# SUMMARY OF AVAILABLE INFORMATION ON REYNOLDS ANALOGY FOR ZERO-PRESSURE-GRADIENT, COMPRESSIBLE, TURBULENT-BOUNDARY-LAYER FLOW

I

By Aubrey M. Cary, Jr. Langley Research Center

#### SUMMARY

An analysis of available experimental data defining the Reynolds analogy between turbulent heat transfer and skin friction has been conducted. For Mach numbers greater than 5, there are insufficient data and too much scatter in the available data to empirically define within desirable accuracy limits the functional dependence of the Reynolds analogy factor on the boundary variables. For Mach numbers less than 4 or 5 and near-adiabatic wall conditions, an empirical definition of the Reynolds analogy factor as presented by Chi and Spalding appears to be valid as a mean of the data; no simultaneous measurements of skin friction and heat transfer were found for this lower Mach number range. There is an indication from the experimental data that decreasing the ratio of wall-to-local-total enthalpy decreases the Reynolds analogy factor. Of the available prediction methods, the Kármán and Kozlov estimates of the Reynolds analogy factor agree best with the general level of the experimental data. It is concluded that experimental turbulent-heat-transfer data cannot in general be used to validate methods for predicting turbulent skin friction until a comprehensive definition of Reynolds analogy is available.

#### INTRODUCTION

There are now available numerous empirical or semiempirical methods which provide reliable estimates of turbulent skin friction for zero-pressure-gradient, compressible, turbulent-boundary-layer flow up to Mach 4 or 5 with zero or moderate heat transfer. (See, for example, refs. 1, 2, and 3.) These same methods can be used to predict heat transfer provided that a Reynolds analogy between skin friction and heat transfer is available. Chi and Spalding (ref. 4) determined a Reynolds analogy factor from available heat-transfer data for Mach numbers less than 5 and ratios of wall-to-total temperature from approximately 0.5 to 1.2 with data restricted to two-dimensional and axisymmetric zero-pressure-gradient flow. By using calculated values of skin friction (from ref. 3) to form the ratio  $2N_{St}/C_{f}$ , where  $N_{St}$  is the local Stanton number and  $C_{f}$  is the local skin-friction coefficient, Chi and Spalding concluded that for their range of conditions the

~

Reynolds analogy factor had no apparent dependence on Mach number or heat transfer and that a value of  $2N_{St}/C_f = 1.16$  provided the best fit to the experimental data. Since the skin-friction predictions for the data conditions included in Chi and Spalding's investigation were previously validated for near-adiabatic wall conditions, the resulting estimate for the Reynolds analogy factor should be reliable for the specified conditions. A Reynolds analogy factor of 1.16 is significantly lower than predictions from Colburn (ref. 5) or Rubesin (ref. 6) but approximates the Kármán prediction, as modified in reference 7, for Prandtl numbers of 0.7 to 0.75.

For Mach numbers greater than 4 or 5 and for other than near-adiabatic heattransfer conditions at all Mach numbers, no theory or method for predicting turbulent skin friction and heat transfer has been consistently validated. Though numerous investigators have attempted to show the desirability of various methods (see, for example, refs. 1, 2, 7, and 8), the considerable leeway afforded each investigator in applying the prediction methods (choice of virtual origin for turbulent flow, choice of the Reynolds analogy factor, etc.) has precluded making a definitive choice. Thus, the considerable body of turbulent-heat-transfer data available for higher Mach numbers and for which skin friction was not also measured cannot be used to establish the Reynolds analogy factor as was done by Chi and Spalding in their analysis.

In the present report, for Mach numbers greater than 5, only data from investigations in which both skin friction and heat transfer were measured simultaneously were used to determine values for the Reynolds analogy factor. Included are the published results for high Mach numbers (M > 4) and high heat-transfer rates on flat plates or nozzle walls (zero pressure gradient), which were found in an extensive literature search (refs. 4 and 7 to 16). A summary of results presented by Chi and Spalding for nearadiabatic wall conditions is also included for completeness.

#### **RESULTS AND DISCUSSION**

Available skin-friction and heat-transfer data from which a Reynolds analogy factor may be deduced can be divided into two classes: those data obtained for Mach numbers less than 4 or 5 with near-adiabatic wall conditions and high Mach number data with significant heat transfer. In the first class, heat-transfer data alone will define a Reynolds analogy factor since current prediction methods for the skin friction may be used with confidence for these flow conditions. In the second class, both skin friction and heat transfer must be measured since no generally acceptable method for predicting skin friction for these conditions exists. An attempt was made to obtain all published data from investigations where skin friction and heat transfer were measured simultaneously.

A summary of the Reynolds analogy factors derived from the available data is presented in figure 1 for flat-plate, turbulent-boundary-layer flow and in figure 2 for turbulent-boundary-layer flow on a nozzle wall (approximately zero pressure gradient at the measuring station) with a favorable pressure-gradient history. The conditions for which flat-plate data defining the Reynolds analogy were available were Mach numbers from 0 to 12 and ratios of wall-to-local-total enthalpy from 0.09 to 1.20. The variation of the data for any given flow condition is indicated in the figures by the width of the bar with each symbol. Most of the data shown in figure 1 for Mach numbers greater than 4 were obtained from reference 12 where skin friction and heat transfer were measured simultaneously on a flat plate in a shock tunnel. These data were rereduced for this investigation by using a recovery factor of 0.89 instead of 1.0 as used in reference 12. Additional details of this data reduction are given in reference 8, and the heat-transfer and skin-friction data reduced by using a recovery factor of 0.89 are given in table I. Difficulty in obtaining accurate measurements of skin friction and heating during the short run time associated with shock tunnels accounts for some of the scatter in the data from reference 12.

To delineate functional dependence, an attempt was made to correlate the experimental data with the local Mach number, the ratio of wall-to-local-total enthalpy, and the Spalding and Chi incompressible skin-friction coefficient  $C_f F_c$ , as presented in figures 1 and 2. Also presented in figures 1 and 2 are predictions of the Reynolds analogy factor from five popular methods; each of these methods is discussed in the appendix. There are two immediate conclusions to be drawn from figure 1. First, there is excessive scatter in the data; part of this scatter may be due to the chosen correlation functions and part due to measurement inaccuracies. Second, the available data are generally either for low Mach numbers ( $M_e < 4 \text{ or } 5$ ) and near-adiabatic wall conditions ( $C_f$  not measured) or for higher Mach numbers and low ratios of wall-to-local-total enthalpy. Because of the excessive scatter in the experimental data and the limited range of conditions, no definitive statements as to the overall variation of the Reynolds analogy factor with the boundary variables can be made. However, for the conditions of Mach

number less than 4 or 5 and near-adiabatic wall enthalpy, Chi and Spalding recommend using  $2N_{St}/C_f = 1.16$ , and for these specified conditions, the Chi and Spalding recommendation appears to be as good a representation of the data as other popular estimates. (See the predictions included in fig. 1.) From the variation of the Reynolds analogy factor with wall-to-local-total enthalpy ratio, a tentative conclusion may be that a decrease in  $2N_{St}/C_{f}$  occurs for the lower range of wall-to-local-total enthalpy ratio  $(0 < H_w/H_t < 0.4)$ . Of the predictions shown in figure 1, the estimates of Kozlov (ref. 17) and Kármán (ref. 18) best represent the general level of the data. The Kármán values were determined by using the modification presented in the appendix of reference 7. Kozlov (ref. 17) presented empirical expressions for the skin-friction and heat-transfer coefficients and arrived at a Reynolds analogy expression by forming the ratio of these two empirical equations. (See appendix.) Predictions using this method for representative boundary conditions perhaps best approximate the data in both level and trend. The predictions of Kozlov for turbulent skin friction and heat transfer are similar to the predictions of the T-prime methods as discussed in references 1, 7, 8, and 16; since these studies show the T-prime methods to be questionable at low wall-to-local-total temperature ratios, the Kozlov method is also in doubt.

The nozzle-wall data shown in figure 2 were obtained in a shock tunnel (refs. 12 and 14) or in a boundary-layer channel (ref. 15) where the wall boundary layer has a pressure-gradient history. Heat-transfer and skin-friction data listings were provided by the authors of reference 15 and are presented here in table II. The scatter of the nozzle-wall data is too great and the range of conditions too restricted to experimentally assess the effects of the boundary variables on the Reynolds analogy factor. The data generally fall below Colburn's prediction (ref. 5) and above Reynolds' original analogy (ref. 19). The Kozlov and the modified Kármán predictions agree best with the level of the data, as they did with the flat-plate data.

An assessment of the data in figures 1 and 2 indicates that a relationship between heat transfer and skin friction for turbulent-boundary-layer flow is not well defined. Thus, it is recommended that experimental heat-transfer data not be used in attempting to validate a skin-friction prediction method until accurate measurements of skin friction and heat transfer are made and, thus, a comprehensive definition of the Reynolds analogy is available.

#### CONCLUDING REMARKS

The main result derived from an analysis of available experimental data on the Reynolds analogy is that for Mach numbers less than 4 or 5 with other than near-adiabatic wall conditions and for Mach numbers greater than 4 or 5, there are insufficient data and too much scatter in the available data to empirically define the Reynolds analogy factor within desirable accuracy limits. Therefore, extreme care must be used in attempting to validate methods for predicting turbulent skin friction by using experimental heattransfer data until a comprehensive definition of the Reynolds analogy is available. <u>Accurate</u> measurements of skin friction and heat transfer (obtained simultaneously) are needed in the lower range of the wall-to-local-total enthalpy below Mach 5 and through the entire range of the wall-to-local-total enthalpy ratio above Mach 5. The data gathered for this analysis are useful but are not definitive from the point of view of the Reynolds analogy. There is an indication that decreasing the wall-to-local-total enthalpy ratio decreases the Reynolds analogy factor. Of the available prediction methods, the Kármán and the Kozlov estimates of the Reynolds analogy factor give the best general agreement with the level of the experimental data. It is clear that a definitive formulation of the Reynolds analogy awaits extensive experimental investigation.

National Aeronautics and Space Administration, Langley Station, Hampton, Va., October 8, 1969.

#### APPENDIX

### FORMULATION OF SEVERAL METHODS FOR PREDICTING THE REYNOLDS ANALOGY FACTOR

#### Reynolds

Reynolds' original expression for the analogy between boundary-layer heat transfer and skin friction for incompressible flow can be obtained in reference 19 as

$$2 \frac{N_{St,i}}{C_{f,i}} = 1.0$$
 (1)

When extended to compressible flow, it is merely assumed that

$$2 \frac{\mathrm{N}\mathrm{St}}{\mathrm{C}_{\mathrm{f}}} = 1.0 \tag{2}$$

#### Colburn

The Colburn form of the Reynolds analogy was empirically derived for incompressible flow in reference 5. This method of predicting the Reynolds analogy factor extended to compressible flow has enjoyed great popularity through the years. The expression for this Reynolds analogy factor is

$$2 \frac{N_{St}}{C_{f}} = N_{Pr}^{-\frac{2}{3}}$$
(3)

where the Prandtl number used for the predictions in the present investigation is taken to be 0.725, and from equation (3) yields a Reynolds analogy factor of 1.24.

### Kármán

Kármán's expression for the Reynolds analogy factor, originally derived for incompressible flow in reference 18 and extended to compressible flow in reference 7, is expressed as

$$2 \frac{N_{St,i}}{C_{f,i}} = \left\{ 1 + 5 \left( \frac{C_{f,i}}{2} \right)^{1/2} \left[ \left( N_{Pr} - 1 \right) + \log_e \left( \frac{5N_{Pr} + 1}{6} \right) \right] \right\}^{-1}$$
(4)

where  $2N_{St,i}/C_{f,i}$  is assumed to be  $2N_{St}/C_{f}$  when  $C_{f,i}$  is taken to be the Spalding

#### APPENDIX

and Chi incompressible skin-friction coefficient  $F_c C_f$  and the Prandtl number is 0.725. A more detailed discussion of this approach is presented in reference 7. It was also stated in reference 7 that these Kármán values of the Reynolds analogy factor are representative of the predictions from reference 20.

#### Kozlov

Empirical expressions for the local skin-friction coefficient and Stanton number were used by Kozlov (ref. 17) to define the Reynolds analogy factor. These expressions based on local conditions at the edge of the boundary layer are

$$C_{f} = 0.085 R_{x,w}^{(-0.29+0.01 \log R_{x,w})} \left(\frac{T_{w}}{T_{e}}\right)^{-0.61} \left(\frac{T_{aw}}{T_{e}}\right)^{-0.19}$$
(5)

$$N_{St} = 0.0296 R_{x,w}^{-0.2} N_{Pr,w}^{-0.57} \left(\frac{T_w}{T_e}\right)^{-0.61} \left(\frac{T_{aw}}{T_e}\right)^{-0.28}$$
(6)

Equations (5) and (6) were derived independently from comparisons with experimental data. According to reference 17, the range of conditions for which equations (5) and (6) are valid within 10 percent are

for equation (5)

$$10^{5} \leq R_{x,w} \leq 10^{9}$$
$$0 \leq M_{e} \leq 10$$
$$0.6 \leq \frac{T_{w}}{T_{aw}} \leq 1.0$$

and for equation (6)

$$5 \times 10^5 \leq R_{x,w} \leq 10^9$$
$$0 \leq M_e \leq 10$$
$$0.1 \leq \frac{T_w}{T_{aw}} \leq 5.0$$

The ratio of equations (5) and (6) gives the Reynolds analogy factor as

$$2 \frac{N_{St}}{C_{f}} = 0.695 R_{x,w} \left( 0.09 - 0.01 \log R_{x,w} \right) N_{Pr,w} - 0.57 \left( \frac{T_{aw}}{T_{e}} \right)^{-0.09}$$
(7)

#### APPENDIX

For equations (5), (6), and (7) the wall Reynolds number is defined as

$$R_{x,w} = \frac{\rho_w u_e x_v}{\mu_w}$$
(8)

where  $\rho_w$  is the density based on wall values of temperature and pressure,  $\mu_w$  is the dynamic viscosity based on wall values of temperature, and  $x_v$  is the distance from the origin of turbulent flow.

### Chi and Spalding

From an analysis of experimental data defining the Reynolds analogy, Chi and Spalding (ref. 4) give the Reynolds analogy factor which best fits experimental data as

$$2 \frac{N_{St}}{C_f} = 1.16 \tag{9}$$
