## SUMMARY

The objective of this work was to test materials prepared by the Pittsburgh Coal Research Center for NASA as anodic catalysts for ammonia in alkaline electrolytes and carbon monoxide in acidic and aqueous carbonate fuel cell electrolytes.

A total of fifty-four samples consisting of carbides, nitrides, borides, nitrocarbides, carbonitrides and Raney alloys of iron, cobalt, and nickel were tested. Corrosion potentials were run to determine usable electrolyte and catalyst combinations. Surface areas measured by double layer capacitance ranged from  $27.1 \text{ Cm}^2/\text{gm}$  to  $117,000 \text{ Cm}^2/\text{gm}$ . In general the areas were found to be: carbides > nitrocarbides > metals > borides and for the metallic moiety: silver > nickel  $\approx$  cobalt >> iron.

Voltammograms at  $25^\circ\text{C}$  under approximately steady-state conditions were run in electrolytes compatible with the materials. Results showed the best materials were less than 2% of the activity obtainable with platinum for the same fuel. When ammonia was the fuel, activity followed the trend: carbides  $\approx$  nitrocarbides >> metals and nickel >> cobalt  $\approx$  silver >> iron. Carbon monoxide activity was generally nitrocarbides >> metals > carbides > borides with silver > nickel > cobalt > iron. With only one exception the sixteen best materials of the twenty-nine tested in acetate buffer contained nickel.

This work was carried out for the National Aeronautics and Space Administration with Mr. E. M. Cohn as Technical Monitor. Principal investigators were T. Webb and J. R. Moser.

## I. INTRODUCTION

The high cost and scarcity of the noble metals prompted a search for cheaper, more abundant fuel cell catalysts. Initial results with Hagg carbide ( $\text{Fe}_2\text{C}$ ) indicated that iron group interstitial carbides might be the answer. Consequently, a total of fifty-four carbides, nitrides, nitrocarbides, carbonitrides, borides and Raney alloys synthesized by Bureau of Mines were tested in this laboratory. Nineteen iron compounds including four carbides, six nitrides, five carbonitrides and four nitrocarbides were tested for corrosion at  $25^\circ\text{C}$  in 30% KOH, saturated  $\text{K}_2\text{CO}_3$ , acetate buffer,  $2\text{N}$   $\text{H}_2\text{SO}_4$  and 85%  $\text{H}_3\text{PO}_4$ . Thirty-five cobalt and nickel materials consisting of nine metallic alloys, eleven carbides, ten nitrocarbides, and five borides were tested for corrosion at  $25^\circ\text{C}$  in 30% KOH, acetate buffer and  $2\text{N}$   $\text{H}_2\text{SO}_4$ . The surface area of each material was determined by double layer capacitance measurements (1).

Compatible catalyst-electrolyte combinations were further tested for anodic activity toward the oxidation of either ammonia or carbon monoxide. Equipment, testing procedures, treatment of catalysts and floating electrode preparation have all been previously described (2-4). All materials were tested during the first three quarters of this contract. No additional materials were received during the fourth quarter.

## II. RESULTS

Surface area measurements and the identity of each material tested are given in Table I. Voltammetric data for the oxidation of ammonia are shown in Tables II and III. Results for carbon monoxide oxidation are listed in Tables IV through VII.

### III. DISCUSSION

#### III.-1 Surface Areas

Double layer capacitance measurements on the 54 materials tested gave values for surface areas from  $27.1 \text{ Cm}^2/\text{gm}$  to  $117,000 \text{ Cm}^2/\text{gm}$ . Our platinum black measured was  $210,000 \text{ Cm}^2/\text{gm}$ .

As a group, the iron compounds exhibited the lowest area. The remaining materials which contained silver generally showed the largest areas. Surface areas according to type of non-ferrous material were usually in the order carbides > nitrocarbides > metals > borides.

#### III.-2 Ammonia Oxidation

Voltammograms for the oxidation of ammonia were run in 30% KOH for all materials stable in that electrolyte. Additionally the iron compounds which were stable in saturated  $\text{K}_2\text{CO}_3$  were tested in that electrolyte.

In 30% KOH the half-cell potential for the reaction was between 0.54 and 0.58 V vs DHF for most catalysts. This corresponds to the calculated value. Five of those tested, however, had lower half-cell potentials; one was higher. All six of these anomalies were due to corrosion of the electrode upon addition of ammonia. This was evidenced by the discolored electrolyte accompanying high exchange currents. The tafel slope for the oxidation with platinum is 0.04 volt while that for most of the other materials is around 0.12 volt. This may be explained by the mechanism of Owen and Salomon (5) who calculated Tafel slopes for the four steps in the reaction:

### III. DISCUSSION (Cont'd)

|       |                                                                                                    | Calculated<br>Tafel Slope |
|-------|----------------------------------------------------------------------------------------------------|---------------------------|
| (i)   | $\text{NH}_3 + \text{M} + \text{OH}^- \rightarrow \text{M-NH}_2 + \text{H}_2\text{O} + \text{e}^-$ | 0.118 volt                |
| (ii)  | $\text{M-NH}_2 \text{ to } \text{H}^- \rightarrow \text{M=NH} + \text{H}_2\text{O} + \text{e}^-$   | 0.039 volt                |
| (iii) | $\text{M=NH} + \text{OH}^- \rightarrow \text{M=N} + \text{H}_2\text{O} + \text{e}^-$               | 0.024 volt                |
| (iv)  | $2 \text{ M=N} \rightarrow 2\text{M} + \text{N}_2$                                                 | 0.010 volt or $\infty$    |

Reaction (ii) is the rate determining step for platinum but reaction (i), the initial dissociative adsorption, seems to be the rate determining step for the other materials.

When saturated potassium carbonate was the electrolyte much lower currents, high Tafel slopes and variable half-cell potentials were obtained. These results were not readily interpreted. This electrolyte was abandoned after the first group of materials was tested.

In general for the oxidation of ammonia all of the materials tested were greatly inferior to platinum. However, those interstitial compounds containing carbon and/or nitrogen were much better catalysts than the pure metals or alloys. The order found for the catalysts activity of metallic constituents was Nickel >> Cobalt  $\approx$  Silver >> Iron.

### III. DISCUSSION (Cont'd)

#### III.-3 Carbon Monoxide Oxidation

Four electrolytes were used in this study. Currents were very low in 85%  $\text{H}_3\text{PO}_4$  and saturated  $\text{K}_2\text{CO}_3$ ; consequently, these systems were abandoned after the first group of materials was tested. The maximum current was obtained with platinum in  $2\text{N H}_2\text{SO}_4$ . All other materials gave currents less than 2% of this value.

The oxidation reaction mechanism for carbon monoxide has not been well established. It is known that for platinum a reaction occurs around 0.26 volt versus DHE during which the electrode is poisoned by a reaction product. The major reaction occurs around 0.96 volt vs DHE where the product is carbon dioxide. For most of the catalysts tested the first reaction is predominant in 85%  $\text{H}_3\text{PO}_4$  and acetate buffer while the second reaction is the major one in  $2\text{N H}_2\text{SO}_4$ . In  $\text{K}_2\text{CO}_3$  the potentials are well scattered. Three Tafel slopes were observed in the acidic electrolytes: 0.040, 0.080 and 0.140 volt. However, the second was absent in  $\text{H}_3\text{PO}_4$  while the third was absent in  $\text{H}_2\text{SO}_4$ . The overall reactions seem to be:

### III. DISCUSSION (Cont'd)

#### III.-3 Carbon Monoxide Oxidation (Cont'd)

The nitrocarbides were much better catalysts than the pure metals or alloys while lowest in activity were the carbides and finally the borides.

The trend in catalytic activity was Silver > Nickel > Cobalt > Iron. Silver is known to strongly adsorb hydroxy ions; unoxidized nickel forms a carbonyl at room temperature -- nickel must catalyze reaction (v) since in acetate buffer with only one exception the sixteen best materials of the twenty-nine tested contained nickel. Two containing nickel and silver were actually better than platinum in this electrolyte although much lower than platinum in  $2N \text{ H}_2\text{SO}_4$ .

#### IV. CONCLUSIONS

The catalytic activity of all the materials tested was greatly inferior to the best results that could be obtained with platinum. For ammonia and carbon monoxide oxidation none of these proved to be a good platinum substitute. The results indicate that catalytic activity was limited by failure of these materials to adsorb the fuels. The reason is in some cases undoubtedly due to the presence of surface oxide (passivation) which also prevents corrosion of the metal by the electrolyte.

#### V. RECOMMENDATIONS

Since all of these materials were originally prepared for possible use as oxygen electrodes in alkaline electrolytes it would be fortuitous if any were found to be suitable as anodes in acid solutions. A thorough understanding of the fuel cell reaction mechanisms would be an extremely desirable asset in selecting potential catalysts. With this knowledge and a systematic approach as used by Bond (6), it should be possible to arrive at the optimum catalyst for a particular reaction under a fixed set of conditions.
