A DEMONSTRATION OF ERTS-1 ANALOG AND DIGITAL TECHNIQUES APPLIED TO STRIP MINING IN MARYLAND AND WEST VIRGINIA

Arthur T. Anderson
and
Jane Schubert

ABSTRACT

The largest contour strip mining operations in western Maryland and West Virginia are located within the Georges Creek and the Upper Potomac Basins. These two coal basins lie within the Georges Creek (Wellersburg) syncline. The disturbed strip mine areas were delineated with the surrounding geological and vegetation features using ERTS-1 data in both analog (imagery) and digital form. The two digital systems used were: (1) the ERTS-Analysis system, a point-by-point digital analysis of spectral signatures based on known spectral values, and (2) the LARS Automatic Data Processing System. The digital techniques being developed will later be incorporated into a data base for land use planning. These two systems aided in efforts to determine the extent and state of strip mining in this region. Aircraft data, ground verification information, and geological field studies also aided in the application of ERTS-1 imagery to perform an integrated analysis that assessed the adverse effects of strip mining. The results indicated that ERTS can both monitor and map the extent of strip mining to determine immediately the acreage affected and indicate where future reclamation and revegetation may be necessary.

A DEMONSTRATION OF ERTS-1 ANALOG AND DIGITAL TECHNIQUES APPLIED TO STRIP MINING IN MARYLAND AND WEST VIRGINIA

INTRODUCTION

The effective exploitation of mineral resources involves a compromise between the need for the resource and the effects of despoilation on the land caused by strip mining. For example, coal mining is extremely profitable, and the product is a needed energy source; but, its effects can be devastating. This point was best summarized by Jane Stein (1973). With the improved mechanical methods of strip mining, coal is easily available and the percentage of affected areas is increasing throughout the United States. At this time, 14 states are affected by strip mining. Emphasis on the discovery of additional deposits has increased due to the current energy crisis. Newspapers and magazine articles have predicted finds of 1400 trillion kg (1.5 trillion tons) of coal within 1800 m (6000 ft) of the surface. Perhaps more practical is the estimate of 90 trillion kg (100 billion tons) of coal in seams 6 to 76 m (20 to 250 ft) below the surface that can quickly be recovered through strip mining techniques. Such possibilities are being investigated with the new discoveries of significant amounts of coal such as in Montana, Wyoming, and North Dakota where an area covering over 8 percent of this tristate region (about half the size of Rhode Island) has been found to contain coal. However, the abundance of coal and the need for the resource are impacted by national and state regulations to limit the yearly output of coal for ecological reasons: a conflict facing many areas of the nation today.

Looking at this situation in terms of smaller, local, and immediate problems, the area of western Maryland and West Virginia within the Potomac River Basin was studied using the Earth Resources Technology Satellite (ERTS-1) imagery and digital data. The principal purpose of this experimental study was to demonstrate the utility and application of ERTS-1 data in an integrated analysis, to both map and monitor strip mining, and to develop the needed methods and techniques to provide a data base for future land use planning. For example, Georges Creek Basin and the Upper Potomac Basin in Garrett and Allegany counties of western Maryland were examined using both an analog technique (photographic interpretation) and digital analysis. This area is now producing over 90 percent of the 1.45 billion kg (1.6 million tons) of coal mined each year in Maryland. These two counties are comprised of 3,044.76 km^2 (721,376 acres). Using aircraft photographs of these same counties, 25.16 km^2 (6216 acres) were categorized as extractive (strip mines) according to the land use classification of 1973 by the State Planning Commission.*

*Thomas, E., et al., private communication, 1973.

STUDY AREA

The strip mine study area is outlined on a 1:250,000 scale map (Figure 1). The area in western Maryland borders the Garrett/Allegany county boundary from Frostburg and extends southward, paralleling Georges Creek and North Branch main-stream-head waters of the Potomac, and ends in Steyer, Maryland. This area is within the great Appalachian coal region which extends from Pennsylvania to Alabama. Physiographically, the Maryland area encompasses the Georges Creek Basin to the north and Upper Potomac Basin to the south divided by the right-angle bend of the Potomac. These two divisions are purely artificial and together constitute a single structural unit of the Georges Creek (Wellersburg) syncline.

The overall area is a gentle elongated shallow syncline which trends northeast-southwest between Dan's Mountain and the Allegheny front on the east and both Big Savage and Backbone Mountains to the west. The mountain ranges form the flanks of the gently dipping syncline within the eastern border region of the Allegheny Plateau and contain geologic formulations of Permian and Pennsylvanian age. Located here are the only coal bearing seams in Maryland. The formations are the Dunkard, Monongahela, Conemaugh, Allegheny, and Pottsville groups. Although these formations are approximately 518 m (1700 ft) thick, about 18.9 m (62 ft) contain usable coal in seams ranging from 0.3 to 4.3 m (1 to 14 ft) in thickness. Specifically, the major coal seams in this area are the Pittsburg, Barton, Franklin, and Sewickley seams.

METHOD

During the preliminary examination of strip mine regions, the first step in this study was to demonstrate the utility and application of the ERTS output for a multilevel analysis of immediate problem areas and for future planning of land use management. With this in mind, it was determined that the use of map-related data, imagery, geologic analysis, and computer processing techniques would provide a more accurate and complete assessment of strip mines for both a total acreage figure and for determining active, inactive, or reclaimed mining areas. It should be noted that strip mines go through various stages of development and reclamation in a period of three months to one year and that some inferences (with the assistance of the Maryland Geological Survey) had to be made in projecting backward in time to determine the approximate stage of development in larger mines. In this context, the study used the September 7, 1972 (1046-15301), ERTS imagery. This imagery provided the best delineation of the strip mines.

the five sample image enlargement areas chosen from the area of study. These five areas shown in Figure 3 were checked and verified in the field, and the 12 different spectral signatures were identified. Finally, a multispectral classification of bands 5 and 7 based on the identified classes was completed, using pattern recognition techniques developed at LARS.

DISCUSSION

The ERTS assessment of the areas affected by strip mining was performed in a two-part analysis through the use of manual image interpretation techniques and the ERTS-Analysis and LARS computer systems using the CCTs. First, it was found that in using manual techniques with ERTS imagery enlarged to 1:125,000 scale, there were limitations due to scale and, consequently, only the boundaries of the geologic formations could be defined in relation to the specific strip mines under investigation. No attempt was made to extract the total acreage of strip mines. These areas are too small in scale to show the desired detail with ERTS-1 imagery; they were no more than 80 to 300 m (260 to 1000 ft) across. This technique was not accurate enough for the purposes of this study to quantify the entire affected areas by planimetry means, the features being too small. The use of the ERTS computer-compatible tapes with both the ERTS-Analysis and LARSYS2 systems provided more reliable answers in the detection and inventory of strip mines. The results of the ERTS-Analysis output can be seen in Figure 4. Results from the computer output were correlated with the U-2 photograph; there was excellent size agreement with the printout. The U-2 photograph was then verified in the field.

Figure 5 presents a compilation of the final results from the ERTS-Analysis technique in identifying strip mine areas in the two basins using this program and shows a sample output registered to a topographic map. This sample output includes the Franklin Hill area which lies northwest of Westernport and outlines the local strip mines. The analysis, computer time, and statistical listing, compiled in approximately 8 hours, identified 140 strip mines totaling 12.58 km^2 (3109 acres) of disturbed land within the two basins and the adjoining area. The stripped, soil covered, and high wall boundaries could be delineated on the output. The table in Figure 6 also shows the size, number, and percentage of strip mines in the study area, and it should be noted that the majority of the mines are less than 0.089 km^2 (22 acres) in size. In addition, the ERTS-Analysis computer output in transparency form registered to the topographic base at 1:24,000 (Figure 5) has already proved to be extremely useful to reclamation studies as a rapid method to show the overall extent of the acreage affected at one specific time, according to James Coffroth of the Maryland Geological Survey (private communication, 1973).

Figure 6. LARSYS2 clustering output, showing the outline and delineation of the strip mine areas and 12 cluster areas, for sample areas 2 and 5 from Figure 3.

The LARSYS2 multispectral clustering and classification system proved to be very reliable in detecting and identifying various ground surface conditions and ground cover of the existing strip mines and vegetation in the study area. The various spectral classes identified in Figures 6 and 7 provide important land use information for future planning and for incorporation into a useful data base. As seen in Figure 6, the 12 clusters of vegetation density and soil cover can be extrapolated spectrally as depicted in the outlined clustered areas. The sampled areas in Figure 3, areas 2 and 5, outline that area shown in Figure 6. This output from LARSYS2 subdivides the 2.86 km^2 (707 acres) (620 pixels) of strip mines (M) in the area (Figure 6). In addition, the classification in Figure 7 resulting from the clustering analysis correlates with the detailed strip mine state topographic map of the previous ERTS-Analysis output. The results of this classification depict the stripped areas (C in Figure 7) and the soil cover overlying the backfilled spoils (open regions in Figure 7).

The analysis of the digital data, compared to manual techniques, proved most advantageous in the evaluation of the strip mines. As determined from the computer analyses, the reclaimed areas which were grassed over within a period of two years or less are somewhat difficult to distinguish from the recently recovered and seeded grass regions. This was due mainly to two factors: the spoil material in the reclaimed areas contain a high degree of carbonaceous content mixed into the original soil cover, and the grass was not dense enough to change the spectral response. Digital computer analyses of affected strip mining areas can be quantitatively examined by applying the advantages of both systems, ERTS-Analysis and LARSYS2. These data reduction and interpretation techniques will provide an added tool and rapid means of strip miné assessment.

CONCLUSION

The use of the ERTS-1 data has been shown to provide an immediate application in detecting, mapping, and inventorying the effects of strip mining in the Upper Potomac and Georges Creek Basins of Maryland and West Virginia. These data will provide the states with a better means of detecting and monitoring future reclamation projects. With the increased needs for fuel, it is estimated that the 1.45 billion kg (1.6 million tons) of annual coal production in Maryland will increase by 10 percent or more in 1974. Through use of the described methods, this increase in strip mining can be monitored throughout the disturbed regions. Also, at the same time, the progress of backfilled, planted, and reclaimed acreage throughout the state can be monitored, which will result in a minimum of ecological impact.

Figure 7. LARSYS2 classification output sample, verified with aircraft and field studies, delineating the strip mines (C) and bare soil reclaimed area) which is open.
