#### SECTION I

#### INTRODUCTION

#### GENERAL

This document, prepared from work done under contract NAS 9-12771 and monitored by Dr. W. E. Fedderson, presents the results of a research program to develop objective methods for psychological assessment of crew members prior to and during long-duration space flights.

The ultimate given of the research program described in this report is the development of an objective method of psychologically assessing both potential space flight crew candidates and their individual and group behavior during long-duration space flight. The long-term aim of the program is to discover and use psychological, performance, and psychophysiological variables that can be monitored in the course of routine mission-oriented behavior and that have indicative and predictive values for psychosocial well-being.

Thus, the long-range research objectives are to develop and evaluate assessment methodology; to test and demonstrate this methodology in situations as closely resembling manned space flight conditions as possible; to modify, update, and validate the methodology under situations of confinement and stress; and ultimately to evolve the assessment techniques and hardware into a system fully compatible with both spacecraft hardware and the anticipated life style of crew members on long-duration missions. The latter is important because crew acceptance is vital for the ultimate utility of the proposed methodology.

The selected research paradigm investigates attentional flexibility as a means of psychological assessment (i.e. the ability to adapt rapidly those functional states of attention that are appropriate for any personal, social, or mission change in orientation, process, or.task). Thus, the near-term objective of the program is to devise tasks requiring high attentional states and to determine the assessment power of various associate performance and psychophysiological variables for evaluating these states of attention.

Attentional behavior was selected as an appropriate psychological process upon which to focus because alterations in attention can occur at several levels of functioning, are detectable, and can be indicative of a wide variety of factors relevant to the well-being of individuals and groups. Psychological assessment methodology was developed using established relationships between various performance and psychophysiological variables and between those aspects second attention necessary to engage successfully in a broad category of functions.

#### WORK ACCOMPLISHED

The orientation taken during this phase of work was to develop and demonstrate a hardware instrumentation system and an experimental paradigm that could be used to collect data in manned isolation chamber experiments. These isolation chamber experiments had been planned for the near future, and the isolation chamber to collect the demonstrative data during those test conditions.

The principal work conducted under this contract and described in the body of this report is as follows:

- (a) A substantive review of pertinent literature
- (b) Selection of appropriate methods of objective psychological evaluation
- (c) Development of techniques for psychological evaluation
- (d) Development of apparatus, instrumentation, computer programs, and procedures to test the methods selected under items (b) and (c) above
- (e) Pilot study experimentation
- (f) Evaluation and report on the pilot study results
- (g) Recommendations for future research and development

#### SECTION II

#### BACKGROUND

#### REVIEW OF RECENT LITERATURE

Reviews of the broad and varied subject of attentional behavior can be found in Koster (1969) (Reference 1), Sanders (1970) (Reference 2), and Mackworth (1970) (Reference 3); in addition, Moray (1969) (Reference 4) proposed six different meanings of attention as used in psychological research. Posner and Boies (1971) (Reference 5), however, provide three general concepts or categories under which most research (as well as Moray's meanings) can be categorized. These are listed below.

> Alertness, or Arousal--A varying state of readiness to detect stimuli in repetitive, boring, or low-stimulus frequency tasks (such as vigilance tasks). The term also relates to level of sensitivity to stimuli during periods of preparation for receiving stimulation. Both performance measures (e.g., Mackworth, 1970) (Reference 3) and physiological measures (e.g., Näätänen, 1970) (Reference 6) of alertness provide rationale for including alertness as a component of attention.

Selective Attention--The ability to select one kind of information from another or to select one source of information from other sources. Studies of selective attention may involve sensory modalities, location of signals, selection of responses, content of the information in the stimulus array, or internal templates, models, and memories of past events.

Limited Central Processing Capability--The difficulty in handling two tasks simultaneously; the delay of signals that arrive during reaction time.

For the purpose of this review, emphasis will be placed on the first two topics above and an additional category, Psychophysiological Factors, will be added. This latter section is presented separately because the nature of certain dependent variables, and their utilization as indicative of major modes of responding on an organismic level, has received great emphasis and aroused considerable controversy.

#### Alertness, Isolation, and Clinical Factors

Fedderson and Kanas (1971) (Reference 7) reviewed the stresses of longduration space flight and argued for improved personnel selection techniques and better understanding of these stresses so that intervention strategies might be developed. Memford (1970) (Reference 8) argued for utilization of responses to stress as indexes for selection of personnel and presented data from psychological, physiological, and chemical tests.

Zubek (1970), (Reference 9) reporting on behavioral and electroencephalographic changes in indiverse, and groups of men during 14 days in isolation, emphasized the changes

Another recent study on "isolation by Serafetinides (1971) (Reference 10) also found an ever-present progressive reduction of cortical activity in cases of sensory deprivation. It appears that this perennially consistent alteration in the EEG could be accepted as prima facie evidence of sensory deprivation.

Evidence that the effects of varied levels of sensory input represent a two-edged sword was obtained by Zuckerman et al. (1970) (Reference 11). Utilizing subjects in confinement, they produced environments designed to provide high, normal, and low levels of arousal by manipulation of sensory variety in the environment. The found that anxiety and adrenocortical responses were elevated in both the sigh arousal and low arousal situations as compared with the control situation. Of the two extreme conditions, subjects preferred the high arousal situation to the low arousal one, which was associated with depression. From this and other work (such as that of Frankenhauser et al.) (Reference 12), some approximation of the optimum level of arousal that should be the design objective for space stations and other long-duration manned systems can be obtained.

Shapiro et al. (1970) (Reference 13) observed the effects of sensory reduction in organs and systems not usually monitored in this type of research. They found that reduction of auditory and vestibular inputs resulted in a marked inhibition of gastric secretion.

In trying to-understand the relationship of monotony to psychophysiological responses, Confinant and Kimmel (1971) (Reference 14) studied a situation in which the occurrence of a brief light flash in the dark would be contingent upon the occurrence of a galvanic skin response (GSR). They found that there was instrumental conditioning of the GSR under these conditions. Consequently, they argued that the occurrence of an orienting response may have a reinforcing effect. Orienting responses are discussed subsequently.

Bohlin (1971) (Reference 15), studied the effect of monotonous stimulation on the rate of sleep onset and habituation of the orienting response. He found that monotonous stimulation put his subjects to sleep more quickly than no stimulation. He also found that the rate of habituation of the orienting response tracked the rate of sleep onset. For a comparison between boring stimulation and boring responses London, H., et al. (1972) (Reference 16) studied change in autonomic arousal during performance of boring tasks. They found higher heart rates with very boring tasks and suggested a curvilinear relationship between information rate and autonomic arousal. It is their suggestion that both boring, highly redundant information and low redundancy, rapidly changing situations will result in higher heart rates than will moderate levels of information processing.

Frankenhauser, et al. (1971) (Reference 12), in studying psychophysiological reactions to understimulation and overstimulation, found that these two conditions increased the rate of adrenaline and nonadrenaline production as compared with controls at moderate levels of stimulation. They also found

that subjects who produced more adrenaline performed better in the understimulation condition, while subjects with less adrenaline production performed better in the overstimulation condition. The same observation was made with heart rate as the dependent variable. They interpret their data as supporting a curvilinear relationship between level of arousal and performance, with performance being optimal at moderate levels of arousal. Averill, J. R. et al. (1972) (Reference 17), in a study on complex emotional study, observed that when subjects were shown an isolated accident scene out of context they invariably responded with slowing heart rates; however, if the accident scene were shown within the context of an action film, the opposite response, heart rate acceleration, was observed.

Rathbart and Mellinger (1972) (Reference 18) studied attention and responsivity to remote dangers and found substantial individual differences in their population, which they characterized as fear repressors and sensitizers.

In a study along similar lines, Rice and Greenfield (1969) (Reference 19), studying the psychophysiological correlates of "LaBelle Indifference" found that patients who remained calm in the face of frightening and disabling impairment showed greater physiological arousal than did control subjects. They concluded that psychological defense does not prevent arousal of covert physiological correlates of emotion.

Schmolling and Lopidus (1972) (Reference 20), studying performance in schizophrenics, found that schizophrenics have an elevated base level of physiological parameters. Consequently, under stressful stimulation (in accord with the law of initial values) little increase is seen above baseline values for physiological measure. They characterize these subjects as being hypervigilant, impaired in attending, and showing difficulty in shifting the response set.

Little recent research has been conducted on shifts of attention or perception. Mackintosh and Little (1969) (Reference 21), using pigeons, have shown that strengthening of attention to a single relevant dimension increases the rate of response reversal. Schell (1971) (Reference 22) in experiments with children strongly resembling "learning set" experiments, also has shown that learning to attend to one stimulus dimension at a time improves the shift of attention from one stimulus dimension to another.

The rate of reversal of the Necker cube illusion was investigated by Roland (1970) (Reference 23). He found that stress, in the forms of cold pressor stimulation, increased the rate of reversal of the illusion. Heart rate also was correlated with the rate of reversal of the illusion.

#### Selective Attention and Performance

Typical studies within this category on sensing modality have been made on visual and auditory signals processing by Mackintosh and Little (1969) (Reference 21) using pigeons, and by Webster and Haslerud (1964) (Reference 24) using humans. Wachtel (1967) (Reference 25) presented a survey of evidence suggesting that attention is like a beam of light focused more or less sharply on particular sources of incoming data. He suggested that a distinction can be drawn between the narrowness of focusing at any time and the extent to which the beam ranges over the field of attentional opportunities. He proposed that characteristic tendencies in these two respects can be regarded as facets of personality varying between types of individuals. For example, highly anxious people can be thought of as tending to have a narrow beam that roams widely over the field so that their attention skips rapidly from item to item, but is intensely directed to any item on which it is actually resting. Welford (1970) (Reference 26) commented that . . ."selection seems commonly to be made in terms of attitudes and hypotheses brought to a present situation from past experience--we perceive what we expect to occur or along the lines of what is familiar. It seems clear, therefore, that selection must often be a high-grade process, concerned with data which have already been processed to a substantial extent by the mechanisms of perception. This may well be true even when selection appears to be made in terms of simple sensory quantities."

Classic data in support of this last statement by Welford was reported by Cabanac (1971) (Reference 27) in a study of alliesthesia. In this study Cabanac demonstrated the effect of changing physiological states on the qualities of incoming stimuli. In his studies temperatures and gustatory and olfactory stimuli judged as pleasant under one set of physiological conditions were judged as unpleasant under another. For example, a pleasant tasting liquid became too sweet for hours following ingestion of glucose.

A wide variety of experimental studies has shown that perceptual selection is a task involving some mental activity by the observer, and the more precise that selection must be, the longer it takes or the higher the risk of error.

Baddeley (1972) (Reference 28) suggests that it is plausible to assume that an increase in arousal will focus the subject's attention more and more narrowly on that aspect of the situation that is of greatest immediate importance to him. If this happens to be the task he is required to perform, then his efficiency will be increased; if not, his performance will deteriorate until he abandons the task.

Fortunately, however, response to a dangerous environment may be much more adaptive than this. Work by Epstein and Fenz (1965) (Reference 29) suggests that the experienced parachutist learns to inhibit anxiety since it tends to disrupt performance. They suggest that both the fear and the inhibition focus on the jump but generalize temporally both to prior and later aspects of the jumping situation, and to other stimuli associated more or less closely with jumping. If one assumes the generalization gradient associated with the inhibition of fear to be steeper than that associated with fear itself, then the point of maximum emotional response will tend to be displaced away from the danger stimulus; the greater the degree of inhibition, the farther away will be the displacement.

It seems then that subjects who are repeatedly exposed to a dangerous situation can in some way learn to inhibit their anxiety and displace it away from the point of maximum danger.

٠. .

Considerable literature already exists on the effects of physiological arousal on performance, much of which suggests that they are related by a function resembling an inverted U; that is, as arousal increases, performance improves up to a maximum beyond which further increments in level of arousal lead to poorer and poorer performance (Hebb, 1955 (Reference 30); Malmo, 1959, (Reference 31)). A good deal of experimental data can be accounted for in terms of the inverted-U function. One weakness is its ability to account for almost any result so long as the exact location on the inverted U of the task in question is not specified in advance. The situation is further complicated, however, by the fact that the peak of the inverted U occurs at quite different levels of arousal for different tasks (Corcoran, 1965) (Reference 32). This is intuitively reasonable; however, unless an objective means of assessing a task in advance is available, prediction of performance under stress becomes even more difficult. It seems unlikely that such an assessment can be made until the cause of the inverted-U relationship is known.

One possible explanation of the relationship lies in the suggestion made by a number of workers that an increase in arousal produces a narrowing of attention, with the subject concentrating more and more on the central features of the task and paying less and less attention to more peripheral ones (Easterbrook 1959, (Reference 33); Teichner 1968, (Reference 34)). Perhaps the strongest experimental evidence for such a view comes from recent work by Hockey (1970 a,b) (References 35 and 36) on the effects of loud noise on performance. In one of his experiments, Hockey (1970a) (Reference 35) required his subjects to perform a centrally located tracking task, while at the same time monitoring a series of six small lights distributed on either side of the central task at varying distances from the center. Occasionally one of these lights would be illuminated briefly; if the subject detected this he pressed an appropriate response button. Subjects were tested both in continuous loud noise and in quieter conditions. Overall tracking performance was significantly higher in the noise condition than in the control condition, which showed a decrement during the session. Detection scores on the peripheral task tended to deteriorate with increasing distance from the center. Noise exaggerated this bias by improving performance on the central lights at the expense of peripheral lights. When no central task was required, noise improved detection performance; thus it appears that noise does not simply impair peripheral vision.

In a subsequent experiment, Hockey (1970b) (Reference 36) showed that subjects missed more peripheral signals in noise because they regarded them as less probable than central signals, not simply because of their peripheral location. A comparable result was recently reported by Cornsweet (1969) (Reference 37) who used threat of electric shock to increase level of arousal.

Although experimental results show a clear effect on breadth of attention of stresses that may reasonably be assumed to influence the subject's level of arousal, so far there is no direct evidence that danger will have such an effect. Evidence that this is the case comes from a study by Weltman and Egstrom (1967) (Reference 38) in which novice divers were required to perform a central task while monitoring a faint peripheral light. While the central task did not affect peripheral vigilance on the surface, during diving a distinct subgroup of the subjects emerged who showed much slower response to the peripheral lights, while showing no impairment on the central task. These subjects appeared to

be more anxious than the other subgroup, which showed no deterioration under water, but unfortunately no objective measure of anxiety was available. This defect was remedied in a subsequent study (Weltman et al., 1971) (Reference 39) in which a similar dual task was performed by naive subjects during a simulated 60-ft dive in a pressure chamber. After an explanation of the potential dangers and emergency procedures, the door of the pressure chamber was bolted and a rise in pressure simulated, although actual pressure did not change. Experimental subjects showed a clear anxiety response in terms of both increased heart rate and subjective ratings. They also showed a clear decrement in detection of peripheral light signals but no drop in performance on the central task, relative to an unstressed control group.

Wachtel (1967) (Reference 25) and Moray (1969) (Reference 4) provide general reviews of performance research in selective attention, while the review of this area by Howarth and Bloomfield (1971) (Reference 40) concentrates on experiments involving attentional phenomena in search performance tasks. One specialized method of evaluating attention is shadowing performance tasks in auditory research. This topical area is thoroughly reviewed by Underwood and Moray (1971) (Reference 41).

Larkin and Greenberg (1970) (Reference 42), in studying the effect of uncertainty in presentation of auditory signals, conclude that selective attention may be a recognition phenomenon and not a detection phenomenon. They suggest that no amount of training should alter the detectability of a signal, but that differential experience, by practice, may enable a listener to recognize one tone more efficiently than another.

Typical studies involving the number of stimuli presented are represented by the studies of Chuprikova (1969) (Reference 43), Teichner (1971) (Reference 44), and Rabbit (1964) (Reference 45). Chuprikova found that increasing the number of signals possible in a representation had a continuously limiting effect on the preparedness of subjects to react. Teichner's thorough study on the effects of the number of possible signals on reaction time and probability of detection found that reaction time increased as a function of the number of possible signals and also that the probability of detection decreased as a function of increasing number of possible signals. Rabbit, using a sorting performance technique, found that scanning visual displays to find certain stimuli involved the process of ignoring other stimuli. Specifically, he found that the number of irrelevant stimuli in a display affected both the speed and the accuracy of the sorting task.

Warm (1971) (Reference 46) investigated partial reinforcement concepts utilizing a vigilance task. With a reaction time measure as a dependent variable and knowledge of results as one of the independent variables, he found that withdrawal of knowledge of results increased reaction time, and the effect of withdrawing the knowledge of results was greater in continuous than in partial reinforcement conditions.

Germana (1969) (Reference 47) manipulated interstimulus intervals and found that when the interstimulus intervals were increased greater than 240 msec, no habituation was found. Germana feels that this may be due to the establishment of the stimulus arrival rate. He also observed that recall was unaffected up to interstimulus intervals of 240 msec.

#### Limited Central Processing Capacity

The principal recent development in this area of attention is the study by Allport et al. (1972) (Reference 48) disproving the "single channel hypothesis" of human information processing. Their alternative hypothesis is that attention operates as if there were a number of independent special processes operating in panel. Each process is limited in capacity per unit time and most processors may be turned to a single specific problem under conditions related to signal importance.

#### PSYCHOPHYSIOLOGICAL FACTORS

Psychophysiological concomitants of attention can be classified into two major categories of research: (1) those studies utilizing the electroencephalograph as the principal dependent variable, and (2) investigations into phenomena associated with the orienting reaction. Studies concentrating on the first category are discussed first; however, the bulk of the discussion will focus on the latter category.

Electroencephalographic Studies--Glaser (1963) (Reference 49) has summarized the correlations between EEG findings and behavior. Electroencephalographic studies have been primarily centered around observations on the contingent negative variation or evoked potential; however, some cogent observations are being made in situations involving operant conditioning or training of EEG components.

Since 1960 there has been growing evidence to support the theory that selective attention and selective perception have their neurophysiological basis in blocking irrelevant sensory impulses. Thus, sensory pathways of unattended modalities lose some degree of their capacity to transmit signals, while the attended modality may be facilitated simultaneously. Näätänen (1971) (Reference 6) produced experimental results that show nonspecific anticipatory cortical activation preceding relevant stimuli. This, he argues, is the real reason for the greater amplitudes of potentials evoked by relevant stimuli. Hillgard et al. (1971) (Reference 50) studied those evoked potentials during auditory signal detection and found that the detected signals evoked potentials several times the magnitude of unevoked potentials. He also found that detection threshold performance was identical with concurrent electrophysiological measures of threshold.

Donald and Goff (1971) (Reference 51) reported that they have found EEG components of attention related to increases in cortical responsivity and dissociated from the contingent negative variations. Gale et al. (1971) (Reference 52) utilized subjective estimates of alertness in a vigilance type task while manipulating signal expectancy. They found EEG changes correlated with changes in expectancy in the task.

Subjective reports of subjects in the Garrett/AiResearch laboratory (Wortz, 1971) (Reference 53), corroborated by personal communication with other researchers (L. Fehmi, 1970 (Reference 54); Kamiya, 1970 (Reference 55)) in the field concerning their findings, lend support to the hypothesis that readily monitored brain wave parameters are correlated with awareness and attentional abilities. Fehmi (1970) (Reference 54), for example, reports that the amplitude of brain wave potentials is observed to be correlated with the way in which visual stimuli are viewed. When artists were instructed to view and critically apprehend their field of vision, a low-voltage, fast-electroencephalographic activity was recorded from five brain loci: midline occipital, parietal and frontal lobes, and the right and left temporal lobes. When the opposite instruction was given to view the visual field with a gestalt orientation or in the attitude that would be assumed while actively engaged in painting, the electroencephalographic activity was characterized by high-voltage, slow waves in the alpha wave region of the frequency spectrum. A grasped, stationary, and critically viewed attentional field was associated with low-voltage activity while a flowing, integrative, gestalt-like approach to the attentional field was associated with high voltage activity.

Gale et al. (1972) (Reference 52), in a study that failed in its main purpose, which was to replicate correlation between EEG, extroversion, time of day, and performance, did find incidentally that higher voltage EEG correlates with better signal detection. Consequently this vigilance task correlates with the contention of Wortz and Fehmi above.

Barry and Beh (1972) (Reference 56) found that duration of the desynchronization of the alpha rhythm of the EEG co-varied with the stimulus intensity, whereas the magnitude of the desynchronization did not.

Invgar (1971) (Reference 57) in a study of cerebral blood flow, arousal, and cerebral metabolism suggests that the EEG correlates of arousal and desynchronization are correlated with an increase in cerebral blood flow. He even indicates that regional changes in cerebral blood flow are dependent on the type of cortical activity at each region.

Orientation Reaction (OR) Studies--Psychophysiological studies of attention also have proceeded from the direction stemming from the work of Sokolov, which is summarized in "Perception and the Conditioned Reflex," (1963) (Reference 58) and reviewed by Lynn (1966) (Reference 59).

This perspective of attention is in terms of what the Russian investigations denoted as the orientation--or what it is--reaction (OR). Essentially, the orientation reaction or reflex involves (behaviorally) the turning of the organism toward the source of a novel stimulus. In addition, however, there are a number of concomitant physiological components of this turning toward a stimulus. The physiological changes include pupillary dilation; reduction of threshold in all sensory modalities; increased electromyographic activity; faster, lower-amplitude EEG; peripheral vasoconstriction; cephalic vasodilation; GSR; delayed respiration followed by increased amplitude and lowered frequency; and slowed heart rate. These physiological changes occur regardless of bodily movement, and their occurrence is used to define the occurrence of an orienting reaction (OR).

Essentially, stimuli that can initiate an OR are those that have signal significance, i.e., are either novel, intense, complex, or incongruous; are surprising; or produce tendencies for competing or conflicting reactions.

In addition to the OR, there are two other basic physiologic reactions of the same class that can occur in response to stimuli and must be distinguished from the OR. These are adaptive reactions and defensive reactions. Adaptive reactions refer to responses that have homeostatic or negative feedback reactions, e.g., vasodilation in response to thermal stress or pupillary dilation in response to decreases in illumination. The defensive reaction (DR), on the other hand, occurs in response to very intense or threatening stimuli and is essentially the startle reaction, which includes eye blink, cephalic vasoconstriction (instead of the cephalic vasodilation seen in the OR), and heart rate acceleration.

The other components of the OR occur in the DR without variance from the OR pattern. In addition to cephalic vasoconstriction and heart rate acceleration, another important difference between the OR and DR is that stimuli that will produce an OR will eventually habituate, and the OR will disappear. This is apparently not the case with the DR; it does not habituate. Although Wortz (1967, 1968, and 1969) (References 60, 61, and 62) has found evidence that upon repeated stimulation this response can develop from a DR into an OR, it is suggested by Wortz (1968) (Reference 61) that high-stimulus intensities just below the DR threshold may at times evoke the DR if the general health or coping mechanisms of the organisms deteriorate.

The classic representation of the relationship of the OR and DR in terms of numbers of stimulus presentations and the intensity of the stimulation is reproduced from Sokolov (1963) (Reference 58) and shown in Figure 2-1. This representation, showing that a constant intensity and tendency is to move from an OR to a DR with increasing number of stimulations, is contrary to the observations of Wortz who observed habituation of the DR evolving into an OR with cutaneous shock. The source of this discrepancy may be due to the type of stimuli employed or to levels of arousal. Sokolov observed the DR as a simple reflex and employed repetitions of a simple stimulus of fixed intensity, while Wortz observed a conditioned reflex response to a repetition of stimulus of fixed intensity.

It is apparent, however, that certain factors may vary the OR/DR threshold for a given stimulus intensity. It is suggested that psychophysiological consequences of presentation of stimuli near this threshold, for a given person and in terms of whether an OR or DR is elicited, may be indicative of fundamental aspects of the perceptual coping mechanisms of that person.

A recent study by Gogan (1970) (Reference 63) measuring psychophysiological response to forces of different intensity provide data that tend to correlate with the previously described studies. One of Gogan's principal observations is a correlation between EMG components of the DR and EEG characteristics at the time of presentation of the signal stimulus (Figure 2-2). His data show that at slower EEG frequencies, the magnitude of the elicited startle response is lower. It can be argued from this data and that of Pilsbury and Meyerowitz (Reference 64) that for stimuli of moderately high intensities, field-dependent individuals are more likely to produce a DR than field-independent subjects. Consequently, if disease does operate to alter the distribution of attention for exteroception, it can be hypothesized that this shift will be reflected in . the mechanisms of the orienting and defensive reactions.

. -

Specifically, it is the most fruitful phenomena to investigate in this regard are the finite threshold region between the OR and DR. Thus it is hypothe finite the OR/DR threshold will vary with attentional load, decreasing as attentional load is increased.

Raskin et al. (1969) (Reference 65) studied cephalic vasomotor and heart rate measures of the OR utilizing 80- and 120-db white noise signals. They always found cephalic vasoconstriction (as measured by forehead blood content or forehead pulse amplitude) to the stimulus, whereas heart rate differentiated between the two intensities. Heart rate deceleration occurred in conjunction with the 80-db stimulus while heart rate acceleration occurred with the 120-db signal.

Keefe (1970) (Ref rence 66) utilized a 1000-Hz tone at 70 db, and observed a biphasic forehead prise response that he interpreted as vasodilation followed by vasoconstriction. The magnitude of vasomotor response was found to be related to the prestimulus level, which corresponds to the law of initial values. He also observed that heart rate acceleration was associated with head pulse constriction.

Fantalova (1970) (Reference 67) used a 1000-Hz tone stimulus and rheography for pulse volume measurements in an attempt to measure organ volumes as a consequence of the OR. He concluded that rheography could be used to detect the time of pulse arrival, but not organ volume.

In a study of procedural aspects of research on the OR, Gliner et al. (1971) (Reference 68) found that alterations in order of stimulus presentation can produce orienting reactions.

Just as important as the occurrence of the OR, if not more so, is the rate of habituation of this response. Gabriel and Ball (1970) (Reference 69), utilizing tactile stimuli, found that the OR magnitude would increase as the novelty of a stimulus increased. They also found a spread of OR habituation effect from a principal finger (which was stimulated) to adjacent fingers. Beideman and Sterm (1971) (Reference 70) found that the occurrence of the orienting response observed at the start of a signal and the terminal orienting response (TOR) observed at the cessation of a signal are related to the content and duration of the stimulus. Essentially, they observed that the OR and TOR habituate in the same manner. The idea is that each successive stimulus provides less information; therefore, the novelty diminishes and consequently both OR and TOR diminish. They observed that the TOR habituates at a faster rate than the OR, presumably because after the onset of a signal its termination is more predictable than the stimulus onset. This determinability of the timing between signals also was studied by Germana (1969) (Reference 47), who manipulated the interstimulus interval. He found that as the interstimulus interval increased, the rate of habituation decreased.

Maltzman et al. (1971) (Reference 71) found that stress slowed the rate of habituation of the OR. In a unique set of experiments they found that undergraduates in a first experimental stress situation habituated more slowly than in a second situation, while graduate students habituated more rapidly in a

first experimental situation than they did in a second situation just prior to taking a stressful examination. This second paradigm (with the stress in a separate area of the subject's life and affecting the rate of OR habituation) is relevant to the proposed research.

Coles et al. (1971) (Reference 72) investigated personality factors and the OR, and suggested that neuroticism is positively resulted to the magnitude of the OR.

Lacey and Lacey (1964) (Reference 73) reported on cardiac deceleration in a simple visual reaction time experiment. They found cardiac deceleration to a warning stimulus and cardiac acceleration to the reaction time signal stimulus. These observations were confirmed by Graham and Clifton (1966) (Reference 74), who, in addition to the heart rate deceleration to the warning stimulus, observed acceleration both before and after the response.

While studying vigilance tasks, Kibler (1967) (Reference 75) found a correlation between the signal detection efficiency and the magnitude of the cardiac deceleration.

The relationship between heart rate and signal stimuli was further explored by Coles et al. (1972) (Reference 76). They also found that a warning signal produced heart rate deceleration and that the signal stimulus produced heart rate acceleration. When they instructed their subjects not to respond to the signal stimulus, the heart rate still accelerated, but at a lower rate than when a response was required. They suggested classifying stimuli as imperative or warning, based on the direction of the change in heart rate.

In linking the cardiac components of the orienting and defensive reflexes to vascular components, Hare (1972) (Reference 77) found that heart rate deceleration was accompanied by cephalic vasodilation while heart rate acceleration was accompanied by cephalic vasoconstriction. Thus, although he replicated the Sokolov model, he made his observation by separating his subjects into types based on their heart rate responses to anxiety-arousing accident scenes. He suggested that the classic patterns of cardiovascular activity occur in only some subjects and only under some conditions and that they may be obscured by undifferentiated group data.

Hare defined his optimal grouping of subjects as accelerators, decelerators, and medium decelerators.

In an earlier report Hare et al. (1971) (Reference 78) reported on autonomic responses to effective visual stimulation consisting of female figures, homicides, and ordinary objects. They found the largest heart rate deceleration in women shown slides of nude females and the largest vasomotor response in women shown slides of homicides. The converse was true for male subjects.

Carrol (1971) (Reference 79), using effective visual stimuli to study forehead vasomotor responses, found an initial decrease in forehead pulse amplitude to all stimuli, followed by an elevation in amplitude above the baseline level across a period of 15 seconds. Wilkinson et al. (1972) (Reference 80) added confusion to this area of study by finding that different psychological measures differ in reflecting apparent arousal. In studying performance and arousal as a function of incentive, information load, and task novelty, he found that pulse volume responded to changes in task difficulty while pulse rate responded to incentive.

Zeiner and Schell (1971) (Reference 81), using skin resistance as a parameter, found faster learning and higher orienting responses to innocuous stimuli than to noxious stimuli. They suggested that the response to these two classes of stimuli may involve different physiological processes.

#### COGNITIVE PROCESSES

In an important paper, Kreitler and Kreitler (1972) (Reference 82) relate the orienting response to cognitive process, i.e., processes involved in the production of meaning. Their contention is that cognitive processes allow a better understanding and more precise prediction of human behavior than other variables. They introduce the concept of cognitive orientation to suggest the cognitive nature of the orienting process. Their primary assumptions are that (a) attempt to achieve cognitive orientation (C.O.) is a primary tendency, (b) human behavior is altered by cognitive orientation, and (c) informationabout C.O. allows the prediction of the course of ensuing behavior.

A few definitions are required in order to prepare for a brief description of this model and its relationship both to the work previously cited and to the work evolving under this contractual program. These definitions are fairly well evolved in the paper by Kreitler and Kreitler and their derivations will not be reiterated here.

First is the idea of meaning dimensions (13 lexical and 10 symbolic dimensions are evolved on the basis of experimental data), which are the rules for the categorizing process that is applied to input stimuli. These rules function as an "address" to direct scanning and matching to neuronal models. Denotive meaning is then the result of a match between input stimulus and the neuronal model. The term "meaning action" is applied to this selection, retrieval, and matching process. The role of meaning action then is to establish meaning values of a kind that enables a defensive reaction (DR), a conditioned response (CR), and an unconditioned response (UR) or an adaptive response (AR) to be elicited. If meaning action fails, i.e. none of the above is obtained, an orienting response (OR) is released. Sufficiency of a denotive meaning then is the habituation of the OR and the elicitation of an AR, CR, DR or UR (UR other than the OR).

When the elicited response is insufficient, the molar behavior is mobilized. This occurs when:

- (a) In spite of the OR, no new information about the stimulus object is achieved and the information available is inadequate for a denotative meaning.
- (b) Denotative meaning was established and a CR was produced, but that method of coping was inadequate.

(c) The pattern of denotative meaning includes a value that expresses the requirement for molar behavior.

The meaning dimensions most likely involved in determination of denotative meaning are the lexical dimensions of sensory qualities, contextual allocation, similarity and contrast, and potentialities for action. Evidence that the application of these meaning dimensions for stimulus recognition are simultaneous are provided by Allport et al. (1972) (Reference 48) and Neisser (1967) (Reference 83).

Although the theoretical paper by the Kreitlers is developed toward the idea of being able to predict behavior from beliefs and belief clusters, (and some evidence is provided for this contention), the relevant point for this project is the interrelationship of OR's and cognitive processes.

#### SECTION III

#### METHOD

#### EXPERIMENTAL PARADIGM

The independent variables selected for this experiment were (1) task and (2) auditory stimulus probe variables. The task variables built into the apparatus are (1) type of signal detection task (task difficulty), (2) time allowed to complete the task, (3) the inclusion of a reaction time task along with the signal detection task, and (4) the reaction time task alone. The auditory stimulus probe variable was the intensity of the auditory signal (variable in 2 db increments from 60 to 120 db).

The independent variables actually used in the pilot testing were task difficulty, inclusion or exclusion of the auditory probe reaction time task, and the intensity of the auditory stimulus. Ten middle-aged male professional engineers were selected as subjects for the pilot study.

The physiological-dependent variables were direction and magnitude of heart rate changes, finger pulse volume changes, ear pulse volume changes, and rheoencephalograph pulse changes. The performance-dependent variables were task completion, number of errors, and reaction times.

The subjects were instrumented and seated in front of a video console and keyboard (Figures 3-1 and 3-2). The subjects were informed that a 40- by 40character alphanumeric matrix would be displayed periodically on the video screen, together with instructions for the task. The alternative sets of instructions were to (1) count the occurrence of a given character, e.g. the letter r, (2) count the number of vowels; and (3) count the occurrence of an inclusive set, e.g. h through 1. The subject was informed of the time allowed for the task at hand, e.g. 99 seconds, also displayed on the video screen. The subject was instructed to strive for speed as well as accuracy and was advised he would be scored in terms of both errors and time to complete the task. In addition the subject was informed that periodically a tone would be initiated in his earphones and when this occurred, he should respond as quickly as possible to eliminate the tone signal by pushing the "interrupt" button on his keyboard.

The different tasks are presented to the subject consecutively with a 120-second rest period between each task. The probe stimulus problem is presented randomly and at random db levels at the discretion of the experimenter.

#### INSTRUMENTATION

#### Discussion of System Design

The psychological assessment (PA) signal conditioner provides interfacing between a test subject and a digital computer. The PA signal conditioner accepts input signals from biosensors located on the test subject's body, amplifies these signals, provides level shifting and level detecting functions, and then conditions the signals for output to a digital computer. The parameters conditioned in this manner are: electrocardiogram (ECG), rheoencephalogram (REG), finger plethysmogram (PG), and ear lobe plethysmogram (EPG). Also included in the PA signal conditioner is an audio response stimulator circuit, used to determine the subject's reaction time and to discriminate between orienting and defensive reactions. The subject's physiological reactions are picked up via sensors, conditioned by the signal conditioner unit, then recorded and analyzed by the digital computer to determine the subject's psychological condition. A block diagram of the signal conditioning system is shown in Figure 3-3. Because of the complexity of the system, the design discussion will be handled separately for each subsystem. The subsystems to be discussed are

> Electrocardiograph (ECG) Rheoencephalograph (REG) Plethysmograph (PG and EPG) Audio response stimulator

Electrocardiogram (ECG) -- The electrocardiogram (ECG) sensors, when placed on the subject's sternum in a trans-thoracic manner, pick up the electrical activity of the heart. This electrical activity indicates heart rate, blood pressure, and heart volume changes. This program is interested only in the heart rate signal. In a typical heart rate signal waveform (ECG) the peak volume at the "R" point has a level of one to two millivolts, depending on the type of sensors used and their placement on the subject. The period between "R" peaks can vary from 1-1/2 sec to 1/2 sec, which corresponds to a heart rate variation of 40 beats/min to 120 beats/min.

The sensors used are silver/silver "floating" biodes, which are held in place with double-sided tape, and make electrical contact to the skin through a liquid medium (biogel) produced especially for this purpose.

The differential voltage level at the output of the ECG sensors ranges from 0.1 to 2 mv peak, while the common mode voltages range from 10 to 100 mv peak. For this reason a differential amplifier with high common-mode rejection (CMR) is required for this subsystem. Drawing LSK 36170 in Appendix C shows that the ECG amplifier consists of three operational amplifier units. The input stage consists of two operational amplifiers (op amps) connected in a high CMR common-feedback configuration. This circuit uses the op amps as noninverting stages. In this mode the input impedance at the positive input terminal

Figure 3-3. Block Diagram of Signal Conditioning System

3-5-2-

Υ.

is greater than 10 meg. The feedback for this first stage uses a common resistor (R3) to determine the stage gain, and provides maximum CMR by matching the gains of the two input op amps. The third op amp is used both as a differential to a single-ended converter stage and as a gain stage. This stage is capacitor-coupled to the first stage to help eliminate baseline (zero) shift due to poor sensor/subject connections. The output of this amplifier is routed to an analog output terminal, and to the PG-ECG-REG level comparator board. This comparator board accepts the ECG analog signal, compares it to an adjustable level, and then uses the square wave obtained from the level comparator to trigger an integrated flip-flop. This flip-flop opens a gate allowing clock pulses coming from the digital computer to flow into a pulse totalizer unit. This flip-flop is reset by a signal generated by the REG/PG amplifiers, thus stopping the flow of clock pulses. The number of pulses that have been accumulated within the pulse totalizer unit is proportional to the time difference between an ECG pulse and a REG/PG pulse. This time difference data is used by the digital computer to help determine the physiological state of the subject.

<u>Rheoencephalograph (REG)</u>--The reheoencephalogram (REG) is a measure of the fluctuation in cerebral tissue impedance due to blood flow pulsations. The sensors used are the same as for the ECG measurement ("floating" biodes). In use, the patient constitutes the unknown arm of a balanced wheatstone bridge, which is excited by a 10- to 50-KHz sine-wave signal. The ac output of the bridge is detected and amplified to yield a 0- to 2-volt peak output signal for a 0- to 5-percent change in cerebral impedance. The REG signal has the waveform shown in Figure 3-4a. The period of this signal ranges from 1/2 to 1/3 sec.

The REG signal is preconditioned by a commercial signal conditioning unit, a biocom impedance converter (BK). The output of this unit is a 0- to  $\pm$ 2-v signal. The signal is routed from the BK to the REG amplifier card (Drawing LSK 36175 in Appendix C).

In this circuit, the first stage (Z1) is connected as a unity gain differential amplifier. This is done to avoid ground loops that may occur between the PA signal conditioner and BK unit. The output of this first stage is applied to a level comparator stage (Z2). This stage compares the REG signal to an adjustable dc level; the square wave thus produced is routed to the REG-ECG-PG comparator card, where it is used to trigger an integrated flipflop. This flip-flop, which is set by the ECG pulse and reset by the REG pulse, gates a clock signal that is used to calculate the time difference between the ECG and REG pulses.

Finger Plethysmograph (PG) and Ear Lobe Plethysmograph (EPG)--The plethysmograph sensors (PG and EPG) are used to measure blood volume change at a specific point on the body. A finger sensor and an ear lobe sensor are employed for this test. Both of these sensors operate by measuring the amount of a specific wavelength of light (7350A) that is abosrbed by the organ being monitored. The light is generated by a small light source and is conducted by the skin of the subject to a nearby photocell. The photocell produces a resistance change proportional to the amount of light falling on it. The photocell is connected into a bridge circuit that translates the resistance

Figure 3-4b. PG Waveform

## Figure 3-4.

Rheoencephalograph (REG) and Finger Plethysmograph (PG) Waveforms

change into a voltage signal (see Drawing LSK 36174 in Appendix C for more details on this bridge circuit; see Figure 3-4b for details on the PG signal waveform). The voltage signals are then routed to the PG and EPG amplifier cards (Drawings LSK 36172 and 36173 in Appendix C). These cards consist of a differential input stage with a gain of 20, a second ac-coupled stage with a variable gain of 1/2 to 6, and a comparator stage that compares the analog signal level with an adjustable dc level. The square wave produced by this comparator stage is used to gate a flip-flop, thus allowing a series of clock pulses to pass into a pulse totalizer unit. The total number of pulses counted at the end of a cycle is proportional to the time between an ECG pulse and a PG pulse. This time difference is used by the digital computer to help determine the subject's psychological state.

Audio Response Simulator (Drawing LSK 36179 in Appendix C)--The audio response simulator generates a variable level tone that is used to test the subject's concentration and reaction time. The audio level is programmed by the digital computer using seven binary bits of information. These bits are applied to the input of a digital-to-analog converter (D/A). The output of this D/A converter is a 0- to 10-vdc level. This signal is applied to the second stage, which performs level shifting and scaling on the D/A signal. The output of the second stage is then applied to the X input of a multiplier. The Y input of the multiplier is fed from a sine wave oscillator located on a PC card (Drawing LSK 36180 in Appendix C). The multiplier is used here as a linear amplitude modulator and provides an output level proportional to the digital binary number input to the D/A converter.

The controlled level output from the multiplier is then applied to the audio drive card (Drawing LSK 36180) where it is amplified sufficiently to drive a set of stereo headphones. The final output sound level is program controllable from 60 to 110 db by the digital computer system. The frequency of the tone also is manually variable using a control on the front panel of the PA signal conditioner package. The frequency range is 1 to 8 KHz. During testing this control is set for maximum subject annoyance.

Additional system schematics are shown in Appendix C (Drawings LSK 36170, 36171, 36176, 36168, 36169, and 36211.

Method of Operation

The method of operation for the PA signal conditioner is broken down into the following step-by-step procedure:

#### STEP 1

Plug the PA signal conditioner unit into a 115-v, 60-Hz power outlet. Connect the cable from the PA unit to the digital computer. Connect the ECT, PG, EPG, and BK cables to the PA unit inputs. Connect the REG sensors to the inputs of the BK unit.

#### STEP 2

Turn on the signal conditioner and allow the unit to warm up while proceeding to Step 3.

#### STEP 3

۲.

Connect the ECG, REG, PG, and EPG sensors to the subject under test. Procedures for each sensor follow:

- ECG Sensors--There are three silver/silver biodes used for the ECG input. The + and - biodes and the reference biode are applied to the sternum (see Figure 3-5a). The procedure for applying each biode follows:
  - (a) Using alcohol, clean the subject's skin in the area to which the biode will be applied. A slight abrasion of the skin using biobrade pads will remove the dry outer layer and thus lower the skin resistance.
  - (b) Remove the double-sided adhesive washer (biocom 1080B) from the wax paper backing, leaving the top wax paper washer in place.
  - (c) Center the hole in the adhesive washer over the cavity in the biode and press the adhesive washer to the biode face.
  - (d) Fill the biode cavity with biogel. Be sure that no voids or air bubbles are left in the gel during this process. The cavity should be slightly over-filled. The excess can then be removed using a stiff, straight edge (heavy paper, knife edge, etc.).
  - (e) Remove the wax paper washer and gently press the biode and washer in place.
    - NOTE: Be sure to clean the silver/silver biodes with alcohol after each usage.
- 2. <u>REG Sensors</u>--The REG sensors consist of two biodes, and are attached using the same procedure as described for the ECG sensors. The placement on the subject is shown in Figures 3-5a and b and 3-6.
- 3. <u>PG Sensors</u>--The finger PG sensor is simply slipped over the subject's finger, with the ball of the forefinger resting over the photocell cutout. The spring-and-cork assembly is then put in place to help hold the finger over the photocel and light source cutouts. See Figure 3-7a and 3-8 for details.

#### STEP 4

Place stereo headphones on subject, ensuring that the level controls located on each headphone are full on. See Figures 3-7b and 3-8 for details.

ر ک

· · . .

Figure 3-6. ECG and REG Sensor Placement

Figure 3-7b. EPG Sensor Placement

Figure 3-7. PG and EPG Sensor Placement

Figure 3-8. PG and EPG Sensor Placement

#### STEP 5

Turn on the BK and balance the unit using the procedure outlined below:

- 1. Turn master switch to "BATT. TEST" position. Note that the meter reads in the green area.
- 2. Turn the master switch to 'AC SHORT' position.
- 3. Turn "BALANCE" control until meter reads in the green area of the scale.
- 4. Turn "GAIN" control fully clockwise.

#### STEP 6

Set the trigger level controls located on the front of the PA conditioner unit so that the (LED) indicators are located under each level control flash at a constant rate. A constant flashing rate indicates that the trigger circuit is set to the proper level for consistent data output.

Turning the level control clockwise from mid-travel gives an increasing positive trigger level; counterclockwise from mid-travel gives an increasing negative level.

#### STEP 7

Set the audio simulator frequency control, located on the right side of the PA conditioner's front panel, to the desired frequency. The PA signal conditioning system is now ready for use.

#### Method of Calibration

The PA signal conditioner has only one circuit that requires calibration. This is the audio response simulator. For this circuit the audio sound level should be calibrated for a range of 60 to 110 db. To aid in this calibration a B&D "Artificial Ear", model 4153, was acquired.

3 - 14

To calibrate the sound response system the following equipment is needed:

Dc power supply (+5V at 100 ma)

Artificial ear (B&K model 4153)

Headphones (part of PA unit)

1/2-in. microphone cartridge (B&K model 4134)

Cathode follower (B&K model 2615)

Sound level meter (B&K model 2203)

Octave filter set (B&K model 1613)

The method of calibrating the audio response system is broken down into the following step-by-step procedure:

STEP 1

- 1. Plug PA signal conditioner into 115-v 60-Hz power line
- 2. Turn on power and allow a 5-min warmup period
- Plug stereo headphones into PA signal conditioner audio output jack (located on front panel)
- 4. Make sure both level controls on headphones are full on
- 5. Set up the B&K equipment per instruction manual BB4153

#### STEP 2

Short together pins F, P, C, D, R, V, U, and K on the computer input connector (connector located on lower right of PA front panel).

#### STEP 3

Apply 5 vdc on pins F (neg) and J (pos).

#### STEP 4

Adjust TRIM pot R8 located on the rear edge of Card 9 (green ejector code), so that a level of +40 db is indicated on the B&K sound level meter. The frequency control should be set at mid-travel for this step.

#### STEP 5

Short together pins P, C, D, R, V, U, and K on the computer input connector and then connect this bus to the 5-vdc positive supply line.

#### STEP 6

The sound should now be adjusted to +100 db using TRIM pot R8 on Card 9. This sets the full-scale sound level. The lower limit can now be checked using Step 2 to determine the total range of the audio response simulator, which should be about 45 db.

The unit is now calibrated for use.

#### COMPUTER PROGRAM

The computer consists of a Texas Instrument (T.I.) 960 control computer with 8000 16-bit words of core memory and several standard input/output interface cards, including one that interfaces to a teletypewriter ASR 33 (TTY) typewriter with paper tape reader and punch, and one that interfaces with a Lear Siegler 7700 interactive display terminal. The TTY is the primary input/ output device to all T.I. 960 software and the display terminal is attached specifically for this particular use of the computer.

Other interface cards consist of an interval timer with 1 msec resolution, a pulse accumulator, and a digital input and digital output card that allows 16 binary bits of information to communicate to the computer in each direction. Seven bits of the digital output interface are attached to an AiResearchmanufactured audio generator and two other bits are used as test information recorded on a strip chart recorder. The interval timer measures reaction times of the test subject and determines the duration of each test section. The pulse accumulator is not used at present; however, it is designed to be used to calculate parameters based on measurements made on the test subject. The intended use of this device would require additional storage or a high-speed output device.

The present purpose of the Texas Instrument computer is two-fold. The main objective is to display a game on the cathode ray tube (CRT) of the Lear Siegler 7700. This game is to be played by the subject while under test. The second objective is to apply a stressing audio signal to the test subject and measure his response time to the signal.

At present, three types of games may be played to count the occurrence of (1) a character; (2) characters between limits, either numbers between two other numbers with a maximum spread of 5, or letters between two other letters with a maximum spread of 4; (3) vowels. In each game the test subject counts the occurrence of a character or characters within a 20-by-20 matrix of characters displayed on the CRT screen. The rules of the game along with the time limit allowed also are displayed on the screen. The computer calculates the correct result, the test subject enters his result through the keyboard of the CRT, and these two results are printed on the TTY. These games are displayed for a fixed period of time (1-999 sec) that is determined before the start of the game. If at the end of this time the test subject has not responded with his answer, the computer designates his answer to be zero, erases the CRT screen, and prints the results. Provision has been made to enter a different period of time for display of the matrix and the rules but the present computer program does not utilize these times.

Throughout the duration of these games the secondary objective of the computer is attained. A background audio signal is applied to the test subject through earphones attached to the audio generator. At random intervals throughout the game (from 2 to 32 sec), a stressing tone of variable volume is applied to the subject. This tone is terminated when the test subject depresses the interrupt key on the CRT keyboard. The length of time taken by the test subject to terminate the tone is logged by the computer. These times, in hundredths of a second, are displayed on the TTY at the end of each game. The background tone volume may be set at the beginning of a game or series of games through the TTY keyboard. This audio level is then transmitted to the digital output card as a seven-bit binary number (0-127).

The computer program is written to allow the test conductor to enter various test options, such as game duration, the volume of the background audio signal, the 20-by-20 character matrix, the type and number of games to be played, and the start of these games. These options are entered by depressing one of several keys on the TTY keyboard. The format of the options and the particular key that initiates the option are described in Appendix A. When the computer program is initially loaded into the computer there is a default condition for the duration of the game and the audio signal. The matrix of characters and the game type must be entered before execution of a game.

The computer program, Appendix B, is so written that other options and other games may be added easily to the existing code. The program is written entirely in SAL/960 code, the assembler language of the TI 960, and operates on a stand-alone basis. The program is loaded into the computer under supervision of the programming supervisor monitor (PSM); however, when execution of the program is initiated, the addresses of the internal and communications register unit interrupt servicing routines are modified.

#### SECTION IV

#### RESULTS

Eleven subjects were tested in the formal pilot study portion of this program. Each subject was presented with three performance tasks in the following test order, in 3 sets of 12 tests with a 2-minute rest break between each task set.

<u>Test No.</u>	Task No.
1	1
2	1
3	2
4	1
5	2
6	3
7	2
8	2
9	2
10	1
11	· 2
12	3

Seven of the subjects were presented with a fourth task set that was identical in order of presentation; however, for this fourth task set, the probe stimulus was not utilized.

Every presentation of the alphanumeric matrix was randomized, as was the temporal interval between occurrences of the probe stimulus. The probe stimulus was presented in four intensities: 90, 100, 110, and 120 db. The amplitude setting of each probe stimulus also was determined randomly.

Data were collected on the reaction time and character count on the performance tasks for all the subjects. These two figures, together with the correct character count, were printed out on the teletype.

Table 4-1 present the mean reaction time data for each subject by the type of task and the of 2 tests (note there is no reaction time data for Test Set 4).

Table 4-2 presents the ratio of each subject's character count to the actual character count on the signal detection task by the type of task and the test set.

The following parameters were recorded in analog fashion as a strip chart:

Channel 1--Time, seconds

- 15

Channel 2--ECG, beat to beat Channel 3--REG, beat to beat and pulse amplitude Channel 4--FPG, beat to beat and pulse amplitude Channel 5--EPG, beat to beat and pulse amplitude Channel 6--Probe stimulus, amplitude (arbitrary scale) Channel 7--Probe stimulus, occurrence; event Channel 8--Test time, start and stop events Channel 9--Heart rate, analog calibrated

¥

A typical example of the analog record is shown in Figure 4-1.

Inspection of this figure reveals that, for example, changes in heart rate are most pronounced in the intervals between tests, when the set of instructions is presented for the next test.

Individual pulses and changes in pulse amplitude can be seen in the REG, FDG, and EPG traces. In addition, differences in timing are discernible among each of them and between the ECG.

Performance became asymptotic after the first series of twelve tests, as shown by the plot of correct responses and reaction time (Figure 4-2). Performance stabilized at an average of approximately 75 percent correct and reaction time stabilized around 450 milliseconds. The effect of the reaction time/probe stimulus task on performance is evident in the fourth test set point, where the average percentage correct performance moves up to 85 percent when the probe stimulus is eliminated.

Figure 4-3 shows the average reaction time for all subjects as a function of the number of trials. This curve is slightly smoothed by employing a running average of three tests per point. It is apparent that reaction time became asymptotic at about the end of the first test set of 12 tests.

Figure 4-2. Average Performance and Reaction Time as a Function of Test Set

۰.

Figure 4-3. Average Reaction Time for All Subjects by Trial

In Figure 4-4, the effects of the different performance tasks are separated out by task, with the data averaged for each of the four sets. It is apparent that better performance, in terms of correct responses, is achieved under Task I conditions than for Tasks II and III. The difference between Task I and the other two tasks is considerably lessened when the probe stimulus/reaction time task requirement is removed from the test situation.

Figure 4-5, which presents a plot of the average time required to complete the tasks, shows that task time for a given task remains relatively constant across the four sets of 12 tests. The tasks separate in terms of apparent difficulty in the same way as in the previous figure, with Task I clearly taking less time.

The relationship between performance on the signal detection and reaction time tasks is plotted in Figure 4-6. Most noteworthy is the fact that signal detection and reaction time performance improve together. The separation of task effects on the joint plot of these two variables is also pronounced. When reaction time is related to task time (Figure 4-7), there appears to be little or no interaction between them.

Figure 4-8 relates performance to task duration by each of the task types. Little change is seen in this relationship as a consequence of experience in the test situation. The removal of the probe stimulus task, however, significantly alters the relationship between these two variables, which suggests that this relationship may be sensitive to further alterations in the subject/task situation.

Table 4-3 presents a matrix of the average heart rate throughout each test for the various test conditions. Generally the average heart rate decreased with experience; however, the average rate increased with the fourth test set for each of the tasks. This may be due in part to the novelty of the fourth test set (no probe stimulus).

Table 4-4 presents a matrix of the average end-of-test (last 5 seconds) heart rate by task type. The relationship among the end-of-test average values for heart rate is similar to that observed for the average heart rates.

The plots of heart rate variability are shown in terms of changes in heart rate greater than 2 beats/minute in any five-second period plotted in terms of (1) sets of 12 tests (Figure 4-9); (2) performance (Figure 4-10); and (3) reaction time (Figure 4-11). Generally it appears that heart rate variability is reduced for difficult tasks and increased for an easy task as a function of experience with the task. It is, however, apparent that heart rate variability is inversely related to task difficulty. When this dependent variable is considered together with correct responding (Figure 4-10), little if any relationship is suggested. There does, however, seem to be an inverse relationship between heart rate change and reaction time (Figure 4-11). This relationship is confounded with the task variable, as might be expected from Figure 4-9.

Figure 4-11. Heart Rate Variability and Reaction Time

;

. . The heart rate at the end of the test period (last five seconds) appears to be related to both <u>meta-mance</u> (Figure 4-12) and reaction time (Figure 4-13). Generally, end-of-tes <u>meta-mance</u> is lower with both improved performance and improved reaction time

Figure 4-14 shows the percentages of the probe stimulus events that were followed by a change in heart rate greater than 2 beats/minute within 5 seconds following the probe stimulus. Clear separation of the data by tasks is shown in this figure. It appears that the probability of the probe stimulus causing a change in heart rate decreases as the difficulty of the task increases. The amount of experience in the situation seems to have little effect.

Figure 4-15 illustrates this same parameter separated by direction of the change in heart rate. With the easy task (Task I), the heart rate acceleration and deceleration appear equally probable. As both task difficulty and experience increase, the expansion probability of heart rate acceleration increases over that of heart rate deceleration.

Figure 4-16 shows these same dependent variables as a function of the intensity of the probe stimulus. Again, for the easy task, the probability of heart rate acceleration and deceleration are quite similar; however, as both task difficulty and probe stimulus intensity increase, the probability of heart rate acceleration increases over the probability of heart rate deceleration.

#### SECTION V

#### SUMMARY CONCLUSIONS AND RECOMMENDATIONS

The specific goal of the program described in this report was to initiate by literature review and pilot study, a program that eventually would result in a psychological assessment technique for assessing objectively the major aspects of the psychological state of an astronaut. This objective assessment must meet the following criteria:

- (a) The method used in the assessment technique must elucidate appropriate methods of medical intervention when necessary.
- (b) The method must be fully compatible with currently accepted space flight practices, values, and procedures.
- (c) The method must be applicable to the assessment of potential space flight crew members.
- (d) The assessment must be on a total organismic level.
- (e) The method must be applicable to the assessment of both individuals and groups.

In general, this phase achieved direction for the program and evaluated the general trend of the recommended approach. Major specific accomplishments were:

- (a) Substantive review of the relevant research.
- (b) Selection of appropriate methods and techniques for application.
- (c) The method selected simultaneously observed the effects of situational variables on performance, physiology, and psychophysiological dependent variables.
- (d) Selection of an experimental paradigm to evaluate the proposed methods (visual and auditory signal detection in the face of visual and auditory noise, under time pressure, competition pressure, and with periodic distracting probe stimuli).
- (e) Selection of simultaneously observed physiological, task performance, threshold, and psychophysiological dependent variables.
- (f) Development of apparatus, instrumentation, computer programs, test procedures, and data reduction techniques to evaluate the recommended approach.
- (g) Performance of pilot studies.

The more important observations made during the pilot study were:

- (a) The performance tasks selected differed in difficulty in terms of correct performance, reaction time, end-of-test heart rate, task time, and heart rate changes following the probe stimulus. The rank order of task difficulty (1, 11, and 111) was consistent for all dependent measures.
- (b) The removal of the probe stimulus/reaction time task substantially improved task performance, slightly increased the time to complete the task, decreased heart rate variability on the difficult tasks, and increased heart rate variability on the easy tasks.
- (c) Heart rate variability increased as task difficulty decreased and also appeared to increase with decreasing reaction time.
- (d) The probability of a heart rate change within 5 seconds of the probe stimulus decreased with increasing task difficulty.
- (e) The probability that a heart rate change within 5 seconds of the probe stimulus would be an acceleration in rate increased with both task difficulty and probe stimulus intensity.
- (f) It also was observed that there were individually unique ways of responding (e.g., vasoconstriction to low levels of the probe stimulus, maintenance of vasoconstriction for extended periods, biphasic vasoconstriction/dilation, difference in temporal intervals between ECG, FPG, and REG pulse signals, etc.).

It is probable that these characteristic types of physiological response will prove predictive of eventual disease states, personality variables, etc.

Due to the pilot nature of this test program and the exigencies of cost and schedule, systematic data reduction was not attempted on REG, EPG, and FPG parameters. Inspection of the data on these dependent variables led to the comments in (f) above.

On the basis of the study and the pilot testing, it is recommended that (1) the line of investigation reported be continued with fully designed experiments; (2) the range of observation and computations be extended to include temporal relationships between the dependent variables; and (3) sufficient data be collected to clarify the effects of the independent variables and the relations between dependent variables, to classify the individually unique ways of responding, and to make a sufficient number of observations to be indicative of normative data.

If the data continue to support the fundamental contention in a fully designed experiment, then the basic approach must be extended to experimentation in multiperson situations and in conjunction with other environmental stressors such as isolation.

### APPENDIX A

# FORMAT OF OPTIONS

#### APPENDIX A

#### FORMAT OF OPTIONS

Certain keys on the teletype keyboard control certain options within the computer. These keys and the options they control are listed below. In each case the computer acknowledges the character by printing a space and ringing the bell of the teletype. Further action by the operator is noted below and any required input must be in the exact format as stated.

Teletype Key	Optional Input	Option
V	DDD	The three-digit number (DDD) (less than 128) volume level of the background audio signal (O represents the quietest, 127 represents the lowest)
м		Reads 400 alphanumeric characters from the paper tape reader as the input matrix. The computer automatically starts the reader.
т	D XXX	Where XXX is a three-digit number represent- ing the time limit in seconds. The digit D represents which of the three time limits is to be modified.
		D=1, the time limit for the entire game
		D=2, the time limit the matrix is to be displayed
		D=3, the time limit the rules of the game are to be displayed (D=2, D=3 are not presently used)
G	D	D is a one-digit number specifying which of three games is to be displayed.
	,	<pre>D=1, count the occurrence of an alphanumeric</pre>
		D=2, count the occurrence of characters between limits
		D=3, count the occurrence of vowels
Teletype Key Optional Input

#### Option

Read a paper tape specifying several games to be played in succession, punched in the following format where NN is a two-digit number specifying the number of games to be read in.

GG----are NN, one-digit numbers specifying which of the three games is to be played.

Starts execution of the game or games specified by a preceding G or P parameter.
