ANALYSIS OF FREQUENCY RESPONSE CHARACTERISTICS OF PROPELLANT VAPORIZATION*

by Marcus F. Heidmann and Paul R. Wieber

Lewis Research Center

SUMMARY

The dynamic response of a droplet vaporization process excited by traveling transverse acoustic oscillations is derived by a linear analysis. Results of a previous non-linear numerical study used to formulate the analytical model are reviewed, and a transfer function representative of the dynamics of the vaporization process is derived. The analysis provides dimensionless parameters related to propellant physical properties that characterize the dynamic behavior of the vaporization process. Application is made to the vaporization of heptane, oxygen, fluorine, ammonia, and hydrazine. The dynamic response of these propellants attains a peak value at a particular frequency. A comparison is made with a burning-rate process described by a characteristic time and an interaction index giving similar behavior.

INTRODUCTION

Acoustic mode instability in a rocket engine combustor occurs when the combustion energy is released in a manner that reinforces the acoustic oscillations. Various combustion processes that can limit or control energy release (chemical kinetics, drop burning, vaporization, jet breakup, drop shattering, etc.) have been suggested as responsible for acoustic reinforcement. Many of these processes have been studied. For example, the dynamic behavior of several individual processes is reported in references 1 to 3, and process behavior measured in terms of combustor stability is given in references 4 to 6. Such studies have isolated specific problem areas in rocket engine instability that require additional study.

Propellant vaporization is a process of particular interest. Reference 4 shows that

*Presented at AIAA Second Propulsion Joint Specialist Conference, Colorado Springs, Colorado, June 13-17, 1966.

variations in vaporization rate can significantly affect combustor stability. The vaporization process alone was studied more thoroughly in reference 7, in which the dynamic behavior of the process was obtained from a nonlinear numerical analysis by using a model that predicts the vaporization rate during the entire drop lifetime. Under certain conditions, the process exhibited dynamic behavior that may cause combustor instability. Such dynamic behavior was related to boundary conditions controlling the vaporization process of heptane drops.

The nonlinear numerical analysis of reference 4 motivated the development of a linear dynamic analysis based on a simplified model for vaporization that gives the same dynamic behavior observed in reference 7. The advantage of the linear analysis is that it provides dimensionless parameters related to propellant properties that may be used to characterize and examine the dynamic behavior of the vaporization process for any propellant.

In this report the results of the nonlinear numerical analysis of reference 7 are reviewed, and the linear analysis is presented and discussed.

-	denotes mean values

RESPONSE FACTOR

A response factor can be defined that is one measure of the magnitude by which the combustion process can reinforce an acoustic oscillation. Such a response factor was introduced in the numerical analysis of reference 7 and will be used in this study to evaluate the dynamic behavior of the vaporization process. This response factor is based on the Rayleigh criterion for acoustic amplification by heat or mass addition. The Rayleigh criterion states that reinforcement or amplification occurs when an excess of heat or mass is added while the pressure is greater than the mean value. A response factor taking into consideration the Rayleigh criterion is expressed for perturbations about a mean value by

$$N = \frac{\int^V \int^t q'(V, t) P'(V, t) dt dV}{\int^V \int^t [P'(V, t)]^2 dt dV} \quad (1)$$

where q' , the fractional heat or mass perturbation, is

$$q' = \frac{q - \bar{q}}{\bar{q}}$$

and P' , the fractional pressure perturbation, is

$$P' = \frac{P - \bar{P}}{\bar{P}}$$

When both q' and P' oscillate with the same periodicity and are uniform over a finite volume, the response factor is usually expressed for one period of oscillation as

$$N = \frac{\int_0^{t_{\sim}} q'(t)P'(t)dt}{\int_0^{t_{\sim}} [P'(t)]^2 dt} \quad (2)$$

For sinusoidal oscillations in pressure, any heat release or mass flow process linearly related to pressure gives the following value of the integral:

$$N = \frac{q'_{\max}}{P'_{\max}} \cos \theta \quad (3)$$

where

$$P'(t) = P'_{\max} \sin \omega t$$

and

$$q'(t) = q'_{\max} \sin(\omega t + \theta)$$

In the analyses of propellant vaporization, the heat release rate q' is generally assumed synonymous with the mass release rate w' . This synonymity was assumed in the nonlinear analysis of reference 7. Also, an average value for the fractional perturbation in mass release rate over a finite volume was determined by a numerical integration (ref. 7). For these evaluations, w' varies nonlinearly with sinusoidal oscillations in pressure. The response factor as defined by equation (2), however, was approximated by numerical techniques over one period of the pressure oscillation.

Numerical values of the response factor within the range -1 to 1 were obtained in reference 7. Negative values indicate that excess heat is added when the pressure is less than the mean pressure (potential damping of acoustic oscillations), and positive values indicate that excess heat is added at pressures above the mean pressure (potential driving of acoustic oscillations).

Some significance can be placed on actual numerical values of the response factor if the acoustic system is assumed to consist only of a heat or mass addition from vaporization (a potential acoustic gain) and a mass loss through an exhaust nozzle (a potential acoustic loss). If quasi-steady behavior is assumed, the combustor pressure and flow perturbations in a critical flow nozzle are in phase. The magnitude of these perturbations for adiabatic flow can be derived from

$$w_t = A_t \rho_t a_t$$

where

$$a_t = \sqrt{\gamma g R T_t}$$

which gives

$$-w'_t = \left(\frac{\gamma + 1}{2\gamma} \right) P'_c$$

If mass flow perturbations in the nozzle are considered analogous to heat or mass flow perturbations in the chamber, then, for sinusoidal oscillations in pressure, the response factor as given by equation (3) is

$$N = -\left(\frac{\gamma + 1}{2\gamma} \right) = (-0.912)_{\gamma=1.2}$$

In a simple feedback loop corresponding to the assumed two-process system, the sum of such a negative nozzle response factor and the response factor of the vaporization process indicates whether an excess of mass is added when the pressure is higher or lower than the mean pressure, and thus, whether acoustic oscillations will decay or grow according to the Rayleigh criterion.

The numerical result from this analysis of nozzle flow process suggests that the response factor for the vaporization process must exceed 0.912 to cause combustion

instability. The exact dynamic behavior of nozzle flow and the magnitude of other acoustic losses and gains in rocket combustors is debatable, and therefore a precise criterion for stability cannot be established. In this study, therefore, attention will be confined to how the vaporization response factor varies with propellant properties and combustor operating conditions.

NUMERICAL ANALYSIS

The response factor as a function of oscillatory frequency was evaluated in the numerical analysis of reference 7 for a representative vaporization process and a specific acoustic mode of resonance. Calculations were made for n-heptane drops vaporizing in a cylindrical combustor containing heptane-oxygen combustion products. Pressure, velocity, and temperature oscillations associated with the first traveling transverse acoustic mode were superimposed on the normal combustion flow process. Drops of constant size were repetitively injected from positions uniformly distributed across the injector face. The drop vaporization theory developed in reference 8 was used. In these calculations, the acoustic oscillations affected the heat and mass transfer processes and the drop acceleration, which gave three-dimensional velocity components to the drops and caused perturbations in drop temperature and vaporization rate.

The perturbation in vaporization rate at a given angular and radial position at which the pressure was uniform at an instant of time along the axis of the chamber was obtained from a summation of the vaporization rates of individual drops. A typical plot of the vaporization rate perturbation for times covering one complete pressure oscillation is shown in figure 1. Equation (4) was used to evaluate the response factor for each angular and radial position. The response factor for the entire chamber was taken as the

average value of the response factor for all angular and radial positions.

These calculations were made for a range of oscillatory frequencies and for a variety of boundary conditions affecting drop vaporization, including variations in combustor pressure, final combustion gas velocity, drop radius, initial drop temperature and velocity, and the amplitude of the pressure perturbation. The frequency response curves calculated for these boundary conditions were correlated by a frequency parameter as shown in figure 2. An equally good single curve representation of results was obtained from a correlation based on drop life-

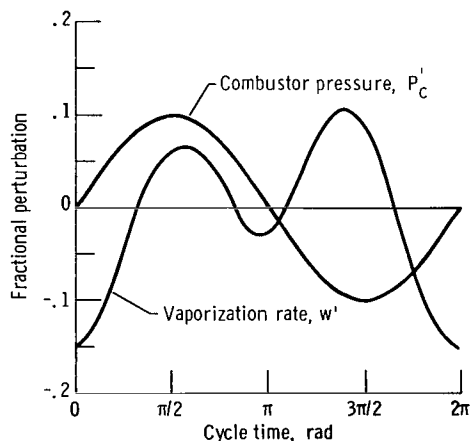

Figure 1. - Nonlinear response of vaporization process (ref. 7).

Figure 2. - Correlation of response factor with vaporization parameters for heptane. Response factors are based on average rather than maximum pressure amplitude (ref. 7).

time; this curve is given in figure 3, which shows the response factor as a function of a dimensionless time equal to the ratio of the drop half-lifetime (time to vaporize one-half the droplet mass) to the period of the oscillation. The response factors shown in figures 2 and 3 are larger than those reported in reference 7. The values have been recalculated and represent the average values of the response factors based on the pressure in each volume rather than the wall pressure used in reference 7.

Figures 2 and 3 show the characteristic response of the vaporization process for heptane. For fixed boundary conditions, the response factor is a maximum at a specific frequency (corresponding to a dimensionless time of about 0.4). The response factor approaches zero at a lower frequency and a constant negative value at higher frequencies. The transition to negative response occurs at a dimensionless time of about 1.4. From these response characteristics, the vaporization conditions conducive to driving and damping of acoustic oscillations can be readily established. It should be noted, however, that the maximum response factor (about 0.8) is less than the nozzle loss (about 0.912) previously calculated for simple dynamic behavior of exhaust flow.

The factors responsible for this behavior of the vaporization process are of fundamental interest. A description of the contributing factors was given in reference 7. Parameter groupings that can characterize specific behavior, however, are not readily deduced from a numerical analysis. Such groupings could be readily evaluated if a linear dynamic analysis were applicable to the problem being studied.

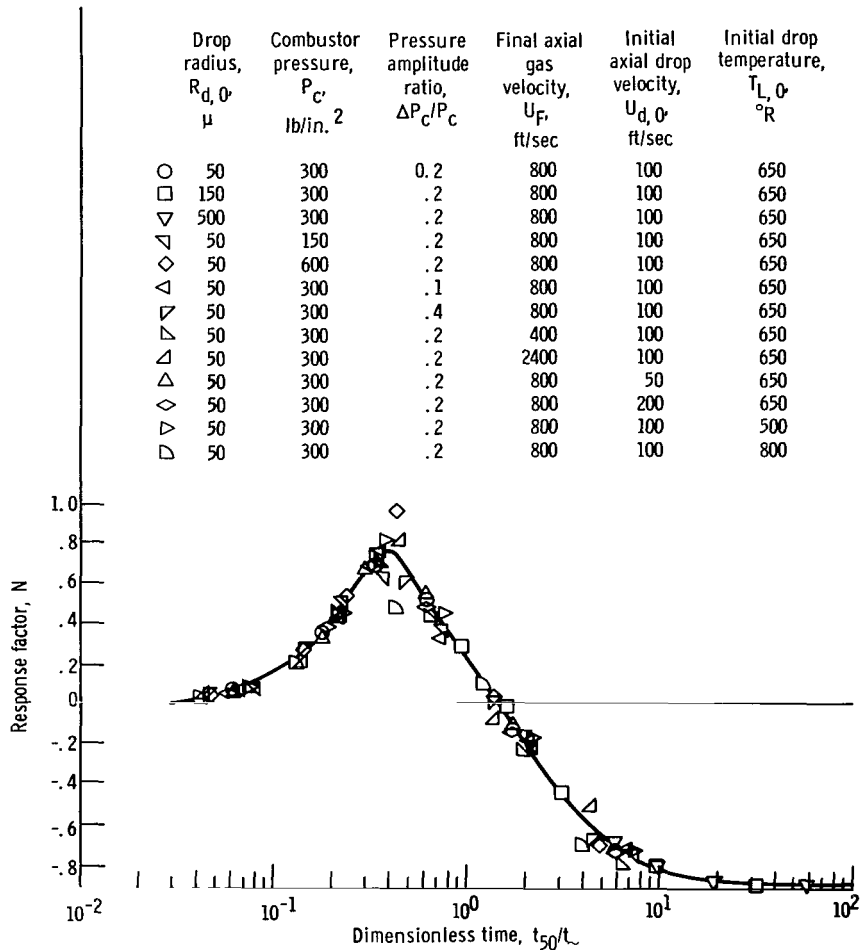

Figure 3. - Correlation of response factor with dimensionless time for heptane. Response factors based on average rather than maximum pressure amplitude (ref. 7).

The primary restriction on a linear analysis is the dependency of the vaporization process on the absolute velocity difference between the drop and the combustion gases. Acoustic particle velocity is a maximum at both high and low pressures during the oscillation. For this reason, velocity difference and vaporization rate attain maximum values at conditions near both maximum and minimum pressure and cause the nonlinear behavior of vaporization rate shown in figure 1. An analysis of the perturbation curves in vaporization rate showed that the velocity difference contributions to the vaporization rate at high and low pressure were nearly equal and thus cancelled effects with regard to response factor evaluations. As an approximation, therefore, the velocity difference effects on vaporization rate can be ignored. With this assumption, a linearization of the vaporization equations is possible. The following section presents a linear dynamic analysis of a simplified vaporization process that is insensitive to perturbations in gas velocity.

LINEAR ANALYSIS

A transfer function that characterizes the dynamic behavior of the vaporization process of various propellants will be derived by a linear analysis of a simplified vaporization model.

Vaporization Model

Analytical relations for the vaporizing drop presented in reference 8 will be used to develop linear equations for perturbations in the vaporization process of a single drop. The equations are assumed to apply to a drop in an array of drops of decreasing size down a combustion chamber.

Drop mass:

$$\frac{dM}{dt} = -w \quad (5a)$$

$$\bar{\tau}_v \frac{dM'}{dt} = -w' \quad (5b)$$

where

$$\bar{\tau}_v = \frac{\bar{M}}{\bar{w}} \quad (\text{mean drop lifetime})$$

Vaporization rate:

$$w = \frac{2\pi D \mathcal{M} r}{RT} \text{Nu}_m P_L \alpha \quad (6a)$$

where

$$\text{Nu}_m = 2 + 0.6(\text{Sc})^{1/3}(\text{Re})^{1/2} \quad (6b)$$

and

$$\alpha = \frac{P_c}{P_L} \ln \frac{P_c}{P_c - P_L} \quad (6c)$$

For this analysis, Nu_m is assumed proportional to $(rP_c)^{1/2}$, D is proportional to P_c^{-1} , and M is proportional to r^3 , so that

$$w = C_1 M^{1/2} P_c^{1/2} \ln \frac{P_c}{P_c - P_L} \quad (6d)$$

and

$$w' = \frac{1}{2} M' + \beta P_L' - \left(\beta - \frac{1}{2} \right) P_c' \quad (6e)$$

where

$$\beta = \frac{\frac{\bar{P}_L}{\bar{P}_c - \bar{P}_L}}{\ln \frac{\bar{P}_c}{\bar{P}_c - \bar{P}_L}}$$

Vapor pressure:

$$\ln P_L = C_2 - \frac{C_3}{T_L - C_4} \quad (7a)$$

$$P_L' = b T_L' \quad (7b)$$

where

$$b = \frac{C_3 \bar{T}_L}{(\bar{T}_L - C_4)^2}$$

Drop temperature:

$$\frac{dT_L}{dt} = \frac{1}{c_p M} (q_{in} - q_{out}) \quad (8a)$$

If the variations in specific heat c_p with drop temperature perturbations are assumed negligible, then

$$\frac{\bar{c}_p \bar{T}_L}{\bar{\lambda}} \bar{\tau}_v \frac{dT'_L}{dt} = q'_{in} - q'_{out} \quad (8b)$$

where

$$\bar{q}_{in} = \bar{q}_{out} = \bar{\lambda w}$$

Heat transfer to drop:

$$q_{in} = 2\pi k \text{Nu}_h r (T_b - T_L) Z \quad (9a)$$

where

$$\text{Nu}_h = 2 + 0.6(\text{Pr})^{1/3} (\text{Re})^{1/2} \quad (9b)$$

If the temperature difference $(T_b - T_L)$ and the correction factor for simultaneous heat and mass transfer Z are constant, Nu_h is proportional to $(rP_c)^{1/2}$, and M is proportional to r^3 , then

$$q_{in} = C_5 M^{1/2} P_c^{1/2} \quad (9c)$$

and

$$q'_{in} = 1/2 M' + 1/2 P'_c \quad (9d)$$

Heat transfer from drop:

$$q_{out} = \lambda w \quad (10a)$$

If variations in the heat of vaporization λ with drop temperature perturbations are assumed negligible, then

$$q'_{out} = w' \quad (10b)$$

The model expressed by the linear equations may be described as follows. A drop

with a mass M and a mean lifetime $\bar{\tau}_v$ is being vaporized. The mass of the drop is perturbing about an average value because the vaporization rate, which represents mass leaving the drop, is varying about an average level. The variations in vaporization rate depend on the mass of the drop and on the difference between the vapor pressure at the drop surface and the combustor pressure. The drop temperature determines the vapor pressure, with the temperature established in a heat reservoir. The heat to the reservoir depends on the combustor pressure and on the mass of the drop or the mass in the reservoir. Heat leaving the drop or reservoir is contained in the vaporizing propellant.

Transfer Function

The linear equations ((5b), (6e), (7b), (8b), (9d) and (10b)) can be combined by using the transform $s = d/dt$ to give a transfer function involving the variables w' and P'_c :

$$\frac{w'}{P'_c} = \frac{1}{2} \left[\frac{2\bar{\tau}_v s}{1 + 2\bar{\tau}_v s} \right] \left[\frac{1 + (1 - 2\beta) \frac{\bar{c}_p \bar{T}_L}{\lambda \beta b} \bar{\tau}_v s}{1 + \frac{\bar{c}_p \bar{T}_L}{\lambda \beta b} \bar{\tau}_v s} \right] \quad (11)$$

This transfer function expresses the dynamic relation between w' and P'_c . Solutions of the form $w'(t) = w'_{\max} \sin(\omega t + \theta)$ can be obtained when $P'(t) = P'_{\max} \sin \omega t$. The amplitude ratio and phase shift obtained from such solutions are

$$\left(\frac{w'}{P'_c} \right)_{\max} = \frac{1}{2} \frac{2\bar{\tau}_v \omega}{[1 + (2\bar{\tau}_v \omega)^2]^{1/2}} \left\{ \frac{1 + \left[(1 - 2\beta) \frac{\bar{c}_p \bar{T}_L}{\lambda \beta b} \bar{\tau}_v \omega \right]^2}{1 + \left(\frac{\bar{c}_p \bar{T}_L}{\lambda \beta b} \bar{\tau}_v \omega \right)^2} \right\}^{1/2} \quad (12)$$

and

$$\theta = \frac{\pi}{2} - \tan^{-1} 2\bar{\tau}_v \omega + \tan^{-1} (1 - 2\beta) \frac{\bar{c}_p \bar{T}_L}{\lambda \beta b} \bar{\tau}_v \omega - \tan^{-1} \frac{\bar{c}_p \bar{T}_L}{\lambda \beta b} \bar{\tau}_v \omega \quad (13)$$

The response factor defined by these solutions is given by the previously defined relation (eq. (3))

Figure 4. - Linear dynamic response of heptane vaporization.

Propellant Evaluations

An evaluation of the response factor N for a heptane drop is shown in figure 4 as a function of the dimensionless time parameter $\bar{\tau}_v \omega$. Response factors for oxygen, fluorine, ammonia, and hydrazine, together with that for heptane, as functions of the dimensionless time parameter $\bar{\tau}_v \omega$ are given in figure 5. Physical properties used for the evaluations are given in table I. The listed properties are for the equilibrium drop temperature condition attained during steady vaporization at a combustor pressure of 300 psi (ref. 8). For comparison of the effects of physical properties on response, figure 6 shows the nonlinear evaluation of N for the condition of oxygen vaporization considered in reference 7.

DISCUSSION

The response curve of heptane vaporization obtained by a linear analysis (fig. 4) has characteristic properties similar to those of the response curve obtained by the numerical analysis (fig. 3). Differences in the response curves are primarily confined to the region of peak response. The linear analysis assumes that vaporization is initiated at an equilibrium drop temperature. A numerical evaluation in reference 7 for drops introduced at their equilibrium temperature gave a peak value of $N = 0.42$, which is the value obtained by the linear analysis. The 800°R initial drop temperature calculation shown in figure 3 also gives comparable values. Heating of the drop from an initial injection temperature apparently introduces nonlinearity that increases the peak value of the response factor.

A comparison of time bases for the response curves obtained by a linear analysis of a single drop and by a nonlinear analysis of a complete array of drops down the chamber shows that t_{50} for this array is larger by a factor of about 4.5 than $\bar{\tau}_v$ for the single drop, where t_{50} is the half-lifetime of the largest or initial drop in the array. The effective mean drop size of an array of drops is significantly less than the largest or initial drop. The relation between the largest drop and the effective mean drop depends on the distribution of drop sizes in the array. When equations (5a) and (6d) are used to specify time histories, however, an effective mean drop size of about one-fourth the initial drop size is obtained. Beyond the limitation of specifying an effective drop size, the linear analysis adequately describes the dimensionless times at which peak, zero, and negative response are obtained. These times are characterized by the parameter

Figure 7. - Component characteristics of transfer function for heptane vaporization.

groupings appearing in the linearly derived transfer function (see eq. (11)). Figure 7 shows the contribution of these parameter groupings to the overall response of heptane vaporization.

The term $2\bar{\tau}_v s / (1 + 2\bar{\tau}_v s)$ characterizes the dynamics related to the quantity of propellant being vaporized. It establishes the response at low frequencies or small vaporization times. In this region, the quantity of propellant in the chamber varies inversely with the vaporization rate. In the extreme condition of zero dimensionless time, the propellant vaporizes as rapidly as it is introduced, and the response factor is zero. At frequencies equal to $1/2\bar{\tau}_v$ and greater, the variations in the quantity of propellant being vaporized become small and do not restrict the vaporization rate.

The parameter $\bar{c}_p \bar{T}_L \bar{\tau}_v / \lambda \beta b$ characterizes the dynamics of heat storage within the propellant. A frequency equal to $1/(\bar{c}_p \bar{T}_L \bar{\tau}_v / \lambda \beta b)$ essentially separates regions of oscillating and constant drop temperature. At lower frequencies the drop temperature oscillations approach an equilibrium condition with the oscillating environment. At higher frequencies, the temperature oscillations are reduced and eventually drop temperature and vapor pressure remain constant.

A condition of constant vapor pressure gives the inverse effect of pressure oscillations on vaporization rate from that obtained when vapor pressure is in equilibrium with the environment (eq. (6e)). With equilibrium conditions (generally low frequencies), an increase in combustor pressure increases the heat transfer to the drop, and the vapor pressure and the vaporization rate give a positive response factor. When vapor pressure is constant (generally high frequencies), an increase in combustor pressure suppresses vaporization rate, and a decrease in pressure accelerates the rate, a condition comparable to flash vaporization. This process gives a negative response. The parameter $(1 - 2\beta)(\bar{c}_p \bar{T}_L \bar{\tau}_v / \lambda \beta b)$ characterizes the dynamics of these two interacting effects on vaporization rate. The values of β for the propellants evaluated in this study are greater than unity. Under such conditions, the transition from a vapor pressure to a combustion pressure controlled process occurs at a frequency that is lower by the factor $1/(2\beta - 1)$ than the frequency characterizing the drop temperature behavior.

These parameters, which characterize the dynamics of the vaporization process, are functions of propellant physical properties. From a knowledge of propellant physical properties, the dynamic response of various propellants can be estimated or computed. Oxygen vaporization (fig. 5) is one example. The region of positive response is broader, and the response factor attains a larger value than for heptane. The numerical evaluation (fig. 6), although incomplete, implies a similar behavior.

Oxygen properties differ from those of heptane in several ways; however, the change in β (1.36 for heptane; 4.143 for oxygen) is the predominant factor causing a difference in response. The value of β for oxygen is large because the equilibrium vapor pressure for oxygen is a larger fraction of the combustor pressure than is the case for heptane. When β is large, the dimensionless time characterizing a constant vapor pressure increases. This phenomena increases and broadens the region of positive response. A large β also increases the perturbation in vaporization rate when vapor pressure is constant and thus increases the magnitudes of negative response as shown in figure 5.

The comparison of various propellants (fig. 5) shows the region of positive response for hydrazine to extend over a broader region of dimensionless time than for heptane or oxygen. Fluorine is nearly identical to oxygen. This comparison implies that a combustion process controlled by hydrazine vaporization would be unstable for a broad range of combustor designs. Reference 8 indicates, however, that decomposition of hydrazine could effect the vaporization process, which would also effect its dynamic behavior.

The dynamic response of other propellants for which physical properties are known or can be estimated can be evaluated in a similar manner. The linear analysis provides a convenient method of surveying the dynamic response of propellants and indicates the conditions in which the more precise numerical evaluation would be useful.

STABILITY CRITERIA

The dynamic response of the vaporization process does not, in itself, specify combustor stability. Stability criteria are acquired from a complete dynamic analysis of the overall combustion system. Such criteria have been derived in reference 9 for any combustion process that can be characterized by the flowing burning-rate expression:

$$w' = n [P'_c(t) - P'_c(t - \tau)] \quad (14)$$

In this expression, the interaction index n and the characteristic time τ specify a particular combustion process. The dynamic response for this burning rate expression is

$$N = n(1 - \cos \tau\omega) \quad (15)$$

A comparison for this dynamic response with the dynamic response of heptane vaporization is shown in figure 8. The region of positive response and particularly the peak response are of primary significance in establishing system stability limits. In this region, the dynamic response of the vaporization process can be approximated by the burning-rate expression (eq. (14)). For the comparison shown in figure 8, the vaporization process is characterized by $n = 1/2 N_{\max}$ and $\tau = 4.5 \bar{\tau}_v$. By a similar comparison with the correlation of the numerical results shown in figures 2 (p. 8) and 3 (p. 9), the value of τ is approximated by

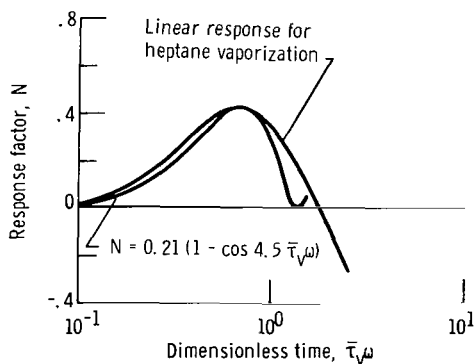

Figure 8. - Comparison of heptane vaporization with burning rate characterized by n and τ .

$$\tau = t_{50} = \frac{1}{2} \left[\frac{1}{600} \left(\frac{R_{d,0}}{50} \right)^{3/2} \left(\frac{300}{P_c} \right)^{1/3} \left(\frac{800}{U_F} \right)^{1/3} \left(\frac{0.2}{P_c} \right)^{-1/3} \right]^{1/3} \quad (16)$$

within the range of boundary conditions considered in the numerical analysis. The value of n is again equal to one-half the peak value of the response

factor, $n \simeq 0.4$. If the dynamic response of the vaporization process is characterized in this manner, the system stability criteria specified in terms of n and τ are directly applicable to a vaporization controlled burning rate. For greater precision, a burning-rate expression may be postulated that more closely approximates the vaporization process and utilizes the method of analysis of reference 9 to establish stability criterion.

CONCLUDING REMARKS

The results of this study show that the dynamic response of the vaporization process can be approximated by a linear analysis that assumes the vaporization rate to be insensitive to gas velocity perturbations. The assumption is based on the net effect of velocity rather than actual insensitivity to velocity, that is, the changes in vaporization rate due to perturbation in velocity are the same at high and low pressures and, therefore, cancel with regard to dynamic response. The assumption appears valid for any transverse mode in the absence of any steady angular or radial flow within the cavity. With such steady flow, however, and in the case of longitudinal modes with axial flow of combustion gases, dynamic response is not insensitive to velocity perturbations (ref. 10). The linear analysis and the results of the numerical analysis do not necessarily apply to such conditions.

"The aeronautical and space activities of the United States shall be conducted so as to contribute . . . to the expansion of human knowledge of phenomena in the atmosphere and space. The Administration shall provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof."

—NATIONAL AERONAUTICS AND SPACE ACT OF 1958

NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

TECHNICAL REPORTS: Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

TECHNICAL NOTES: Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

TECHNICAL MEMORANDUMS: Information receiving limited distribution because of preliminary data, security classification, or other reasons.

CONTRACTOR REPORTS: Technical information generated in connection with a NASA contract or grant and released under NASA auspices.

TECHNICAL TRANSLATIONS: Information published in a foreign language considered to merit NASA distribution in English.

TECHNICAL REPRINTS: Information derived from NASA activities and initially published in the form of journal articles.

SPECIAL PUBLICATIONS: Information derived from or of value to NASA activities but not necessarily reporting the results of individual NASA-programmed scientific efforts. Publications include conference proceedings, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

Details on the availability of these publications may be obtained from:
