Short Title: IP Shock Correlation Study

*NAS/NRC Postdoctoral Research Associate, Now at Lunar and Planetary Laboratory, The University of Arizona, Tucson, Arizona 85721
ABSTRACT

We have examined 93 SSC's during the four year period from 1968 to 1971 at and near the peak of the solar activity cycle. Of the 93 SSC's 81 could be associated with solar activity, such as solar flares and radio bursts of Type II and Type IV. The mean propagation speeds of these flare-associated events ranged from 400 to 1000 km/sec with an average speed of 600-700 km/sec. Disturbances associated with 48 of the SSC's have been studied in detail using the corresponding interplanetary (IP) magnetic field, and plasma data when they were available. We found that 41 of the 48 disturbances corresponded to IP shock waves, and the remaining seven events were tangential discontinuities. Thirty percent of the IP shocks had thick structure (i.e. the magnetic field jump across the shock occurred over a distance much greater than 50 proton Larmor radii). Also given is a statistical study of the gross geometry of a "typical" or average shock surface based on multiple spacecraft sightings and their relative orientation with respect to the solar flare and/or solar activity. By considering the orientations of 22 well-determined shock normals in relation to the positions of the parent flares on the solar disk, which is a modification of a method given by Taylor (1969), it is suggested that a typical shock front propagating out from the sun at 1 AU has a radius of curvature on the order of 1 AU. Also given are some general properties of oblique IP flare-shocks.
Introduction

It is generally believed that most IP shock waves originate at or near the sun, in particular from a solar active region (Gold, 1955; Hirshberg, 1968; Hirshberg et al., 1970; Hundhausen, 1970; and Hundhausen et al., 1970). Some theoretical models of the propagation of flare-associated shock waves in an ambient solar wind based on similarity solutions of the hydrodynamic equations, were developed by Parker (1961), Simon and Axford (1966), Dryer (1970), and Korbeinikov (1969). Hundhausen and Gentry (1969a,b) used numerical solutions of hydrodynamic equations to simulate the propagation of flare-associated disturbances. De Young and Hundhausen (1971) found that, even for a blast confined to a cone of half-angle equal to or less than 15°, the shock front upon reaching 1 AU becomes quasi-spherical centered at approximately 0.5 AU. For a model of flare-associated IP shocks, shocks are expected to form in the vicinity of the sun and propagate outward with a shock thickness on the order of a few proton Larmor radii during most of their passage through IP space. Spherical symmetry of the shock surface may be disturbed due to IP inhomogeneities (Heinemann and Siscoe, 1973) or abrupt discontinuities (Lepping and Burlaga, 1973).

Hirshberg (1968) derived an average shape of an IP shock front from a statistical study of the magnitudes of SSC's. She concluded that flare ejected plasma is emitted on a broad front but with considerable departure from heliocentric spherical symmetry. Taylor (1969), utilizing IMP 3 observations, found that the shock front at 1 AU can be well approximated by a spherical surface whose curvature is \( \approx 0.75 \) AU and centered at \( \approx 0.5 \) AU.
In this paper we present an observational study of 38 flare-associated shocks. The shock speeds and normals have been computed accurately for 22 of these cases through the use of multiple spacecraft (S/C) observations; the speeds and normals for the remaining 16 shocks are also obtained.

The Experiments

IP data have been collected from eight S/C (Explorers 33, 34, 35, 41, 43, Pioneers 7 and 8, and OGO 5), which, taken together, cover the four year period of interest (1968 through 1971). We are primarily dealing with IP magnetic field data and the positions of pertinent S/C during the time of onset of the events. Only in a few cases were the detailed IP plasma data available to us; we used them mainly to check results obtained from the multiple S/C method and to obtain local plasma bulk speeds. Table 1 shows the S/C and the associated principal investigators for the experiments from which we obtained this data. Many of the events have been observed by more than one S/C. However, in some intervals only the magnetic field data were available. Hence, only a limited study could be made for those periods.

The Method of Study

Sudden commencements (SSC's) identified by 20 or more magnetic observatories were selected for the years 1968 to 1971 inclusive. Then for a given event the IP magnetic field data from the experiments on the S/C listed in Table 1 were examined. For the events for which the IP data were available the associated discontinuities in the magnetic field were selected. When the events had been observed by more than one S/C,

</table>
multiple S/C methods could be used to find the normal and speed of these discontinuities. In order to find an accurate normal and speed for a given event, we used the following procedure:

First, the magnetic field data were selected for each event. The average values and their standard deviations were computed for both sides of each discontinuity (here discontinuity means shock or tangential discontinuity). The time intervals over which the averages were taken depended on the behavior of the fluctuations of the vector quantity $\vec{B}$ in the vicinity of the discontinuity. Time intervals were chosen over which this quantity displayed relatively steady behavior; these were in general 3 to 5 min long. Then, the shock normal $\hat{n}_s$ was computed for each S/C observation using the magnetic coplanarity theorem (Colburn and Sonett, 1966). The uncertainty of $\hat{n}_s$ is closely related to the fluctuations of the magnetic field in the analysis interval. However, for most IP events the computed $\hat{n}_s$'s have an uncertainty within $\approx 20^\circ$. If the discontinuity was a tangential one, the normal to the discontinuity plane should be in the direction $\hat{n}_t$ where $\hat{n}_t = \frac{\vec{B}_1 \times \vec{B}_2}{|\vec{B}_1 \times \vec{B}_2|}$. The direction $\hat{n}_t$ was also computed for each observation, where $\vec{B}_1$ and $\vec{B}_2$ are the average magnetic field before and after the discontinuity, respectively. The comments above concerning the expected error in $\hat{n}_s$ hold for $\hat{n}_t$; however, in general the error in $\hat{n}_t$ should be smaller, since $(\vec{B}_2 - \vec{B}_1)$ is not involved. Then the normals $\hat{n}_s$ and $\hat{n}_t$ were computed in every case regardless of whether the actual event corresponded to a shock or tangential discontinuity, and ideally they should be at 90° with respect to each other. Since in practice $\hat{n}_s$ and $\hat{n}_t$ can be distinguished from each other with
only an error of $\approx 30^\circ$ ($=\sqrt{2} 20^\circ$), the ideal $90^\circ$, being a factor 3
greater, generally enables highly reliable differentiation. Choosing
which of the two normals was correct is another matter and is discussed
below.

Secondly, multiple S/C methods, which were also used, are now
described. If there were two S/C observations available, the relative
position vector of these two S/C, $\Delta \mathbf{R} = (\mathbf{R}_2 - \mathbf{R}_1)$, is related to the
propagation speed of the discontinuity, $V_d$, and to the time difference,
$\Delta t$, between observations of the discontinuity at these two S/C in the
following way:

$$\Delta \mathbf{R} \cdot \mathbf{n}_d = V_d \Delta t$$ (1)

where $\mathbf{R}_1$ and $\mathbf{R}_2$ are the position vectors of the two S/C and $\mathbf{n}_d$ and $V_d$
are the normal and the local speed of the discontinuity, respectively.
Note that we do not yet specify the type of discontinuity, i.e., shock
or tangential. This calculation is based on a geometric configuration
only—and kinematic assumptions to be discussed—but is independent
of specific identification. Also since the normal component of the
magnetic field is continuous across any type of discontinuity, then
$\Delta \mathbf{B} (=\mathbf{B}_2 - \mathbf{B}_1)$ is parallel to the surface of the discontinuity, i.e.,
the condition

$$\Delta \mathbf{B} \cdot \mathbf{n}_d = 0$$ (2)

holds for any type of discontinuity. It is important to note that on a
scale of the order of 0.01 AU a shock front usually remains planar and
propagates at a constant speed (Ogilvie and Burlaga, 1969; Chao, 1970),
and similarly for tangential discontinuities on the order of 0.002 AU.
(Burlaga and Ness, 1969). In all of the computations done for this study involving more than one S/C, we have assumed in fact that the discontinuities can be approximated as planar and propagate at a constant speed within the distance of the S/C separations ($< 0.004$ AU). However, the magnetic field can change over all scale lengths. That is, the $\Delta B$'s are not necessarily equal to each other for the two S/C observations, even though the normals remain the same. Hence, it was often useful to provide two equations of the type Eq(2), one each for the two S/C observations. Then solving Eqs(1) and (2) together yielded $V_d$ and $\hat{n}_d$ for the discontinuity.

If three S/C observations were available, two equations of the type Eq(1) and any one equation of the type Eq(2) were enough to determine $V_d$ and $\hat{n}_d$. In the case of four S/C observations having been available, three equations of the type Eq(1) were used to determine $\hat{n}_d$ and $V_d$. This case was completely kinematically determined from the geometric configuration and onset times alone.

For a few cases that were well known to be shocks, and when plasma data were available, one of the best-fit methods using a subset of the shock conservation equations was employed to obtain $\hat{n}_s$ (Chao, 1970; Lepping and Argentiero, 1971).

The normal $\hat{n}_d$, computed from the multiple S/C method, was compared with both $\hat{n}_t$ and $\hat{n}_s$, obtained from the single S/C magnetic field measurements. And when available the solar wind speed was compared to the estimated discontinuity speed divided by the radial component of the unit normal. It is, in general, possible to differentiate a shock wave
from a tangential discontinuity by these comparisons. Well known shock and tangential discontinuity signatures in the magnetic field data (Burlaga, 1968) also may be used as a guide in the discrimination. By combining the single and multiple S/C methods, it was possible in general to lessen the uncertainty of the estimate of the normal of the discontinuity, yielding final errors usually of approximately \( \pm 10^\circ \). The preceding scheme and assumptions form the basis for the method used to obtain the identification and kinematic properties of the discontinuity.

The Observations

For the active period of the solar cycle from 1968 to 1971 inclusive, we selected 93 world-wide SSC's which have been reported by more than 20 geomagnetic stations each (Solar-Geophysical data, published by ESSA, U.S. Department of Commerce). Then the solar activity which occurred one to four days before the SSC's were examined. The SSC's usually could be associated with a flare of importance 1B or stronger and radio bursts of Type II and Type IV. On an average the solar activity association of these events can be made with a reasonable degree of certainty, as we will demonstrate in a later section.

Of the 93 SSC's 81 could be associated with solar activity. Eighty-five percent of these associations included radio bursts of Type II or Type IV. Therefore, we believe our statistics of these 81 events are significant.

The IP magnetic field data from the S/C listed in Table 1 were available for 48 of the 93 SSC events. From these IP data our analysis shows 7 of the 48 events were tangential discontinuities and the remaining
41 were shock waves. However, only 38 of these 41 shocks had adequate
IP data to obtain shock normals and speeds.

Chao (1973) has shown two examples of IP shock-like discontinuities
which had a "shock" transition region of a thousand proton Larmor radii
or wider. These two events steepened into shock waves in the vicinity of
the earth. These two "shocks" can be associated with solar flares and
with radio bursts of Type II and Type IV. We examined the thickness
of the magnetic field transitions of the 38 shocks and found that 30% of
the "shocks" had a transition region larger than 50 proton Larmor radii,
$R_p$. In most of the thick-structure events, the transition regions were
more than a few hundred $R_p$ in width. We do not claim that the events with
a thick transition zone are fully formed shocks. We would like to suggest
that what we are observing in these cases is the formation of shocks.

Out of the 38 shocks, 22 shock normals and speeds were computed
accurately, and their solar activity associations were relatively
reliable. We will study IP shock correlation with solar activity using
these 22 events. Table 2 gives a summary of the results discussed in
this section.

Results

If we assume that the 81 flare-associated events represent distur-
bances such as shock waves propagating over 1 AU from the flare site to
the earth's vicinity, then the average transit velocity of such a distur-
bance can be computed using the difference between the occurrence of the
flare and the onset of the SSC at earth. A histogram of these mean speeds
is given in Figure 1. There is a peak at 600 - 700 km/sec. The
Table 2

Some Statistics of SSC-Associated Events

Period of Study: January 1968 to December 1971

93 world-wide SSC's were selected.

81 of the SSC's were associated with flares and in some cases radio
bursts (Type II and/or IV).

48 had available interplanetary (IP) magnetic field and in some
cases plasma data for the associated IP events.

Analysis of 48 IP events yielded:

7 tangential discontinuities

\[
\begin{align*}
&\text{3 had unknown normals and speeds.} \\
&\text{41 shocks} \\
&\quad\text{38 had known normals and speeds:} \\
&\quad\quad\text{26 were thin structures} \\
&\quad\quad\text{12 were thick structures}
\end{align*}
\]

22 of the 38 shocks had accurate shock normals and speeds estimated
and all 22 were flare associated.
distribution in the upper and lower speed portions may not be reliable due to the difficulty of selection for the extremes. However, the peak of the distribution is significant. This mean speed of 600-700 km/sec implies that the shock speed is not on an average very much greater than the solar wind speed, i.e., the shock is of intermediate strength.

The shock normals of the 38 shocks are shown in Figure 2. The normals are given in solar ecliptic coordinates where $\Theta_{SE}$ is the latitude angle and $\phi_{SE}$ is the azimuth angle measured in the ecliptic plane. The dotted arrows represent those events with larger uncertainties than those with solid arrows; the latter set (22 shocks) usually correspond to multiple spacecraft observations and are well determined. These normals are rather symmetrically distributed with respect to the sun-earth line. For those 15 of the 38 shocks for which plasma data were available the dependence of the shock speed in the solar wind frame of reference on the local solar wind speed in the pre-shock state was studied. Figure 3 shows the local shock speed in the solar wind frame, $W$, versus the solar wind speed $V_{SW}$. The figure shows that the pre-shock solar wind speeds occur in the range 350 to 420 km/sec, which corresponds to the most probable solar wind conditions. $W$, however, ranges from 40 to 300 km/sec.

Next, we compare the mean shock speed with the local shock speed as computed by the multiple spacecraft method. Figure 4 shows a plot of the mean transit velocity $<V_S>$ versus the local shock speed $V_S$. Notice that most of the events lie below the diagonal line. That is, the mean speed $<V_S>$ is larger than $V_S$ for most events. This shows that, in general, flare-produced shocks slow down during propagation over 1 AU.
The orientation of shock normals and their positions relative to the parent flares can be studied to obtain an average shock front. Individual locally-determined shock surface orientations may severely deviate from this front (Lepping and Chao, 1972). The 22 shock events (for which normals have been accurately computed), their normals, and information about the identification of the probable parent flares are listed in the top section of Table 3. The remaining 16 of the 38 shocks are listed at the bottom of the table. The first two columns give the dates and times of the SSC events, respectively. The third column gives the Code number which identifies each event. The fourth through eighth columns give the following for each flare: the time of onset, position in latitude, importance, and the time of onset of radio bursts of Type II and Type IV, respectively. The next three columns give the shock normal in solar ecliptic coordinates θₛ and φₛ (φₛ = 0° in the solar direction), and the local speed computed from the multiple S/C method, respectively. The average sun-earth transit speed is given in the last column.

These 22 events are related to their parent flares in Figure 5 according to a method by Taylor (1969), and recently repeated by Bavassano et al. (1973) using the Pioneer 8 data. Figure 5 is a plot of the orientations of the 22 shock surfaces in the ecliptic plane at the appropriate heliocentric longitude relative to the flare. The longitudes are specified as seen from the earth. For example, the flare associated with the SSC of November 20, 1968 occurred at 90°W on the solar disk and thus is plotted at 90°E of the flare as shown in the figure (Code no. 19). This figure shows that the average shock surface in the ecliptic plane

near the earth's orbit lies on a circle centered at the sun with a radius of 1 AU. A few events have been observed near the west limb but these also lie well on the circle. The mean deviation of these shock surfaces from the circle is $5^\circ \pm 9^\circ$, i.e. $\langle \phi \rangle = 175^\circ$ for the average normal, with a standard deviation ($\sigma$) from the mean surface of about $22^\circ$. The mean deviation of the remaining 16 shock surfaces from the circle is $3^\circ \pm 18^\circ$ and $\sigma \approx 36^\circ$. This is somewhat different from the results given by Hirshberg (1968), Taylor (1969) and Bavassano et al. (1973) which suggest smaller radii of curvature by approximately a factor of 2.

Figure 6 shows the orientation of the 22 shock surfaces in the meridional plane at the appropriate heliocentric latitude relative to the flare position. The shock surfaces are clumped above and below the ecliptic plane at about $\pm 20^\circ$. The figure shows that there is a tendency for the average shock surface in the meridional plane near the earth's orbit also to lie on a circle centered at the sun with a radius of 1 AU. The mean deviation of these shock surfaces from the circle is $0.6^\circ \pm 10^\circ$ with a $\sigma$ of about $24^\circ$. For the remaining 16 shocks the corresponding values are $3^\circ \pm 20^\circ$ and $39^\circ$, respectively. This implies that the average shock surface does not deviate much from a spherical shape in the meridional plane.

Using the 22 flare-associated shock waves, we obtained statistics about the correlation between shock waves, flares and radio bursts of Type II and Type IV. Table 4 gives the probability of solar activity being associated with interplanetary shock waves. We have divided the solar activity into three classes, namely: flares, radio bursts of

Type II and Type IV, which are believed to be most strongly related to interplanetary shock waves (Wild, 1970). From this table one can see that, of radio bursts, Type II have the stronger correlation with IP shocks. Note that in general one can always find a flare-association with a given IP shock, because there are so many flares reported over any four day period. On the other hand, if the radio data are included, it is seldom possible to make more than one association with a given IP shock. This table shows that we apparently do have a meaningful association with IP shocks and solar activity.

In order to test our method of associating solar flares with the observed IP shocks, we artificially generated random IP shock times and repeated the association procedure as if the times were real shock onsets (or SSC's) at 1 AU. The day of occurrence was generated by computer assuming a uniform distribution and an expected rate of 2 shocks per month for 2 years (1968-1969). The hour of day was derived by throwing a die so that resulting "onset times" had a quantization of 4 hours duration. (Over a large number of throws the value showing on the die is expected on average to be 3-1/2; in our case of 48 throws it was 3.46.) Using these times we attempted to associate solar flares, Type II-, and/or Type IV-solar bursts just as we had done in the cases of the real IP shocks. For all but two random shocks we were able to find some flare association. For these 46 cases a histogram of mean speeds was produced as shown as a solid curve in Figure 7, corresponding to Figure 1 for the real cases. In some instances radio bursts were associated, and the percentage of these associations is shown in Table 5, corresponding to
Table 4 for the real cases. For some of the associations it was necessary to ignore the more impressive solar flare, by importance designation, in favor of a lesser flare because of the existence of radio bursts, Type II and/or IV at the time of the lesser flare. This was also done in the real cases but not as frequently. Firstly, we point out that the histogram in Figure 7 (solid line) shows a skewed distribution with respect to the histogram in Figure 1, which is shown in Figure 7 as a dashed curve, properly scaled, for comparison. Secondly, the most probable speed is shifted to an unrealistically low value of $\approx 500$ km/sec, instead of 650 km/sec for the real cases. (The average post shock solar wind speed alone over 1 AU is expected to be greater than 500 km/sec). Thirdly, and most important, as Tables 4 and 5 show, the percentage of occurrences of solar radio bursts in any combination is much lower than in the real cases. In particular compare Flare, Type II or Type IV for random (50%) to real cases (85%). Also the flare importance designation was necessarily lower, on an average, for the random case associations. Lastly, we point out the difference of the mean speed averages but the similarity of the $\sigma$'s, as Table 6 shows. We conclude that the method of using an IP shock-solar association based on Flares, and Type II and IV bursts when present, for this statistical study yielded reasonably trustworthy results. But we caution that one must be exceedingly careful about individual shock studies based on such a method.

Some Flare-Shock Properties

In this section we list and discuss those properties of oblique IP flare-shocks which depend explicitly on magnetic field quantities and

shock normals only, based on the shocks in Table 3, top. In particular we are concerned with giving a general characterization of typical magnetic field jumps across such shocks. And we are interested in the expected importance of thermal anisotropy on estimating shock parameters and normals using a fitting scheme based on shock conservation equations (Lepping and Argentiero, 1971). Also we wish to check the accuracy of the estimated normals presented in this paper. Only the most accurate set, according to the shock normal estimates, of the 22 shocks will be examined. These shocks will be characterized by the quantities defined in Table 7. In the table column-number refers to the respective column in Table 8, where the results are presented. The parameter $R$ in column 7 provides a means of measuring the importance of anisotropy (Lepping, 1972). That is, for $0 \leq R \leq 1/2$ and for expected anisotropy conditions in the vicinity of the interplanetary shock (Hundhausen et al., 1967; Chao and Goldstein, 1971) departure from the assumption of thermal isotropy is in general unnecessary (Lepping, 1972). Below we show that indeed $R \leq 1/2$. Concerning column 9, $\vec{A} \cdot \hat{n} = 0$ must be satisfied across the shock; checking it gives the degree of consistency of estimated normals with this constraint, where $\delta = 0^\circ$ indicates perfect agreement. $S$ and $S_o$ are arbitrarily defined measures of the "probable strength" of the shock when plasma data is unavailable; $F_2/F_1$ is a similar indicator. All other quantities in the Table 7 are self-explanatory.

These quantities were calculated for the 22 shocks and the results are presented in Table 8. In obtaining these results the following rules were applied. Only data from one S/C were used, $\alpha \geq 10^\circ$, $\delta \leq 10^\circ$.

</table>
and where a close choice had to be made among different S/C the event with the smallest $\delta$ and/or largest $\alpha$ was chosen, where judicious weighting between these rules was used on occasion. Only 18 shocks remain out of 22, as the table shows. Only two of the discarded cases (Codes 5 and 7) were due to the possibility of inaccurate normals ($\delta = 23^\circ$ and $68^\circ$, respectively) but most likely were due to poorly determined $\Delta B$'s. (Code 7 refers to a thick "shock" and undoubtedly had a rather poorly determined $\Delta B$ but probably a good normal.) The other 2 cases (Codes 80 and 82) arose because of small $\alpha$. This was due to the shocks being nearly perpendicular types ($\beta_1 \approx 85^\circ$), and our interest in this section is in oblique shocks. Ideally $R_2 = \beta_1 + \alpha$ according to the magnetic coplanarity theorem. Comparing columns 4 and 6 shows that this closely holds in almost every case; one should note that this result was not forced (by a circular argument), since the associated normals for these shocks were almost exclusively obtained by multiple S/C methods.

The table shows that in almost all cases $R \leq 1/2$ and for this set a typical value is $R \approx 1/3$, the average being 0.37. The particular values of $\beta_1$ shown occur partly by selection, but it is interesting that $\alpha$ rarely exceeds $35^\circ$—and recall that S/C data giving small $\alpha$ were discarded for this table. It is not obvious which of the three parameters $F_2/F_1$, $S$, or $S_0$ best reflects probable shock strength, without accompanying plasma data, but the obvious inverse relationship between $R$ and $F_2/F_1$ is intriguing. Figure 8 shows a plot of $F_2/F_1$ vs. $R$ for these 18 shocks.
The figure suggests the statistical relationship (with a least squares rms = 0.39):

\[
\frac{F_2}{F_1} \approx 3.5 - 3.7 R
\]  

(9)

where \( R = \tan \theta_1 / \tan \theta_2 \). Chao (1970) demonstrates that

\[
\frac{F_2 \sin \theta_2}{F_1 \sin \theta_1} = \frac{M_A^2 - 1}{M_A^2(N_1/N_2) - 1}
\]

(4)

for a thermally isotropic medium, where \( M_A \) is the pre-shock Alfvén Mach number and \( N \) is the plasma number density. Since the normal component of the magnetic field across the shock front is continuous, i.e. since \( F_2 \cos \theta_2 = F_1 \cos \theta_1 \), Eqs. 3 and 4 can be combined to yield

\[
M_A \approx \sqrt{\frac{F_2/F_1 + 0.2}{3.7 N_1/N_2 + F_2/F_1 - 3.5}}
\]

(5)

Hence, the strength of an oblique IP shock at 1 AU for the isotropic assumption depends, in a statistical way, only on the scalar quantities \( F_2/F_1 \) and \( N_1/N_2 \). In general the empirical relationship given by Eq. (5) may not be very accurate for any particular shock, but it suggests a typical property of oblique IP shocks at 1 AU. However, we tested it for several previously studied specific shocks which were parameter-fitted according to schemes developed by Chao (1970) and Lepping and Argentiero (1971), and it yielded estimates of \( M_A \) which when compared to best-fit values gave discrepancies ranging from 30% to only 10%. It appears that when \( N_1/N_2 \) gets too small (say \( < 0.3 \)) relationship (5) yields unreliable estimates of \( M_A \).

Discussion

Firstly, we would like to point out that our criterion for selecting SSC's, which was based on the agreement of reports from 20 or more magnetic
observatories, was consistent with assuming SSC events are caused by interplanetary shocks. From 48 events for which interplanetary magnetic field and/or plasma data were available, only 15% were caused by tangential discontinuities. For a continuation of the study described above and for completeness we relaxed our criterion for SSC-selection by including also those events identified by only a few (5 to 10) observatories. In those cases less than approximately 15% of the SSC's were caused by IP shocks; the identification of these IP events was not always unambiguous. The results of the extended study are not reported here. Hence, large and universally observed SSC's tend overwhelmingly to be caused by IP shocks, and the lesser "SSC's" also may be caused by IP shocks but more likely by tangential discontinuities and other solar wind inhomogeneities.

Secondly, we wish to stress the distinction between this statistical study and detailed studies on a single shock surface geometry (Mariani et al. 1970; Lepping and Chao, 1972). Figure 5 suggests that the average shock surface near the earth's orbit lies on a circle centered at the sun with a radius of 1 AU. However, the standard deviation from the mean surface is about 22°. This indicates that an individual shock surface geometry can deviate rather markedly from a spherical shape. From a physical point of view a spherically symmetric shock near the sun propagating through IP space will interact with interplanetary discontinuities (Lepping and Burlaga, 1973) and IP large scale inhomogeneities, such as streams and gradients in density, temperature, velocity, etc. (Heinemann and Siscoe, 1973). That is, it appears that an individual shock front may be distorted not only in gross geometry from a spherical shape,
but also experience a "rippling" on the scale of the correlation length of IP tangential discontinuities. A collection of these various perturbations on shock surfaces may result in an ensemble average of such surfaces being spherical with a relative large standard deviation even though few of the individual shock surfaces were actually spherical. In this sense the RMS deviation of the normals is probably more important than their average.

Figures 5 and 6 (especially 5), showing a tendency for a radius of curvature of 1 AU at 1 AU regardless of the location of the flare site with respect to the shock observation point, tend to suggest that the initial (solar) shock shape is less important than IP processes in causing shock normal scattering over 1 AU ($\sigma \approx 23^\circ$). In fact, the symmetry indicated by these figures is rather remarkable from the viewpoint of IP shock normals. However, an equally striking asymmetry exists which suggests a relationship about IP shock survivability. Notice that of the 33 shocks listed in Table 3 having a flare site association, 11 have an East solar longitude designation but 22 have a West designation. That is, it appears that an observer at 1 AU is twice as likely to find shocks related to West longitude flares as East longitude; the average for the set of 33 flares is 17°W. Even the limited set of 22 shocks (Table 3, top, and Figure 5) give essentially the same results: 14 West longitude and 8 East longitude. Sakurai (1973 a,b) finds an apparently related asymmetrical tendency also based on SSC-flare associations: his statistical study shows that a maximum mean speed direction lies $\approx 30^\circ W$ of the central meridian of the solar disk, i.e. near to the mean spiral
direction. The IP shock geometry for the Feb. 15-16, 1967 shock discussed by Lepping and Chao (1972) indicates a strong similarity. It appears that a shock experiences a greater chance of survival beyond 1 AU if it propagates along a direction approximately parallel to that average spiral which maps back to the flare site. This is not unreasonable according to the model by Heinemann and Siscoe (1973), which crucially depends on the IP spiral geometry and on large scale interactions of IP shocks with streams. The meridional plane statistics are less interesting: 19 North latitude and 14 South latitude for the set of 33 shocks, and 13 North and 9 South for the set of 22 shocks.

In conclusion, interplanetary shock waves and geomagnetic storm sudden commencements (SSC's) are correlated with the solar activity of flares, radio bursts of Type II and/or Type IV. The average IP shock front at 1 AU has a radius of curvature on the order of 1 AU. However, the geometry of the shock front deduced to be of spherical shape is obviously not representative of any individual event, because an individual shock front may be severely distorted over 1 AU by IP processes.

Acknowledgements

We are indebted to Dr. L. F. Burlaga for suggesting that we undertake this work and we thank him and Dr. K. W. Ogilvie for helpful comments and criticisms.

We would like to thank the investigators listed in Table I and their associated groups for the use of their magnetic field and solar plasma data.
Also we are grateful to Dr. K. Sakurai for his help in making some of the radio burst associations with the SSC events, and to Dr. G. L. Siscoe for suggesting the simulated random-shock study.
