# TRECEDING PAGE BLANK NOT FILMED. No. 106 WAVELENGTH DEPENDENCE OF POLARIZATION X. INTERSTELLAR POLARIZATION\*

by G. V. COYNE S.J., AND T. GEHRELS May 25, 1967 N 69 - 18303

#### ABSTRACT

A survey of O and B stars was started with the new 154-cm Catalina reflector. The equipment is described and results are given for 33 stars. Of these, seven stars show variable polarization. Striking discrepencies from the mean interstellar polarization-wavelength dependence are found near Orion. The brighter component of  $\theta^2$  Orionis, a spectroscopic binary with a 21-day period, shows variations of  $\pm 0.5\%$  in the ultraviolet. The spectroscopic binary  $\varphi$  Per shows variations of about  $\pm 0.2\%$ . Both stars have a strong wavelength dependence of the polarization position angles. A time dependence of the position angle is found for the spectroscopic binary and shell star  $\zeta$  Tau.

### 1. Introduction

S a continuation of a program of study of the wave-A Sa continuation of a program of a stellar polari-length dependence of interstellar and stellar polarization, a survey of the polarization of O and B stars as faint as V=8.0 near the galactic plane and well distributed in galactic longitudes was undertaken. The first results of this survey are presented in Sec. III. A subsequent paper will give further observations and a more thorough discussion of the results. In Papers II and VIII (see references) we found a mean interstellar polarization curve, with a maximum at about 5200 Å decreasing rapidly towards longer wavelengths and less rapidly towards shorter wavelengths. On the other hand, several stars show large deviations from such a mean curve (Paper VIII), indicating a large dispersion in the wavelength dependence of interstellar polarization. With the additional observations contained in the present paper, we rediscuss this mean interstellar polarization curve and the degree of dispersion in the polarizationwavelength dependence for various stars (Sec. IV).

In the course of the survey several stars were found to have variable polarization. Available observations on these stars are limited. In anticipation of further observations a preliminary discussion of these variations is presented (Sec. V).

### 2. The Equipment

In November 1965 the 154-cm reflector of the Lunar and Planetary Laboratory, situated at an elevation of 2510 m in the Santa Catalina Mountains north of Tucson, was first used for polarization measurements. The observations in this paper represent the first group of polarization measurements made with this telescope. The telescope has Cassegrain arrangements only, and both the f/13 and f/45 secondary mirrors are used in this program.

For a determination of instrumental effects we observed 20 stars within 51 pc and with less than 0.04% polarization over a wide range of galactic coordinates (Behr 1956). The instrumental polarizations for the seven filters from Infrared to Nickel

\*Reprinted from the Ast. J., Vol. 72, No. 7, Sept., 1967, with permission.

sulfate, described below, are respectively 0.03, 0.07, 0.11, 0.11, 0.13, 0.17, and 0.14%, and their equatorial position angles respectively 146, 144, 152, 148, 147, 150 and 153°. These amounts are known with a probable error of  $\pm 0.01\%$ . No difference between f/13 and f/45 was found. We are indebted to J. H. Richardson of the Kitt Peak National Observatory for the care with which he aluminized the three mirrors.

Figure 1 shows the polarimetric equipment at the Catalina 154-cm telescope. The polarimeter is the same as that used previously (Gehrels and Teska 1960); the paper referred to also has a description of the calibration of polarization position angles. The polarimeter has, successively, a slide for the Lyot depolarizer, a field-viewing eyepiece, a slide for diaphragms (0.25 to 10 mm in diameter), an eyepiece for centering, a filterslide, a Wollaston prism, a Fabry field lens, and two photomultiplier tubes. Seen in Fig. 1 is the Wollaston neck and the dry-ice box for S-1 phototubes; there is a separate Wollaston neck and ice box for blue-sensitive tubes. For photometry with these boxes, the Wollaston neck is clamped in a fixed orientation, or a separate 1P21 ice-box is put on instead of the Wollaston arrangements.

The output of the phototubes is simultaneously received by two Weitbrecht integrators and recorded on the strip chart on top of the console. The recorder is currently used only for visual display and as a diary for the observer, since all data is punched on paper tape. The outputs are digitized by the voltmeter seen under the recorder. Below the digital voltmeter is a high-voltage power supply for the phototubes, and below it are the programmer, and the clock/timer. The time is displayed in binary code ( $1^{h}35^{m}4$  is shown). To the right is the paper-tape punch with the integrator power supply on top.

Since Paper VIII, the following improvements have been made. D. L. Brumbaugh designed the clock/timer and he and V. J. Borg improved the digitization equipment, especially its speed. The integration time for objects brighter than eighth visual magnitude is ordinarily 7 sec, during which occur the readout and the punching of the Wollaston angle, object identification, time, depolarizer state, filter and star/sky identification.

Fig. 1. Photopolarimeter with dry-ice box and Weitbrecht integrators mounted on the Catalina 61-in. (154-cm) telescope. Strip-chart recorder, digital console, paper punch, and integrator power supply are also shown.

After the integration, the readout and punching of the measured intensities takes 5 sec. During this latter 5 sec of readout an experienced observer has just enough time to change the Wollaston angle or the depolarizer state, and to check the centering, in order to start the next integration. E. H. Roland made the new dry-ice box for the S-1 phototubes (RCA 7102) so that the refrigeration is considerably improved. T. M. Teska selected the best blue-sensitive tubes; the EMI 6255S were replaced by 6255B, and those in turn by EMI D205R (super S-11 with quartz window).

The characteristics of the filters used in this program have been given in Paper VII. The filter at  $1/\lambda = 1.39$ was replaced by an orange interference filter (Baird Atomic B-5; "Peak: 6450A+50A-25A. Total width at half peak: 1032A-1290A. Peak transmission: 50-60%"). The effective wave numbers for all filter/tube combinations used in the current study were estimated anew. For white light (which approximates the reddened B stars of this paper) at 1.3 air masses they are 1.06, 1.21, 1.56, 1.93, 2.33, 2.78,  $3.03 \ \mu^{-1}$ , and for a reddened K star 1.05, 1.19, 1.54, 1.91, 2.29, 2.75, and  $3.00 \ \mu^{-1}$ . These wave numbers are uncertain by  $\pm 0.02$  since the

tube responses are not measured but adopted from the manufacturer's mean curvc.

Figure 2 shows the response curves for the various filter/tube combinations. The letter used to designate each filter is as in Paper VII. The new interference filter described above is the O filter. In the tables to follow, these filters are designated by the effective wave numbers given above for white light and an extinction of 1.3 air masses. Only three stars with spectral type later than B occur in the tables, and these are indicated. The nearly complete absence of red leakage for the  $U(1/\lambda = 2.78)$  and  $N(1/\lambda = 3.03)$  filters is periodically checked, on the reddest objects. We are grateful to S. F. Pellicori for the determination of the filter and tube characteristics.

### 3. The Observations

Most of the observations were made between June 1966 and February 1967; a few were made earlier in 1966 or later in 1967.

The observations at each filter are made by taking measurements with and without depolarizer at each of six orientations of the Wollaston prism, the orientations being separated by intervals of 30°. On the average this routine is repeated three times giving a total of 18 pairs of measurements. For faint stars, for stars with small polarization, and especially for the filters at  $1/\lambda = 1.06$  and  $1/\lambda = 3.03$  a total of 24 to 30 pairs of measurements is usually made, in order to obtain the desired accuracy. Such a set, of about 18 pairs of measurements at a given filter, is defined as a single observation. A least-squares solution for the percentage polarization and position angle is run at the Numerical Analysis Laboratory of the University of Arizona. We are indebted to D. L. Coffeen and Mrs. L. C. Hess for certain improvements in the data processing. The instrumental polarization appropriate to each orientation of the Wollaston prism is subtracted from the measured value of the polarization at that orientation. Each final value of the percentage polarization is multiplied by a factor of 1.004, the measured value for the depolarizer deficiency.

Tables I and II are a journal of observations for stars which, in the course of this program, show no variable polarization and for stars with indications of variable polarization, respectively. The polarization position angle,  $\theta$ , is in the equatorial coordinate frame. The dates are given in Universal Time.

Table III gives the weighted mean percentage of polarization during the present observing period. Five stars (HD 37041, 36371, 37202, 134320, 134335) in Table III and in subsequent tables have been previously observed (Paper VIII). Only in the case of HD 36371 have we combined the previous observations with the new ones. In the cases of HD 37041 and HD 37202 there are indications of variability (discussed in Sec. V); the Paper VIII results for IID 134320 and 134335 are considered too poor to be combined with the new values. A few entries marked with a semicolon represent single observations. All other entries represent the weighted mean value of two (in some cases three) independent observations made on separate nights. In previous papers we used the inverse of the probable error as the weighting factor rather than the inverse of the probable error squared. The statistics were poor, with only six measurements per least-squares solution. This is no longer true. Hence the weights assigned here are the inverse of the squares of the probable errors obtained from each separate least-squares solution. The

average probable error of the weighted mean values is  $\pm 0.04\%$ . This probable error is largest ( $\pm 0.06\%$ ) for  $1/\lambda = 1.06$  and  $1/\lambda = 3.03$  and smallest ( $\pm 0.02\%$ ) for  $1/\lambda = 1.93$ . Colons in Table III indicate probable errors greater than  $\pm 0.10\%$ .

Table IV lists the equatorial position angles. Again we have the weighted mean values from two (in a few cases three) independent observations, with weights equal to the reciprocal of the square of the individual probable errors. These errors in position angle are proportional to the error in percentage polarization divided by the polarization (Hall and Serkowski 1963); and weights have been assigned on this basis. The average probable error for the position angle is  $\pm 1.21$ . This average probable error is largest ( $\pm 1.66$ ) at  $1/\lambda = 1.06$  and smallest ( $\pm 0.08$ ) at  $1/\lambda = 1.93$ . Single observations in Table IV are indicated by a semicolon; colons indicate probable errors greater than  $\pm 3^\circ$ .

Table V presents some of the fundamental data for the stars observed in this program. This table has been constructed in the same way as Table VI of Paper VIII (see references there), with the addition of a column

TABLE I. Journal of observations, Nonvariable polarization.

which lists our observed mean value of the polarization position angle. An exclamation mark (!) in this column indicates wavelength dependence of the position angle. The  $P_{\rm vis}$  column now gives the weighted mean of the polarizations at  $1/\lambda = 1.56$ , 1.93 and 2.33 (colons and semicolons are given half weight). The photometric data for HD 37061 are from Lee (1966).

## 4. Interstellar Polarization

Table VI gives the normalized polarizations. The normalization is performed by setting the straight

average of the polarizations at  $1/\lambda = 1.93$  and  $1/\lambda = 2.33$ equal to 100%. In this way we can both compare stars which are variously polarized to one another, and also combine the observations for various stars in order to study the more general features of interstellar polarization. Colons are us 1 in Table VI to indicate that the probable error for the normalized polarization is  $\pm 8\%$  or greater. Semicolons are for single observations.

Figures 3(a) to 3(e) give the normalized polarization curves both for the stars observed in the present study (solid curves) and for the stars of Paper VIII (dashed

i.

curves). The average probable error for the normalized polarizations plotted in Figs. 3(a) to 3(e) is  $\pm 3.0\%$ . Where the probable error is greater than  $\pm 8\%$ , an open square is used; open circles represent single observations. Omitted from the figures because of unusually large uncertainties are 11D 83953 of this paper and the following stars of Paper VIII: 11D 24431, 134320, 134335, 193443. The irregular red variable  $\mu$ Cephei (III) 206936) has also been omitted since its large amplitude variation in percentage polarization (approx 2%) will be discussed in a subsequent paper in

this series. The observation at  $1/\lambda = 3.03$  for HD 134320 has not been plotted, since the probable error is  $\pm 22\%$ . For  $\zeta$  Tau (HD 37202) the combined values from Table X of Paper VIII and the present Table VI (colons and semicolons half weight) are plotted. Since  $\theta^2$  Orionis (HD 37041) has variable polarization only the 1964 observations are plotted.

The marked similarity of a majority of the curves is a noteworthy feature of Figs. 3(a) to 3(c), as are the departures from this "characteristic" curve. We have combined the observations for 52 of the stars in order

ñ,

to obtain a mean interstellar polarization curve. All stars in Figs. 3(a) to 3(e) except HD 6675, 35468, 37041, and 37202 have been used for this purpose.

In Table VII we list the results obtained by taking the weighted mean of the normalized polarizations for all stars at a given wavelength and the curve is plotted at the bottom of Fig. 3(e). The error bars there give the average probable error, which is a measure of the precision of determining polarization for a single star at the respective wavelength. It does not indicate the dispersion in interstellar polarization for various stars.

The mean curve shows the characteristic broad maximum centered at about 5200 Å with a sharper decrease at larger than at shorter wavelengths. We have also determined a separate mean ir terstellar polarization curve for stars with  $P \ge 2\%$  and P < 2%, respectively, at  $1/\lambda = 1.93$ . There is no significant difference between the two groups. It is to be noted,

however, that all of the stars in Figs. 3(a) to 3(d) which show marked peculiarities have polarizations less than 2%. We include among such stars the following: HD 6675, 25291, 25940, 35468, 37041, 37202, 37367, 40111.

Table VIII lists the residuals of the observed position angles from the weighted mean position angle (see Table V). In determining this mean, colons and semicolons in Table IV are given half weight. Colons in Table VIII indicate probable errors greater than  $\pm 3^{\circ}$ ; semicolons indicate single observations. Exclamation marks (!) behind the HD number note stars for which there is an appreciable rotation of the plane of polarization with wavelength. The judgment that a star shows rotation is based both upon the probable errors and the smoothness of the variation of the residuals with wavelength.

### 5. Variable Polarizations

There is a growing problem in polarization studies as to whether the interstellar polarization is varying or whether all the variations which we observe are intrinsic to a star, stellar system, or circumstellar clouds. Intrinsic variations are now well established for various types of stars including the spectroscopic binary  $\beta$  Lyrae (Shakhovskoi 1964; Appenzeller 1965;

TABLE III. Observed percentages of interstellar pelarization. Weighted mean values.

\* These stars are K-type stars and the corresponding effective wave numbers are 1.05, 1.19, 1.54, 1.91, 2.29, 2.75, and 3.00  $\mu^{-1}$ .

## TABLE IV. Observed position angles of interstellar polarization. Weighted mean values.

• In the relative distance column, near stands for 0.1-0.3 kpc and far for 0.6-1.5 kpc. • In the position angle column, an exclamation mark (1) indicates wavelength dependence of position angle.

\* All stars of Table X in Paper VIII and of the present Table VI except HD 6675, 24431, 35468, 37041, 37202, 83953, 193443, and 206936.

Belton and Woolf 1965; Serkowski 1965; Rucinski 1966), the irregular red variable  $\mu$  Cephei (Grigoryan 1959; Coyne and Gehrels 1966; Serkowski 1966), and various Mira type variables (Serkowski 1966).

Tables IX and X list the difference of our observations made during 1966–1967, with those of other observers extending from 1949 to 1965. The second column in each of these tables lists the difference between our observations at  $1/\lambda = 2.33$  and those of Hall (1958); the third column lists the difference between our observations at  $1/\lambda = 1.93$  and Hiltner (1956); the

fourth column gives the difference between the weighted means of our observations at  $1/\lambda = 1.93$  and  $1/\lambda = 2.33$  with those of Behr (1956); and the last column gives the average of the differences between our observations at  $1/\lambda = 1.93$ , 2.33, and 2.78 with Serkowski's green, blue, and ultraviolet filters, respectively. The Serkowski observations were supplied to us directly by the author, corrections being applied in the same way as described in Sec. III of Paper VIII (see references there). At the bottom of each table the systematic difference is the straight average, and the mean residual the average of the absolute value, of the residuals exclusive of those in parentheses.

In Table X, with the exception of HD 35468 there are no significant residuals. Large residuals in Table IX for HD 7902, 10898, and 25914 may indicate variations in percentage of polarization. All three of these stars have large polarizations (greater than 3%) and they are relatively distant.

We now discuss the polarimetric observations of the B2III star,  $\gamma$  Orionis (HD 35468). In Table X, the residuals of the position angle in both the Hall and Behr columns are remarkably large (of the order of 50°) and similar. Our determination of  $\theta$  is the result of measurements at seven independent wavelengths

made on three different nights (see Table II). The largest probable error for the combined value at a single wavelength is  $\pm 1.9^\circ$ . For a total of ten other stars observed on three different nights on which we observed  $\gamma$  Orionis the mean absolute residual in position angle, Coyne-Hall, is  $\pm 4^{\circ}$ . It appears that either the plane of polarization of  $\gamma$  Orionis has rotated or that we or Hall and Behr are in error by some 50° for  $\gamma$  Orionis. There also appears to be a dependence of  $\theta$  on wavelength (see Table VIII) and a monotonically increasing polarization with decreasing wavelength [see Tables III and VI, and Fig. 3(c)]. Although the percentage of polarization is small with a maximum of 0.3% at  $1/\lambda = 3.03$ , the average probable error of the combined observations from two different nights is also small,  $\pm 0.01\%$ . The remarkable wavelength dependence of the percentage of polarization depicted in Fig. 3(c), which suggests a small mean particle size for the scatterer, as well as the indications of a rotation of the plane of polarization with wavelength and time, suggest  $\gamma$  Orionis as a candidate for more detailed observations, especially in the far ultraviolet.

For the spectroscopic binary and shell star,  $\zeta$  Tau (HD 37202) we find no change in the percentage

polarization between 1964 and 1967. There is, however, a change in the position angle. The mean angle for the 1964-65 observation is 26°8; for the 1967 observations it is 35%. For both epochs there appears to be a rotation of position angle with wavelength of the order of 5° to 10°. The rotation, however, is in the opposite sense for the two epochs, such that the difference in the position angle at  $1/\lambda = 3.03$  between the two epochs is 20°.

 $\mathcal{H}$ 

12

We have checked the internal consistency of the position angles for both the 1964-65 and the 1967 observations by intercomparisons of observations on other stars and planets observed on the different nights during each of the two observing runs when HD 37202 was observed. There appear to be no systematic effects.

In Table II, in addition to HD 35468 and HD 37202 for five other stars suspected of variability in polarization the individual observations are given. Four of these stars are spectroscopic binaries. HD 10516 ( $\varphi$  Persei) is of particular interest since its period is 127 days and the variations in the percentage polarization are of the order of  $0.2\% \pm 0.02$  occurring over a period of about 4 months. Furthermore, there is a rotation of the plane of polarization with wavelength of the order of 30°. Likewise HD 37041 ( $\theta^2$  Orionis), a spectroscopic binary with a period of 21 days, has a variation in the ultraviolet polarization of  $0.5\% \pm 0.04$ and a rotation of the plane of polarization with wavelength of the order of 20°.
