their curve for the absorption intensity showed a minimum at about 2015 A. They used pure ozone obtained by vaporizing liquid ozone instead of the ozonized oxygen used by the earlier experimenters. Tanaka et al., however, remarked that "the results of Vassy, and Ny and Choong, who measured down to 2020 A and 2135 A respectively, are somewhat higher than the present data. The difference was about 10 percent at 2200 A and about 40 percent at 2020 A as compared with the data reported by Vassy. The discrepancies are greater than can be explained by ordinary experimental errors, and might be due to their use of the ozonized oxygen and photographic detection as opposed to the use of purer ozone and photoelectric detection."

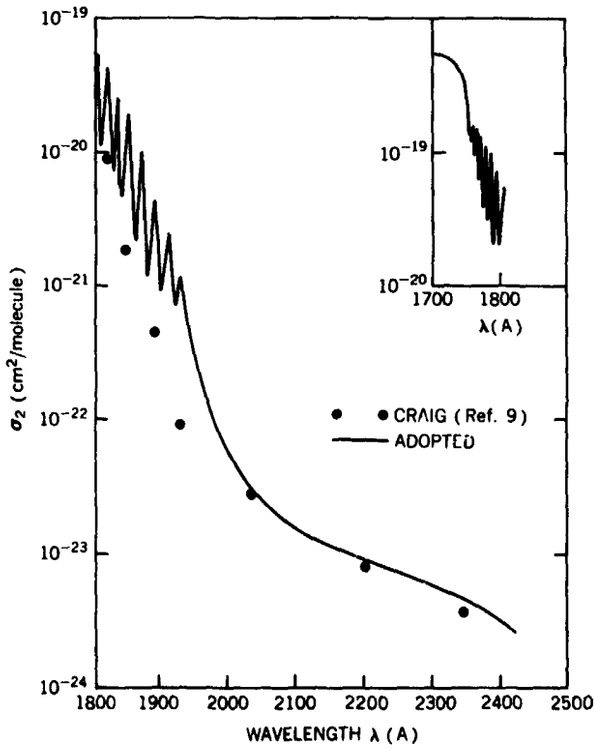

FIGURE 6.—Absorption coefficients of oxygen.

But Tanaka et al. have observed chemiluminescence of pure ozone in their experiment. It is possible that the presence of such chemiluminescence of pure ozone in the investigation of Tanaka et al. may have been responsible for somewhat smaller values of the absorption coefficients of ozone.

As an extension to the measurements made by Tanaka et al., Inn and Tanaka (Reference 26) measured the ozone absorption in the near ultraviolet from 2000 to 3500 A and in the visible region from 4000 to 7000 A.

Vigroux (Reference 27) studied the absorption of ozone in the Hartley, Huggins, and Chappuis bands using photographic photometric method and ozonized oxygen. He also studied the temperature dependency of the absorption coefficient of ozone. However, his observations do not extend to wavelengths shorter than 2300 A in the Hartley bands.

Gast (Reference 20) has tabulated the absorption coefficients of ozone from 2200 to 3000 A determined by Inn and Tanaka. For the region 3000-3500 A he has listed the absorption coefficients measured by Vigroux which he remarks are "recommended" by Inn and Tanaka. Gast has presented the absorption coefficients of ozone at 18°C and also (suitably applying the temperature correction given by Vigroux) at −44°C. The value corresponding to −44°C is better suited to calculate transmission of solar energy in the atmosphere.

In the present study the absorption coefficients of ozone at wavelengths longer than 2200 A are adopted from the tables presented by Gast as shown in Figure 7(a). At wavelengths shorter than 2200 A there is apparently a large difference between the absorption coefficients obtained by Tanaka et al., using pure ozone, and Vassy, who used ozonized oxygen.

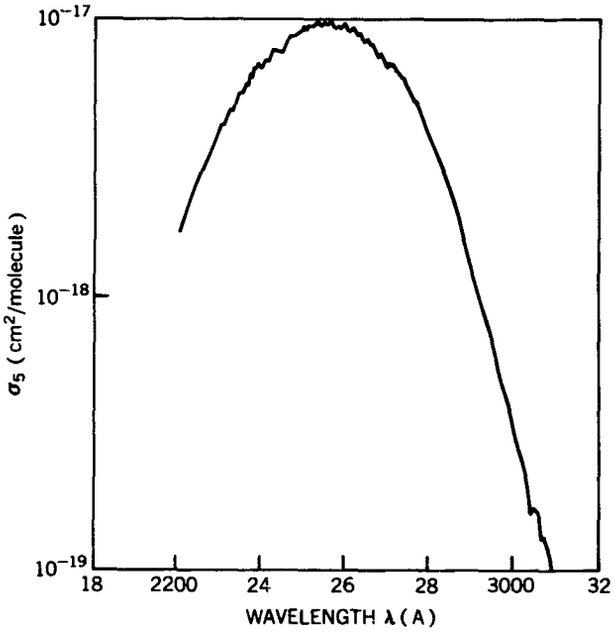

FIGURE 7a.—Absorption coefficients of ozone between 2200–3100A.

In this study the absorption coefficients of Vassy in the spectral region 2020 to 2200 A have been adopted after reducing them by 10 percent to be consistent with the measurements of Inn et al. at 2200 A. The absorption curve thus constructed after Vassy between 2020 and 2200 A is then extrapolated to agree with that of Tanaka et al. at 1800 A as shown in Figure 7(b).

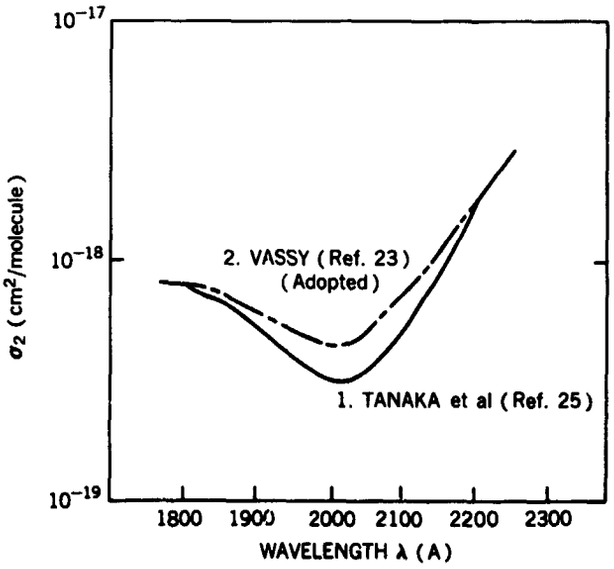

FIGURE 7b.—Absorption coefficients of ozone between 1800–2200A.

Temperature and density distributions for the solstices are taken from Murgatroyd (Reference 28) as a function of altitude and latitude. The value of the temperature and density below 16 km, the lowest level given by Murgatroyd, are obtained from the investigations of London et al. (Reference 29).

The reaction rate coefficients K_2 and K_3 are adopted from Campbell and Nudelman's (Reference 30) least square analysis of Glissmann and Schumacher's (Reference 31) data on thermal decomposition of ozone in the temperature range from 70°–110°C. According to Campbell and Nudelman, the functional form of K_2 and K_3 is given by

$$K_2 = 1.87 \times 10^{14} \text{ Exp } 1.49 \times 10^2/T \quad \text{cm}^6 \text{ gm mol}^{-2} \text{ sec}^{-1},$$

$$K_3 = 5.44 \times 10^{12} \text{ Exp } 2.133 \times 10^3/T \quad \text{cm}^3 \text{ gm mol}^{-1} \text{ sec}^{-1}.$$

The ratio of these two coefficients K_2/L_3 is compared in Figure 8 with that obtained by Eucken and Patat (Reference 32) in their study on the temperature dependence of the photochemical formation of ozone. The logarithm of the ratio K_2 K_3, when plotted against 1/T, where T is the temperature in °K, gives a straight line as shown in Figure 8.

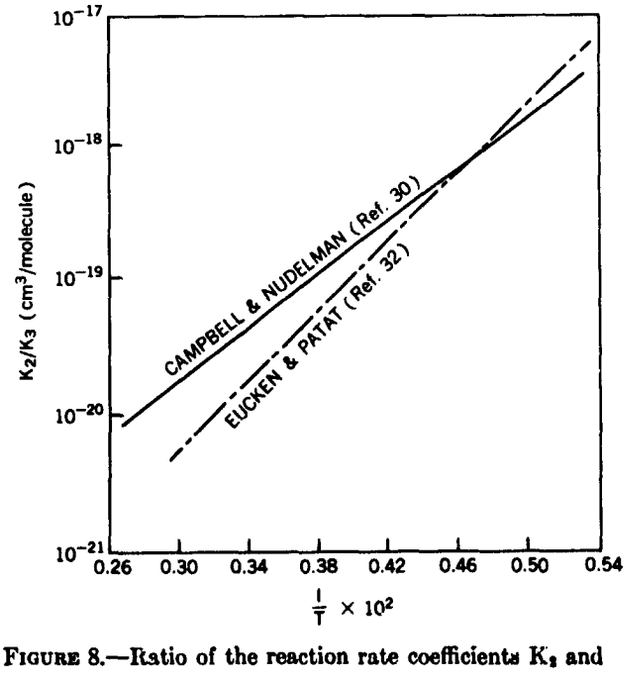

FIGURE 8.—Ratio of the reaction rate coefficients K_2 and K_3 vs. 1/T°K.

Method of Obtaining the Meridional Distribution of Ozone When Transport Processes Are Present

Solution of Equation 33 gives us the meridional distribution of $\bar{\chi}$ and hence of ozone. To solve 33, the following numerical procedure is adopted.

The meridional plane from pole to pole and between 41 km to the height of the tropopause is divided into a grid, the gridpoints in which are spaced 10° of latitude apart horizontally, and 2 km apart vertically as shown in Figure 9. The

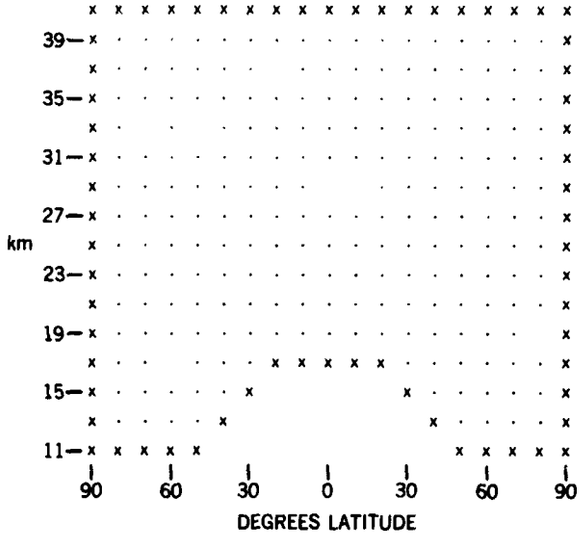

FIGURE 9.—Grid used for the numerical calculations.

boundary at 41 km representing the layer 42 to 40 km is chosen for the reason that ozone is reasonably undisturbed from its photochemical equilibrium at and above this level.

The boundary conditions used to solve 33 are:

(1) The flux of ozone through the vertical boundaries at the poles is zero.

(2) Photochemical equilibrium is assumed at 41 km, the upper boundary. However, during the polar night in the winter hemisphere, it is assumed that from 60° to the pole the photochemical equilibrium is constant at 41 km.

(3) On the lower boundary at the tropopause level, the value of the ozone concentration is specified from the "observed" model of the meridional distribution of ozone given by Paetzold and Piscalar (Reference 7).

The boundary condition (1) is purely a mathematical constraint and does not call for any knowledge of the distribution of ozone along the verticals at the poles. The boundary condition (2) at the 41 km level is quite justified from considerations of the photochemical theory, while the boundary condition (3) lacks rigor of the preceding two conditions, and hence is subject to question. Further discussion of the boundary condition (3) is presented in the results.

The complete form of Equation 33, after expansion of the term $\left[\frac{\partial \bar{\chi}}{\partial t}\right]_a$, is seen to be

$$-\frac{2f_3}{M}\frac{(M\bar{\chi})^2}{(N_3^* + M\bar{\chi})} + 2f_2\frac{O_2}{M}\left[\frac{N_3^* - M\bar{\chi}}{N_3^* + M\bar{\chi}}\right] - \left(\bar{v}\frac{\partial\bar{\chi}}{\partial y} + \bar{w}\frac{\partial\bar{\chi}}{\partial z}\right)$$

$$+\left(K_y\frac{\partial^2\bar{\chi}}{\partial y^2} + \frac{\partial K_y}{\partial y}\frac{\partial\bar{\chi}}{\partial y} + K_z\frac{\partial^2\bar{\chi}}{\partial z^2} + \frac{\partial K_z}{\partial z}\frac{\partial\bar{\chi}}{\partial z} + K_z\frac{1}{M}\frac{\partial M}{\partial z}\frac{\partial\bar{\chi}}{\partial z}\right) = 0 . \quad (34)$$

$\bar{\chi}$, the ozone mixing ratio at each gridpoint, is calculated implicitly from Equation 34. Numerical integration of the above equation is performed at each gridpoint starting from 80° latitude in one hemisphere at the upper boundary, and proceeding downward along the vertical to the lower boundary, and then recommencing at the upper boundary, at the next latitude, and so on until 80° latitude in the other hemisphere is reached.

The parameters f_2 and f_3 at each gridpoint depend on the solar energy reaching that point. However solar energy transmitted to any given height in the atmosphere is a function of the zenith angle of the sun. In order to simplify the calculations it is assumed that the sun radiates at a mean zenith angle [ie., 1/2 (zenith angle at sun rise+zenith angle at noon)] corresponding to the given latitude and season. Further, to take into account the variation of the length of day, f_2 and f_3 at each gridpoint are multiplied by the ratio (daylight hours/24 hours) corresponding to each given latitude and season.

The finite difference scheme adopted here to solve Equation 34 involves the central difference approximation to the second order space derivatives. For the first order space derivatives arising from advective terms, the Lelevier (Richtmyer, Reference 33) method of approximation is used. The basic idea behind Lelevier's method is to get the advection from the windward side of the gridpoint using non-centered differences.

The finite difference approximations to the various terms in 34 are written below with the help of Figure 10.

All of the parameters χ, M, v, w, K_Y, and K_Z are subscripted with the numbers 1, 2, 3, or 4 denoting the value of the parameter at the respective gridpoints in Figure 10. The value of any of these parameters denoted without a subscript refers to the central point.

Further, we denote the horizontal velocity v as positive in the y direction pointing to the north. Similarly, the sign of the vertical velocity w is taken positive when directed upward along z.

$$-\bar{v}\frac{\partial\bar{\chi}}{\partial y} \simeq \begin{cases} -v\dfrac{(\chi-\chi_4)}{\Delta y}, & (v>0) \\ -v\dfrac{(\chi_2-\chi)}{\Delta y}, & (v<0) \end{cases} \tag{35}$$

$$-\bar{w}\frac{\partial\bar{\chi}}{\partial z} \simeq \begin{cases} -w\dfrac{(M+M_2)}{2M}\dfrac{(\chi-\chi_2)}{\Delta z}, & (w>0) \\ -w\dfrac{(M+M_1)}{2M}\dfrac{(\chi_1-\chi)}{\Delta z}, & (w<0) \end{cases} \tag{36}$$

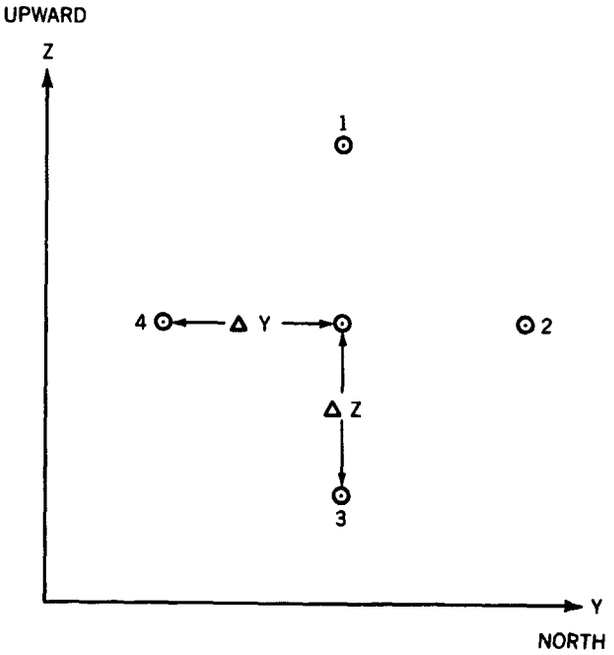

FIGURE 10.—Finite difference scheme.

The coefficients $\frac{M+M_2}{2M}$ and $\frac{M+M_1}{2M}$ in 36 arise due to the variation of density along z.

$$\left.\begin{aligned} K_y\frac{\partial^2\bar{\chi}}{\partial y^2} &\simeq K_y\frac{\chi_2+\chi_4-2\chi}{(\Delta y)^2} \\ \frac{\partial K_y}{\partial y}\frac{\partial\bar{\chi}}{\partial y} &\simeq \frac{(K_{y2}-K_{y4})}{(2\Delta y)}\frac{(\chi_2-\chi_4)}{(2\Delta y)} \end{aligned}\right\}, \tag{37}$$

$$\left.\begin{aligned} K_z\frac{\partial^2\bar{\chi}}{\partial z^2} &\simeq K_z\frac{\chi_1+\chi_2-2\chi}{(\Delta z)^2} \\ \frac{\partial K_z}{\partial z}\frac{\partial\bar{\chi}}{\partial z} &\simeq \frac{(K_{z1}-K_{z3})}{(2\Delta z)}\frac{(\chi_1-\chi_3)}{(2\Delta z)} \\ K_z\frac{1}{M}\frac{\partial M}{\partial z}\frac{\partial\bar{\chi}}{\partial z} &\simeq K_z\frac{M_1-M_3}{2M\Delta z}\frac{(\chi_1-\chi_3)}{2\Delta z} \end{aligned}\right\}. \tag{38}$$

With the finite difference approximations 35 to 38, we can transform Equation 34 into an equation for χ at the central gridpoint:

$$\begin{aligned} \chi = \Bigg\{ & 2f_2\frac{O_2}{M}\left[\frac{N_3^*-M\chi}{N_3^*+M\chi}\right] + K_y\frac{\chi_2+\chi_4}{(\Delta y)^2} + \frac{(K_{y2}-K_{y4})}{2\Delta y}\frac{(\chi_2-\chi_4)}{2\Delta y} \\ & + K_z\frac{\chi_1+\chi_3}{(\Delta z)^2} + \frac{(K_{z1}-K_{z3})}{2\Delta z}\frac{(\chi_1-\chi_3)}{2\Delta z} \\ & + K_z\left[\frac{M_1-M_3}{2M\Delta z}\right]\frac{(\chi_1-\chi_3)}{2\Delta z} + v\frac{\chi_4}{\Delta y} + w\left[\frac{M+M_3}{2M}\right]\frac{\chi_3}{\Delta z}\Bigg\} \\ & \div\left\{2f_3\frac{M\chi}{N_3^*+M\chi} + \frac{v}{\Delta y} + \frac{w}{\Delta z}\left[\frac{M+M_3}{2M}\right] + 2\frac{K_z}{\Delta z^2} + 2\frac{K_y}{\Delta y^2}\right\}. \end{aligned} \tag{39}$$

Equation 39 is solved by successive approximations to the value of χ. For example, the first guess to χ, let us say, is χ'. Then substituting χ' in the right-hand side of 39, we calculate a new value for χ denoted χ''. Now the new guess for χ, namely χ''', is obtained from

$$\chi''' = \frac{\chi' + \chi''}{2} . \tag{40}$$

Successive approximations to χ are made until the criterion

$$\left| 1 - \frac{\chi'''}{\chi''} \right| \leq 0.02 \tag{41}$$

is satisfied. After the criterion 41 is satisfied, the ozone concentration $M\chi$ at the center of the layer is obtained.

The boundary conditions (2) and (3) do not present any problem since they are specified to start with. But the boundary condition (1) has to be satisfied implicitly whenever Equation 39 is being solved along the vertical at 80°N or 80°S latitude. This is achieved by solving Equation 39 with the condition that, in any layer, χ at 80° latitude is equal to χ at the pole. In other words, along the vertical at 80° latitude, we solve the equation

$$\chi = \left\{ 2f_2 \frac{O_2}{M} \left[\frac{N_3^* - M\chi}{N_3^* + M\chi} \right] + K_y \frac{\chi_4}{\Delta y^2} + \frac{(K_{y2} - K_{y4})}{2\Delta y} \frac{(\chi_2 - \chi_4)}{2\Delta y} \right.$$

$$+ K_z \frac{\chi_1 + \chi_3}{\Delta z^2} + \frac{(K_{z1} - K_{z3})}{2\Delta z} \frac{(\chi_1 - \chi_3)}{2\Delta z}$$

$$\left. + K_z \frac{(M_1 - M_3)}{2M\Delta z} \frac{(\chi_1 - \chi_3)}{2\Delta z} - v \frac{\chi_4}{\Delta y} + w \left[\frac{M + M_3}{2M} \right] \frac{\chi_3}{\Delta z} \right\} \div$$

$$\left\{ 2f_3 \frac{M\chi}{N_3^* + M\chi} + \frac{v}{\Delta y} + \frac{w}{\Delta z} \left[\frac{M + M_3}{2M} \right] + 2 \frac{K_z}{\Delta z^2} + \frac{K_y}{\Delta y^2} \right\} . \tag{42}$$

Equation 42 is applicable at 80°N latitude. A similar equation for 80°S can be easily obtained by substituting $K_y \frac{\chi_2}{\Delta y^2}$ for $K_y \frac{\chi_4}{\Delta y^2}$ in the numerator of the right-hand side of (42).

After the entire field from 80°S to 80°N has been scanned by Equations 39 and 41, a fresh iteration of the whole field is started again from 80°S. The whole field is then iterated several times until the values of χ or O_{3E} at any point in the whole field from two successive iterations do not differ by more than 1 percent—that is, if the value of χ is $[\chi]_1$ at any given point from preceding iteration, and $[\chi]_2$ from the succeeding iteration, the convergence criterion requires

$$\left| 1 - \frac{[\chi]_1}{[\chi]_2} \right| < 0.01 . \tag{43}$$

To solve Equation 39 and to obtain the steady state distribution of ozone corresponding to either the time of solstices or equinoxes, we do not have to specify the distribution of ozone in the interior of the field. One may start with the photochemical equilibrium distribution in the interior of the field as the first guess. It is observed that about 50 iterations of the entire field are adequate to get a convergence level of less than 1 percent stipulated by Equation 43.

General Survey of the Investigations on the Transport Processes in the Stratosphere

To make an investigation on the problem of seasonal variations of atmospheric ozone, it is necessary to know about the large scale diffusive and advective phenomena. Studies made on the transport processes in the atmosphere have in general a tendency to empasize one of the two major transport phenomena: diffusion, or advection. Theories constructed on the basis of either one of these two seem to be capable of explaining phenomena such as the spread of radioactive debris in the stratosphere. An attempt is made here to present an account of both of these schools of thought.

Brewer (Reference 34), from his frost point hygrometer measurements of water vapor content in the lower stratosphere over Great Britain, observed a rapid fall of humidity mixing ratio above the tropopause. The humidity mixing ration at a height of 1 km above the tropopause was about one-tenth of its value at the tropopause. The frost points at 15 km were as low as the lowest temperatures measured in the upper troposphere near the equator. Thus he argued that such extremely dry air present in the polar stratosphere must have originated in the equatorial upper troposphere. Brewer explained the vertical distribution of water vapor in the lower polar stratosphere as a result of upward diffusion of water vapor opposed by a slow sinking of very dry air from above. A reverse current from the troposphere into the stratosphere in the equatorial region was postulated to balance such a slow sinking of air in the higher latitudes from the stratosphere into the troposphere.

Brewer estimated from the observed vertical profiles of water vapor distribution a value of 1.8×10^{-5} to 5×10^{-5} cm^{-1} for the ratio w/K_z, where w(cm/sec) is the velocity of the sinking motion, and K_z (cm^2/sec) is the vertical eddy diffusion coefficient, in the lower stratosphere. He also suggested that the effect of horizontal advection could be only one-tenth of sinking. These ideas of Brewer were accepted by Dobson (Reference 35) to explain the seasonal distribution of ozone in the atmosphere. The circulation model thus came to be known as the "Dobson-Brewer" model.

The most important factor, namely the nature of the vertical distribution of water vapor in the stratosphere, which led Brewer to postulate his model of the organized circulation in the stratosphere, does not appear to be a general characteristic of the stratosphere on the whole globe. The water vapor mixing ration is observed sometimes to increase with height in the stratosphere (Mastenbrook et al., Reference 36).

Murgatroyd and Singleton (Reference 37), neglecting the influence of large scale diffusion, have made a calculation of meridional circulation sufficient to transport heat between radiational sources and sinks in the stratosphere (15–55 km) and mesophere (55–80 km). Combining suitably the radiative heating values of Ohring (Reference 38) and Murgatroyd and Goody (Reference 39), and modifying slightly the combined radiative field to get a solution, they computed the meridional circulation. The radiative heating and the atmospheric temperature needed as a function of time in their computations were obtained with an implicit assumption that these two quantities are in phase with the sun.

The circulation model thus obtained has a rising motion of air below 30 km over the tropical latitudes, with an outflow from the tropics to higher latitudes in both hemispheres. The order of magnitude of the vertical velocity is 10^{-1} cm/sec, and below 40 km the horizontal velocity is about 10^2 cm/sec.

Cross sections of meridional and vertical velocities from pole to pole at different times of the year computed by Murgatroyd and Singleton (Reference 37: page 130, Figure 2) are presented in the Figure 11.

Broadly speaking, the circulation model of Murgatroyd and Singleton suggests rising motion in the tropical latitudes somewhat following the sun in its transit from one hemisphere to the other during the year. In the summer hemisphere at higher latitudes most of the stratosphere is covered with rising motion, and in the winter hemisphere there is correspondingly an intense sinking motion. The circulation model for autumn and spring shows an appreciable difference between the circulation on either side of the equator, with relatively intense mean air motions in spring and weak circulation in autumn. The poleward velocity in general in all seasons intensifies as one goes to lower levels in the stratosphere.

This circulation model of Murgatroyd and Singleton supports the ideas of the "Dobson-Brewer" model. However, the authors remarked that systems on the scale of cyclones and anticyclones, and possibly also diffusion, must play a large part as transport processes in the atmosphere, and that the circulation model obtained by them can be no more than a resultant mean effect.

Spar (see Stebbins, Reference 40), from his analysis of the spread of an artificial radioactive nuclide, W^{185} (Tungsten 185), introduced by the U.S. Hardtack nuclear explosions in 1958, derived meridional and vertical eddy diffusion coefficients

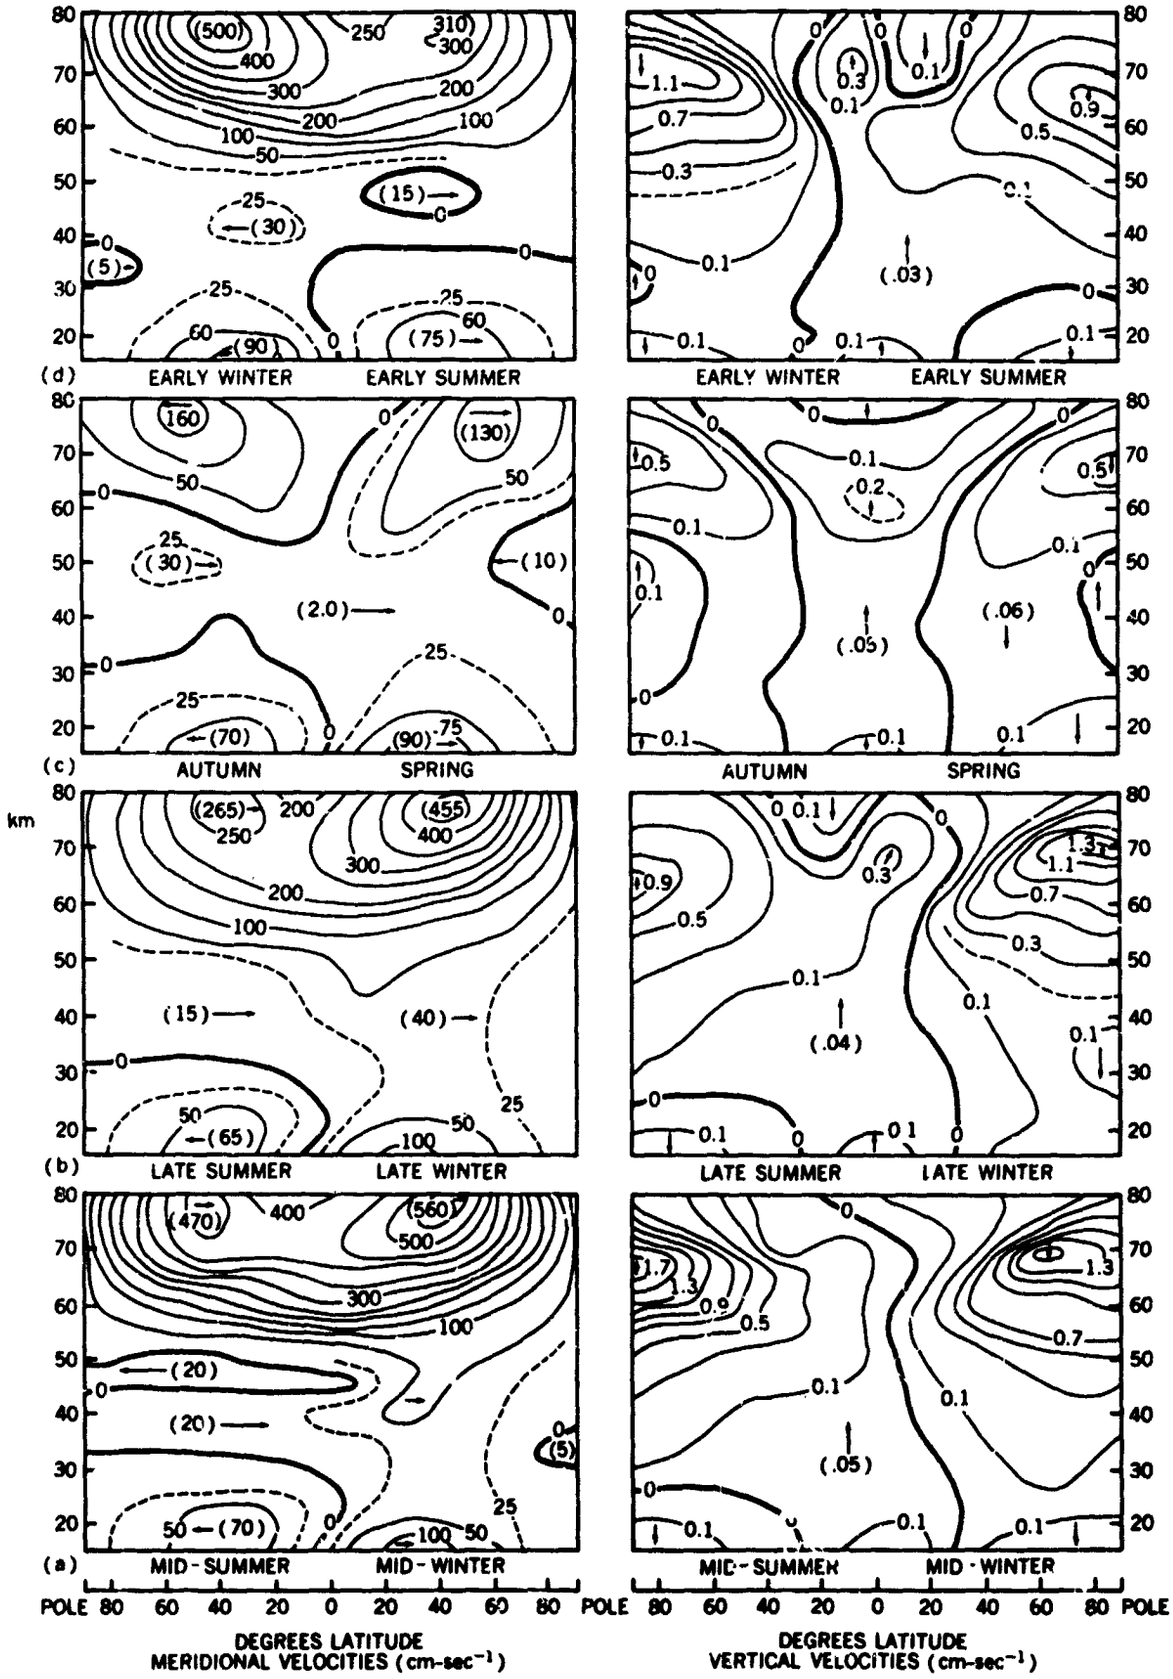

FIGURE 11.—Cross section of meridional and vertical velocities (cm/sec) from pole to pole at different times of the year (after Murgatroyd and Singleton, Reference 37; courtesy of the Royal Meteorological Society Quarterly Journal.)

for the stratosphere. Assuming that the radioactive cloud has a normal distribution of debris about the maximum, he obtained h, the half width of the cloud, as $h=1.67\sqrt{Kt}$, where K(cm²/sec) is the eddy diffusion coefficient and t is the time elapsed after detonation. He thus estimated that the value of the vertical eddy diffusion coefficient was 2×10^4 cm²/sec at the polar latitudes and 4×10^3 cm²/sec at the equatorial latitudes. The estimates of the meridional eddy diffusion coefficient ranged from a low value of about 5×10^5 cm²/sec to a value almost as high as 10^{10} cm²/sec. However, the latitudinal variation of the meridional eddy diffusion coefficient could not be ascertained from this investigation.

W^{185} was observed to have a zone of maximum concentration around 65,000–70,000 ft at the equatorial stratosphere and sloped down toward the poles. Furthermore, the height of the zone of maximum concentration was found to be virtually stationary from September 1958 to April 1960 (Feely and Spar, Reference 41), contradicting the "Dobson-Brewer" calculation model, which hypothesizes an organized meridional circulation with air moving upward through the equatorial tropopause, then horizontally poleward at high levels, and sinking back into the troposphere in the polar region.

Feely and Spar (Reference 41) to explain such an observed distribution of W^{185}, hypothesized a mixing mechanism in which lateral mixing occurs within a sloping layer which decreases in height toward the poles. However, they pointed out "the fact that the mixing surfaces slope more steeply than the isentropic surfaces may indicate the existence of a systematic sinking of the radioactive debris relative to the air as it mixes poleward, possibly by gravitational settling or some other mechanism, or a systematic subsidence of air itself as it mixes into the polar region. There is no indication, however, of a large scale subsidence of polar stratospheric air from very high levels."

Considering the rate at which the half width of the W^{185} cloud, in the north-south direction, increases with time, Spar (see Friend et al., Reference 42) has deduced an effective meridional (poleward) velocity of 8 cm/sec which he states is about one fifth that of Murgatroyd and Singleton's value. Further to account for the inclination, 1:1000, of the zone of W^{185} maximum from equator to pole, he has shown that there should be a rising motion of about 0.01 cm/sec at the equatorial region and a sinking motion of the same magnitude at the higher latitudes. This is about one tenth of the vertical velocity Murgatroyd and Singleton in the lower stratosphere. Thus the terminal velocity of the tungsten-bearing particles, which are apparently held stationary in the rising motion at the equatorial region, must be 0.01 cm/sec. From Stoke's law, one would find the radii of these particles to be about 0.2 micron, which Spar mentions is in good agreement with the size of the observed particles.

Murgatroyd and Singleton conclude from their trajectory calculation that "most of the air in the stratosphere, up to 25 km at least, must have passed through the equatorial tropopause region within the last one year or so." Commenting on this statement, Spar (see Friend et al., Reference 42) points out that if this were so the radioactive debris from nuclear tests would be almost depleted in one year or so. Such a rapid depletion of radioactive debris, however, does not seem to get support from the observed amount of debris contained in the stratosphere.

An interesting feature concerning the meander of the center of W^{185} maximum about the equator was revealed from the investigations of Friend et al. (Reference 42). The W^{185} maximum, although held at a stationary height, was found to migrate to the southern hemisphere during winter, and by early summer was back in the northern hemisphere. This phenomenon suggests a tendency of the peak of the W^{185} cloud to follow the sun.

Spar (see Friend et al., Reference 42) indicated that direct vertical mixing through the tropopause appeared to be too small to account for the stratospheric fallout.

A recent survey by Newell (Reference 43) is very helpful in assessing the relative importance of large scale diffusion processes and mean meridional motions in the stratosphere. Newell has estimated the horizontal eddy transport of ozone by an elegant and simple method. Assuming that the ozone concentration in the layer 12–24 km is correlated with total ozone measured at the gound, he has evaluated the large scale meridional horizontal eddy flux of ozone from the winds in

that layer. This computation was based on data obtained during the I.G.Y. from twenty-five ozone stations that had local upper air wind observations. He had also estimated the meridional transport of ozone due to mean meridional motion. Newell's investigations suggest that the transport due to mean meridional motion. For instance, the values of the eddy transport and the transport due to mean motion at 50°N during spring 1958, according to him, are in the proportion 11.0:1.8. Both these transports of ozone are directed toward the north. Newell further demonstrates quantitatively that these transports are capable of accounting for the observed build-up of ozone at higher latitudes during winter and spring.

DISCUSSION OF THE RESULTS

Computed Models of the Meridional Distribution of Ozone

The photochemical equilibrium distributions of ozone calculated for the solstices and the equinoxes are presented in Figures 12 and 13. Both these distributions indicate a center of ozone high located at about 30 km height at the latitude ovre which the sun is overhead. The concentration of ozone decreases in all directions from this center. A clear symmetry of the ozone distribution about the vertical at the latitude over which the sun is overhead may be noticed.

A comparison of the photochemical equilibrium distributions of ozone shown in Figures 12 and 13 with those of the "observed" models in Figures 1

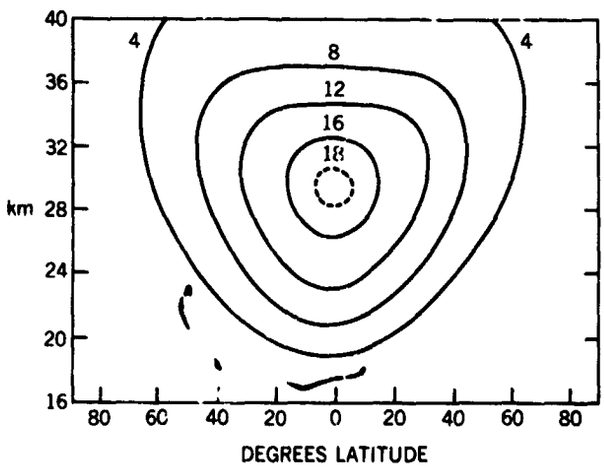

FIGURE 12.—Photochemical equilibrium distribution of ozone (D.U./km) for the equinoxes.

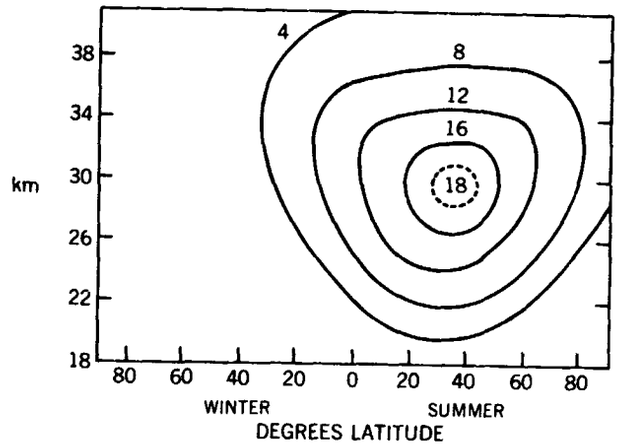

FIGURE 13.—Photochemical equilibrium distribution of ozone (D.U./km) for the solstices.

and 2 reveals all the inadequacies of the pure photochemical theory. Further, we are led to infer from such a comparison the important part played by transport mechanisms present in the atmosphere.

From the earlier discussion (in the section starting on page 18) on the transport processes—namely, large scale diffusion and mean meridional motions—it is not easy to arrive at a comprehensive unified picture of these transport processes. A computation of such a unified model of the transport processes that includes both diffusion and mean meridional motions is beyond the scope of this work. Instead, an attempt is made in this study to combine the mean meridional motions depicted by Murgatroyd and Singleton and the diffusion model of Spar with the help of investigations made by Newell in which an evaluation of the relative importance of each one of these transport processes is made.

The large scale diffusion model of Spar for the stratosphere suggests that the vertical eddy diffusion coefficient increases from a low value of 4×10^3 cm^2/sec in the tropics to 2×10^4 cm^2/sec at the polar latitudes. The variation of the horizontal eddy diffusion coefficient with latitude could not be so readily ascertained. Hence the variation of the horizontal eddy diffusion coefficient has to be elicited from an experimentation with the calculations on the model of the meridional distribution of zone.

The experimentation on the meridional distribution of ozone under steady state condition for the equinoxes is first undertaken.

From a few trial calculations with a constant value of 2×10^9 cm²/sec for the horizontal eddy diffusion coefficient, a rapid increase in the value of K_z, the vertical eddy diffusion coefficient from tropical latitudes to the polar latitudes as shown in Table 1, is chosen.

From similar experimentation an optimum value of about 20 percent of the Murgatroyd and Singleton circulation (comprising the meridional and vertical velocities) for the equinoxes is arrived at. Apparently this estimate of the mean meridional circulation, in a broad sense, is in agreement with the estimate of the mean meridional motion arrived at by Friend et al. (Reference 42) from their investigation on the rate at which the half width of the W^{185} cloud increased in the north-south direction. Newell's (Reference 43) estimate of the mean meridional motion also seems to support this evaluation of the Murgatroyd and Singleton mean meridional circulation.

The model of the distribution of ozone calculated for the equinoxes as explained in the section on page 13, with the above scheme of transport processes, is shown in Figure 14.

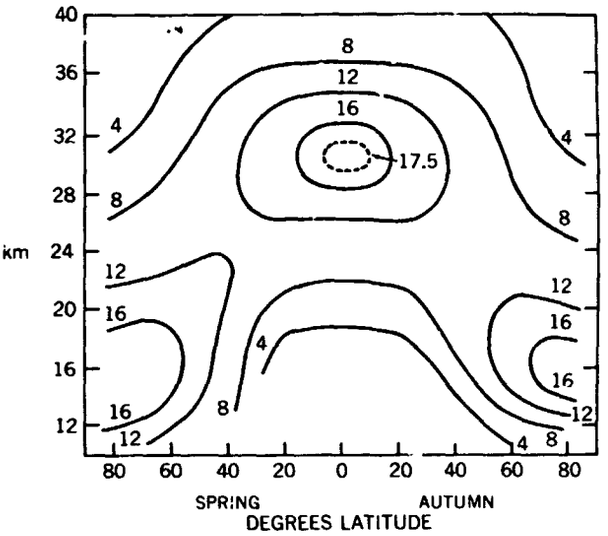

FIGURE 14.—Steady state distribution of ozone (D.U./km) computed for the equinoxes with constant value of K_Y (2×10 cm/sec), K_z (Table 1) increasing toward pole, and 20 percent of Murgatroyd and Singleton's (Reference 37) mean meridional circulation.

The concentration of ozone on the tropopause, the lower boundary of the model, is specified with the help of the "observed" distribution of Paetzold et al. (Figure 4) for spring and autumn.

The computed model thus obtained for the equinoxes still shows the ozone high produced by solar radiation over the tropical latitudes. However, there is a reasonably good lateral spread of ozone that is best illustrated in Figure 15(b) in which the latitudinal variation of total ozone calculated for the equinoxes is plotted. The total ozone obtained from the photochemical equilibrium calculation for equinoxes is shown in Figure 15(a) for comparison.

From the scheme of the transport processes used to calculate this (Figure 14) distribution of ozone, it is obvious that the diffusion pattern is symmetrical about the equator. There is, however, asymmetry of circulation present between the spring and autumn hemispheres. Such superficial argument cannot be carried further to conclude that the difference between the distribution of ozone between spring and autumn is due entirely to the difference in circulation intensity. Such a conclusion is misleading. The large scale diffusion processes in the vertical and horizontal directions interact in a nonlinear fashion with the mean meridional circulation. It is more justified to infer that the difference between the latitudinal distribution of ozone in spring and autumn is a result of the mutual interaction of the circulation and diffusion phenomena.

The increase of total ozone with latitude shown in Figure 15(b) is inadequate to explain the total ozone increase with latitude portrayed by London (Reference 10) for spring and autumn. This immediately leads one to an examination of the horizontal eddy diffusion coefficient. Spar's investigations show that the horizontal eddy diffusion coefficient has a large range of values.

Table 1

Variation of K_z with Latitude for the Equinoxes.

Degrees latitude	0	10	20	30	40	50	60	70	80	90
K_z (10^4 cm²/sec)	0.4	0.4	0.6	0.9	1.4	2	2	2	2	2

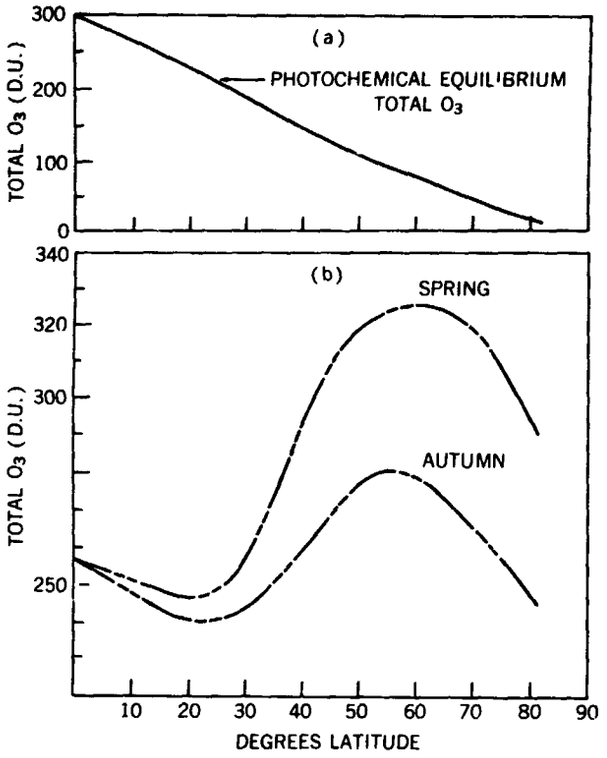

FIGURE 15.—Comparison between the total ozone variation with latitude obtained from pure photochemical theory (Figure 12), and from the combined effects (Figure 14).

Therefore further experimentation on the meridional distribution of ozone has been done, increasing the horizontal eddy diffusion coefficient from tropical latitudes to polar latitudes. Eventually a variation of K_Y somewhat analogous to the variation of K_Z with latitude has been found suitable. The variation of K_Y thus arrived at is shown in Table 2.

The meridional distribution of ozone, calculated with such a variation of K_Y along with the model of the K_Z and mean meridional motion used in the preceding computation, is shown in Figure 16. The variation of the total ozone with latitude given by this distribution is plotted in Figure 17.

The increase of total ozone from tropical latitudes to the polar latitudes shown in Figure 17 is

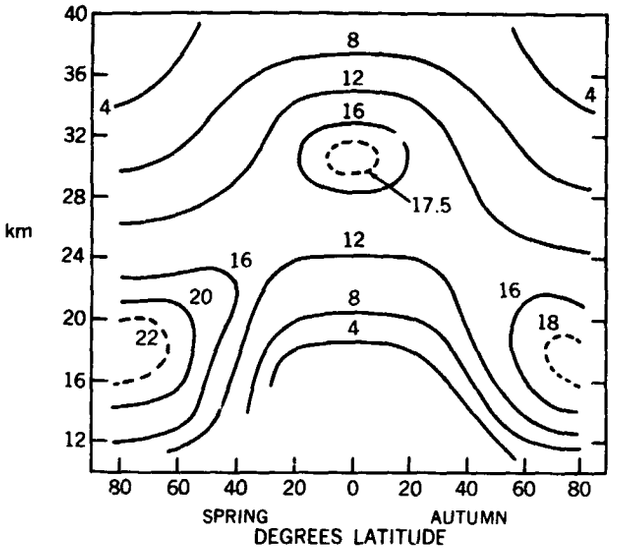

FIGURE 16.—Steady state distribution of ozone (D.U./km) computed for the equinoxes with K_Z (Table 1) increasing with latitude, and 20 percent of Murgatroyd and Singleton's (Reference 37) mean meridional circulation.

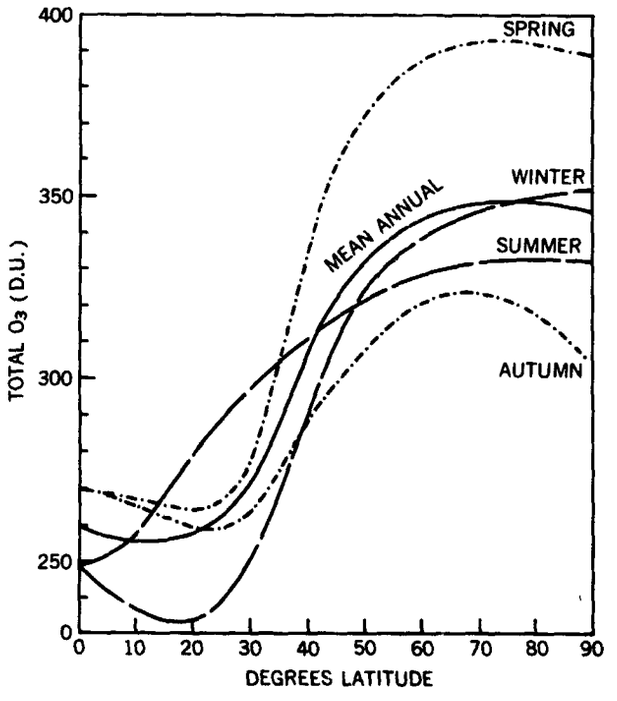

FIGURE 17.—Computed seasonal and latitudinal variation of total ozone corresponding to Figures 16 and 18.

Table 2

Variation of K_Y with Latitude for the Equinoxes.

Degrees latitude	0	10	20	30	40	50	60	70	80	90
$K_Y (10^{10}$ cm^2/sec)	0.2	0.2	0.4	0.6	0.8	1.0	1.0	1.0	1.0	1.0

in better agreement with that of London's curves for spring and autumn. On the basis of reasonable agreement between the observed total ozone curves and the computed ones, it is felt that, in order to explain the spring buildup of ozone at higher latitudes by the steady state approach, increase of the horizontal eddy diffusion coefficient from tropical latitudes to polar latitudes is necessary.

After having studied in detail the behavior of the various transporting mechanisms for the spring and autumn seasons, it is straightforward to proceed to the summer and winter seasons. Furthermore, the quantitative model of the transport mechanisms developed to explain the distribution of ozone for spring and autumn may now be checked in the computation of the steady state distribution of ozone for summer and winter.

From the observations made by Friend et al. (Reference 42) on the W^{185} cloud it is apparent that the center of the cloud has a tendency to move with the sun. This interesting detail suggests a shift of the whole pattern of the diffusion field along with the sun. In other words, the hemisphere tilted toward the sun has a comparatively weak pattern of diffusion, while the hemisphere tilted away from the sun has a correspondingly more intense mixing. Such an idea seems to be quite consistent with the relatively stable lapse rates of temperature in the summer stratosphere and comparatively less stable lapse rates and polar night jet stream (Hare, Reference 44) in the winter stratosphere.

The above ideas have been suitably used to adjust the diffusion pattern for the summer and winter hemispheres as shown in Table 3.

With the pattern of vertical and horizontal eddy diffusion shown in Table 3, and with 20 percent of Murgatroyd and Singleton's mean meridional circulation for the solstices, a steady state distribution of ozone is calculated as explained in the section on page 1313.

The boundary condition on the tropopause is again specified from the Paetzold et al. model. It is tacitly assumed here that the concentration ozone on the tropopause in winter is similar to that in spring, and in summer is similar to that in autumn. Such an assumption may not be unreasonable if one considers the latitudinal distribution of total ozone during these seasons. Incidentally this assumption provides a good ground to test the influence of the lower boundary condition on the distribution of ozone in the interior of the field of computation.

The distribution of ozone resulting under steady state condition for solstices calculated with the above boundary condition on the tropopause is shown in Figure 18. The variation of total ozone with latitude computed for the corresponding seasons is plotted in Figure 18.

The latitudinal increase of total ozone for winter and summer shown in Figure 18 reveals some significant departures from the corresponding curves of London (Reference 10). The solar radiation incident normally at 23.5° latitude on the summer hemisphere in the computed model has apparently contributed to comparatively larger values of the total ozone in the tropical latitudes. In the winter hemisphere the total ozone from the computed model in the tropical latitudes seems to be appreciably smaller than that given by London's curve. The relatively

K_z (10^{10} cm²/sec)	0.4	0.6	0.8	1.0	1.0	1.0	1.0	1.0	1.0	1.0

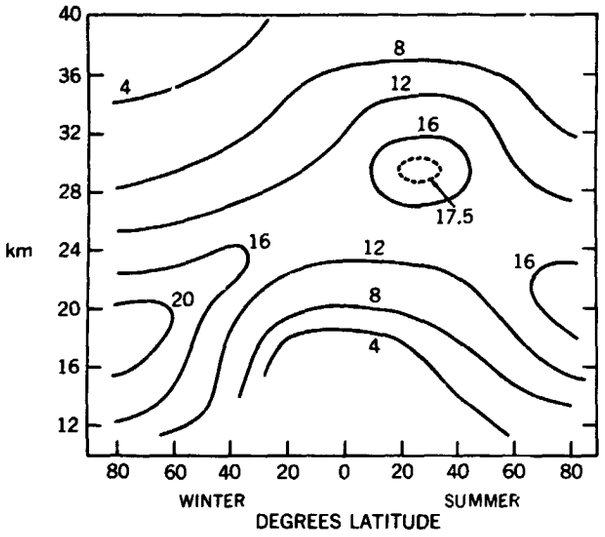

FIGURE 18.—Steady state distribution of ozone (D.U./km) computed for the solstices with K_Y and K_Z (Table 3) increasing from subsolar point, and 20 percent of Murgatroyd and Singleton's mean meridional circulation.

larger total amounts of ozone in summer and smaller amounts in winter in the tropical latitudes shown by London's curves lend a qualitative support to the computed results. London's curves show a maximum difference of about 30 D.U. between the summer and winter at the equator with a mean total ozone of about 250 D.U. The computed total ozone curves show a maximum difference of about 48 D.U. at about 25° latitude with a mean total of about 258 D.U.

Although the total ozone variation with latitude computed for the four seasons shown in Figure 17 qualitatively agrees with the observed curves (London's), there is considerable disagreement between the two. The total ozone computed for spring and winter is still short of the observed increase of ozone for those seasons. On the other hand, the calculated total ozone for summer and autumn is considerably larger than that suggested by the observed values. The difference between the winter and summer total ozone from the observed values, at higher latitudes, is almost double that obtained from the computations.

The seasonal variation of ozone in this study is computed with an assumption of steady state conditions. Such an assumption may not be justified for each season, but should be valid for the mean annual ozone distribution with latitude. The mean annual total ozone distribution is obtained from the computed total ozone curves for the four seasons as shown in Figure 19. The mean annual total ozone distribution constructed in this fashion is in reasonable agreement with that of the observed total ozone curves (London, Reference 10).

Until now the discussion on the computed meridional distributions of ozone has been based on the total ozone variation with latitude. The emphasis laid on the total ozone rather than the details of its distribution in the meridional plane is mainly due to the fact that the total ozone is the only parameter of atmospheric ozone known with a good degree of accuracy.

In general, all of the computed models of the meridional distribution of ozone do not quite resemble the "observed" models. Each one of the computed models clearly show three ozone highs. One of these ozone highs is evidently produced by the solar radiation and is in the tropical stratosphere centered around 30 km height. The other two ozone highs are a result of the transport processes, and their centers are located around 18 km height at the poles in spring, autumn, and winter hemispheres. This center is around 20 km height at the summer pole.

The "observed" models of the meridional distribution of ozone do not indicate the existence of an ozone high in the tropical stratosphere.

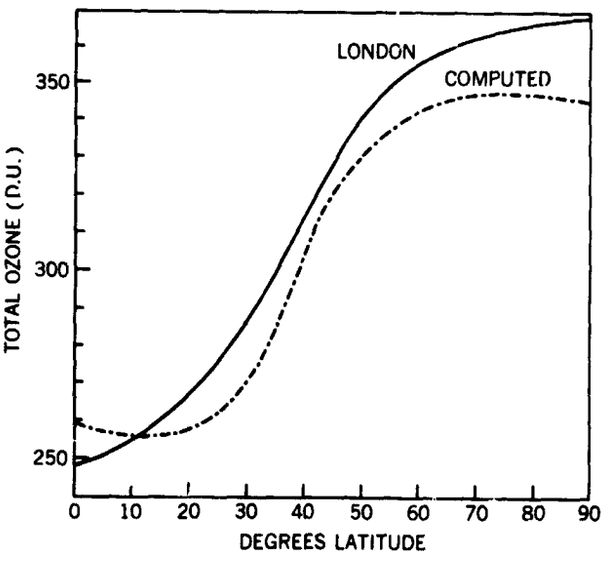

FIGURE 19.—Comparison of the computed mean annual total ozone distribution with that of London (Reference 10).

The ozone high close to the pole is present only in the model of Paetzold in the spring hemisphere.

In the computed models at higher latitudes, large horizontal and vertical gradients of ozone are present close to the tropopause during spring, autumn, and winter, while during summer a rather weak gradient is developed. The distribution of ozone in the lower stratosphere during summer is thus considerably different from the other three seasons. This is primarily a consequence of the weak diffusion pattern and the rising air motions present over large portions of the stratosphere in the summer hemisphere.

The "observed" models suggest the presence of strong horizontal and vertical gradients of ozone in the lower stratosphere at high latitudes during spring and probably during late winter.

The zone of ozone maximum, formed by the three ozone highs in both the equinoctial and the solsticial models of the steady state distribution of ozone calculated in this study, slopes down steeply from the subsolar point to the poles. The "observed" models apparently do not indicate such a steep slope for the zone of ozone maximum.

From the above brief discussion of the meridional distribution of ozone, it may be remarked that the computed models differ from the "observed" models in many details, but the general patterns in both the computed and the "observed" models are similar. Until our knowledge of the "observed" distribution of ozone in the atmosphere is better than it is at present, it will not be possible to judge quantitatively the details of the computed models.

To test the influence of the lower boundary condition on the computed distribution of ozone in the interior of the field, a calculation of the ozone distribution for the solstices is made with radically different boundary condition on the tropopause. In the computed distribution shown in Figure 18 the lower boundary condition has been taken to be exactly the same as that used for spring and autumn. Now in order to test the significance of the lower boundary condition, the distribution of ozone on the tropopause for winter is taken to be half that of spring, and for summer, twice that of autumn. Such an alteration of the boundary condition, however, is done from 40° latitude to the pole on either hemisphere as shown in Table 4.

In order to bring to light the significance of the lower boundary condition, the total ozone variation with latitude corresponding to the two sets of lower boundary condition for solstices is presented in Figure 20. Besides this, in Figure 21

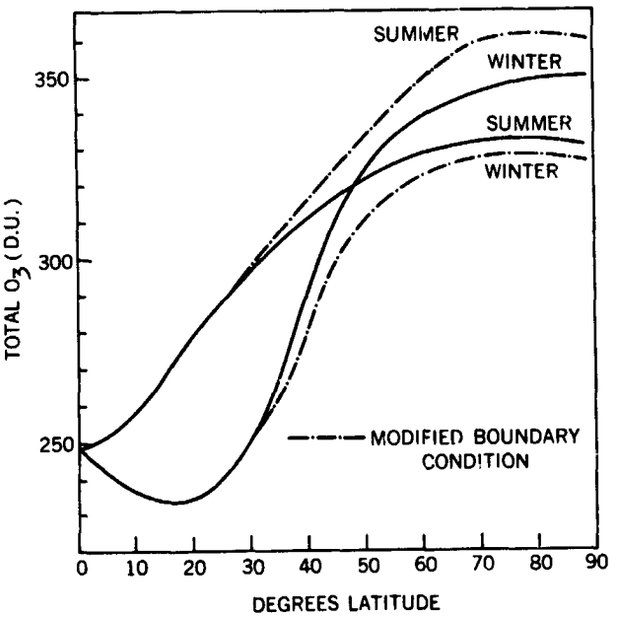

FIGURE 20.—Influence of the boundary condition at the tropopause on the computed total ozone.

the vertical distribution of ozone, taken from the meridional distributions of ozone computed with these two different boundary conditions at 60° latitude in the winter and summer hemispheres, is presented.

From Figure 21 it may be observed that changing the lower boundary condition does not affect

Table 4

Modified Value of the Ozone Concentration (10^{12} molecules/cm^2) at the Tropopause in Winter and Summer.

Degrees latitude	0	10	20	30	40	50	60	70	80	90
Winter	0.54	0.54	0.67	1.08	1.41	1.34	1.48	1.75	2.00	2.00
Summer	0.54	0.54	0.54	0.54	0.08	1.08	2.16	2.64	3.20	3.20

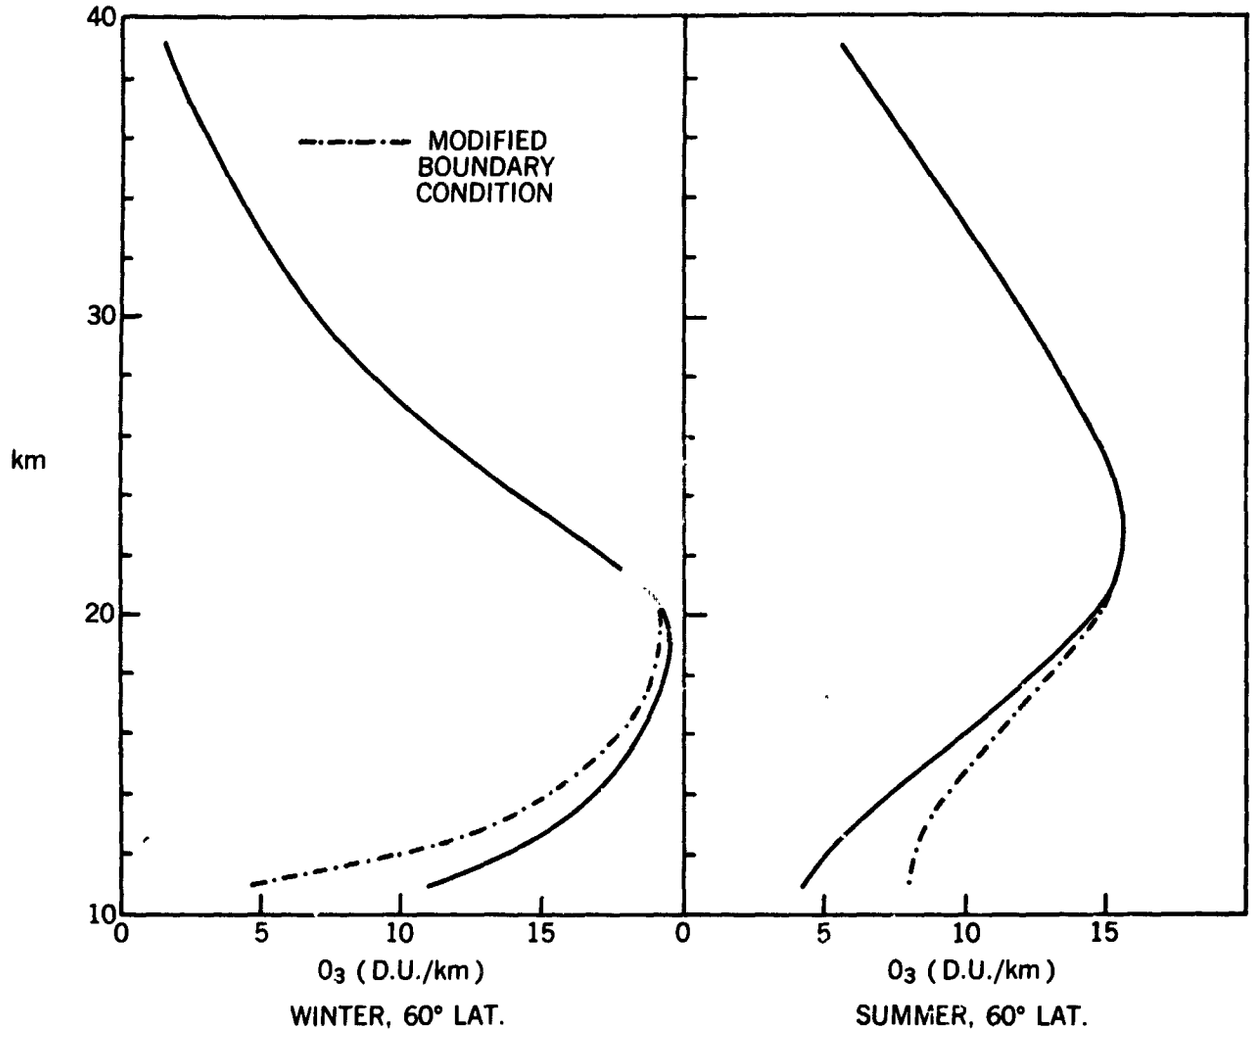

FIGURE 21.—Modification of the vertical distribution of ozone, at 60° latitude in the summer and winter hemispheres produced by changing the boundary condition at the tropopause.

the ozone distribution above about 20 km. The influence of the boundary value rapidly decreases with height. Changing the boundary by a factor of 2 has altered the total ozone by about 8 percent. This comparatively small change is obviously due to the effect of the transport processes that strongly control the distribution of ozone within the interior of the field.

Limitations of the Study

The study of the meridional distribution of ozone made in this investigation is purely a numerical experiment.

In this study the absorption coefficient of ozone in the spectral interval 2200 to 2020 A is adopted, with suitable modification, from Vassy's (Reference 23) photographic photometric measurements. If, however, the absorption coefficient of ozone, in the same spectral interval, reported by Tanaka et al. (Reference 25) is used, one would get much larger photochemical production of ozone, especially at tropical latitudes. Then in order to reduce such large amounts of ozone produced at the tropical latitudes to the amounts observed, it is necessary to use rising motions in the tropical stratosphere of about the same magnitude as shown Murgatroyd and Singleton's (Reference 37) model. So the present study in which Vassy's absorption coefficient of ozone is used cannot unequivocally place the stratospheric meridional

circulation at 20 percent of that of Murgatroyd and Singleton.

The calculation of the meridional distribution of ozone for different seasons has been made as though the mean seasonal transport processes and the mean solar insolation for the season tend to produce a quasi-stationary pattern of ozone. Such an assumption can make the results obtained in this study not applicable into the real atmosphere in which both the solar insolation and transport processes are varying with time. The seasonal variations of ozone computed in this study are especially subject to such a limitation. The mean annual total ozone distribution is probably the least affected quantity obtained in this investigation with the steady state assumption.

A more satisfactory study of atmospheric ozone would be that in which one does not have to invoke the quasi-stationary seasonal distribution of ozone. Such a study would call for an approach to this problem as an initial value problem. This implies that one should have a detailed and reliable initial distribution of ozone, and also good quantitative information on the seasonal variation of large scale transport processes in the atmosphere. In view of the lack of this detailed information demanded by the initial value problem, the present study has been made by taking a less satisfactory but more simple approach. Hence caution must be exercised in interpreting the results obtained from this study with a steady state assumption. The present investigation can be no more than a starting point to more sophisticated and realistic future studies of the atmospheric ozone. The satisfactory manner in which the present investigation has accounted for the observed total ozone in the atmosphere can at best be only a crude but quantitative demonstration of the importance of the transport processes in distributing ozone in the atmosphere.

The models of the transport processes used in this investigation lack rigorous dynamical basis. The efforts made to synthesize the advective and diffusive fields in the atmosphere are purely from the point of view of explaining the seasonal variation of the atmospheric ozone. The ability of such a scheme of transport processes to explain the seasonal variation of temperature or W^{185} in the stratosphere is still questionable. The only justification that can be attributed to this scheme of transport processes is that it is within reasonable limits laid by the current theoretical and observational findings.

The variations of ozone in the east-west direction are by no means negligible. The investigations of the variation of total ozone by Bidner (Reference 45) over Western Europe strongly suggest such zonal variations. The assumption of zonal symmetry of ozone made in this study is a very broad assumption.

The height of the tropopause is assumed to vary smoothly from tropical latitudes to higher latitudes. On the contrary, the observed shape of the tropopause shows a discontinuity between the tropical and middle latitudes. Brewer (Reference 6) and Friend et al. (Reference 42) have discussed at length the important part played by this break in the tropopause and the jet stream present at this break in the exchange of ozone and nuclear debris, respectively, between the troposphere and stratosphere. With the information available at present, it does not seem possible to introduce such features on a quantitative basis in this study.

The influence of the large scale fluctuating vertical velocities in the early spring, which produce explosive warming and a large rise of ozone (Reference 46), has not been included in this study. Also the meridional transport due to the meandering waves and vertical motions associated with the jet stream present in the polar night (Hare, Reference 44) has not been quantitatively incorporated.

SUMMARY AND CONCLUSIONS

In the light of the new data on solar radiation and other parameters necessary for photochemical calculations, a computation of the meridional distribution of photochemical equilibrium of ozone for solstices and equinoxes is made. It is found, in agreement with ideas of the earlier investigators, that the photochemical theory by itself cannot explain the latitudinal and seasonal variation of ozone.

To study the part played by transport processes in the stratosphere, the necessary equation which includes the combined effects of photochemical and transport processes has been developed for steady state conditions. With such an equation and using a scheme of transport process that is

within reasonable agreement with the current ideas on transport processes in the stratosphere, meridional distribution of ozone produced under steady state conditions is calculated for equinoxes and solstices. The seasonal and latitudinal variation of total ozone thus obtained is in qualitative agreement with the observed variations of total ozone in the atmosphere shown by the investigations of London (Reference 10).

Considering the limitations of this study, it is hard to say that all the problems concerning the behavior of ozone in the atmosphere have been answered quantitatively. But it may be remarked that the technique developed in this investigation is potentially good for studying the problem of atmospheric ozone. It is hoped that such a quasi-stationary approach would put the problem of ozone, at least as a first step, on a quantitatively understandable level.

ACKNOWLEDGMENTS

The author is very grateful to Prof. Jerome Spar and Prof. Julius London for their valuable advice. The computational work was carried out on the IBM 7090 computer at the Institute for Space Studies of NASA, with the kind permission of Prof. R. Jastrow.

ELECTRON MICROSCOPY OF METEORITIC AND ARTIFICIALLY SHOCKED GRAPHITE*

THOMAS P. SCIACCA AND MICHAEL E. LIPSCHUTZ†

Samples of graphite, partly converted to diamond by shock, and meteoritic graphite were studied by transmission electron microscopy. The shocked graphite remained in the form of single crystals and was mildly deformed while the diamond which had formed was anhedral and polycrystalline. The meteoritic graphite contained minor amounts of troilite (FeS) and elemental sulfur but no detectable carbon phase other than graphite.

As an adjunct to an x-ray crystallographic study of meteoritic diamonds (*1*) we have studied the morphology of the phases present in meteoritic graphite, and in graphite which has been artificially shocked at pressures high enough (300 kbar) to produce diamond (*2*).

Samples of the starting material, high-purity graphite (*3*), as well as the resulting shock-product, and graphite from the interior of a 1.1-g graphite nodule from the Canyon Diablo iron meteorite were crushed to 100 mesh. Slurries in ethanol were then placed in an ultrasonic generator for 5 minutes to disperse the sample uniformly. The suspensions were placed on Formvar, collodion, or carbon substrates for examination in a Hitachi HU-11 electron microscope. Phases were identified by electron diffraction of selected areas with gold and palladium as standards.

Figure 1*a* shows a typical graphite-diamond intergrowth from the artificially shocked graphite. All of the diamonds formed in this manner were anhedral and polycrystalline. The graphite flakes seemed mildly deformed although they remained single crystals. Figure 1*b* shows a typical graphite flake from the starting material.

In both the starting material and shock product the only other phase that we found was in the

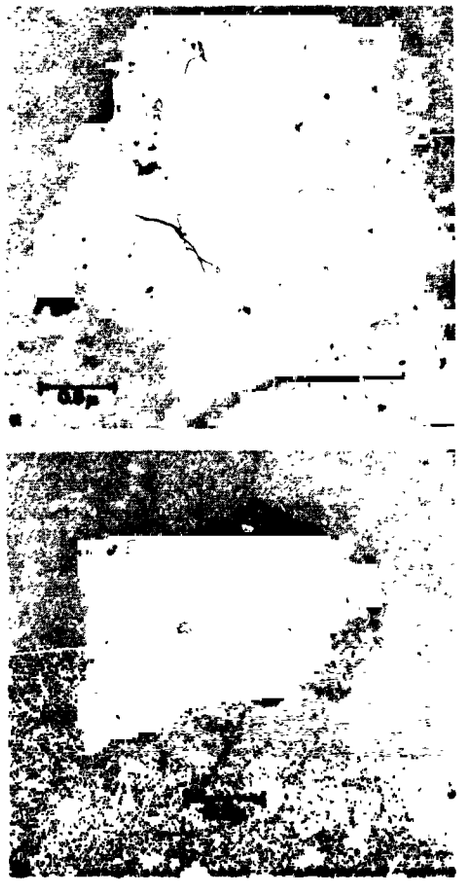

FIGURE 1.—(a) Diamond-graphite intergrowth in artificially shocked graphite. Note the anhedral morphology of the larger diamond grains (D). (b) Typical flake from the graphite starting material. The texture of this flake may be compared with that of the untransformed graphite in (a).

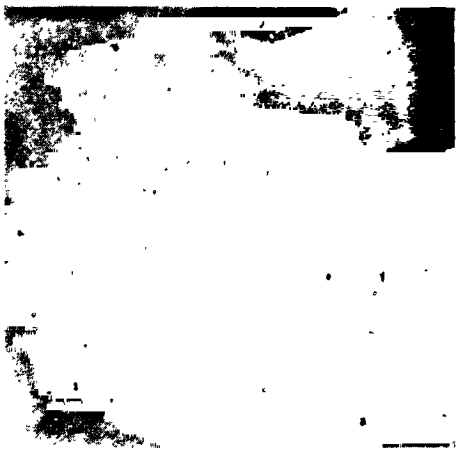

FIGURE 2.—Unidentified species present in both starting material and shock product. The cell dimension of these cubes is similar to that of the "carbon II" phase reported by Aust and Drickamer (4.)

form of euhedral cubes (Fig. 2) which were single crystals of uncertain origin. The cell dimension of these simple cubic crystals ($\alpha_0 = 5.55$ Å) corresponds very closely to that of the "carbon II" phase ($\alpha_0 = 5.545$ Å) reported by Aust and Drickamer (*4*). Inasmuch as the cubes were present in very small numbers ($<<1$ percent) in both the starting material and product we cannot say that they were produced by shock or, in fact, that they were composed of carbon. It seems very unlikely that some extraneous material would possess exactly the same cell dimension and crystallographic habit as "carbon II". Yet the cubes' euhedral appearance, the general perfection of these crystals, and their low abundance suggest that they were contaminants and not shock-formed. It could also be that these cubes were, indeed, "carbon II" which had grown relatively slowly during preparation of the original artificial graphite block. Unfortunately, all three alternatives (contamination, shock-formation, or slow growth) seem equally unlikely and it is impossible to decide among them with the available data.

The anhedral morphology of the artificial diamond might be expected from the short time available for crystal growth under the experimental shock conditions. Shocks generated during asteroidal collision (*1*) on the other hand, no doubt were of longer duration and might well be expected to result in the formation of subhedral diamond grains. These grains would probably be polycrystalline aggregates, since the shock-induced conversion of graphite to diamond apparently proceeds by a mechanism other than the orderly diffusion and addition of carbon atoms to diamond nuclei (*1*, *2*).

X-ray fluorescence analysis of the interior of the Canyon Diablo nodule indicated the presence of only iron and sulfur. The only carbon phase detected was normal graphite. The cubic phase seen in the starting material and shock product was not observed in the Canyon Diablo nodule.

The sulfur in the Canyon Diablo material apparently exists in two forms; as free rhombic sulfur and as troilite (FeS). Figure 3*a* shows anhedral single crystals of sulfur in a graphite matrix at an electron accelerating voltage of 75 kv. At 100 kv, the normal operating voltage

FIGURE 3.—(a) Sulfur (S), graphite mixture from Canyon Diablo (75-kv electrons). (b) The same area examined with 100-kv electrons. The higher accelerating voltage has sufficiently increased the temperature to melt the sulfur grains.

in these studies, the temperature reached was high enough to melt the sulfur (m.p. 113°C), and further aided in its identification (Fig. 3*b*). The troilite in the graphite nodule was identified by both x-ray and electron diffraction. It was present in amounts greater than about 5 percent while the sulfur was present in lesser amounts (about 2 percent).

The coexistence of troilite and elemental sulfur has been observed previously in Type I carbonaceous chondrites (*5*) although in these meteorites there is considerably more sulfur than troilite. Free sulfur has not previously been reported in iron meteorites. It may be that the sulfur was formed by terrestrial weathering of the troilite, the iron thus liberated forming amorphous limonite (*6*). An alternative is that these minerals are preterrestrial. If this was the case it is expected that the S^{32}/S^{34} ratios in the troilite and sulfur may differ.

A.C. CONDUCTIVITY OF A PLASMA*

C. S. SHEN† AND R. L. W. CHEN‡

This paper computes the electrical conductivity of a fully ionized, spatially homogeneous plasma under the influence of a uniform, periodically alternating electric field. The velocity distribution of the electrons is determined by solving the linearized Fokker-Planck equations. All the terms in the collision integral are retained, including those representing electron-electron interactions. The resultant values of conductivity is expected to be valid in the range of frequencies from zero to below the plasma frequency.

I. INTRODUCTION

The purpose of this paper is to calculate the a.c. conductivity of a spatially homogeneous plasma using the Fokker-Planck equation. The d.c. conductivity of a plasma has been calculated in the well-known works of COHEN *et al.* (1950) and SPITZER Jr. and HÄRM (1953). Their results are in good agreement with the later experimental works of LIN *et al.* (1955). BERNSTEIN and TREHAN compute the a.c. conductivity assuming a Lorentz gas model (1960). The a.c. conductivity of a real gas should approach that of a Lorentz gas at high frequencies (see detailed discussions in Section 4). Toward lower frequencies their departure is expected to increase so that their ratio becomes nearly 2 in the d.c. limit, in accordance with COHEN *et al.* and SPITZER and HÄRM. The recent works on a.c. conductivity by DAWSON and OBERMAN (1962) consider the time variation of the two-particle distribution, which is necessary when dealing with a.c. currents of ultra-high frequencies. However, the domain of applicability of their work is limited to frequencies much higher than the collision frequency. Thus, a more precise calculation for the low and intermediate range of ω appears desirable and we proceed to do this in accordance with methods to be described in the next section. After completion of most of the numerical work, a paper by ROBINSON and BERNSTEIN (1962) came to our attention. They computed the a.c. conductivity using a variational technique. Our results obtained by direct integration of the Fokker-Planck equation will be compared to theirs in Section 4.

We begin with the Boltzman equation:

$$\frac{\partial f_i}{\partial t}+\mathbf{v}\cdot\frac{\partial f_i}{\partial \mathbf{r}}=\frac{F}{m}\cdot\frac{\partial f_i}{\partial \mathbf{v}}+\left(\frac{\delta f_i}{\delta t}\right)_c \qquad (1)$$

where f_i is the distribution function of particles of type i, $\left(\frac{\delta f_i}{\delta t}\right)_c$ is the change of f_i produced by collisions.

Equation (1) is deduced from Liouville theorem to describe a many-particle system under two assumptions:

(i) That the characteristic dimensions of the inhomogeneities are much larger than the average impact parameter for the particles participating in the collision.

(ii) That the characteristic time variation of the process is much longer than the duration of an average collision, or in other words, a collision is completed and the correlation function is 'relaxed' before the distribution function itself makes any appreciable change.

It should be noted here that the term 'duration of collision' is different from the so-called 'collision time'; collision time is the time between two collisions. For particles interacting through long-range forces, this time may be regarded as the time in which deflexions gradually deflected the considered particle by 90°. Duration of collision is the time during which an interaction takes place. In a plasma it is of the order ω_p^{-1}. In Fig. 1 a

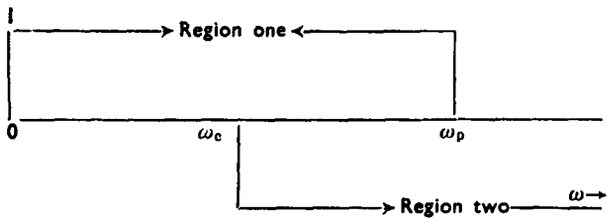

FIGURE 1.—The ranges of validity computed a.c. conductivities. The values of a.c. conductivity obtained in this paper is valid in region one. When omega exceeds ω_c—region two—the values calculated by Dawson and Oberman begin to be valid. Here ω_c is the collision frequency, ω_p is the plasma frequency.

time-scale diagram is drawn, and the validity of our calculation and those of DAWSON and OBERMAN are indicated.

The explicit expression of $\left(\frac{\delta f_i}{\delta t}\right)_c$ depends on the nature of the interaction force. In a fully ionized plasma, the particles interact through the long-range Coulomb forces. The cumulative effect of 'weak' deflexions resulting from the relatively distant collisions outweighs the effect of occasional large deflexions due to relatively close collisions, so one may neglect the contribution by those very close encounters (COHEN *et al.*)—encounters which result in deflexions of 90° or larger.

Also, the effect of distant particles lying outside the Debye length λ_D may be neglected because of the shielding of inner particles. Thus, in the computations of $\left(\frac{\delta f_i}{\delta t}\right)_c$, it is only necessary to consider the collisions with impact distance intermediate between λ_D and b_0, where $b_0=\frac{e^2}{KT}$ is the impact parameter yielding a 90° deflexion. The effects of these collisions are cumulative, and the total deflexion produced in an interval of time is similar to that of the Brownian motion; hence, one may expand $\left(\frac{\delta f_i}{\delta t}\right)_c^2$ in powers of $[\Delta \mathbf{v}]$, where $[\Delta \mathbf{v}]$ is the average velocity change due to collisions (COHEN *et al.*, CHANDRASEKHAR, 1943). This procedure leads to the following Fokker–Planck collision integral (ROSENBLUTH *et al.*, 1957):

$$\left(\frac{\delta f_i}{\delta t}\right)=\Gamma_i\left\{-\frac{\partial}{\partial \mathbf{v}}\left(f_i\frac{\partial h_i}{\partial \mathbf{v}}\right)+\frac{1}{2}\frac{\partial^2}{\partial \mathbf{v}\partial \mathbf{v}}\left(f_i\frac{\partial^2 g}{\partial \mathbf{v}\partial \mathbf{v}}\right)\right\} \quad (2)$$

where

$$h_i=\sum_j\frac{m_i+m_j}{m_j}\int d\mathbf{v}' f_j(\mathbf{v}')\,|\mathbf{v}-\mathbf{v}'|^{-1} \quad (3)$$

$$g=\sum_j\int d\mathbf{v}' f_j(\mathbf{v}')\,|\mathbf{v}-\mathbf{v}'| \quad (4)$$

and

$$\Gamma_i=\frac{4\pi z^2 e^4}{m_i^2}\ln\frac{m_i m_j v_{th}^2 \lambda D}{2(m_i+m_j)e^2}. \quad (5)$$

The summation in h_i and g sums over all species, m_i is the mass of the i-th species, e is the electronic charge, $\lambda_D=\left(\frac{KT}{4\pi ne^2}\right)^{\frac{1}{2}}$ is the Debye length, and v_{th} is the relative thermal velocity.

In this paper we consider only plasma with singly-charged ions. The extension of the present method to those with multiply-charged ions is straightforward.

2. DERIVATION OF EQUATIONS AND FORMULAE

If the distribution function f has an azimuthal symmetry about a certain axis, then, following ROSENBLUTH *et al.*, the collision term may be written down explicitly in spherical polar co-ordinates in velocity space:

$$\begin{aligned}\left(\frac{\delta f_i}{\delta f}\right)_c=\Gamma_i\Bigg\{&-v^{-2}\frac{\partial}{\partial v}\left[f_i v^2\frac{\partial h_i}{\partial v}\right]-v^{-2}\frac{\partial}{\partial \mu}\left[f_i(1-\mu^2)\frac{\partial h_i}{\partial \mu}\right]\\&+(2v^2)^{-1}\frac{\partial^2}{\partial v^2}\left[f_i v^2\frac{\partial^2 g}{\partial v^2}\right]\\&+2(v^2)^{-1}\frac{\partial^2}{\partial \mu^2}\Bigg[f_i\Bigg\{v^{-2}(1-\mu^2)^2\frac{\partial g^2}{\partial \mu^2}\\&+v^{-1}(1-\mu^2)\frac{\partial g}{\partial v}-v^{-2}\mu(1-v^2)\frac{\partial g}{\partial \mu}\Bigg\}\Bigg]\\&+v^{-2}\frac{\partial^2}{\partial \mu\partial v}\left[f_i(1-\mu^2)\left\{\frac{\partial^2 g}{\partial \mu\partial v}-v^{-1}\frac{\partial g}{\partial \mu}\right\}\right]\\&+(2v^2)^{-1}\frac{\partial}{\partial v}\Bigg[f_i\Bigg\{-v^{-1}(1-\mu^2)\frac{\partial^2 g}{\partial \mu^2}-2\frac{\partial g}{\partial v}\\&+2\mu v^{-1}\frac{\partial g}{\partial \mu}\Bigg\}\Bigg]+(2v^2)^{-1}\frac{\partial}{\partial \mu}\Bigg[f_i\Bigg\{v^{-2}\mu(1-\mu^2)\frac{\partial^2 g}{\partial \mu^2}\\&+2\mu v^{-1}\frac{\partial g}{\partial v}+2v^{-1}(1-\mu^2)\frac{\partial^2 g}{\partial \mu\partial v}-2v^{-2}\frac{\partial g}{\partial \mu}\Bigg\}\Bigg]\Bigg\}\end{aligned} \quad (6)$$

where $\mu=\cos\theta$ is the direction cosine between $\mathbf{v}$ and $\mathbf{E}$. Equation (6) is an exact expression of the Fokker–Planck equation in spherical co-ordinates for a distribution function with azimuthal symmetry.

We assume that the system is subject to a weak electric field $\mathbf{E}_0 e^{i\omega t}$ whose direction lies along z-axis. Then following CHAPMAN and COWLING (1939) and SPITZER Jr. we expand f_i in a power series of E:

$$f_i(\mathbf{v},t)=f_i^{(0)}(v)+E_0 f_i^{(1)}(\mathbf{v},t)+E_0^2 f_i^{(2)}(\mathbf{v},t)+\cdots \quad (7)$$

where $f_i^{(0)}(v)$ is a time-independent Maxwellian distribution and $f^{(1)}(\mathbf{v},t)$, $f^{(2)}(\mathbf{v},t),\cdots\cdots$ are the perturbed part due to applied electric field. When a steady state has been reached and no transient current exists, the time-dependent part of $f_i^{(j)}(\mathbf{v},t)$ must be proportional to $e^{i\omega t}$. Since the average energy imparted to the electrons between encounters is small compared with their kinetic energy, the velocity-dependent part of $f_i^{(j)}(\mathbf{v},t)$ can be written as $e^{-(m_i v^2/2kt)}D_i^{(j)}(v)\mu$. Therefore, we have

$$f_i^{(j)}(\mathbf{v},t)=\frac{m^{3/2}}{(2\pi KT)^{3/2}}e^{-m_i v^2/2KT}D_i^{(j)}(v)\mu e^{i\omega t}. \quad (8)$$

Combining equations (1), (6) and (7) keeping only terms linear in E_0, we obtain

$$\frac{\partial f_i^{(1)}}{\partial t}+\frac{e}{m_i}e^{i\omega t}\mathbf{E}_0\frac{\partial}{\partial \mathbf{v}}f_i^{(0)}=\left(\frac{\delta f_i^{(1)}}{\delta t}\right)_c \quad (9)$$

where $(\delta f_i/\delta t)_c{}^{(1)}$ is the linearized Fokker-Planck collision integral.

Since the ions' contribution to electric current is negligible compared to electrons, we will consider only electron distributions and drop the subscript i in the distribution function hereafter.

Substituting equation (8) into equation (9) we find, after some algebraic manipulations, the following second-order linear integral-differential equation:

$$D''(\chi)+P(\chi)D'(\chi)+Q(\chi)D(\chi)=R(\chi)+S(\chi) \quad (10)$$

where

$$P(\chi)=-2\chi-\frac{1}{\chi}+\frac{2\chi^2\Phi'(\chi)}{H(\chi)} \quad (11)$$

$$Q(\chi)=\frac{-iB\chi^3+2(1+\Phi=2\chi^3\Phi')}{H(\chi)}+\frac{1}{\chi^2} \quad (12)$$

$$R(\chi)=-\frac{2d\chi^4}{H(\chi)}-\frac{8(2\cdot 4\chi^6-2\chi^4)}{3\pi^{1/2}H(\chi)}I_0(\infty) \quad (1\upsilon)$$

$$S(\chi)=\frac{16}{3\pi^{1/2}H(\chi)}\{\chi I_3(\chi)-1\cdot 2\chi I_5(\chi) -\chi^4 I_0(\chi)(1-1\cdot 2\chi^2)\} \quad (14)$$

$$\Phi(\chi)=\int_0^\chi e^{-y^2}dy \quad (15)$$

$$H(\chi)=\Phi(\chi)-\chi\Phi'(\chi) \quad (16)$$

$$I_n(\chi)=\int_0^\chi y^n D(y)e^{-y^2}dy \quad (17)$$

$$I_0(\infty)=\int_0^\infty D(y)e^{-y^2}dy \quad (18)$$

with

$$\alpha=-E_0KT/\pi e^3 n\ln\lambda \qquad \lambda=\lambda_D/b_0$$

$$\chi=v\Big/\left(\frac{2KT}{m}\right)^{1/2} \qquad B=\frac{4\sqrt{2}\lambda\omega}{\omega_p\ln\lambda}=\frac{\omega}{\omega_c},$$

where ω_c is approximately the 90° deflexion time of a particle with thermal velocity. When $\omega=0$, equation (10)* reduces to equation (8) of SPITZER Jr. which considers d.c. electric conductivity.

In a d.c. electric field, the electrons are not accelerated in a steady state. Hence, the inertia force term is zero and $I_0(\infty)=\frac{3\pi^{\frac{1}{2}}}{8}\alpha$.

3. SOLUTION OF EQUATION

Equation (10) is a linear integral-differential equation whose unknown $D(\chi)$ is a complex function of a real variable. The present section will discuss the method of its solution. As will be evident in what follows, the procedure for numerical integration is far from straightforward.

On the one hand, we encounter the problem of the instability of the solution at small and at large χ. Because of the existence of singularities in equation (10) at $\chi=0$ and at $\chi=\infty$, a slight deviation of $D(\chi)$ at either small or large χ, tends to be built up quite rapidly. In order to obtain a physically acceptable solution, it is required that $D(\chi)$ does not approach infinity too fast, leading to infinite conductivities. The starting value of D at small χ can be obtained by means of a series solution. Because of the instability, we cannot proceed to integrate in a step-wise manner. To overcome this difficulty, we adopted a scheme

*Note that $I_0(\infty)$ is essentially the total change of momentum of electrons arising from electronion interactions. Since the mutual electronic interaction cannot change the total momentum of the electrons, $I_0(\infty)$, by Newton's second law, must equal the total force exerted on the electrons by the applied field minus the inertia force of electrons. This relation gives us:

$$I_0(\infty)=\frac{3\pi^{\frac{1}{2}}}{8}\alpha-\frac{iB}{2}I_3(\infty).$$

used by COHEN *et al.* We shall refer to their paper for full details.

On the other hand, we note that $I_0(\infty)$ is no longer a known quantity as it is in the case of d.c. conductivity; it depends on the solution $D(\chi)$ itself. We proceed as follows: Since we want conductivities at different frequencies, it is necessary to obtain solutions for different values of the parameter B. We begin with a small value $B=0{\cdot}05$. Using an $I_0(\infty)$ taken from the d.c. case, i.e. $I_0(\infty)=0{\cdot}655$, we obtain a solution to equation (10) from which we get a new $I_0(\infty)$. Next, we pass on to $B=0{\cdot}1$ using the $I_0(\infty)$ obtained for the previous B. In this way, we proceed to ever-increasing values of B, until the initial adopted $I_0(\infty)$ and the final calculated $I_0(\infty)$ differ by no more than 2 percent. This occurs at $B=1{\cdot}37$. From this point on, we resort to a method of systematic trials. The initial and final $I_0(\infty)$ for all values of B agree to within 2 percent, which is considered sufficiently accurate for the present purposes.

4. RESULTS AND DISCUSSION

The current is given by

$$\mathbf{J}=-e\int \mathrm{d}\mathbf{v}\mathbf{v}f_1[(\mathbf{v},t)=AE_0e^{i\omega t}I_3(\infty) \qquad (19)$$

where

$$I_3(\infty)=\int_0^\infty \chi^3 D(\chi)\mathrm{e}^{-x^2}\mathrm{d}\chi$$

$$A=\frac{2}{3}\frac{(2KT)^{3/2}}{\pi^{3/2}m^{1/2}e^2\ln\lambda}. \qquad (20)$$

Since $J=\sigma E$, we have the complex conductivity

$$\sigma=AI_3(\infty), \qquad (21)$$

the impedance

$$Z=\frac{1}{AI_3(\infty)}=\frac{c}{I_3(\infty)}, \qquad (22)$$

the resistance

$$R=\frac{1}{A}\frac{ReI_3(\infty)}{|I_3(\infty)|^2}=\frac{cReI_3(\infty)}{|I_3(\infty)|^2}, \qquad (23)$$

and the reactance

$$X=\frac{1}{A}\frac{ImI_3(\infty)}{|I_3(\infty)|^2}=\frac{cImI_3(\infty)}{|I_3(\infty)|^2}, \qquad (24)$$

with

$$c=\frac{1}{A}=\frac{3}{2}\frac{1}{(2KT)^{3/2}}\pi^{3/2}m^{1/2}e^2\ln\lambda.$$

It may be remarked here that the a.c. conductivity depends on three factors:

(i) The inertia of the conducting electrons.
(ii) The mutual interaction among electrons and ions.
(iii) The mutual interaction among electrons themselves.

The mutual electronic interactions have no direct effect on conductivity since the total change of momentum due to such interactions is zero. Nevertheless, they alter the distribution of electrons and thereby modify the effect which electron-ion collisions and electron inertia have in impeding the current. When ω is small, the conductivity is primarily determined by collisions. The inclusion of electron-electron interactions reduces the conductivity by a factor of approximately two. As ω increases and becomes of order ω_c, this effect becomes less and less important because there is then insufficient time in each a.c. cycle to allow an effective modification of the distribution by electron-electron interactions. When ω well exceeds ω_c, we may neglect this effect and $D(\chi)$ reduces to

$$D_i(\chi)=\frac{\chi^4}{1+\frac{iB}{2}\chi^3} \qquad (25)$$

and the corresponding conductivity becomes

$$\sigma_i(\chi)=A\int_0^\infty \frac{\chi^7\mathrm{e}^{-x^2}}{1+\frac{iB}{2}\chi^3}\mathrm{d}\chi \qquad (26)$$

which is just the a.c. conductivity of a Lorentz gas (BERNSTEIN and TREHAN).

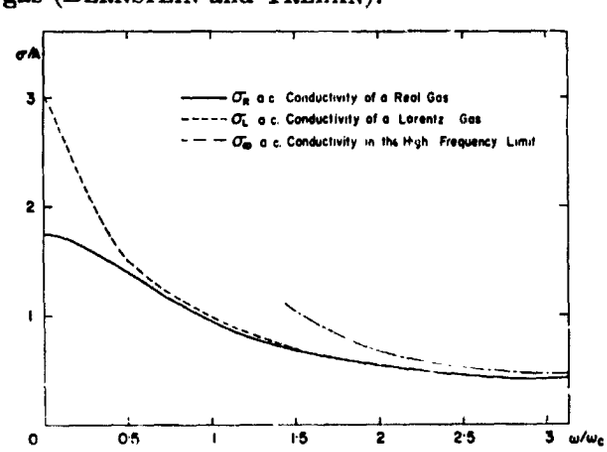

FIGURE 2.—A. C. conductivities.

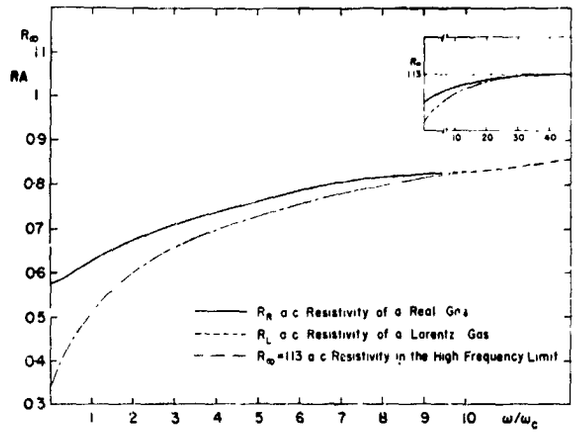

FIGURE 3.—A. C. resistivities

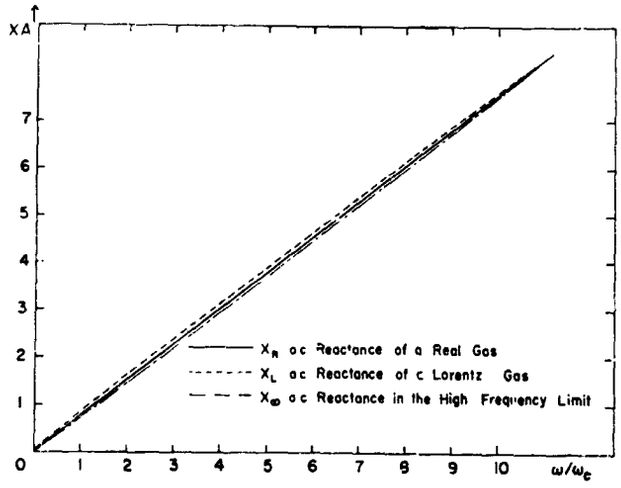

FIGURE 4.—A. C. reactances

If we further increase ω, the inertia of electrons become dominant. Then we may treat collision effect as a perturbation and obtain

$$\sigma_\infty = A\left(-\frac{3\pi^{1/2}}{4}i+\frac{2}{B^2}\right)\frac{1}{B} \tag{27}$$

$$Z_\infty = \frac{1}{A}\,\frac{4B^2}{64+9\pi B^2}(8+3\pi^{1/2}iB) \tag{28}$$

$$R_\infty = \frac{1}{A}\,\frac{32}{9\pi}\left(1-\frac{64}{9\pi B^2}\right) \tag{29}$$

$$X_\infty = \frac{1}{A}12\pi^{1/2}B\left(1-\frac{64}{9\pi B^2}\right). \tag{30}$$

In Table 1 the values of $D(\chi)$ for $B=1$ are given and compared with the corresponding values for the d.c. case obtained by SPITZER Jr. and HÄRM.

In Table 2 the resistance, the reactance and the absolute value of conductivity are given for various B from 0 to 10. For $B>10$, one may use

equation (26) to compute them. The error will be within 2 percent. For $B>50$ the collisions become unimportant and equations (27)–(30) will give the correct values to within 2 percent. However, there the validity of the Fokker-Planck equation already becomes questionable and one should use DAWSON-OBERMAN'S values instead of ours.

In Table 3, the complex conductivity calculated in this paper are compared with those obtained by ROBINSON and BERNSTEIN. They showed that transport coefficients obtained from the Fokker-Planck equation should possess an extremal nature, and proceed to calculate conductivities using the variational technique. Their Table 6 gives conductivities for various values of the logarithm of ω/ω_c including very large values of ω_c. In our Table 3 only those values are included for comparison which fall within the range of validity of the Fokker-Planck equation. The discrepancy between the two results are generally within 5 percent.

TABLE 3.—*Comparison of the a.c. conductivities obtained in this paper (direct integration) with those obtained by Berstein and Robinson (variational calculation)*

ω/ω_c	*Log X* $(X=4\sqrt{2\omega/\omega_c})$	$Re\sigma/A$		$-Im\sigma/A$	
		BERNSTEIN ROBINSON	SHEN–CHEN	BERNSTEIN–ROBINSON	SHEN–CHEN
0.0	$-\infty$	1.734	1.734	0.000	0.000
0.0057	−3.0	1.734	1.734	0.004	0.002
0.0179	−2.5	1.730	1.732	0.649	0.408
0.0565	−2.0	1.705	1.722	0.154	0.151
0.179	−1.5	1.605	1.608	0.447	0.443
0.565	−1.0	0.992	0.987	0.816	0.813
0.901	−0.8	0.637	0.632	0.785	0.787
1.425	−0.6	0.357	0.353	0.645	0.649
2.261	−0.4	0.183	0.179	0.477	0.482
3.559	−0.2	0.087	0.084	0.329	0.336
5.65	0.0	0.040	0.038	0.201	0.204

We should add that our results can be readily applied to the case of conductivity in the presence of a uniform magnetic field. The addition of the magnetic field leads to equations which are entirely similar to (10). If the electric field is parallel to the magnetic field, the conductivity is not affected. If it is perpendicular to the magnetic field, the conductivity becomes $\sigma_H(\omega)\equiv\sigma(\omega+\omega_H)$, where σ is the function obtained in this paper and $\omega_H=eH/mc$.

PARTIAL WAVE THEORY OF DIATOMIC MOLECULES, II*

N64-20589

A. TEMKIN AND A. K. BHATIA†

The method of expanding the wave function of diatomic molecules in a series of orbital angular momentum eigenfunctions (partial waves) is extended to two-electron homonuclear molecules. The angular momentum is a function of the Euler angles only; a symmetric choice of these angles is used which greatly facilitates the description of the exchange character of the wave function. As a result, explicit equations for the 3 dimensional "radial" functions can be derived for all the different magnetic parity, and exchange states. For Σ states the partial wave sums only go over alternate values of the angular momentum giving rise to the expectation of an even more rapidly convergent series in these cases.

I. INTRODUCTION

In a previous paper[1] as well as others,[2] the idea of expanding the wave function of a (homonuclear) diatomic molecule in a series of angular momentum eigenfunctions was introduced for the purpose of affording a very natural method of successive approximations in these problems.

Previous calculations[1,2] using this idea have almost exclusively been confined to the one-electron molecule H_2^+. In that case, the formalism is rather easily constructed, and the results are in the nature of a check as the problem is amenable to exact calculation.[3] The comparison with the exact results is nevertheless most encouraging.[1]

The main immediate goal of this approach is two-electron molecules for which there is no analytically exact solution. As a prerequisite for effecting this approach, however, it is necessary that two electron atoms be completely understood. Although the general approach to the two-electron atomic problem is quite old[4], only results for specific angular momentum states have until recently been derived. The difficulty lay in the description of the character of the wave function under the exchange of electron coordinates which becomes very complicated[4] with the original choice of Euler angles[5]. The explicitly complete solution has required a symmetrical choice of Euler angles, which Holmberg[6] has provided, and has therefore only just been carried out[7].

In section II, we very briefly review the main results of that investigation and present some additional transformation properties of the Euler angles and vector spherical harmonics which bear on the present application. In section III we describe the construction of the molecular wave functions, and in section IV we derive the radial equations. These equations couple states of different angular momentum through the potential energy, but the kinetic energy acts in the same way as in the atomic case. The new feature is, therefore, only the coupling terms of the molecular potential and this in turn depends on integrals over three vector spherical harmonics. The heart of section III is the resulting formulae for these integrals and the selection rules for its non-vanishing. This latter consideration leads to the decoupling of the Σ states according to even $(+)$ or odd $(-)l$. This decoupling is not present for other m states corresponding to the absence of the $\pm$ quantum numbers in those cases; thus the Σ states provide particularly favorable cases for the rapid convergence of the partial wave expansion.

Section V presents the zeroth-order equation for the Σ_g^+ states and discusses a specific calculation which can be related to the accuracy of this approximation and which by inference bears upon the convergence properties of the entire sequence of approximations which this paper projects.

II. THE EULER ANGLES AND TRANSFORMATION PROPERTIES

The Schrödinger equation of a two-electron homonuclear molecule whose nuclei are considered fixed (Born-Oppenheimer approximation) will depend on the two vectors of the electrons $\mathbf{r}_1$ and $\mathbf{r}_2$ which can be measured relative to an origin defined as the midpoint between the nuclei and parametrically on the internuclear separation R_{AB}.

In place of the six coordinates $\mathbf{r}_1$, $\mathbf{r}_2$ one can introduce the three Euler angles and three residual variables; the Euler angles describe the orientation of the plane containing the two unit vectors $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{r}}_2$ relative to a space-fixed coordinate system (whose z-axis is by definition the internuclear axis).

The particular Euler angles we use where introduced by Holmberg[6] and have the advantage of being symmetrically disposed with respect to the

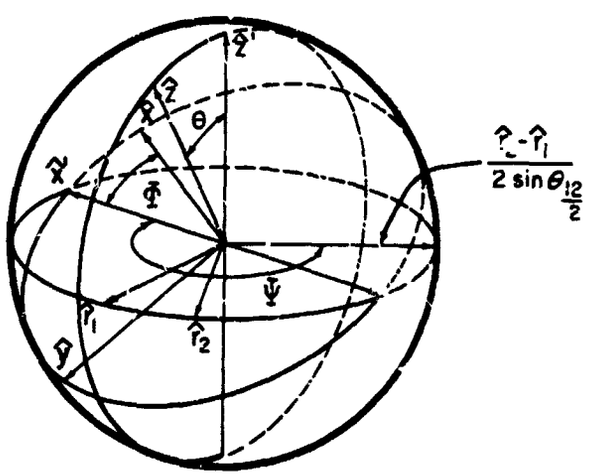

FIGURE 1.—Perspective drawing of (Holmberg's) Euler angles and the unit vectors of the problem.

two-electron. Figure 1 contains a diagrammatic representation of these angles and the unit vectors with which we shall be concerned.

The axes are defined by

$$\hat{\mathbf{z}}' = (\hat{\mathbf{r}}_1 \times \hat{\mathbf{r}}_2)/\sin\theta_{12} \tag{2.1}$$

$$\hat{\mathbf{x}}' = (\hat{\mathbf{z}} \times \hat{\mathbf{z}}')/\sin\theta \tag{2.2}$$

$$\hat{\mathbf{y}}' = \hat{\mathbf{z}}' \times \hat{\mathbf{x}}' \tag{2.3}$$

The Euler angles are obviously: θ = angle between $\hat{\mathbf{z}}$ and $\hat{\mathbf{z}}'$; Φ = angle between $\hat{\mathbf{x}}$ and $\hat{\mathbf{x}}'$; Ψ = angle between $\hat{\mathbf{x}}'$ and $(\hat{\mathbf{r}}_1 - \hat{\mathbf{r}}_2)$. Trigonometric relations between these angles and the particles spherical angles have been worked out in reference 7; the reader is encouraged to familiarize himself with that discussion, although we shall attempt to make this treatment reasonably self-contained. Specifically, we shall repeat here the relation of the x, y and z components of $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{r}}_2$ to the Euler angles in order that the transformation properties given below can readily be checked.

$$\frac{x_1}{r_1} = \sin\vartheta_1\cos\varphi_1 = \cos\Phi\sin(\psi - \tfrac{1}{2}\theta_{12}) + \cos\theta\sin\Phi\cos(\psi - \tfrac{1}{2}\theta_{12}) \tag{2.5}$$

$$\frac{y_1}{r_2} = \sin\vartheta_1\sin\varphi_1 = \sin\Phi\sin(\psi - \tfrac{1}{2}\theta_{12}) - \cos\theta\cos\Phi\cos(\psi - \tfrac{1}{2}\theta_{12}) \tag{2.6}$$

$$\frac{z_1}{r_1} = \cos\vartheta_1 = -\sin\theta\cos(\psi - \tfrac{1}{2}\theta_{12} \tag{2.7}$$

The formulae for analogous components of $\hat{\mathbf{r}}_2$ may be obtained from the above by letting $\theta_{12} \rightarrow -\theta_{12}$. The angle θ_{12} is the angle between $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{r}}_2$. It is not one of the Euler angles, but rather one choice of residual coordinate, the other two usually being chosen as the two distances r_1 and r_2. The residual coordinates are often called generalized radial coordinates; an alternate choice is r_1, r_2, r_{12}, the latter being the interelectron distance.

The distinguishing feature of the Euler angles as opposed to residual coordinates is the fact that the angular momentum depends only on the Euler angles. In this connection, it is well known that square of the total orbital angular momentum, $\mathbf{M}^2$, can be conserved in atoms but not in diatomic molecules, whereas the z-component of the angular momentum, M_z, is a possible constant of the motion in both cases. A central role in the atomic problem is therefore played by the eigenfunctions of the total angular momentum $D_l^{m,k}(\theta,\Phi,\Psi)$:

$$D_l^{m,k}(\theta,\Phi,\psi) = \frac{\sqrt{2(2l+1)}}{4\pi} e^{i(m\Phi+k\psi)} d_l^{m,k}(\theta) \tag{2.8}$$

where

$$d_l^{m,k}(\theta) = (-1)^{\frac{1}{2}(|k-m|+k-m)} \frac{4\pi}{\sqrt{2(2l+1)}} N_{lmk} \sin^{|k-m|}\left(\frac{1}{2}\theta\right)\cos^{|k+m|}\left(\frac{1}{2}\theta\right) F\left(-l+\frac{\beta}{2}-1,\ l+\frac{\beta}{2},1+|k-m|,\sin^2\frac{\theta}{2}\right) \tag{2.9}$$

$$\beta = |k+m| + |k-m| + 2 \tag{2.10}$$

and

$$N_{\ell mk} = \frac{1}{(|k-m|)!}\left[\frac{(2\ell+1)}{8\pi^2}\,\frac{(\ell+\frac{1}{2}|k+m|+\frac{1}{2}|k-m|)!}{(\ell-\frac{1}{2}|k+m|-\frac{1}{2}|k-m|)!}\times\frac{(\ell-\frac{1}{2}|k+m|+\frac{1}{2}|k-m|)!}{(\ell+\frac{1}{2}|k+m|-\frac{1}{2}|k-m|)!}\right]^{\frac{1}{2}} \tag{2.11}$$

The eigenfunction character of these functions is then given by

$$\mathbf{M}^2 D_\ell^{m,k} = \hbar^2 \ell(\ell+1) D_\ell^{m,k} \tag{2.12}$$

$$\mathbf{M}_z D_\ell^{m,k} = \hbar m D_\ell^{m,k} \tag{2.13}$$

where the explicit form of $\mathbf{M}^2$ and $\mathbf{M}_z$ has been derived in reference 7 and in any case is known[8]. In the atomic problem if we are describing a state of definite orbital angular momentum ℓ with z-component m, then the wave function is at most a finite sum over the $(2\ell+1)$ function for the given ℓ and m:

$$\Psi_{\ell m}(\mathbf{r}_1,\mathbf{r}_2) = \sum_{k=-\ell}^{\ell} g_\ell^{m,k}(r_1,r_2,\theta_{12}) D_\ell^{m,k}(\theta,\Phi,\psi) \tag{2.14}$$

Actually the above sum is more general than what is needed. Specifically one has an additional operation which commutes with the Hamiltonian and therefore gives rise to an additional constant of the motion. This is the operation of space inversion (called parity, p, in the atomic application[7]), usually labelled iE in molecular applications[9] corresponding to the operation $\mathbf{r}_1 \rightarrow -\mathbf{r}_1$, $\mathbf{r}_2 \rightarrow -\mathbf{r}_2$ in all cases. It turns out that only the Euler angles are involved in this transformation, and if we denote them by a three component vector, (θ, Φ, Ψ), then[7]

$$iE\begin{pmatrix}\theta\\ \Phi\\ \psi\end{pmatrix} = \begin{pmatrix}\theta\\ \Phi\\ \pi+\psi\end{pmatrix} \tag{2.15}$$

and

$$iE D_\ell^{m,k}(\theta,\Phi,\Psi) = (-1)^k D_\ell^{m,k}(\theta,\Phi,\Psi) \tag{2.16}$$

Therefore, the wave function (2.14), if it is to be an eigenfunction of iE, must be restricted to even or odd k. Since the action of the Schrödinger equation is to couple all possible $g_\ell^{m,k}$ functions for the given ℓ and m, it can be seen that the invocation of parity halves the number of functions, and thus among other things is of considerable practical utility.

In the case of diatomic molecules the invariance against rotations, except those around the z-axis, is lost. Thus according to the above arguments only the rotation quantum number m survives. The idea of the partial wave theory, then, is to expand the molecular wave function in terms of the orbital angular momentum:

$$\Psi_m = \sum_{\ell=|m|}^{\infty} \Psi_{\ell m}$$

The above sum too may be delimited according to the symmetry properties of the states we intend to describe. These symmetry operations are well known for the diatomic molecule,[9], and except for exchange, ϵ_{12}, they all involve only the Euler angles. The transformation involved in the residual variables for ϵ_{12}, is $r_1 \rightleftarrows r_2$ independent of whether the third variable is taken as θ_{12} or r_{12}.

In Table I we have summarized the transformation properties of the Euler angles and the vector spherical harmonics under some of the major symmetry operations of the two-electron homonuclear diatomic molecule.

In the next section we shall utilize these properties to construct wave functions with the desired symmetry properties. We emphasize that *not* all these properties are independent. Thus for example a full space inversion is the product of the inversion about each of the axes separately:

$$iE = \sigma_h \sigma_{vx} \sigma_{vy}$$

where the factors on the right can be written in any order. Therefore, the operation σ_h is redundant.

The effect of additional symmetry operations such as σ_v on the angular momentum eigenfunctions and variables can easily be worked out from Table I by noting, in this case, that

$$i\sigma_v = iE \cdot \sigma_v$$

Not all symmetry operations commute with M_z. Specifically σ_v does not commute with M_z. This may be easily ascertained by envisaging a vector

TABLE 1.—*Symmetry properties of the Euler angles and the angular momentum eigenfunctions.*

Transformation Property	θ	Φ	Ψ	$D_l^{m,k}$

σ_{vz} reflection through z−x plane (inversion of y-coordinates)	$\pi-\theta$	$2\pi-\Phi$	Ψ	$(-1)^{l-k} D_l^{-m,k}$
σ_v, reflection through z−y plane (inversion of x-coordinates)	$\pi-\theta$	$\pi-\Phi$	Ψ	$(-1)^{l+m-k} D_l^{-m,k}$
ϵ_{12} exchange of particles*	$\pi-\theta$	$\Phi+\pi$	$2\pi-\Psi$	$(-1)^l D^{m,-k}$

*This operation also affects the residual coordinates. See text.

whose projection in the x-y plane is in the first quadrant. If first you reflect it through the y-z plane (σ_{vy}), thus putting in the second quadrant and then rotate around the z-axis by 90°, this vector will end up with a projection in the third quadrant. If first you rotate by 90°, putting it in the second quadrant, and then reflect through the y-z plane, you put it back into the first quadrant. Thus

$$[\sigma_v, M_z] \neq 0 \tag{2.19a}$$

This means that in general one can't construct simultaneous eigenfunctions of M_z and σ_v.

There is one exception to that situation, and that is Σ states.

For in that special case

$$M_z D_l^{0,k} = 0, \tag{2.17}$$

so that

$$[\sigma_v, M_z] D_l^{0,k} = 0, \tag{2.18}$$

or

$$[\sigma_v, M_z]_{m=0} = 0 \tag{2.19b}$$

We shall see in the next section that because of this fact the structure of the Σ wave function and the resulting Σ radial equations is quite different from all other states.

III. WAVE FUNCTIONS AND THE POTENTIAL ENERGY

In order to facilitate the derivation of the radial equations, it is convenient to construct an alternate set of orthonormal vector spherical harmonics which for $m=0$ are real[7]. We define

$$D_l^{(m,\varkappa)+} \equiv (\sqrt{2}+\delta_{0\varkappa}(2-\sqrt{2}))^{-1} (D_l^{m,\varkappa}+D_l^{m,-\varkappa}) \tag{3.1a}$$

$$D_l^{(m,\varkappa)-} \equiv (\sqrt{2}i)^{-1}(D_l^{m,\varkappa}-D_l^{m,-\varkappa}) \tag{3.1b}$$

The important point about these alternate sets of vector spherical harmonics is that they are eigenfunctions of exchange:

$$\epsilon_{12} D_l^{(m,\varkappa)\pm} = \pm(-1)^l D_l^{(m,\varkappa)\pm} \tag{3.2}$$

while still retaining their eigenfunction character with respect to parity, $\mathbf{M}^2$, and M_z (with eigenvalues $(-1)^\varkappa$, $\hbar^2\ell(\ell+1)$, $\hbar\, m$ respectively).

For $m \neq 0$ we have already indicated in the previous section that the correct expansion of the complete wave function is

$$\Psi_m = \sum_{l=|m|}^{\infty} {\sum_{\varkappa}}'' (f_l^{(m,\varkappa)+}(r) D_l^{(m,\varkappa)+} + f_l^{(m,\varkappa)-}(r) D_l^{(m,\varkappa)-}) \tag{3.3a}$$

The double prime on the summation indicates that every second value of the summation index (in this case $\varkappa$) is to be taken. This insures as stated, that the wave function is an eigenfunction of iE. It is precisely this property which distinguishes the homonuclear from the heteronuclear molecule. Thus there is established in the present homonuclear case two classes of solutions for a given m, one for even and one for odd $\varkappa$. These are of course the gerade and ungerade states respectively.

The radial functions $f_l^{(m,\varkappa)\pm}(r)$ are written as functions of r which is short for the generalized radial coordinates, either r_1, r_2, θ_{12} or r_1, r_2, r_{12}. The superscript indicates that the radial functions depend on the magnetic quantum number m. However the well-known degeneracy of the energy with respect to $\pm m$ indicates that the radial functions for $\pm m$ states must be simply related to each other. The relation is undefined up to a $\pm$ sign, but a consistent choice is (see below)

$$f_l^{(-m,\varkappa)\pm}(r_1,r_2,\theta_{12})=(-1)^{\beta}f_l^{(m,\varkappa)\pm}(r_1,r_2,\theta_{12})$$

The derivation of radial equations divides itself into two parts, the kinetic energy and the potential energy. The kinetic energy is diagonal with respect to ℓ and m but by no means trivial with respect to how mixes the allowable $\varkappa$ components. However, this aspect of its behaviour has been derived in detail in reference 7 and will not change in this application.

The potential energy in the atomic problem depends only on the generalized radial variables r_1, r_2, r_{12} and therefore acts as additional, completely diagonal terms in the atomic radial equations. On the other hand the molecular potential energy is precisely what destroys the spherical symmetry of the Hamiltonian. Specifically for nuclei of charge z (energy in units of rydbergs) to complete molecular potential is

$$v_{m0\ell}+\frac{2}{r_{12}}=-\frac{2z}{R_{A1}}-\frac{2z}{R_{A2}}-\frac{2z}{R_{B1}}-\frac{2z}{R_{B2}}+\frac{2}{r_{12}} \tag{3.4}$$

The last term is the interelectron repulsion and since it commutes with the angular momentum as discussed above need not be considered further. For the rest we can expand

$$V_{m0\ell}=-4z\sum_{\lambda\ \text{even}}{}''\, g_\lambda(\tfrac{1}{2}R_{AB},r_1)P_\lambda(\vartheta_1) -4z\sum_{\lambda\ \text{even}}{}''\, g_\lambda(\tfrac{1}{2}R_{AB},r_2)P_\lambda(\vartheta_2) \tag{3.5}$$

where

$$g_\lambda(x,y)\equiv\begin{cases}\dfrac{x^\lambda}{y^{\lambda+1}} & x<y\\[2ex] \dfrac{y^\lambda}{x^{\lambda+1}} & y<x\end{cases} \tag{3.6}$$

R_{AB} is the internuclear separation. The Legendre polynomials $P_\lambda(\vartheta)$ (note what we mean is eg. $P_1(\vartheta)=\cos\vartheta$ *not* $P_1(\vartheta)=\vartheta$) can further be expanded in terms of the Euler angles and θ_{12}[7]:

$$P_\lambda(\vartheta_1)=\frac{4\pi}{(2\lambda+1)^{\frac{1}{2}}}\sum_{\mu\ \text{even}}{}''\,[\alpha_\lambda^{\mu+}(\theta_{12})D_\ell^{(0,\mu)+} -\alpha_\lambda^{\mu-}(\theta_{12})D_\ell^{(0,\mu)-}] \tag{3.7a}$$

Applying ϵ_{12}, we get from the above

$$P_\lambda(\vartheta_2)=\frac{4\pi}{(2\lambda+1)^{\frac{1}{2}}}\sum_{\mu\ \text{even}}{}''\,[\alpha_\lambda^{\mu+}(\theta_{12})D_\lambda^{(0,\mu)+} -\alpha_\lambda^{\mu-}(\theta_{12})D_\lambda^{(0,\mu)-}] \tag{3.7b}$$

where

$$\alpha_\lambda^{\mu+}(\theta_{12})=(-1)^\mu P_\lambda^\mu(\pi/2)\left[\frac{(\lambda-\mu)!}{(\lambda+\mu)!}\right]^{\frac{1}{2}}\left\{\frac{\delta_{0\mu}}{\sqrt{2}} +(1-\delta_{0\mu})\cos\left(\frac{\mu}{2}\theta_{12}\right)\right\} \tag{3.8a}$$

$$\alpha_\lambda^{\mu-}(\theta_{12})=(-1)^\mu P_\lambda^\mu(\pi/2)\left[\frac{(\lambda-\mu)!}{(\lambda+\mu)!}\right]^{\frac{1}{2}}\sin\left(\frac{\mu}{2}\theta_{12}\right) \tag{3.8b}$$

The associated Legendre polynomials are understood to have the phase of Magnus and Oberhettinger[10], and their argument is understood to be inserted in the transcendental form of these functions as parenthesized above.

Since $P_\lambda(\vartheta)$ has parity $(-1)^\lambda$ and from (3.5) λ is even, it follows the sums in (3.7) go over only even μ as indicated.

The point of these expansions is that when the wave function (3.3) is substituted into the Schrödinger equation

$$H\Psi_m=E\Psi_m \tag{3.9}$$

where

$$H=T+V_{m0\ell}+2/r_{12} \tag{3.10}$$

and T is the kinetic energy, only $V_{m0\ell}$ will couple terms of different ℓ. The decompositions, Eqs. (3.7), then tell us that the coupling from a state (radial function) with quantum members ℓ, $\varkappa$, m to one with quantum numbers ℓ_f, $\varkappa_f$, m (the molecular interaction is still diagonal in m) will be governed by integrals over *three* vector spherical harmonics. Two of these angular functions come from the coupled states and one from the interaction; the integral in question is therefore a linear

combination of integrals of the form

$$\int_0^{\pi}\int_0^{2\pi}\int_0^{2\pi}(D_{\ell_i}^{m,\varkappa_i})^* D_{\lambda}^{0,\mu} D_{\ell_f}^{m,\varkappa_f}\sin\theta d\theta d\Phi d\psi = \sqrt{\frac{(2\ell_i+1)(2\lambda+1)}{8\pi^2(2\ell_f+1)}}(\ell_i\lambda-m0\,|\,\ell_f-m)(\ell_i\lambda-\varkappa_i\mu\,|\,\ell_f-\varkappa_f) \quad (3.11)$$

The formula for this integral given on the *rhs* of the above equation is well known[11] in terms of the Clebsch-Gordan (C-G) coefficients. The selections for the vanishing of this integral can therefore be deduced from those of the C-G coefficients.

Consider first Σ states ($m=0$). In this case the first C-G coefficient becomes $(\ell\ \lambda\ 00/\ell'0)$. This coefficient vanishes unless $\ell+\lambda+\ell'=$even (integer). But λ is an even integer, Eq. (3.5, therefore:

$$\ell+\ell'=\text{even}$$

This says that for Σ states only radial functions of even ℓ will be coupled together and only odd ℓ states will be coupled but there will be no intermixing. Thus for Σ states the expansion of the wave function, Eq. (3.3a), separates into two classes defined by the evenness or oddness of ℓ:

$$\Psi_0=\sum_{\ell}^{''}\sum_{\varkappa}^{''}(f_\ell^{(0,\varkappa)+}(r)D_\ell^{(0,\varkappa)+} + f_\ell^{(0,\varkappa)-}(r)D_\ell^{(0,\varkappa)-}) \quad (3.12)$$

The molecular quantum numbers $\pm$ are determined by the parity of ℓ which is the eigenvalue of $i\,\sigma_{xy}$. This then constitutes the exception to the noncommutivity of σ_{xy} with M_z which was noted in Eq. (2.19).

The quantum lables of the Σ states are compiled in the entries of the following simple array:

$\varkappa$ \ ℓ	even	odd
even	gerade, +	gerade, −
odd	ungerade, +	ungerade, −

For $m\neq 0$, the relevant C-G coefficient is not necessarily zero when $\ell+\lambda+\ell'=$odd. Thus the decoupling according to even or odd ℓ ($\pm$symmetry) does not occur, corresponding to the noncommutivity of σ_y with M_z, Eq. (2.19b). Here, however, there exists a well known degeneracy in energy with respect to $\pm m$ eigenfunctions. If the eigenfunction for $+m$ is given by (3.3a) and that for $-m$ is given by

$$\Psi_{-m}=\sum_{\ell=|m|}\sum_{\varkappa}^{''}(f_\ell^{(-m)\varkappa)+}D_\ell^{(-m,\varkappa)+} + f_\ell^{(-m,\varkappa)-}D_\ell^{(-m,\varkappa)-}), \quad (3.3b)$$

the obvious question is what is the relation of the $f_\ell^{(m,\varkappa)\pm}$ to $f_\ell^{(-m,\varkappa)\pm}$. The answer to this question still resides in the same C-G coefficient, in this case in the symmetry property[11]:

$$(\ell\lambda m0\,|\,\ell'm)=(-1)^{\ell+\lambda+\ell'}(\ell\lambda\text{--}m0\,|\,\ell'-m) \quad (3.13)$$

Since $\lambda=$ even, we see the sign of the coupling of an ℓ to an ℓ' state is reversed for Ψ_{-m} relative to what it is for Ψ_m if $\ell+\ell'=$odd (i.e., ℓ and ℓ' have opposite parity). If the radial functions change sign in the same way, then the equations (and hence the eigenvalues) will in fact not change. i.e., we must have

$$f_\ell^{(-m,\varkappa)\pm}=(-1)^l f_\ell^{(m,\varkappa)\pm} \quad (3.14a)$$

This relation could be altered by a minus sign; the relation

$$f_\ell^{(-m,\varkappa)\pm}=(-1)^{\ell+m} f_\ell^{(m,\varkappa)\pm} \quad (3.14b)$$

is equally acceptable and has the advantage that the first radial function that appears in the expansion of Ψ_m will be the one which doesn't change sign when used in Ψ_{-m}.

In all cases we have by virtue of the very simple exchange property of $D_\ell^{(m,\varkappa)\pm}$, Eq. (3.2), that the complete spatial wave function Ψ_m will be symmetric (upper sign) or antisymmetric (lower sign) if the radial functions have the exchange property

$$f_\ell^{(m,\varkappa)+}\left(r_2,\ r_1,\begin{Bmatrix}\theta_{12}\\ r_{12}\end{Bmatrix}\right) = \pm(-1)^\ell f_\ell^{(m,\varkappa)+}\left(r_1,\ r_2,\begin{Bmatrix}\theta_{12}\\ r_{12}\end{Bmatrix}\right) \quad (3.15a)$$

and

$$f_\ell^{(m,\varkappa)-}\left(r_2,\ r_1,\begin{Bmatrix}\theta_{12}\\ r_{12}\end{Bmatrix}\right) = \pm(-1)^{\ell+1} f_\ell^{(m,\varkappa)-}\left(r_1,\ r_2,\begin{Bmatrix}\theta_{12}\\ r_{12}\end{Bmatrix}\right) \tag{3.15b}$$

These properties essentially halve the independent variable space over which the equations need to be integrated[7].

IV. RADIAL EQUATIONS

The foregoing discussion together with the knowledge of the kinetic energy operator[7] essentially allows us to write down the "radial" equations for arbitrary m. Specifically substituting (3.12) or (3.3a) into the Schrödinger equation, multiplying on the left by $D_\ell^{(m,\varkappa)*}$ and integrating over the Euler angles, one obtains

$$\left[L_{\theta 12}+\frac{2m}{\hbar^2}\left(E-\frac{2}{r_{12}}\right)\right]f_\ell^{(m,\varkappa)+}(r)-\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\left[\left\{\frac{\ell(\ell+1)-\varkappa^2}{2\sin^2\theta_{12}}+\frac{\varkappa^2}{4}-\frac{\cot\theta_{12}}{2\sin\theta_{12}}\delta_{1\varkappa}(1-2A_\varkappa^\ell)\right\}f_\ell^{(m,\varkappa)+}(r)\right.$$
$$+(\varkappa+1)(\varkappa+2)\frac{\cot\theta_{12}}{\sin\theta_{12}}B_{\ell,\varkappa+2}f_\ell^{(m,\varkappa+2)+}(r)+\frac{\cot\theta_{12}}{4\sin\theta_{12}}\frac{(1+3\delta_{0,\varkappa-2})}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1))}\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{\beta_{\ell\varkappa}}f_\ell^{(m,\varkappa-2)+}(r)\Big]$$
$$+\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)\left[\varkappa\left(\frac{\cos\theta_{12}}{2\sin(\frac{1}{2}\theta_{12})}-\cot\theta_{12}-\frac{1}{2\sin\theta_{12}}\right)f_\ell^{(m,\varkappa)-}(r)-\varkappa\frac{\partial f_\ell^{(m,\varkappa)-}(r)}{\partial\theta_{12}}\right.$$
$$-\frac{\delta_{1\varkappa}(1-2A_\varkappa^\ell)}{2\sin\theta_{12}}f_\ell^{(m,\varkappa)-}+\frac{(\varkappa+1)(\varkappa+2)}{\sin\theta_{12}}\beta_{\ell,\varkappa+2}f_\ell^{(m,\varkappa+2)-}(r)$$
$$\left.-\frac{1}{4\sin\theta_{12}}\frac{(1-\delta_{0,\varkappa-2})}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1))}\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{\beta_{\ell\varkappa}}f_\ell^{(m,\varkappa-2)-}(r)\right]$$
$$+\frac{2m}{\hbar^2}4\pi\sum_{\gamma_f}\sum_{j=1}^{2}\sum_{\gamma_\lambda(\text{even})}^{\prime\prime}g_\lambda\left(\frac{1}{2}R_{AB},\ r_j\right)(1-2\delta_{2j}\delta_{\epsilon_\lambda -})\alpha_\lambda^{\mu\epsilon_\lambda}(\theta_{12})I_m(\ell\varkappa+,\ \gamma_\lambda,\ \gamma_f)f_\ell^{(m,\varkappa_f)\epsilon_f}(r)=0 \tag{4.1a}$$

$$\left[L_{\theta 12}+\frac{2m}{\hbar^2}\left(E-\frac{2}{r_{12}}\right)\right]f_\ell^{(m,\varkappa)-}(r)-\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\left[\left\{\frac{\ell(\ell+1)-\varkappa^2}{2\sin^2\theta_{12}}+\frac{\varkappa^2}{4}+\frac{\cot\theta_{12}}{2\sin\theta_{12}}\delta_{1\varkappa}(1-2A_\varkappa^\ell)\right\}f_\ell^{(m,\varkappa)-}(r)\right.$$
$$+\frac{\cot\theta_{12}}{\sin\theta_{12}}(1-\delta_{2,\varkappa+2})(\varkappa+1)(\varkappa+2)B_{\ell,\varkappa+2}f_\ell^{(m,\varkappa+2)-}(r)+\frac{\cot\theta_{12}}{4\sin\theta_{12}}(1-\delta_{0,\varkappa-2})\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{\beta_{\ell\varkappa}}f_\ell^{(m,\varkappa-2)-}(r)\Big]$$
$$+\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)\left[-\varkappa\left(\frac{\cos\theta_{12}}{2\sin\left(\frac{\theta_{12}}{2}\right)}-\cot\theta_{12}-\frac{1}{2\sin\theta_{12}}\right)f_\ell^{(m,\varkappa)+}(r)+\varkappa\frac{\partial f_\ell^{(m,\varkappa)+}(r)}{\partial\theta_{12}}-\frac{\delta_{1\varkappa}(1-2A_\varkappa^\ell)}{2\sin\theta_{12}}f_\ell^{(m,\varkappa)+}(r)\right.$$
$$\left.-\frac{(1-\delta_{2,\varkappa+2})(\varkappa+1)(\varkappa+2)}{\sin\theta_{12}}B_{\ell,\varkappa+2}f_\ell^{(m,\varkappa+2)+}(r)+\frac{1}{4\sin\theta_{12}}\frac{(1+3\delta_{0,\varkappa-2})}{(1+\delta_{0,\varkappa-2}(\sqrt{2}-1))}\frac{A_{\varkappa-2}^\ell A_{\varkappa-1}^\ell}{\beta_{\ell\varkappa}}f_\ell^{(m,\varkappa-2)+}(r)\right]$$
$$+\frac{2m}{\hbar^2}4\pi\sum_{\gamma_f}\sum_{j=1}^{2}\sum_{\lambda_\gamma(\text{even})}^{\prime\prime}g_\lambda\left(\frac{1}{2}R_{AB},\ r_j\right)(1-2\delta_{2j}\delta_{\epsilon_\lambda -})\alpha_\lambda^{\mu\epsilon_\lambda}(\theta_{12})I_m(\ell\varkappa-,\ \gamma_\lambda,\ \gamma_f)f_\ell^{(m,\varkappa_f)\epsilon_f}(r)=0 \tag{4.1b}$$

The index γ in the above formulae represents the triple indices ℓ, $\varkappa$, ϵ. For example

$$\gamma_f=\ell_f,\ \varkappa_f,\ \epsilon_f \tag{4.2}$$

A summation with respect to this index means:

$$\sum_{\gamma_f}\equiv\sum_{\ell_f}\sum_{\varkappa_f}\sum_{\epsilon_f} \tag{4.3a}$$

and in particular

$$\sum_{\gamma_\lambda(\text{even})}^{\prime\prime}=\sum_{\lambda\,(\text{even})}^{\prime\prime}\sum_{\mu\,(\text{even})}^{\prime\prime}\sum_{\epsilon_\lambda}^{\prime\prime} \tag{4.3b}$$

ϵ is a symbol which can be + or −, so that a sum over ϵ consists of only these two terms.

Aside from these abbreviations, the radial equations have been written above in a fairly explicit

form (with a corresponding sacrifice of elegance). For an arbitrary ℓ the coupling is reasonably complicated although as we shall see in the next section for ℓ small the equations simplify greatly. The nature of the coupling is nevertheless contained in the equations themselves via the selection rules for the various coefficients. Regarding the effect of the kinetic energy coupling, a verbal description of the nature of that coupling is given in reference 7.

The equations in the form given here are appropriate to the radial coordinates r_1, r_2, θ_{12} with

$$L_{\theta_{12}}=\frac{1}{r_1}\frac{\partial^2}{\partial r_1{}^2}r_1+\frac{1}{r_2}\frac{\partial^2}{\partial r_2{}^2}r_2 +\left(\frac{1}{r_1{}^2}+\frac{1}{r_2{}^2}\right)\frac{1}{\sin\theta_{12}}\frac{\partial}{\partial\theta_{12}}\left(\sin\theta_{12}\frac{\partial}{\partial\theta_{12}}\right) \tag{4.4}$$

Also the fact that one has two functions (and hence two equations) for a given ℓ and $\varkappa$ indicates that the functions are in symmetric form. Hence the solutions may be confined to the region, say, $r_1>r_2$ with the boundary condition

$$\left[\frac{\partial f_\ell^{(m,\varkappa)\epsilon_1}}{\partial\eta}\right]_{r_1=r_2}=0 \tag{4.5a}$$

and

$$[f_\ell^{(m,\varkappa)\epsilon_2}]_{r_1=r_2}=0 \tag{4.5b}$$

where $\partial/\partial n$ is the normal derivative and ϵ_1 and ϵ_2 are the two choices of $+$ and $-$, being so selected according to (3.15) to give either the space symmetric (singlet) or the space antisymmetric (triplet) solution of the Schrödinger equation.

The coupling due to the potential energy is given in the last term of each of the radial equations. It can be seen that it alone is m dependent, and coupling coefficients I_m are:

$$I_m(\gamma,\gamma_\lambda,\gamma_{\ell'})=\frac{4\pi}{(2\lambda+1)^{\frac{1}{2}}}\int_0^{\pi}\int_0^{2\pi}\int_0^{2\pi}(D_\ell^{(m,\varkappa)\epsilon})^*D_\lambda^{(0,\mu)\epsilon_\lambda}D_{\ell'}^{(m,\varkappa')\epsilon'}\sin\theta d\theta d\Phi d\psi \tag{4.6a}$$

This quadrature, which is a linear combination of integrals of the form (3.11), yields:

$$I_m(\gamma,\gamma_\lambda,\gamma_{\ell'})=\frac{[(1+\delta_{0m}\delta_{0\varkappa}(\sqrt{2}-1))(1+\delta_{0\mu}(\sqrt{2}-1))(1+\delta_{0m}\delta_{0\varkappa'}(\sqrt{2}-1))]^{-1}}{\{\epsilon\}^*\{\epsilon_\lambda\}\{\epsilon_{\ell'}\}}$$
$$\sqrt{\frac{2(2\ell+1)}{(2\ell'+1)}}(1+\epsilon\epsilon_\lambda\epsilon_{\ell'}(-1)^{\ell+\ell'})(\ell\lambda-m0|\ell'\varkappa')[(\ell\lambda-\varkappa\mu|\ell'-\varkappa')+\epsilon_{\ell'}(\ell\lambda-\varkappa\mu|\ell'\varkappa')$$
$$+\epsilon_\lambda(\ell\lambda-\varkappa-\mu|\ell'-\varkappa')+\epsilon(\ell\lambda\varkappa\mu|\ell'-\varkappa')] \tag{4.6b}$$

Here the ϵ's are to be thought as the numbers ±1, and

$$\{\epsilon_\sigma\}=\{(1+\epsilon_\sigma)^{\frac{1}{2}}+i(1-\epsilon_\sigma)^{\frac{1}{2}}\} \tag{4.7}$$

These coefficients are subject to many restrictions if they are not to vanish. Also only one of the C-G coefficients in the final square bracket will not vanish when any of these indices are non-zero. (When $\varkappa=\mu=0$ all four terms contribute.)

V. TRUNCATION AND THE Σ_g^+ STATE OF H_2

The coupling in ℓ' and λ contained in the potential terms in principle includes a doubly infinite sum. If one truncates the sum in ℓ' at $\ell'=L$, then only a finite number of terms in the λ sum survive. The inclusion of all λ terms for a given L, then constitutes a given order of approximation in the context of the partial wave theory.

It is now our assertion that the solutions of successive approximation converges usefully. By this we mean two things; first that for a given L the $f_\ell'r)^{(m,\varkappa)\epsilon}$ from $\ell=\ell_i$ to $\ell=L$ get smaller in some sense. Secondly in going from one L to the next the $f_\ell(r)^{(m,\varkappa)\epsilon}$ for a given set of indices $(\ell,\varkappa,\epsilon)$ does not change much.

In view of the complicated nature of these equations this would be a very difficult thing to prove rigorously. The heuristic argument, however, follows that for the one-electron diatomic molecule[1]. Namely, in the centrifugal terms, which are those multiplied by $(r_1^{-2}+r_2^{-2})$ in the above

equations, there is a repulsive term proportional to $\ell(\ell+1)$ which tends to diminish the amplitude of each succeeding $f_\ell(r)$ component in the region of interaction.

Since, however, there are considerably more terms than this $\ell(\ell+1)$ term, the cogency of this argument is considerably more obscure than its one-electron counterpart[1] and in any event it is known from at least one atomic example that there can be resonance regions in which an additional ℓ component can in fact dominate its predecessors.[12]

We shall therefore examine one case in which there exist numerical results. Consider the Σ_g^+ states of H_2. In zeroth order ($L=0$) these states which include the ground state, are governed by the equation ($z=1$):

$$\left[\frac{1}{r_1}\frac{\partial^2}{\partial r_1^2}r_1+\frac{1}{r_2}\frac{\partial^2}{\partial r_2^2}r_2+\frac{1}{\sin\theta_{12}}\frac{\partial}{\partial\theta_{12}}\left(\sin\theta_{12}\frac{\partial}{\partial\theta_{12}}\right)+\frac{2m}{\hbar^2}\left(E-2/r_{12}+4g_0\left(\frac{1}{2}R_{AB},r_1\right)+4g_0\left(\frac{1}{2}R_{AB},r_2\right)\right)\right]f(r_1,\,r_2,\,\theta_{12})=0 \quad (5.1)$$

This is a three-dimensional partial differential equation for a single function ($f\equiv f_0^{(0,0)+}$). The expression in square brackets is manifestly invariant with respect to exchange, $r_1\rightleftarrows r_2$, and the singlet and triplet solutions are distinguished by the boundary conditions:

$$\left[\frac{\partial}{\partial n}f(r_1,\,r_2,\,\theta_{12})\right]_{r_1=r_2}=0 \qquad \text{singlet} \quad (5.2a)$$

$$[f(r_1,\,r_2,\,\theta_{12}]_{r_1=r_2}=0 \qquad \text{triplet} \quad (5.2b)$$

Below we shall outline a systematic approximation procedure for solving this equation. For completeness, however, we shall give this equation with r_1, r_2, and r_{12} as the independent variables:

$$\left[\frac{1}{r_1}\frac{\partial^2}{\partial r_1^2}r_1+\frac{1}{r_2}\frac{\partial^2}{\partial r_2^2}r_2+\frac{2}{r_{12}}\frac{\partial^2}{\partial r_{12}^2}r_{12}+\frac{r_1^2+r_{12}^2-r_2^2}{r_1r_2}\frac{\partial^2}{\partial r_1\partial r_{12}}+\frac{r_2^2+r_{12}^2-r_1^2}{r_1r_2}\frac{\partial^2}{\partial r_2\partial r_{12}}+\frac{2m}{\hbar^2}\left(E-2|r_{12}+2g_0\left(\frac{1}{2}R_{AB},r_1\right)+2g_0\left(\frac{1}{2}R_{AB},r_2\right)\right)\right]f(r_1,\,r_2,\,\theta_{12})=0 \quad (5.3)$$

This form of the zeroth order equation is appropriate for solution in terms of Hylleraas-type expansions. In reference 7 other ways of writing these equations are given, involving in particular asymmetric functions $F\left(r_1,\,r_2,\begin{Bmatrix}\theta_{12}\\ r_{12}\end{Bmatrix}\right)$.

A methodical way of solving the θ_{12} equation is to make a *relative* partial wave expansion of f:

$$f(r_1,\,r_2,\,\theta_{12})=\sum_{n=0}^{\infty}\frac{1}{r_1r_2}\Phi_n(r_1r_2)P_n(\theta_{12}) \quad (5.4)$$

The Legendre polynomials $P_n(\theta_{12})$ are selected because they are the eigenfunctions of the θ_{12} derivative term in (5.1). Also the interelectron repulsion $1/r_{12}$ has a well known expansion in terms of $P_n(\theta_{12})$, so that one can easily derive an infinite set of two dimensional partial differential equation, which are essentially those that already have been derived in the case of the scattering of electrons from atomic hydrogen[13]. One can then truncate the sum at $n=N$ and expect convergence in N in a completely analogously way as one expects convergence in L in the partial wave theory as a whole.

Alternatively one can expand the total wave function in the form (considering here only the singlet case):

$$\Psi(1,2)=\sum_{n_1n_2}\sum_{\nu_1\nu_2}\sum_{\mu}C_{n_1n_2\nu_1\nu_2\mu}[R_{n_1\nu_1}(r_1)r_2^{\nu_2}\cdots)Y_{\nu_1\mu}^{n}(\Omega_1)Y_{\nu_2\mu}(\Omega_2)+(1\rightleftarrows 2)] \quad (5.5)$$

If one restricts this sum to $\nu_1=\nu_2$ and all values of μ for each ν_1, then this expansion is equivalent

to (5.4). A detailed investigation of the ground Σ_g^+ state of H_2 using (5.5) has been carried out by Hagstrum and Shull[14]. They have in fact relaxed the condition $\nu_1 = \nu_2$, so that what they approximate in those cases is a hybrid of approximations within the partial wave theory. They have, however, examined the $\nu_1 = \nu_2 = 0$ (spherically averaged) approximation. This is equivalent to including one term in (5.4) within the $L = 0$ (zeroth order) approximation. They obtain $E = -2.0894$ ryd. (1 ryd. = 13.6 eV) at $R_{AB} = 1.4$ Bohr radius. It is quite clear that the inclusion of all $\nu_1 = \nu_2$ and with their associated μ terms will lower this energy to below -2.1 ryd. Such a value is to be compared to $E = -2.34\ 884$ ryd., the very accurate nonrelativistic value (including the nuclear repulsion) of Kolos and Roothan[15]. The differences between these numbers, less than 0.2 ryd., is very close to the difference between the zeroth order and exact H_2^+ energies near their minimum ($R_{AB} = 2$)[1]. This is just what our heuristic argument would lead us to expect in view of the fact, this being a Σ state, that the next angular momentum, $\ell = 2$, is two units greater than the included $\ell = 0$ component of the zeroth order problem, in complete analogy with the case for the H_2^+ molecular ion[1]. In addition for the exact solutions of the partial wave approximations the analogy carries through regarding the upper boundedness of the energies of the ground and excited state solutions and of their mutual orthogonality[1].

HYPERFINE STRUCTURE IN THE MICROWAVE SPECTRUM OF NH_2D*

P. THADDEUS,† AND L. C. KRISHER‡ AND P. CAHILL‖

Hyperfine structure in the $3_{13} \rightarrow 3_{03}$ rotation-inversion transition of deuterated ammonia NH_2D at 18 807.7 Mc/sec has been studied with a beam maser microwave spectrometer giving a linewidth of 7 kc/sec. All details of the observed hyperfine structure have been accounted for in terms of the various quadrupole, spin-rotation, and spin-spin interactions of the four coupling nuclei. The hyperfine coupling constants which have been determined with the aid of a digital electronic computer are, for the 3_{13} state: $(eq_zQ)_D = -62.5 \pm 1.0$ kc/sec, $C_D = -2.7 \pm 0.3$ kc/sec, $C_H = -13.6 \pm 0.5$ kc/sec; and for the 3_{03} state: $(eq_zQ)_D = -73.9 \pm 1.0$ kc/sec, $C_D = -2.7 \pm 0.3$ kc/sec, $C_H = -12.3 \pm 0.5$ kc/sec. On the assumption that the electric field at the deuteron is cylindrically symmetric about the N–D bond direction ξ, we find that $(eV_{\xi\xi}Q)_D = 282 \pm 12$ kc/sec, or $V_{\xi\xi} = 1.38 \pm 0.06 \times 10^{15}$ statV/cm², where $V_{\xi\xi}$ is the second derivative of the electrostatic potential along ξ.

I. INTRODUCTION

In a previous paper,[1] which we refer to as I, the results were reported of a study with a beam-maser microwave spectrometer of hyperfine structure (hfs) due to two nuclei in the rotational spectrum of the asymmetric-top molecules HDO, HDS, CH_2O, and CHDO. Linewidths in the centimeter region of about 5 kc/sec were obtained, allowing an investigation of deuteron quadrupole, spin-rotation, and spin-spin hyperfine interactions. The K-type doublet transitions of such light asymmetric-top rotors are especially favorable for beam-maser study, since a given state is well populated, and electrostatic state selection is not usually inhibited by other nearby rotational states.

In the present paper we report the observation with the same beam-maser spectrometer [2] of hfs in the $3_{13} \rightarrow 3_{03}$ rotation-inversion transition of the ammonia molecule NH_2D. Hfs in this molecule is due to four nuclei, and is so complex that it was not found possible to interpret the spectrum by means of calculations done on a desk calculator alone. With an electronic computer and automatic curve plotter, however, we have succeeded in determining the hyperfine coupling constants to the same precision obtained for HDO, HDS, CH_2O, and CHDO.

II. THEORY

The rotation-inversion spectrum of the partially deuterated ammonias has been extensively studied by Weiss and Strandberg[3] with a Stark-modulated microwave spectrometer. Successive deuteration progressively lowers the ammonia inversion frequency from about 24 000 Mc/sec for NH_3 to about 12 000, 5000, and 1500 Mc/sec for NH_2D, NHD_2, and ND_3, respectively. *Partial* deuteration in addition destroys the molecular symmetry (Fig. 1), and splits the degenerate symmetric-top levels into the well-known K-type doublets. The doublet splitting is comparable to the inversion frequency, and varies considerably from doublet to doublet. Therefore, while the strong lines of the NH_3 inversion spectrum are clustered around 24 000 Mc/sec, the rotation-inversion spectra of the partially deuterated ammonias are scattered over the entire microwave region.

The $(3_{13}, 3_{03})$ K-type doublet of NH_2D, for example, is shown in Fig. 2. The allowed transitions at 18 807 and 43 042 Mc/sec correspond to

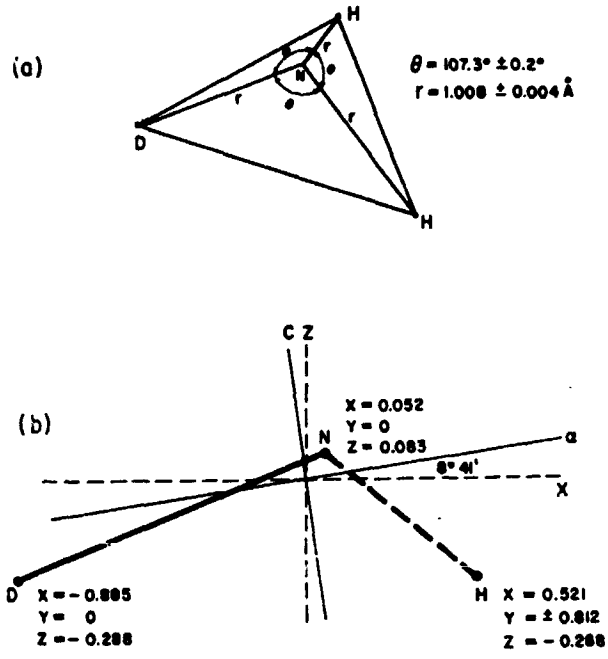

FIGURE 1.—Geometry of the NH_2D molecule. (a) shows the bond angle and length taken from Ref. 3. (b) shows how deuteration rotates the principal axes of inertia away from the symmetry axis. The xyz frame is centered on the center of mass, with Z parallel to the axis of charge symmetry.

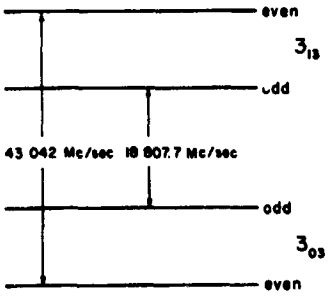

FIGURE 2.—The $(3_{13}, 3_{03})$ K-Type doublet of NH_2D split by the inversion frequency showing the allowed microwave transitions. The symmetry of the wave function on exchange of the protons is indicated as even (e) or odd (o).

the NH_3, $J=3$, $K=3$ inversion transition at 23 870 Mc/sec—the strongest absorption line in the centimeter region of any molecule, and the one with which Gordon, Zeiger, and Townes[4] first obtained maser oscillation in 1954. The 18 807-Mc/sec line in absorption is the strongest NH_2D transition at X or K band, and was selected for study since it was accessible to the microwave apparatus used in I.

All four nuclei in NH_2D contribute to the hfs. An estimate of the hierachy of the hyperfine interactions can be made from the many previous studies of NH_3,[4-6] and the measurement of the deuteron quadrupole coupling constant by Herrman,[7] who studied with a Stark-modulated spectrometer the inversion spectrum of ND_3 near 1500 Mc/sec. The quadrupole interaction of the nitrogen in NH_2D is expected to be over an order of magnitude larger than the quadrupole interaction of the deuteron, or the spin-rotation $(\mathbf{I}\cdot\mathbf{J})$ interactions of the protons. The following coupling scheme was therefore used to theoretically interpret the hfs:

$$\begin{aligned}\mathbf{J}+\mathbf{I}_N&=\mathbf{F}_1,\\ \mathbf{F}_1+\mathbf{I}_D&=\mathbf{F}_2,\\ \mathbf{F}_2+\mathbf{I}_H&=\mathbf{F},\end{aligned}\qquad(1)$$

where $\mathbf{I}_H$ is the sum of the proton spins,

$$\mathbf{I}_H^{(1)}+\mathbf{I}_H^{(2)}=\mathbf{I}_H.\qquad(2)$$

Since the deuteron quadrupole and proton $\mathbf{I}\cdot\mathbf{J}$ interactions are of nearly the same strength, the order of coupling following F_1 is in fact unimportant.

The coupling scheme (2) yields an $I_H=1$ symmetric, and an $I_H=0$ antisymmetric spin state. In Ref. 3 it is shown that both of the rotation-inversion states of the 18 807-Mc/sec transition are antisymmetric on exchange of the protons, and therefore for these states only the $I_H=1$ spin state exists. The two protons thus couple to the rest of the molecule like a single spin 1 nucleus, and the hyperfine Hamiltonian in the notation of I can be written in the symmetrical form

$$\mathcal{H}=\frac{(eq_JQ)_N}{2I_N(2I_N-1)\,J(2J-1)}\left[3(\mathbf{I}_N\cdot\mathbf{J})^2+\frac{3}{2}(\mathbf{I}_N\cdot\mathbf{J})-\mathbf{I}_N^2\mathbf{J}^2\right]+C_N(\mathbf{I}_N\cdot\mathbf{J})\qquad(3a)$$

$$+\frac{(eq_JQ)_D}{2I_D(2I_D-1)\,J(2J-1)}\left[3(\mathbf{I}_D\cdot\mathbf{J})^2+\frac{3}{2}(\mathbf{I}_D\cdot\mathbf{J})-\mathbf{I}_D^2\mathbf{J}^2\right]+C_D(\mathbf{I}_D\cdot\mathbf{J})\qquad(3b)$$

$$+\frac{g_H^2\mu_N^2\,(d_J)_{HH}}{2I_H(2I_H-1)J(2J-1)}\left[3(\mathbf{I}_H\cdot\mathbf{J})^2+\frac{3}{2}(\mathbf{I}_H\cdot\mathbf{J})-\mathbf{I}_H^2\mathbf{J}^2\right]+C_H(\mathbf{I}_H\cdot\mathbf{J})\qquad(3c)$$

$$+\frac{g_H g_D \mu_N^2 (d_J)_{HD}}{J(2J-1)}\left\{\frac{3}{2}[(\mathbf{I}_H\cdot\mathbf{J})(\mathbf{I}_D\cdot\mathbf{J})+(\mathbf{I}_D\cdot\mathbf{J})(\mathbf{I}_H\cdot\mathbf{J})]-(\mathbf{I}_H\cdot\mathbf{I}_D)\mathbf{J}^2\right\} \quad (3d)$$

$$+\frac{g_H g_N \mu_N^2 (d_J)_{HN}}{J(2J-1)}\left\{\frac{3}{2}[(\mathbf{I}_H\cdot\mathbf{J})(\mathbf{I}_N\cdot\mathbf{J})+(\mathbf{I}_N\cdot\mathbf{J})(\mathbf{I}_H\cdot\mathbf{J})]-(\mathbf{I}_H\cdot\mathbf{I}_N)\mathbf{J}^2\right\} \quad (3e)$$

$$+\frac{g_D g_N \mu_N^2 (d_J)_{DN}}{J(2J-1)}\left\{\frac{3}{2}[(\mathbf{I}_D\cdot\mathbf{J})(\mathbf{I}_N\cdot\mathbf{J})+(\mathbf{I}_N\cdot\mathbf{J})(\mathbf{I}_D\cdot\mathbf{J})]-(\mathbf{I}_D\cdot\mathbf{I}_N)\mathbf{J}^2\right\}. \quad (3f)$$

Terms (3a) are the quadrupole and spin-rotation interactions of the nitrogen, and (3b) are the same interactions for the deuteron. The coupling constants for these interactions, together with C_H of (3c), will be determined from experiment for both the 3_{13} and 3_{03} states. The coupling constants of the four spin-spin interactions of (3c), (3d), (3e), (3f), however, can be calculated to higher precisions from the geometry of Fig. 1 than they can be experimentally determined with the present resolution. The spin-spin constants calculated from Eq. (9) of I are listed in Table I. It should be noticed that the mutual spin-spin interaction of the protons has the same dependence on the coupling momenta as a quadrupole interaction.

III. EXPERIMENT

a. Sample Preparation

Since hydrogen is readily exchanged between ammonia molecules, a sample of 100 percent of the partially deuterated ammonias cannot be prepared. A maximum of $\frac{4}{9}NH_2D$ can be produced in a sample in which the ratio of protons to deuterons is 2:1. The sample used in this experiment was prepared by mixing commercial ammonia in a vacuum system with the appropriate mixture of ordinary water and heavy water, condensing the mixture out in a liquid-nitrogen trap and warming to room temperature several times to assure equilibrium. The ammonia was subsequently separated from the water by vacuum distillation.

TABLE I.—*The spin-spin constants calculated from the molecular geometry of Fig. 1.*

Nuclei	$g_A g_B \mu_N^2 (d_J)_{AB}$, kc/sec	
$A-B$	3_{13} state	3_{03} state
H–H	8.59	2.99
H–D	1.82	1.94
H–N	1.09	0.29
D–N	0.58	0.71

b. Microwave Spectrometer

The microwave spectrometer used in this work has been described in detail elsewhere.[2] Sufficient microwave power (about 1 mW) to operate the superheterodyne receiver was at first furnished by the second harmonic of a very stable Varian X–13 klystron using a Varactor doubler. Subsequently a Varian V40B klystron was used directly at 18 807 Mc/sec.

Frequency markers less than 1 kc/sec wide were obtained by mixing the output of the klystron with the appropriate harmonic of a Gertsch FM–4 frequency generator locked to the Laboratory frequency standard. The difference frequency was coaxially mixed with a tunable low-frequency oscillator, a Rohde-Schwarz XUA frequency synthesizer, and then detected with a Collins receiver. The receiver was kept at a constant frequency, and the marker frequency changed by varying the frequency of the Rohde-Schwarz synthesizer.

c. Results

The observed hfs, except for the $\Delta F_1=\pm 1$ nitrogen quadrupole satellites which are over 1 Mc/sec to either side, is shown in Fig .3. In all three traces the most intense $\Delta F_1=\Delta F_2=0$ transitions have been deliberately saturated to bring out the finer detail, and therefore appear weaker than calculated. Equation (3a) shows the three $\Delta F_1=0$ transitions, and the theoretical structure calculated only on the basis of the nitrogen[6] and deuteron[7] quadrupole coupling. Deuteration, as expected, by destroying the molecular symmetry spreads these transitions into a wide triplet, and the much smaller deuteron quadrupole interaction adds even further structure. It is apparent from the additional structure seen in the more magnified traces of (3b) and (3c), however, that the magnetic

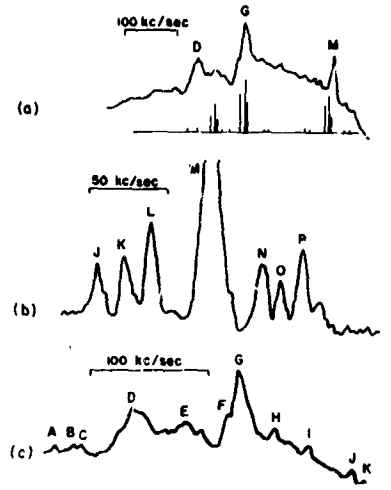

FIGURE 3.—Oscilloscope traces of the observed hfs. (a) shows the three $\Delta F_1=0$ transitions against the background of the maser cavity response, with, for comparison, the theoretical structure due to the nitrogen and deuteron quadrupole interactions. (b) shows the $F_1=3\rightarrow3$ transition in detail. (c) shows the $F_1=4\rightarrow4$ and $2\rightarrow2$ transitions. The letters indicates the features whose frequency was accurately measured. The vertical scale varies from trace to trace.

interactions of the protons are important for a detailed understanding of the hfs.

The frequencies of the prominant features of the hfs lettered in Fig. 3 are listed in Table II. All frequencies are given relative to the strong central line M of the $F_1=3\rightarrow3$ transition.

IV. HYPERFINE CONSTANTS

All the matrix elements of the Hamiltonian of Eq. (3) and the intensity matrix were calculated from Eqs. (22), (23), (24), and (31) of I, using tabulated values of the $6j$ coefficients.[8] For the spin-spin interactions, after the various 27×27 (highly reducible) operators $\mathbf{I}_i\cdot\mathbf{I}_j$ and $\mathbf{I}_i\cdot\mathbf{J}$ were calculated, the indicated matrix products and summations of Egs. (3d), (3e), (3f) were performed with an IBM 7094 digital computer.

Since the nitrogen quadrupole interaction is much larger than the deuteron quadrupole interaction, terms in the Hamiltonian off-diagonal in F_1, which contribute diagonal frequencies (energies) somewhat smaller than $(eq_JQ)_D{}^2/(eq_JQ)_N \approx 2$ kc/sec, can be ignored. This leads to the considerable simplification that any one of the three $\Delta F_1=0$ transitions can be analyzed separately.

TABLE II.—*Measured frequencies relative to M of the features of the hfs identified in Figs. 3 and 5. The uncertainties are estimated to be 1 kc/sec. The intervals calculated on the basis of the best-fit constants of Table 3 are also listed.*

Feature	Observed frequency (kc/sec)	Calculated frequency (kc/sec)
A	−344.6	−345.7
B	−318.0	−318.9
C	−295.7	−294.3
D	−268.1	−2[illegible]1
E	−238.3	−236.1
F	−205.9	−204.9
G	−195.1	−195.1
H	−162.5	−160.1
I	−125.7	−122.9
J	−70.0	−69.4
K	−49.6	−49.4
L	−34.2	−35.0
M	0.0	0.0
N	35.3	36.0
O	48.7	50.2
P	61.2	62.4

Accordingly, a machine program was written for the 7094 computer that for a given set of coupling constants calculated the hfs for a given one of the $\Delta F_1=0$ transitions. A Gaussian lineshape was assumed. The results were plotted out directly with a General Dynamics SC 4020 plotter to allow direct comparison with the observed hfs. A typical plot of the $F_1=3\rightarrow3$ transition, which required less than 1 min of machine time, is shown in Fig. 4. Figure 3 shows that the structure of this transition is more highly resolved than that of the overlapping $F_1=4\rightarrow4$ and $2\rightarrow2$ transitions. The coupling constants were therefore determined from this transition alone, the other two being used only as a check.

Since in practice the six coupling constants which determine the hfs within one of the $\Delta F_1=0$ transitions could not all be varied, it was important to use the symmetry of the molecule and the results of previous work to reduce the number of independent constants. It was therefore at first assumed that the electric field at the deuteron is cylindrically symmetric along the D–N bond direction ξ, and the coupling constant along the

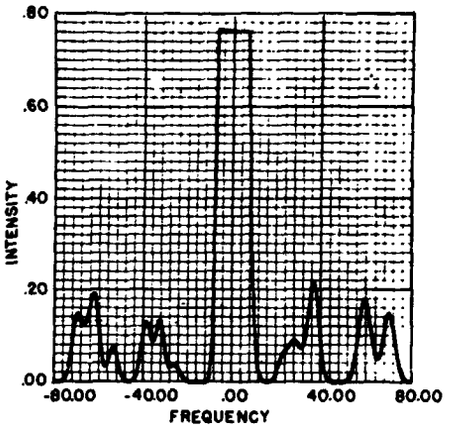

FIGURE 4.—Direct plotter output for the initial theoretical estimate of the $F_1=3\rightarrow3$ hfs.

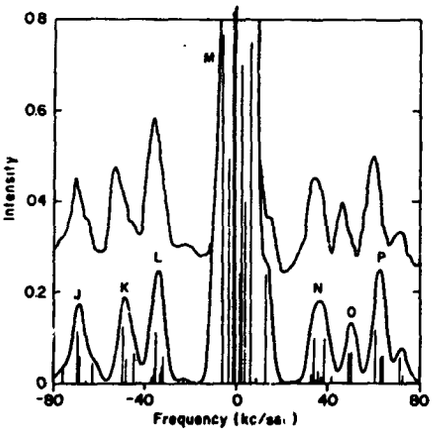

FIGURE 5.—Theoretical spectrum of the $F_1=3\rightarrow3$ transition, with Figure 3(b) traced in to show the close agreement with observation. The hump on the right side of the main line is weaker than calculated due to power saturation. (see text).

bond, $(eV_{\xi\xi}Q)_D$ was taken from the work of Herrman on ND_3 to be 200 kc/sec. On this basis $(eq_JQ)_D$ is calculated to be -42.6 kc/sec for the 3_{13} state and -52.9 kc/sec for the 3_{03} state.

Moreover, since the c axis is only rotated some 8° from the electronic symmetry axis, the magnetic field at the protons is expected to be nearly equal to that at the deuteron, so it was assumed that

$$C_D=(g_D/g_H)C_H=0.18\ C_H.$$

It was further assumed that

$$C_H(3_{13})=C_H(3_{03})=-18.8\ \text{kc/sec},$$

the value found for the (3, 3) state of NH_3 by Gordon.[6] The hfs calculated on these assumptions is shown in Fig. 4. It is seen to fit the observed $F_1=3\rightarrow3$ transition rather poorly.

By increasing $(eV_{\xi\xi}Q)_D$ and decreasing C_H a much better fit was soon found. Close agreement with experiment, however, was arrived at only after varying the hyperfine constants independently by slight amounts in either state. The theoretical best-fit $F_1=3\rightarrow3$ transition is shown in Fig. 5—a tracing of the plotter output with the 40 odd significant lines drawn in. All observed features were fit to within 3 kc/sec, and the well-resolved details of the $F_1=3\rightarrow3$ transition were fit to within 1.5 kc/sec. The best-fit full line-width at half maximum was found to be 7 kc/sec.

Taking the six constants found from the 3→3 transition, the hfs of the $F_1=4\rightarrow4$ and $2\rightarrow2$ transitions was calculated, and was found to reproduce all the features of the observed spectrum. Finally, from the intervals D and G (Table II) between the main peaks of the three $\Delta F_1=0$ transitions, it was possible to determine the difference between the nitrogen coupling constants for the 3_{13} and 3_{03} states. No attempt was made to analyze the nitrogen quadrupole satellites, which would have given the individual nitrogen constants, since the signal-to-noise ratio for these transitions was low. All the hyperfine constants found are listed in Table III, and the three calculated $\Delta F_1=0$ transitions are shown in Fig. 6.

V. FIELD GRADIENT AT THE DEUTERON

From the measured value of $(eq_JQ)_D$ in both the 3_{13} and 3_{03} states, the coupling constant $(eV_{\xi\xi}Q)_D$ along the D–N bond direction ξ, and the asymmetry parameter η may be calculated. It is found that

$$(eV_{\xi\xi}Q)_D=282\pm12\ \text{kc/sec},$$

TABLE III.—*The best-fit hyperfine coupling constants for the deuteron and the protons. Uncertainties are estimated. In addition, the nitrogen coupling constants in the 3_{13} minus those in the 3_{03} states are found to be: $\Delta(eq_JQ)_N=-197.3\pm0.6$ kc/sec, and $\Delta C_N=0.3\pm0.2$ kc/sec.*

State	$(eq_JQ)_D$ (kc/sec)	C_D (kc/sec)	C_H (kc/sec)
3_{13}	-62.5 ± 1.0	-2.7 ± 0.3	-13.6 ± 0.5
3_{03}	-73.9 ± 1.0	-2.7 ± 0.3	-12.3 ± 0.5

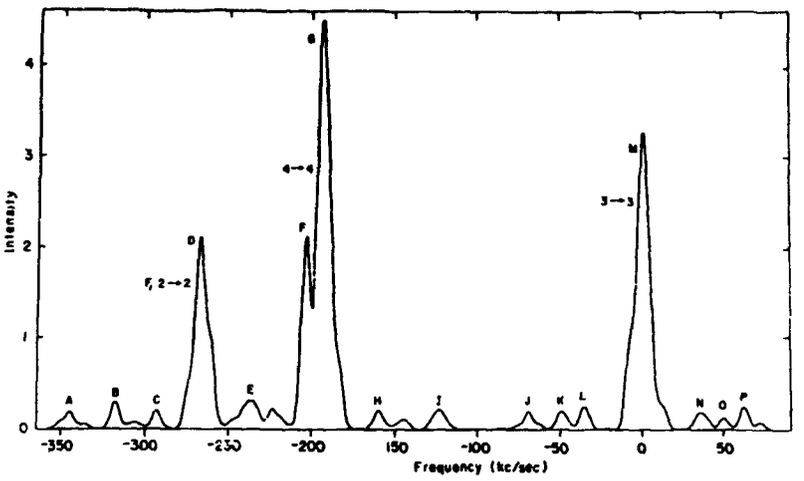

FIGURE 6.—Theoretical spectrum of all the $\Delta F_1 = 0$ transitions.

somewhat higher than the value 200 ± 20 kc/sec found by Herrman[7] from his study of ND_3. Taking the quadrupole moment of the deuteron to be[9] 2.82×10^{-27} cm^2, this gives for the second derivative of the electrostatic potential along the bond at the deuteron

$$V_{\xi\xi} = 1.38 \pm 0.06 \times 10^{15} \text{ statV/cm}^2,$$

comparable to the values found for the deuteron in HDO, HDS, and CHDO.[1]

If the asymmetry parameter is defined as

$$\eta = (V_{\xi\xi} - V_{\chi\chi})/V_{\xi\xi},$$

where ξ is parallel to the b axis, and χ lies in that plane of molecular symmetry, it is calculated that

$$\eta \approx 0.05 \pm 0.06.$$

It may therefore be concluded that to within experimental uncertainty the electric field at the deuteron is cylindrically symmetric about the D–N bond.

VI. DISCUSSION

A word should be said concerning the most effective plan of attack on the hfs of molecules as complex as NH_2D. The presence of equivalent nuclei implies that the structure of certain states will be much simpler than that of others. Both rotation-inversion states, for example, of the high-frequency $3_{13} \rightarrow 3_{03}$ transition of NH_2D at 43 042 Mc/sec are even on exchange of the protons (Fig. 2), which therefore have a total spin $I_H = 0$, and do not contribute to the hfs. Qualitatively, the structure is then expected to resemble the simple theoretical spectrum shown in Fig. 3(a), from which the deuteron quadrupole and spin-rotation constants can be easily and precisely determined. In the present case, it is clear that prior precise knowledge of the deuteron constants would have considerably simplified the analysis of the 18 807-Mc/sec transition, and that in general in a study of NH_2D and similar molecules, it is most reasonable to first study states which are even on exchange of the protons (for equivalent deuterons, the converse is true).

The frequency range of the available microwave apparatus did not permit this procedure in the present case. However, the necessity to interpret a very complex hyperfine spectrum has led to the development of electronic data-processing programs that should be adequate for the majority of the transitions in the deuterated ammonias, and indicates that a number of other molecules with three and four spins can now be profitably studied.

Further experimental investigations of the deuterated ammonias and other molecules are now in progress in this Laboratory, with emphasis on attaining higher frequencies. In particular, we are interested in finding for NH_2D all three of the diagonal elements M_{gg} of the tensor that determines the spin–rotation constants in the rigidrotor approximation,[1] or in observing any departures from the theory based on this approximation, such as have been observed in HDO.[1,10]

ACKNOWLEDGMENTS

We are indebted to the staff of the Radiation Laboratory for support and assistance given during the course of this work. H. Lecar and E. Ballik aided in the taking of data during the initial phase of the experiment, and E. Schreier was of invaluable assistance in checking the many numerical calculations. We wish especially to thank Ohseun Koh, who wrote the program for the calculation of the hyperfine structure.
