ABSTRACT

The neutral composition of the mesosphere is reviewed with emphasis on nitrogen oxides and oxygen allotropes. Then ionization sources in the D region are studied including the effects of recent experimental results. Finally, the negative ion chemistry is discussed including the calculation of an "effective attachment factor, β_{eff} ." On the basis of the experimental β_{eff} , a new fast binary attachment process is considered.

In the appendix, relevant experimental data is tabulated, and the diurnal variation of atomic oxygen and ozone concentrations is presented, based on recent values for the relevant rate coefficients.

1. D-REGION NEGATIVE-ION CHEMISTRY

1.1 Introduction

Electron-density distribution is, at this time, the best known parameter in the D region. From recent work, a general picture of this parameter can be deduced (Mechtly and Smith 1968a,b; Mechtly and Shirke 1968). Unlike the upper ionized regions, D-region structure is characterized by the attachment of electrons to neutral molecules to form, through complex chemistry, a large number of negative ions of variable distribution and mass. Electron density is therefore strongly controlled by the negative-ion chemistry. This, in turn, is determined by the rates of reactions that produce or eliminate different species of negative ions. Reaction rates depend upon the rate coefficients now quite well established by laboratory measurements (Fehsenfeld et al, 1967; Fehsenfeld and Ferguson, 1968) and upon the concentration of neutral species such as O, O₃ and NO. The experimental knowledge about the odd allotropes of oxygen is very limited, and theoretical computations depend upon several factors still doubtful. Recent direct estimates of NO concentration (Barth 1966; Pearce 1968) show much larger values than those obtained with indirect ionospheric methods based upon electron-density data and ion-reaction schemes widely accepted at this time. To accept the experimental data for the NO concentration will force a re-evaluation of the negative-ion chemistry, in a search for missing reactions, in order to reconcile those data and direct measurements of electron density.

The first chapter of this report will review the neutral composition of the mesosphere, where D-region ionized species are very minor constituents. Nitrogen oxides and oxygen allotropes distributions will be discussed in more detail.

The second chapter will be devoted to a review of the sources of ionization in the undisturbed D region for both daytime and nighttime. The impact of high values of NO concentrations (Pearce, 1968) in relation to the ionization of nitric oxide by Lyman-alpha radiation will be described. The importance of precipitation of electrons, as a source of ionization during nighttime will be considered.

In the third chapter, the negative-ion chemistry will be discussed. An "effective attachment factor" β_{eff} is defined, this being the only term in the continuity equation for electrons and ions that depends upon the negative-ion schemes. Assuming steady state conditions, β_{eff} is computed from experimental electron-density profiles, calculated rate of ionization and laboratory deionization data. The problem introduced by different values of NO concentration will become evident during the discussion. It will be shown that in order to obtain theoretically the experimental β_{eff} a new fast binary attachment process should be postulated when NO concentration measurements are used.

2. NEUTRAL COMPOSITION OF THE MESOSPHERE

2.1 Introduction

The atmospheric region between roughly 50 and 90 km, called the mesosphere, is chemically very active. Photodissociation produces atomic species that, in a relatively dense medium, can react rapidly with other constituents forming a large number of more or less stable minor species. The absorption of solar ultraviolet radiation by ozone at wavelengths of 2100-3000 Å is a strong source of heating. The effect of this is the large temperature observed around 50 km. A decrease in temperature is observed above that height up to 80-90 km. This altitude gradient of temperature is important to the chemistry of the mesosphere because many reaction rate coefficients are strongly temperature dependent.

In the region of 50 to 90 km there are a number of three-body reactions among both neutral and ionic species. The passive third body is represented in most cases by the general atmospheric molecule, i.e., the concentration of the third body involved is the atmospheric number density itself.

Both the COSPAR International Reference Atmosphere (1965) and the U.S. Standard Atmosphere Supplement (1966) give experimental models of the neutral gas densities, temperature, and other parameters as a function of height, season and latitude. Below approximately 80 km a constant mean molecular mass or, what is equivalent, a constant mixing ratio can be assumed for the major constituents. The neutral atmospheric region between 80 and 120 km is the least known experimentally, and constituent distribution is still uncertain. Variations of O₂ distribution are very important because dissociation of molecular oxygen controls the chemistry of the odd allotropes of oxygen and

also some aspects of the ion chemistry. Figure 1 shows the concentration of O_2 from winter and summer at 45° latitude and low solar activity from the U.S. Standard Atmosphere Supplement (1966).

As a product of the chemical activity of the mesosphere, numerous neutral species are present in that region. Most of them have concentrations smaller by several orders of magnitude of O_2 or N_2 . Such species are called minor constituents. Photodissociation of O_2 , N_2 , H_2O and CH_4 is the first step in the formation of: O , O_3 , NO , NO_2 , N_2O , H , OH , HO_2 , H_2O , etc. Other minor constituents in the mesosphere could be clusters of neutral molecules like $(H_2O) \cdot NO$ could be produced in the region of low temperature around 80 km. Also chemically important is CO_2 .

At this time, all the species mentioned above, the odd allotropes of oxygen and the oxides of nitrogen are considered the most important ones to the negative-ion chemistry. Hydrogenous compounds appear to be of indirect importance because they represent only perturbations introduced in the chemistry of oxygen. The role played by neutral clusters is unknown.

2.2 Odd Allotropes of Oxygen

The experimental knowledge about O and O_3 distribution at D-region altitudes is very limited. Only one nighttime preliminary profile of mesospheric oxygen concentration has been published (Fedynskii et al, 1967). Daytime ozone measurements have been carried out by Johnson et al, (1954) and by Rawcliffe et al, (1963). Nighttime profiles have been obtained by Carver et al. (1966), Mikirov (1965) and Reed (1968). Figure 2 summarizes these experimental results.

Theoretical computations of O and O_3 distribution are based upon the knowledge about: fluxes of the solar radiation capable of photodissociating

Figure 1. Molecular oxygen concentration at 45° latitude derived from U.S. Standard Atmosphere Supplement 1966. Full line indicates summer conditions; broken line indicates winter conditions.

Figure 2. Experimental profiles of atomic oxygen and ozone concentrations. 1. Daytime ozone concentration by Johnson, et al. (1954); 2. Daytime ozone concentration by Rawcliffe, et al. (1963); 3. Nighttime ozone concentration by Carver, et al. (1966); 4. Nighttime ozone concentration by Reed (1968); 5. Nighttime ozone concentration by Mikirov (1965) and 6. Atomic oxygen nighttime concentration by Fedynskii, et al. (1967).

O_2 and O_3 , dissociation cross sections as a function of the radiation wavelength, and rates of the chemical reactions involved. The latter represents the less known factor.

The basic photochemical reactions of atmospheric oxygen are:

Cross sections and fluxes of radiation involved in reactions (1) and (2) are shown in Figures 3 and 4.

The diversity of published laboratory values for the rate coefficients of (3), (4) and (5) is very wide. It reflects the complications introduced in the experimental determinations by the effect of hydrogenous and nitrogenous trace impurities and the formation of metastable species (Schofield, 1967).

A recent discussion of experimental studies of reactions (3), (4) and (5) has been given by Kaufman (1967). This author adopts for the range between 190 and 400°K, the value of $k_3 = 3.0 \times 10^{-33} \left(\frac{T}{300}\right)^{-(2.6 \pm 0.4)}$ obtained by combining several data when $M \equiv N_2$. Also $k_5 = (1.4 \pm 0.3) \times 10^{-12} \exp \left[-\frac{(3.0 \pm 0.4)}{RT} \right]$ is adopted by the same author. It must be noted that some discrepancies among different experimental studies of these reactions still exists. Table 1 shows the individual results of some of these studies

	$\exp\left(-\frac{3000 \pm 400}{RT}\right)$		

$R = 1.987 \text{ cal/}^\circ\text{K mole}$

for the range of atmospheric temperatures, together with the data adopted by Kaufman (1967).

Theoretical models of O and O₃ have been calculated by several authors. Some of them considered a photochemical reaction scheme based upon an oxygen alone atmosphere as represented by reactions (1) and (5), (Craig, 1950; Hunt, 1966a; London, 1967; Maeda and Aikin, 1968). However, some of these authors are mainly concerned with stratospheric ozone. It must be noted that the rate coefficients used in the above-mentioned studies are notably different from the values adopted by Kaufman (1967) using all experimental data available at this time.

Models of O and O₃ that take into account reactions of hydrogenous compounds in the chemical scheme have been published by Hampson (1965) and Hunt (1966b). However, they have used reaction rate coefficients that differ sensibly from the ones that are considered correct at this time. Of particular importance, besides the basic oxygen reactions rates already discussed, is the rate coefficient of reaction:

Hunt (1966a) assumed a value of $k_6 = 10^{-12} \text{ (cm}^3 \text{ sec}^{-1}\text{)}$. A more realistic one appears to be: $k_6 = 5 \times 10^{-11}$ as deduced from McGrath and McGarvey (1967).

A more sophisticated approach is to consider an oxygen-hydrogen atmosphere including also the dynamics terms. Konashenok (1967) and Hesstvedt (1968) introduced vertical eddy transport in their calculations. From the work of these authors it is clear that the dynamical terms can change the vertical and geographic distribution of atomic oxygen and ozone. It must be

Figure 5. Theoretical profiles of noon atomic oxygen and ozone concentration at 45° N. Full line indicates summer profiles; broken line indicates winter profiles. These values were computed for oxygen alone atmosphere.

Figure 6. Theoretical profiles of midnight atomic oxygen and ozone concentration at 45° N. Full line indicates summer profiles; broken line indicates winter profiles. These values were computed for oxygen alone atmosphere.

noted however that the reaction rate coefficients of reactions (3) and (5) adopted in all the studies mentioned above, differ notably from the Kaufman (1967) values which, at this time, should be considered more representative.

It is convenient to compute the temporal and spatial variations of O and O_3 based on the Kaufman rate coefficients for the reactions (3) and (5) and also on recent values of solar fluxes. In this way a basic photochemical model and a function of time and latitude is obtained. It can be changed as a second step, by introducing hydrogenous compound reactions and dynamical terms. Time variations as a function of height, latitude and season are computed by solving the continuity equations in the differential forms:

$$\begin{aligned} \frac{d[O]}{dt} = & 2j_2 [O_2] + j_3 [O_3] - 2k_3 [O]^2 [M] - k_4 [O] [O_2] [M] \\ & - k_5 [O] [O_3] \end{aligned} \quad (7)$$

$$\frac{d[O_3]}{dt} = k_4 [O] [O_2] [M] - k_5 [O] [O_3] - j_3 [O_3] \quad (8)$$

The computer programs used and the input values of cross sections, solar radiation fluxes, atmospheric temperature, and densities adopted in the calculations are given in the Appendix. Detailed tabulation of the output data (atomic oxygen and ozone concentrations) are also given there. Figures 5 and 6 show the computed O and O_3 profiles for 45° of latitude north, summer and winter, and noon and midnight. Figures 7, 8 and 9 show the latitudinal variation of atomic oxygen and ozone concentrations at 70, 80 and 90 km. A full discussion of these data will be given elsewhere.

Figure 7. Theoretical values of diurnal latitudinal and seasonal variation of atomic oxygen and ozone for an oxygen alone atmosphere (70 km).

Figure 8. Theoretical values of diurnal latitudinal and seasonal variation of atomic oxygen and ozone for an oxygen alone atmosphere (80 km).

Figure 9. Theoretical values of diurnal latitudinal and seasonal variation of atomic oxygen and ozone for an oxygen alone atmosphere (90 km).

2.3 Nitrogen Oxides

Minor constituents of great importance to the chemical aeronomy and, in particular, to the D-region ionization are nitric oxide and, in a minor scale, nitrogen dioxide. NO is the relevant specie to the chemistry of the D region as considered by Nicolet and Aikin (1960). Their paper represents one of the first attempts to explain theoretically what was known at the end of the fifties about the D region. These authors introduced the hypothesis that the basic process of formation during low solar activity was the ionization of NO by Lyman-alpha solar radiation with a production peak between 75 and 80 km. Until 1964 no direct experimental data on the nitric oxide distribution were published. The only methods used to derive NO concentration were the indirect ionospheric estimates as the ones obtained by Mitra (1966) and Wagner (1966) for D-region heights. A final model deduced using the same methods has been published recently by Mitra (1968). His NO distribution is expressed by:

$$[\text{NO}] = 4 \times 10^{-1} \exp \left(- \frac{3700}{T} \right) [\text{O}_2] + 5 \times 10^{-7} [\text{O}] \quad (9)$$

Figure 10 shows Mitra's (1968) distribution of NO.

Direct photometric measurements of the NO airglow were made by Barth (1964, 1966) from Wallops Island during low solar activity. The data obtained from a rocket flight in November 1963 shows an NO concentration of $6.2 \times 10^7 \text{ cm}^{-3}$ at 75 km and 6.0×10^7 at 95 km. These values are much higher than the ones deduced by indirect ionospheric methods. For some time the Barth (1966) values were considered doubtful, but a recent rocket photometric experiment by Pearce (1968) again shows very high values of nitric oxide concentration at all heights in the mesosphere. His values are also plotted in Figure 10.

Figure 10. Nitric oxide concentration as a function of height by Mitra (1968) and Pearce (1968).

The more comprehensive theoretical study of the NO distribution has been published by Nicolet (1965a,b). This author shows the importance of atomic oxygen and ozone as reactants in the chemistry of the oxides of nitrogen in the atmosphere. He shows also that in order to conciliate the values given by Barth (1964) it was necessary to introduce ionic reactions in the chemical scheme.

Nitrogen dioxide distribution in the atmosphere have not been determined experimentally. However its chemistry is strongly related to that of nitric oxide.

The basic reaction scheme of the oxides of nitrogen appears to be (Nicolet, 1965a,b) as follows:

Rate coefficients for these reactions are given in Table 2.

TABLE 2
Reaction rate coefficients for the oxides of nitrogen

<u>Reaction</u>	<u>Reaction Rate Coefficient</u>	<u>Source</u>
$N + O_3 \xrightarrow{k_{11}} NO + O_2$	5.7×10^{-13}	Phillips and Schiff (1962)
$N + O + M \xrightarrow{k_{12}} NO + M$	$1.1 \times 10^{-33} \left(\frac{T}{300}\right)^{-0.5 \pm 0.2}$	Kaufman (1968)
$N + O_2 \xrightarrow{k_{13}} NO + O$	$(1.4 \pm 0.2) \times 10^{-11}$ $\exp - \left(\frac{7100 \pm 400}{RT}\right)$	Clyne and Thrush (1961)
$N + NO \xrightarrow{k_{15}} O + N_2$	$(2.2 \pm 0.6) \times 10^{-11}$	Phillips and Schiff (1962)
$NO + O_3 \xrightarrow{k_{16}} NO_2 + O_2$	$9.5 \times 10^{-13} \exp - \left(\frac{2450 \pm 150}{RT}\right)$	Clyne <u>et al.</u> (1964)
$R = 1.987 \text{ K cal } (^\circ\text{K mole})$		

Mesospheric distribution of NO obtained by using the above-mentioned radiation scheme give values much lower than the experimental data obtained by Barth (1966) and Pearce (1968). A possible way of explaining high values of NO concentration around 80 km is by taking into account vertical downward motions of NO from the lower thermosphere as discussed recently by Geisler and Dickinson (1968). Large amounts of nitric oxide can be produced below 120 km by the ion-molecule reaction:

as shown by Ryan (1968).

2.4 Hydrogenous Compounds

The basic hydrogenous compound in the atmosphere below 90 km is water vapor. The only experimental data available on the concentration of water vapor are the data by Fedynskii et al. (1967) which show very large values in the mesosphere up to an altitude of approximately 85 km. Water vapor is dissociated by solar radiation of wavelength less than 2400Å:

Both atomic hydrogen and hydroxyl are chemically very active and are capable of undergoing a very complex series of reactions with atomic oxygen and ozone. The problem of the presence and distribution of hydrogenous compounds in the mesosphere and stratosphere has been studied in detail by Hesstvedt (1964, 1965, 1968). The chemistry of water vapor is closely related to the chemistry of oxygen. For example, the reaction:

is capable of reducing the concentration of ozone in the mesosphere as indicated originally by Nicolet (1964) and shown by Hunt (1966b).

Other basic reactions of hydrogen and hydrogenous compounds are:

Table 3 gives the rate coefficients of these reactions. Hydrogen peroxide is an additional compound that could be present in the mesosphere but in very small concentration. Its presence gives rise to a large number of secondary reactions. A very detailed chemical scheme has been given recently by Hesstvedt (1968). In the same paper, theoretical models of hydrogen and hydrogenous compounds, distributions are shown. As a comment to these models, it should be noted that when dynamical vertical transport is taken into account, the dominant hydrogenous constituent is water vapor up to a height of about 85 km. This fact indicates that H and OH (both very active and important for the oxygen chemistry) are less abundant than expected, reducing their effect on the distribution of other species.

TABLE 3

Reaction rate coefficients for hydrogen and hydrogenous compounds

<u>Reaction</u>	<u>Reaction Rate Coefficient</u>	<u>Source</u>
$H + O_3 \xrightarrow{k_{20}} OH + O_2$	$(2.6 \pm 0.5) \times 10^{-11}$	Phillips and Schiff (1962)
$OH + O \xrightarrow{k_{21}} H + O_2$	$(5 \pm 2) \times 10^{-11}$	Kaufman (1968)
$H + O_2 + M \xrightarrow{k_{22}} HO_2 + M$	$3 \times 10^{-32} \left(\frac{273}{T}\right)^{1.3}$	Schofield (1967)
$HO_2 + O \xrightarrow{k_{23}} OH + O_2$	$\geq 10^{-11}$	Kaufman (1964)
$HO_2 + O_3 \xrightarrow{k_{25}} OH + 2O_2$	$\sim 10^{-14}$ (estimate)	Hunt (1963)

2.5 Carbon Dioxide

The importance of carbon dioxide in the heat balance of the region below 90 km has been recognized for a long time (Gowan 1947a,b). In their study of the photochemistry of the atmospheric CO₂, Bates and Witherspoon (1952) deduced that carbon dioxide should be in constant mixing ratio up to 100 km, approximately. A recent discussion of the role of CO₂ in the mesosphere has been given by Craig (1965). However, no detailed calculations have been made of the distribution variations that can be expected. Also, no direct measurements of this constituent above the troposphere are available at this time.

The photochemistry of CO₂ can be expressed basically by the reactions:

Carbon dioxide absorption cross sections are smaller by an order of magnitude with respect to the equivalent molecular oxygen cross sections. The rate coefficient k_{28} is still doubtful, (Kaufman, 1968) but is considered very slow. At 293°K Clyne and Thrush (1962) found $k_{28} < 8 \times 10^{-35}$.

In summary, it can be said that the chemistry of atmospheric carbon oxides is at this time practically unknown.

3. RATES OF IONIZATION

3.1 Introduction

Several sources of ionization can act in the atmosphere below 90 km. The most important one is considered to be, at this time, solar Lyman-alpha radiation ionizing nitric oxide. However, the uncertainties about the mesospheric concentration of this constituent which were mentioned in the last chapter, make difficult a correct estimate of the relative importance of Lyman-alpha and other radiation in the ionization of the D region. Solar X-rays and ultraviolet radiation of 1027-1118Å wavelengths between 85 and 90 km, and cosmic rays below 70 km, are capable of ionizing the atmospheric gas. At night, scattered Lyman-alpha radiation and precipitated electrons could be effective sources of ionization between 70 and 90 km.

3.2 Ionization by Solar Lyman-Alpha

A very intense radiation is emitted from the sun at a wavelength of 1215.7Å. Its photon flux is equal, for average low solar activity, to 2.7 photons cm⁻² sec⁻¹ equivalent to 6 erg cm⁻² sec⁻¹. The hydrogen Lyman-alpha line originates in the absorbing region between the photosphere and the chromosphere. The kinetic energy of solar protons in that region is lost through the radiative recombination with electrons. Lyman-alpha radiation is mostly absorbed by O₂ and an interesting fact is that one of the absorption "windows" of molecular oxygen atmosphere corresponds to the same wavelength as shown in Figure 11. The corresponding absorption cross section is $\sigma_{O_2} = 1.04 \times 10^{20} \text{ cm}^2$ (Watanabe, 1958), Lyman-alpha radiation can penetrate as low as 65-70 km. The only atmospheric constituent that can be ionized by this radiation, below 90 km, is nitric oxide, and it becomes a strong

Figure 11. Absorption coefficient of molecular oxygen in the far ultraviolet (Watanabe, et al., 1953).

source of ionization in the D region. NO ionization cross section is $\sigma'_{\text{NO}} = 2 \times 10^{-18} \text{ cm}^2$ (Watanabe, 1954). With cross section and flux data it is possible to compute the rate of NO ionization by Lyman-alpha. This is done by using the expression:

$$q_{\text{L}\alpha}(h) = \sigma'_{\text{NO}} [\text{NO}] \exp(-\sec \chi \sigma_{\text{O}_2} \int_h^{\infty} d[\text{O}_2] dh) \quad (29)$$

where $q_{\text{L}\alpha}$ indicates the rate of ionization, h the altitude, brackets indicate concentration, and χ is the solar zenith angle. $\sec \chi$ is substituted by the Chapman function for angles greater than 80° .

By using Mitra (1968) and Pearce (1968) nitric oxide distributions shown in Figure 3, different rates are computed and are drawn in Figure 12. The Pearce data results in a very large rate of ionization which overdraw the effects of X-rays and in part, of cosmic rays as effective sources of ionization as will be seen below.

3.3 Ionization by X-Rays

Quasi-thermal X-ray emissions of wavelength $< 100\text{\AA}$ originates in the corona of the sun. This radiation is highly variable as is shown in Figure 13, reproduced from de Jager (1967).

Solar X-rays of wavelength between 1 and $40\text{\AA}$ can penetrate in the D region down to an altitude of 50 km, ionizing all the constituents of the mesosphere. However, the low photon fluxes available during low solar activity are not capable of producing important ionization below 85 km. Under such conditions the X-ray contribution to the formation of the D region is limited to its upper part. During solar flares when the X-ray fluxes increase by several orders of magnitude, this radiation increases greatly the ionization of all the D region.

Figure 12. Daytime D-region rates of ionization due to different sources. 1 is the ion-pair production by $L\alpha$ radiation on NO concentration given by Mitra (1968). 2 is ionization of NO with Pearce (1968) distribution. 3 is x-ray ion-pair production from Ohshio, *et al.* (1966) and Hinterreger, *et al.* (1965). 4 and 5 are rates of ionization of $\text{O}_2(^1\Delta_g)$ given by Hunten and McElroy (1968).

Figure 13. Solar x-ray emission for various solar conditions. The curves drawn are based on measurements in three wavelength bands, as indicated by the heavy bar segments. The slopes of the bar segments are the slopes of the assumed x-ray emission functions used to reduce the photometer responses to the plotted energy fluxes. The energy fluxes refer to values observed at the earth's distance above the atmosphere (from H. Friedman, 1963).

A summary of the absorption and ionization cross sections for X-rays and O_2 and N_2 has been given by Hinterreger et al. (1965) and are reproduced in Table 4, together with their estimates of photon fluxes for quiet conditions of low solar activity. From these data the rate of ionization due to X-rays of wavelength from 1 to $40\text{\AA}$, can be computed by using the expression:

$$q_{XR}(h, \chi) = \sum_i \sum_j \sigma_{ij} [X]_j \exp - \sec \chi_j \int_h^\infty \sigma_{ij} [X]_j dh \quad (31)$$

where i represents wavelength, j constituent, and the other symbols have been defined above. Ohshio et al. (1966) using Hinterreger et al. (1965) cross sections, computed the rate of ionization produced by a unit photon flux for all solar radiation. They included the band from 1 to $40\text{\AA}$ X-rays. With their data and the fluxes of Table 4, the rate of ionization for undisturbed low solar activity are also shown in Figure 7.

3.4 Ionization of Metastable Molecular Oxygen

Recently (Hunten and McElroy, 1968) it has been suggested that a major source of ionization in the upper D region could be the ionization of the metastable species $O_2(^1\Delta_g)$ by solar ultraviolet radiation on the wavelength band 1027-1184 $\text{\AA}$. Ionization of the metastable molecular oxygen requires less energy than the non-excited O_2 . Experimental measurements of $O_2(^1\Delta_g)$ shows that its concentration is large in the mesosphere as is shown in Figure 14, taken from Hunten and McElroy, (1968). The rate of ionization obtained by the same authors is also shown in Figure 12.

3.5 Ionization by Precipitated Electrons

It is known that the auroral excitation and ionization in the lower ionosphere is produced mostly by the precipitation of energetic electrons in the atmosphere (Hultqvist, 1965 and references therein). Electrons

Figure 14. The concentrations of $O_2(^1\Delta_g)$ above 70 km, from the dayglow measurement of Evans, et al. (1968). The smooth version shown dashed was used for the calculations in this paper.

TABLE 4

Absorption and ionization coefficients for O_2 and N_2 in the X-ray region

Wavelength Region or line (Å)	Photon Energy (eV)	Flux		Effective Cross Sections (10^{-18} cm^2)			
		$(10^9 \frac{\text{ph}}{\text{s}} \text{ cm}^{-2})$	$(\text{erg} \frac{\text{cm}^{-2}}{\text{s}})$	Total O_2	N_2	Ionization O_2	N_2

precipitating in the region of the South Atlantic anomaly (Ghielmetti et al., 1965; Paulikas et al., 1966 and references therein) can be a substantial source of ionization in that area, both at night and in the day (Zmuda, 1966).

In July 1964, O'Brien et al. (1965) measured for the first time simultaneously, both the flux of precipitating electrons ($E \geq 40$ keV) and nightglow emissions including the 3914Å line using rocket techniques. On that occasion, they recorded a flux of 40 electron $\text{cm}^{-2} \text{sec}^{-1}$. Tulinov (1967) and Tulinov et al. (1969) have measured directly the flux of daytime and nighttime energetic particles with a system of Geiger counters aboard rockets. Values of particles fluxes as a function of latitude obtained are shown in Figure 15. The same author computed the rate of ionization that is drawn in Figure 16. The figure also shows the rate of ionization computed by using O'Brien et al. (1965) particle flux and assumed spectrum. This computation has been carried out by using the formulation of Lazarev (1967) which is essentially the same as developed by Rees (1963) but more adequate for a complete computation.

It has been shown (Radicella, 1968) that nighttime ionization in the upper D region can be explained assuming ionization by electron precipitation. His computations were based upon a chemical scheme that will be discussed in the next chapter and on the rate of nighttime ionization given by Ivanov-Kholodyny (1965). By using the same formulation given by Radicella (1968) and the rate of ionization obtained from O'Brien et al. (1965) data, the electron density shown in Figure 17 is computed. The figure also shows an experimental profile measured by Mechtly and Smith (1968a). It can be seen that measured electron precipitation can produce at night the necessary ionization in the upper D region.

Figure 17. Comparison of experimental and theoretical electron densities in the nighttime D region.

3.6 Ionization by Cosmic Rays

Almost forty years ago Hulburt (1930) used Millikan's measurements to compute ionization by cosmic radiation in the region below 60 km. Nicolet and Aikin (1960), in their early theory of the D region, attributed the ionization of the lower part of that region to galactic cosmic rays. Values of the rate of ionization produced by galactic cosmic rays is shown also in Figure 7. The computed values were obtained by using the empirical relation given by Arnold and Pierce (1963):

$$q = 1.5 \times 10^{-18} [M] \cos^{-4} \theta \left[1 - \frac{3}{22} (y - 1964)\right] \quad (32)$$

where

q = ion pair production ($\text{cm}^{-3} \text{ sec}^{-1}$)

θ = geomagnetic latitude

y = year

$[M]$ = neutral gas density.

4. NEGATIVE-ION CHEMISTRY IN THE D REGION

4.1 Laboratory Measurements of Negative-Ion Reaction Rates

On the basis of the known laboratory measurements of attachment reactions and mesospheric composition it appears that the basic process of negative-ion formation in the D region is:

with a rate coefficient (Phelps, 1967):

$$k_{33} = 1.4 \times 10^{-29} \left(\frac{300}{T}\right) e^{-\frac{600}{T}} .$$

Other three-body attachment reactions involving minor constituents are unimportant. Reaction:

is very slow (Fehsenfeld and Ferguson, 1968) and as a result, O^- is not considered as an initial negative ion of importance. It should be considered also that binary attachment reactions involving heavy neutrals like NO_3 could have rate coefficients as high as $10^{-7} \text{ cm}^3 \text{ sec}^{-1}$.

Molecular oxygen negative ions are short lived because electrons can be detached from them by collision with atomic and excited species, and because they can charge exchange with neutral molecular species.

The only abundant atomic species in the D region is atomic oxygen which reacts rapidly with O_2^- :

where $k_{34} = 3 \times 10^{-10}$ (Fehsenfeld et al., 1967). Also the excited species $O_2(^1\Delta_g)$ detaches electrons through:

where $k_{36} = 2 \times 10^{-10}$ (E. E. Ferguson, 1968 private communication).

Recently, several charge exchange reactions have been measured in the laboratory. In particular:

where $k_{37} = 3 \times 10^{-10}$ (Fehsenfeld et al., 1967) and $k_{38} = 1 \times 10^{-9}$ (Fehsenfeld and Ferguson, 1968; Rutherford and Turner, 1967).

The reaction:

suggested by Nicolet (1965b) has been found to be slow in laboratory measurements, Ferguson (1967). At this time, reaction (35) appears as the basic charge exchange for O_2^- . Reaction 36 could be important only at night below 70 km where it will eventually provide an effective process in formation of NO_2^- .

Possible three-body reactions leading to the formation of heavy and stable negative ions should be investigated in the laboratory because of their potential importance at D-region heights. Experimental observations of negative ions spectra Narcisi (1968), for example, suggest the presence of heavy negative ions below 100 km.

Negative ion O_3^- can exchange its charge with molecular species:

where $k_{40} = 4 \times 10^{-10}$ and $k_{41} = 1 \times 10^{-11}$ at room temperature, as found by Fehsenfeld et al., (1967). Reaction (40) is always more effective than reaction (41) because the ratio $[CO_2]/[NO]$ is much larger than one below 90 km, also if the large values estimated by Barth (1966) and Pearce (1968) are accepted.

NO_3^- is a stable negative ion. This is not the case with CO_3^- which can react with atomic oxygen regenerating O_2^- as shown by Fehsenfeld et al., (1967)

where $k_{42} = 8 \times 10^{-11}$.

Another possible reaction is:

where $k_{43} = 9 \times 10^{-12}$ (Fehsenfeld et al., 1967). Reaction (42) is more effective than (43) if:

$$[O] \gg \frac{k_{43}}{k_{42}} [NO] \approx 10^{-1} [NO] .$$

It can be said safely that above 55 km during daytime and above 70 km at night, reaction (42) is the main charge exchange process of CO_3^- . However,

the formation of O_2^- by (42) and the rapid detachment that takes place through reactions (35) and (36), tend to produce an excess of electrons below 90 km during both daytime and nighttime, contrary to the experimental evidence. To avoid this difficulty in studying nighttime D region, Radicella (1968) postulated another fast charge exchange reaction dealing with a stable negative ion, suggested originally by Whitten and Poppoff (1964):

assuming $k_{44} = 10^{-13} \pm 1$. However, F. C. Fehsenfeld (private communication 1968) studied this reaction in the laboratory and found it to be very slow ($k_{44} < 10^{-15} \text{ cm}^3 \text{ sec}^{-1}$) at room temperature.

It must be noticed, however, that the final implicit equation used by Radicella (1968) in order to compute nighttime electron-density profiles for steady-state conditions (see his Appendix 2, Equation A12) is independent of the particular reaction that produces the stable negative ion. That equation is formally identical with equation below.

Final processes that involve electrons and stable negative ions in the D region are recombination and mutual neutralization. The rate coefficient for dissociative recombination:

has been analyzed recently by Biondi (1967).

A value of $k_{45} = 7 \times 10^{-7}$ at 200°K (D-region temperature) with a temperature dependence of the type T^{-1} appears to be reasonable, when $XY^+ \equiv NO^+$.

The present experimental knowledge about the rate of mutual neutralization:

is not very good. However, a rate coefficient $k_{46} = 4 \times 10^{-8}$ for atmospheric ions has been measured by Hirsch et al. (1967) and this value agrees with the theoretical estimate of $k_{46} = 5 \times 10^{-8}$ by Baulknight and Bortner (1964).

A summary of the rate coefficients of negative-ion reactions is given in Table 5. In the above discussion, we confined our attention on a rather reduced number of reactions involving the major constituents and the minor constituents of larger concentration. A simple inspection of the rate coefficients for the many negative-ion reactions involving the known minor atmospheric constituents including hydrogenous compounds. (DASA Reaction Rate Handbook: 1967) shows that they are of very little importance in the negative-ion chemistry of the normal D region.

4.2 General Schemes of D-Region Negative-Ion Chemistry

Let reaction (33) be the initial step in the formation of negative ions. Time variations of the ionic species at a given altitude can be written:

$$\frac{d[e]}{dt} = \sum q + \delta [O_2^-] [P_1] - \beta [e] [M]^2 - \alpha_e [e] [XY^+] \quad (47)$$

$$\frac{d[O_2^-]}{dt} = \beta [e] [M]^2 - \delta [O_2^-] [P_1] - \gamma [O_2^-] [P_2] \quad (48)$$

$$\frac{d[M^-]}{dt} = \gamma [O_2^-] [P_2] - \alpha_i [XY^+] [M^-] \quad (49)$$

where brackets indicate concentrations, e indicates electron, $P_1, P_2, \dots$ are neutral molecules or atoms, M is the atmospheric gas as a whole, N^- is the final molecular stable negative ion, XY^+ is the general molecular positive ion, and $\sum q$ is the ion pair production rate due to the sum of all possible sources of ionization. $\alpha_e, \alpha_i, \beta, \gamma, \delta$ are, respectively, rate coefficients of recombination, mutual neutralization, attachment, charge exchange and detachment. It can be assumed also that:

$$[XY^+] \approx [e] + [N^-] \quad (50)$$

because the stable negative ion will be always more abundant than other intermediate negative ions like O_2^- . When:

$$\frac{d[e]}{dt} = \frac{d[O_2^-]}{dt} = \frac{d[M^-]}{dt} = 0 \quad (51)$$

is assumed, i.e. when steady-state conditions are considered, solutions of Equations (47), (48) and (49) will not be changed if intermediate charge exchange reactions take place. The steady-state solution of Equation (48) gives:

$$[O_2^-] = \frac{\beta[M]^2[e]}{\gamma[P_1] + \delta[P_2]} \quad (52)$$

By substitution in 47 the following equation is obtained:

$$\sum q - \frac{\gamma[P_2]}{\gamma[P_1] + \gamma[P_2]} \beta[M]^2[e] - \alpha_e[XY^+][e] = 0 \quad (53)$$

or:

$$\sum q - \beta_{\text{eff}}[e] - \alpha_e[XY^+][e] = 0 \quad (54)$$

where:

$$\beta_{\text{eff}} = \frac{\gamma[P_2]}{\delta[P_1] + \gamma[P_2]} \beta[M]^2 \quad (55)$$

can be called an "effective attachment factor". Taking into account Equation (50), it can be written:

$$\sum q - (\beta_{\text{eff}} + \alpha_e [N^-])[e] - \alpha_e [e]^2 = 0 \quad (56)$$

$$\beta_{\text{eff}}[e] - \alpha_i [e][N^-] - \alpha_i [N^-]^2 = 0 \quad (57)$$

This system of equations can be solved in terms of e and N^- if the ion-pair function and coefficients are known. An implicit equation in β_{eff} is written as follows:

$$[e] = \frac{\sum q}{\alpha_e \left\{ \frac{[e]}{2} + \sqrt{\frac{[e]^2}{4} + \beta_{\text{eff}} \frac{[e]}{\alpha_i}} \right\} + \beta_{\text{eff}}} \quad (58)$$

which is formally equal to Equation A12 of Radicella (1968). If the electron density is known an implicit equation in β_{eff} is:

$$\beta_{\text{eff}} = \frac{\sum q}{[e]} - \alpha_e \left\{ \frac{[e]}{2} + \sqrt{\frac{[e]^2}{4} + \beta_{\text{eff}} \frac{[e]}{\alpha_i}} \right\} \quad (59)$$

Equations (47) to (49) have been written considering only the detachment process with a rate $\delta[P_1][O_2^-]$. If an additional process with a rate $\delta'[P_1'] [O_2^1]$ is taken into account, reactions (56) and (57) are formally maintained, but now is:

$$\beta_{\text{ef}} = \frac{\gamma[P_2]}{\delta[P_1] + \delta'[P_1'] + \gamma[P_2]} \beta[M]^2 \quad (60)$$

If the charge exchange with rate $\gamma[P_2][O_2^-]$ is such that:

$$\gamma[P_2] \gg \delta[P_1]$$

Equation (23) reduces to:

$$\beta_{\text{eff}} = \beta[M]^2 \quad (61)$$

Another possibility appears if the charge exchange reaction or chain of reactions is not capable of producing a large concentration of stable negative ions. The effect will be:

$$\beta_{\text{eff}} \ll \beta[M]^2 \quad (62)$$

that is equivalent, in terms of electron density, to reducing Equation (26) to:

$$[e] = \sqrt{\frac{\Sigma q}{\alpha_e}} \quad (63)$$

A final case results if an additional attachment process is postulated with a rate $\beta^1[X]$, where X is an unknown constituent, and such that Equation (23) becomes:

$$\beta_{\text{eff}} = \beta^1[X] + \frac{\gamma[P_2]}{\delta[P_1] + \gamma[P_2]} \beta[M]^2 \approx \beta^1[X] \quad (64)$$

From the above discussion it is clear that each of the different forms of β_{eff} reflects a different negative-ion scheme. It is possible now to analyze

the problem of the apparent contradictions between daytime-measured electron densities and NO concentration. If measured NO concentration (Pearce, 1968) is accepted together with reactions (33), (34), (35), (36), (37), (40), (41), (42), (43), (45), and (46), which represent the most accepted set, and which will refer as the "basic schemes", the effective attachment factor will be written as:

$$\beta_{\text{eff}} = 1 \frac{\frac{k_{43}[\text{NO}]}{k_{43}[\text{NO}] + k_{42}[\text{O}]}}{\frac{[\text{O}] + \frac{2}{3} [\text{O}_2(^1\Delta\text{g})]}{[\text{O}_3]} + \frac{k_{43}[\text{NO}]}{k_{43}[\text{NO}] + k_{42}[\text{O}]}} k_{33}[\text{O}_2]^2 \quad (65)$$

As it is mentioned before, during daytime, above 55-60 km, and at night above 70-75 km:

$$k_{42}[\text{O}] \gg k_{43}[\text{NO}] \quad ,$$

Then:

$$\beta_{\text{eff}} \approx \frac{\frac{k_{43}[\text{NO}]}{k_{42}[\text{O}]} [\text{O}_3]}{[\text{O}] + \frac{2}{3} [\text{O}_2(^1\Delta\text{g})] + \frac{k_{43}[\text{NO}]}{k_{42}[\text{O}]} [\text{O}_3]} k_{33}[\text{O}_2]^2 \quad (66)$$

where:

$$\frac{\frac{k_{43}[\text{NO}]}{k_{42}[\text{O}]} [\text{O}_3]}{[\text{O}] + \frac{2}{3} [\text{O}_2(^1\Delta\text{g})] + \frac{k_{43}[\text{NO}]}{k_{42}[\text{O}]} [\text{O}_3]} \ll 1 \quad . \quad (67)$$

This case corresponds then to the condition given by Equation (63). The electron distribution can be computed by using Equations (58) and (66) and the ion-pair production rate given in Chapter 2 when Pearce (1968) NO

concentration is adopted. The result is shown in Figure 18 together with experimental data and it can be seen that below 85 - 90 km the electron density is much larger than expected on the basis of experimental evidence (Mechtly and Smith, 1968b).

By using the basic sequence plus an additional fast charge exchange of the type given by Radicella (1968):

where:

$$k_{68}[X] \gg k_{46}[CO_2] \quad .$$

The effective attachment factor will be:

$$\beta_{\text{eff}} = \frac{[O_3]}{[O] + [O_3] + \frac{2}{3} [O_2(^1\Delta g)]} k_{33} [O_2]^2 \quad (69)$$

which is equivalent to Equation (60). Again by using (58) and (69) the electron density is computed and it is shown in Figure 19. Once more, this theoretical computation shows a larger electron density than what expected experimentally. This is also the case if a fast charge exchange reaction of the type:

such that:

$$k_{70}[X] \gg k_{35}([O] + \frac{2}{3} [O_2(^1\Delta g)])$$

is accepted. The effective attachment factor reduces then to:

Figure 18. Comparison of daytime electron densities. Experimental by Mechtly and Smith (1968b); theoretical from Equations (58) and (66) and NO concentration by Pearce (1968).

Figure 19. Comparison of daytime electron densities. Experimental by Mechtly and Smith (1968b); theoretical from Equations (58) and (69) and NO concentration by Pearce (1968).

$$\beta_{\text{eff}} = k_{33}[\text{O}_2]^2 \quad (71)$$

which is formally equal to Equation (61). The computed electron density for this case is shown in Figure 20 and again no agreement is reached with the experimental data.

The only possibility left in order to obtain an agreement between the experimental electron density and the measured NO concentration is to search for new attachment reactions faster than the attachment to O_2 between 70 and 90 km. This is done by means of β_{eff} . It can be computed by using Equation (59), daytime experimental values of $[\text{NO}]$ and $[e]$, and accepted deionization coefficients. The effective attachment factor can be also derived theoretically from (69) and (71). Figure 21 shows these computed values of β_{eff} . It can be seen that the profile based upon experimental data, is quite different from the two theoretical profiles. The only way to conciliate experimental values of $[\text{NO}]$ and $[e]$ and theoretical computation is to postulate a binary attachment reaction of the type:

where Z^- is a stable negative ion and such that:

$$k_{72}[\text{ZW}] \gg k_{33}[\text{O}_2]^2$$

or:

$$\beta_{\text{eff}} = k_{72}[\text{ZW}]$$

which corresponds to Equation (64).

Figure 20. Comparison of daytime electron densities. Experimental by Mechtly and Smith (1968b); theoretical from Equations (58) and (71) and NO concentration by Pearce (1968).

Figure 21. Comparison of effective attachment values. Computed from experimental data of Mechtly and Smith (1968b) and Pearce (1968) and from Equations (69) and (71).

Accepting reaction (72) where [ZW] could be a heavy neutral, and a tentative rate coefficient $k_{72} \sim 10^{-7} \text{ cm}^{-3} \text{ sec}^{-1}$, β_{eff} experimental in Figure 21 will indicate that the specie [ZW] would be a minor constituent with a peak concentration of $\sim 5 \times 10^6$ at around 80 km. Such a minor contamination at that height could be accepted, but its eventual nature is at this time unpredictable. Possible conglomerates of neutral particle in the region of low temperature could form heavy neutrals.

In summary it can be said, that the negative-ion chemistry can be represented by an effective attachment coefficient β_{eff} as shown by Equation (54) which takes different forms depending upon the negative-ion processes involved. To conciliate the high values of [NO] given by Pearce (1968) with experimental values of electron density and recombination, and mutual neutralization rates, a new attachment process must be postulated. This should be able to form a stable negative ion and could be a fast binary reaction involving heavy neutral molecular compounds or conglomerates formed under the low temperature conditions of the D region. However, further complications appear in the lower mesosphere where the experimental values of β_{eff} suggest the existence of fast detachment reactions.

APPENDIX I

1. SOURCES OF DATA

1.1 Introduction

The computations for the oxygen atmosphere were based on Equations (7) and (8) of the text. The values of k_3 , k_4 and k_5 were taken from the Kaufman adopted data in Table 1.

The O_2 and O_3 absorption cross sections and the solar photon flux are tabulated in Table A1. The same data is shown graphically in Figures 3 and 4 of the text. A list of the references from which the cross sections and fluxes were taken is given in Table A2. The solar flux is the unattenuated photon flux outside the earth's atmosphere. The data numbers in Table A2 refer to those in Table A1. Below $2425\text{\AA}$ the O_2 absorption cross sections are very small according to Hunt (1963) SAD 123, so corrections below $2425\text{\AA}$ are assumed to be zero for these calculations. Between $1775\text{\AA}$ and $1975\text{\AA}$ the solar flux was read from a graph in the Handbook of Physics at $5\text{\AA}$ intervals. These values were then averaged over $50\text{\AA}$ intervals to give an average flux for each $50\text{\AA}$ interval.

1.2 Neutral Atmosphere Parameters $[O_2]$, $[M]$

The attenuation of solar radiation as it passes through the atmosphere depends on the number of absorbing molecules between the altitude of interest and the outside of the earth's atmosphere. For these calculations O_2 was assumed to be the only species which significantly attenuated the solar flux. From 300 to 120 km, the values of $[O_2]$ were obtained from the U.S. Standard Atmosphere Supplement 1966 for the 3 cases: Winter Model, Exospheric Temperature = 1000°K , Summer Model, Exospheric Temperature = 1000°K , and Spring/Fall Model, Exospheric Temperature = 1000°K .

Below 120 km it was necessary to convert the absolute atmospheric density

given in the U. S. Standard Atmosphere Supplement 1966 to $[O_2]$ and $[M]$ by using the mean molecular weight and the percent composition of O_2 . Below 90 km the densities were converted to $[O_2]$ and $[M]$ by assuming a constant mean molecular weight of 28.96 (CIRA 1965) and constant ratio of $[O_2]$ to $[M]$ of .2091 for all seasons. This ratio was calculated from the 90 km values of $[N_2]$, $[O_2]$, $[O]$, and $[A]$ given in CIRA 1965 page 12. At 120 km the mean molecular weight and percent composition of O_2 to M for each season was calculated from data in the U. S. Standard Atmosphere Supplement 1966. Between 90 and 120 km the mean molecular weight and the percent composition were assumed to vary linearly with altitude so as to match the boundary values of 90 and 120 km. The boundary values of composition and mean molecular mass at 90 km and 120 km are given in Table A3. The resultant values of $[O_2]$ were then used to calculate the integral $\int_z^{300 \text{ km}} [O_2] dh$ which is used in the calculation of the photodissociation rates. Above 300 km $[O_2]$ contributed negligibly to the integral.

The photodissociation rate J_k of the k th constituent was calculated according to the formula:

$$J_k = \sum_{\lambda} \sigma_{k\lambda} R_{\lambda} \exp(-\sec \chi \sigma_{\lambda}(O_2) \int_z^{300 \text{ km}} [O_2] dh)$$

where: $\sigma_{k\lambda}$ = the average value of the photodissociation cross section of the k th constituent in the λ th wavelength interval

R_{λ} = the total solar photon flux with wavelength in the λ th interval

$\sec \chi$ = the secant of the solar zenith angle χ

$\sigma_{\lambda}(O_2)$ = the average absorption cross section of O_2 in the λ th interval

$\int_z^{300 \text{ km}} [O_2] dh$ = the integral of the O_2 concentration from 300 km to Z , the altitude of interest.

TABLE A3

	90 km	Mean Molecular Mass	Composition
Summer		28.96	20.91%
Winter		28.96	20.91%
Spring/Fall		28.96	20.91%

	120 km	Mean Molecular Mass	Composition
Summer		26.76	13.17%
Winter		27.12	14.40%
Spring/Fall		26.90	13.61%

In the calculation of the photodissociation rates, it was assumed that only O_2 significantly attenuated solar radiation. It was also assumed that the quantum efficiency for O_2 and O_3 was unity; i.e. every photon absorbed by the molecule resulted in the dissociation of that molecule. Thus, the absorption cross sections are the same as the photodissociation cross sections.

1.3 Initial Values for the Oxygen Atmosphere

Initial values of O and O_3 were calculated for latitudes ranging from $45^\circ N$ to $45^\circ S$ in 15° intervals with a constant solar declination of $23.5^\circ N$. The appropriate temperature profiles for the rate coefficients, as well as $[O_2]$, and the $[O_2]$ integrals, were obtained from the data in U.S. Standard Atmosphere Supplement 1966. The solar zenith angle used in computing the photodissociation rates was calculated from the formula:

$$\cos \chi = \sin(\text{latitude}) \sin(\text{declination}) + \cos(\text{latitude}) \cos(\text{declination})$$

The steady state concentrations of O and O_3 were approximated by:

$$[O] = \left[\frac{J_2 [O_2]}{[M] (k_3 + k_4 k_5 [O_2])} \right]^{1/2}$$

$$[O_3] = \frac{k_4 [O] [O_2] [M]}{J_3}$$

k_3 , k_4 , k_5 are the Kaufman reaction rates given in Table 1 of the text.

J_2 , J_3 = photodissociation rates of O_2 and O_3 respectively.

$[O]$, $[O_2]$, $[M]$, $[O_3]$ are the concentrations of O , O_2 , M , and O_3 , respectively.

1.4 Time-Dependent Oxygen Atmosphere

The time-dependent oxygen atmosphere used the values of $[O]$ and $[O_2]$ from the steady-state approximation as initial values. The basic data for reaction rates, temperatures, cross-sections, solar fluxes, and $[O_2]$ profiles were identical in both models. The time dependence was incorporated into the

solar zenith angle χ in the form $\cos\chi = \sin(\text{latitude}) \sin(\text{declination}) + \cos(\text{latitude}) \cos(\text{declination}) \cos(\text{hour angle})$ where the hour angle uniformly increased at the rate of 24 hours per day. An approximation to the Chapman function was used for the solar zenith angle χ between 80° and 90° to lessen errors due to the curvature of the atmosphere. The values of the Chapman function $Ch(\chi, x)$ were taken from M.V. Wiles. (In this notation χ = solar zenith angle, and $x = \frac{h+R_e}{H}$ where h is the altitude of observation above the earth's surface, R_e is the radius of the earth, and H is the scale height of O_2 at that altitude.) At the altitudes and densities involved, the resultant values of x were quite large, of the order of 1000. To approximate the Chapman function, the region between 80° and 90° was broken into 1° intervals. Within each interval the Chapman function was approximated quite well as a linear function of x about the value at $x = 1000$. When $\chi \geq 90^\circ$ all dissociation rates were set to zero because the solar radiation must pass through very dense layers of O_2 for larger values of χ . Near sunrise and sunset the equations are only rough approximations because only absorption by O_2 is considered. In reality at sunset the sun's rays must pass through dense layers of the atmosphere so that absorption by constituents such as O_3 also becomes important. The results of the time-dependent oxygen atmosphere are depicted graphically in Figures A1 through A24. Numerical tabulations of the O and O_3 variation during a 24 hour period are given in Table A4 to A37. Profiles were computed and plotted for 90 km, 80 km, 70 km, and 60 km for each of the latitudes 45° , 30° , 15° , 0° , -15° , -30° , -45° for a constant solar declination of $+23.5^\circ$, corresponding to a summer solstice in the + latitudes. In addition, profiles were computed at 85 km, 75 km, and 65 km for $\pm 45^\circ$ latitude and declination of 23.5° . The solutions for each latitude and altitude were generated until the concentration

of O_3 at successive noons was within 5% of each other or until a maximum time of 6 days was reached. At all altitudes, except 90 km, the solutions stabilized to within 5% at successive noons before six days passed, and at 90 km the profiles indicate that stabilization would have been reached within another 24 hour period.

2. COMPUTATIONAL CONSIDERATIONS

The entire computer program used in numerical integration of the O and O_3 differential equations is given in Tables A38 through A42. Many important notes are contained on the comment cards within each subprogram. All computations directly involved in the numerical integration of the differential equations were done in double precision to decrease round-off errors. The program is written in Fortran IV for the IBM System/360. The actual numerical integration is done by the DRKGS Subroutine which is provided for the IBM System/360 by IBM. The integration was done by means of the fourth order Runge-Kutta formulae in the modification due to Gill. The comment cards in Table A42 contain more information on this method. The maximum absolute error in concentration per integration was limited to a factor of roughly .0005 times the initial value of the concentration for each constituent O and O_3 . It is unlikely that such errors would accumulate significantly as the integration proceeds because an excess or dearth of a species results in a corresponding increase or decrease of its rate of destruction. During most of the calculations this error limit was satisfied while integrating in 15-minute jumps, but at sunrise and sunset, the integration interval dropped to 1 second or less. The typical IBM System/360 computer running time for a 6-day profile of O and O_3 was about 3 minutes.

Following is a list of notes pertaining to the programs. Additional information is contained on comment cards within each program.

Main Program Table A38

$Z\phi 2$ = integral of $\phi 2$ from 300 km to altitude of interest, LAT = latitude, DEC = declination TXPLOT, TYX, TYPLOT, SIZEX, SIZES are control vectors for the "calcomp" plotter. All statements of the form CALL CCP . . . are plotting

commands, W and S are used in controlling print-out. R = photon flux; S2 = O₂ absorb. cross-x; S₃ = O₃ absorb. cross-x, the 13 VA values are the y intercept values for the Chapman function approximations for 1° intervals from 80° to 93°. The 13VB values are the slopes of the Chapman function linear approximations for the 1° interval from 80° to 93°. PRMT, DERY, NDIM, AUX, Y, X are described in Table A42.

The values of R, S2, and Se were incorporated into the program in a Bloch DATA subprogram which was in common with the labelled common /BFLUX/.

Subroutine FCT TABLE A39

This subroutine is called by the integration routine DRKGS. It calculates the time rate of change of O₃ (DERY(2)) from the values of O(Y(2)) which have been calculated in subroutine DRKGS. Subroutine FCT calls Subroutine Flux to calculate the dissociation rate Jo₂(F₂) and Jo₃(F₃).

Subroutine Flux TABLE A40

This subroutine calculates the photodissociation rates Jo₂ and Jo₃ (F₂ and F₃) as the solar zenith angle χ changes. COSCHI = cos χ where χ is the solar zenith angle. COSCHI is calculated from the latitude, declination, and hour angle in subroutine flux. For $\chi > 90^\circ$, COSCHI is less than zero in ISN 13 so all dissociation rates are set to zero in ISN 14 and 15. For $\chi > 90^\circ$, the values are checked in ISN 17 to determine whether the Chapman function approximation is required. From ISN 22 to ISN 29 new values of the dissociation rates F₂ and F₃ are summed over contributions from all 87 wavelength intervals in which solar flux and cross section data were tabulated. ISN 26 checks for large negative arguments and sets contributions from such terms to zero to avoid an exponential underflow.

Subroutine ØOTP TABLE A41

This subroutine controls the printing of the relevant data.

NIN = number °/ time that output has been called by the equation solving Subroutine DRKGS. Hence, it represents the number of integrations that have been required to that point.

X = TIME in seconds

CHI = Solar zenith angle in degrees calculated from the cosine of chi calculated in Subroutine Flux. The differential equation routine integrate for 6 days under the values of O₃ concentration are with 5% at successive noons in which case the program terminates by setting PRMI(5) = 5.0. This check and resultant termination results in ISN 29 through ISN 33.

ALAT, ADEC are the latitude and declination in degrees. A typical sheet of output is shown in Table A43.

H and SH = integration increment.

Subroutine DRKGS TABLE A42

This is a library subroutine furnished by IBM. It is the subroutine which actually integrates the differential equation. The subroutine has been modified slightly by including the variable H in the arguments of all Subroutine Output statements to transmit the integration interval. Also the card DRKG 0216 has been replaced by the card, 25 CONTINUE, to permit unlimited bisections of the initial integration interval.

C	CARD DRKG 0216 WAS REPLACED BY A CARD (#25 CONTINUE) TO ALLOW UNLIMITED	
C	BISECTIONS OF THE INITIAL INTEGRATION INTERVAL IN ORDER TO REACH THE	
C	DESIRED ACCURACY	
C	PURPOSE	DRKG 60
C	TO SOLVE A SYSTEM OF FIRST ORDER ORDINARY DIFFERENTIAL	DRKG 70
C	EQUATIONS WITH GIVEN INITIAL VALUES.	DRKG 80
C		DRKG 90
C	USAGE	DRKG 100
C	CALL DRKGS (PRMT,Y,DERY,NDIM,IHLF,FCT,OUTP,AUX)	DRKG 110
C	PARAMETERS FCT AND OUTP REQUIRE AN EXTERNAL STATEMENT.	DRKG 120
C		DRKG 130
C	DESCRIPTION OF PARAMETERS	DRKG 140
C	PRMT - DOUBLE PRECISION INPUT AND OUTPUT VECTOR WITH	DRKG 150
C	DIMENSION GREATER THAN OR EQUAL TO 5, WHICH	DRKG 160
C	SPECIFIES THE PARAMETERS OF THE INTERVAL AND OF	DRKG 170
C	ACCURACY AND WHICH SERVES FOR COMMUNICATION BETWEEN	DRKG 180
C	OUTPUT SUBROUTINE (FURNISHED BY THE USER) AND	DRKG 190
C	SUBROUTINE DRKGS. EXCEPT PRMT(5) THE COMPONENTS	DRKG 200
C	ARE NOT DESTROYED BY SUBROUTINE DRKGS AND THEY ARE	DRKG 210
C	PRMT(1)- LOWER BOUND OF THE INTERVAL (INPUT),	DRKG 220
C	PRMT(2)- UPPER BOUND OF THE INTERVAL (INPUT),	DRKG 230
C	PRMT(3)- INITIAL INCREMENT OF THE INDEPENDENT VARIABLE	DRKG 240
C	(INPUT),	DRKG 250
C	PRMT(4)- UPPER ERROR BOUND (INPUT). IF ABSOLUTE ERROR IS	DRKG 260
C	GREATER THAN PRMT(4), INCREMENT GETS HALVED.	DRKG 270
C	IF INCREMENT IS LESS THAN PRMT(3) AND ABSOLUTE	DRKG 280
C	ERROR LESS THAN PRMT(4)/50, INCREMENT GETS DOUBLED.	DRKG 290
C	THE USER MAY CHANGE PRMT(4) BY MEANS OF HIS	DRKG 300
C	OUTPUT SUBROUTINE.	DRKG 310
C	PRMT(5)- NO INPUT PARAMETER. SUBROUTINE DRKGS INITIALIZES	DRKG 320
C	PRMT(5)=0. IF THE USER WANTS TO TERMINATE	DRKG 330
C	SUBROUTINE DRKGS AT ANY OUTPUT POINT, HE HAS TO	DRKG 340
C	CHANGE PRMT(5) TO NON-ZERO BY MEANS OF SUBROUTINE	DRKG 350
C	OUTP. FURTHER COMPONENTS OF VECTOR PRMT ARE	DRKG 360
C	FEASIBLE IF ITS DIMENSION IS DEFINED GREATER	DRKG 370
C	THAN 5. HOWEVER SUBROUTINE DRKGS DOES NOT REQUIRE	DRKG 380
C	AND CHANGE THEM. NEVERTHELESS THEY MAY BE USEFUL	DRKG 390
C	FOR HANDLING RESULT VALUES TO THE MAIN PROGRAM	DRKG 400
C	(CALLING DRKGS) WHICH ARE OBTAINED BY SPECIAL	DRKG 410
C	MANIPULATIONS WITH OUTPUT DATA IN SUBROUTINE OUTP.	DRKG 420
C	Y - DOUBLE PRECISION INPUT VECTOR OF INITIAL VALUES	DRKG 430
C	(DESTROYED). LATERON Y IS THE RESULTING VECTOR OF	DRKG 440
C	DEPENDENT VARIABLES COMPUTED AT INTERMEDIATE	DRKG 450
C	POINTS X.	DRKG 460
C	DERY - DOUBLE PRECISION INPUT VECTOR OF ERROR WEIGHTS	DRKG 470
C	(DESTROYED). THE SUM OF ITS COMPONENTS MUST BE	DRKG 480
C	EQUAL TO 1. LATERON DERY IS THE VECTOR OF	DRKG 490
C	DERIVATIVES, WHICH BELONG TO FUNCTION VALUES Y AT	DRKG 500
C	INTERMEDIATE POINTS X.	DRKG 510
C	NDIM - AN INPUT VALUE, WHICH SPECIFIES THE NUMBER OF	DRKG 520
C	EQUATIONS IN THE SYSTEM.	DRKG 530
C	IHLF - AN OUTPUT VALUE, WHICH SPECIFIES THE NUMBER OF	DRKG 540
C	BISECTIONS OF THE INITIAL INCREMENT. IF IHLF GETS	DRKG 550
C	GREATER THAN 10, SUBROUTINE DRKGS RETURNS WITH	DRKG 560
C	ERROR MESSAGE IHLF=11 INTO MAIN PROGRAM. ERROR	DRKG 570
C	MESSAGE IHLF=12 OR IHLF=13 APPEARS IN CASE	DRKG 580
C	PRMT(3)=0 OR IN CASE SIGN(PRMT(3)).NE.SIGN(PRMT(2)-	DRKG 590
C	PRMT(1)) RESPECTIVELY.	DRKG 600
C	FCT - THE NAME OF AN EXTERNAL SUBROUTINE USED. THIS	DRKG 610
C	SUBROUTINE COMPUTES THE RIGHT HAND SIDES DERY OF	DRKG 620
C	THE SYSTEM TO GIVEN VALUES X AND Y. ITS PARAMETER	DRKG 630
C	LIST MUST BE X,Y,DERY. SUBROUTINE FCT SHOULD	DRKG 640
C	NOT DESTROY X AND Y.	DRKG 650
C	OUTP - THE NAME OF AN EXTERNAL OUTPUT SUBROUTINE USED.	DRKG 660
C	ITS PARAMETER LIST MUST BE X,Y,DERY,IHLF,NDIM,PRMT.	DRKG 670
C	NONE OF THESE PARAMETERS (EXCEPT, IF NECESSARY,	DRKG 680
C	PRMT(4),PRMT(5),...) SHOULD BE CHANGED BY	DRKG 690
C	SUBROUTINE OUTP. IF PRMT(5) IS CHANGED TO NON-ZERO,	DRKG 700
C	SUBROUTINE DRKGS IS TERMINATED.	DRKG 710
C	AUX - DOUBLE PRECISION AUXILIARY STORAGE ARRAY WITH 8	DRKG 720
C	ROWS AND NDIM COLUMNS.	DRKG 730
C		DRKG 740

Table A42 (Continued)

C	REMARKS	DRKG 750
C	THE PROCEDURE TERMINATES AND RETURNS TO CALLING PROGRAM, IF	DRKG 760
C	(1) MORE THAN 10 BISECTIONS OF THE INITIAL INCREMENT ARE	DRKG 770
C	NECESSARY TO GET SATISFACTORY ACCURACY (ERROR MESSAGE	DRKG 780
C	IHLF=11),	DRKG 790
C	(2) INITIAL INCREMENT IS EQUAL TO 0 OR HAS WRONG SIGN	DRKG 800
C	(ERROR MESSAGES IHLF=12 OR IHLF=13),	DRKG 810
C	(3) THE WHOLE INTEGRATION INTERVAL IS WORKED THROUGH,	DRKG 820
C	(4) SUBROUTINE OUTP HAS CHANGED PRMT(5) TO NON-ZERO.	DRKG 830
C		DRKG 840
C	SUBROUTINES AND FUNCTION SUBPROGRAMS REQUIRED	DRKG 850
C	THE EXTERNAL SUBROUTINES FCT(X,Y,DERY) AND	DRKG 860
C	OUTP(X,Y,DERY,IHLF,NDIM,PRMT) MUST BE FURNISHED BY THE USER.	DRKG 870
C		DRKG 880
C	METHOD	DRKG 890
C	EVALUATION IS DONE BY MEANS OF FOURTH ORDER RUNGE-KUTTA	DRKG 900
C	FORMULAE IN THE MODIFICATION DUE TO GILL. ACCURACY IS	DRKG 910
C	TESTED COMPARING THE RESULTS OF THE PROCEDURE WITH SINGLE	DRKG 920
C	AND DOUBLE INCREMENT.	DRKG 930
C	SUBROUTINE DRKGS AUTOMATICALLY ADJUSTS THE INCREMENT DURING	DRKG 940
C	THE WHOLE COMPUTATION BY HALVING OR DOUBLING. IF MORE THAN	DRKG 950
C	10 BISECTIONS OF THE INCREMENT ARE NECESSARY TO GET	DRKG 960
C	SATISFACTORY ACCURACY, THE SUBROUTINE RETURNS WITH	DRKG 970
C	ERROR MESSAGE IHLF=11 INTO MAIN PROGRAM.	DRKG 980
C	TO GET FULL FLEXIBILITY IN OUTPUT, AN OUTPUT SUBROUTINE	DRKG 990
C	MUST BE FURNISHED BY THE USER.	DRKG1000
