16. Abstract

The historical development of analytical methods for predicting the lift, drag, and pitching moment of complete light aircraft configurations in cruising flight is reviewed. Theoretical methods, based in part on techniques described in the literature and in part on original work, are then developed in detail. These methods form the basis for understanding the computer programs presented in the remainder of the work. Programs are given to: (1) compute the lift, drag, and moment of conventional airfoils, (2) extend these two-dimensional characteristics to three dimensions for moderate-to-high aspect ratio unswept wings, (3) plot complete configurations, (4) convert the fuselage geometric data to the correct input format, (5) compute the fuselage lift and drag, (6) compute the lift and moment of symmetrical airfoils to M = 1.0 by a simplified semi-empirical procedure, and (7) compute, in closed form, the pressure distribution over a prolate spheroid at $\alpha = 0$. Comparisons of the predictions with experiment indicate excellent lift and drag agreement for conventional airfoils and wings for $C_L < 0.8$. Limited comparisons of body-alone drag characteristics yield reasonable agreement. Also included are discussions for interference effects and techniques for summing the results of 1-5 above to obtain predictions for complete configurations.

GENERAL INTRODUCTION

The successful prediction of the performance of a new or modified aircraft depends as much on the availability of an accurate estimate of the configuration's lift and drag characteristics as on any one thing. Despite the importance of this task, the procedure used in the light aircraft industry and that taught in most universities has remained essentially a semi-empirical correlation of wind tunnel and flight test data plus a collection of useful rules of thumb. The major airframe manufacturers and their cognizant governmental laboratories have for some time sought both to reduce the time needed to develop these predictions and to increase their accuracy and reliability through the use of large-scale digital computers. Employing long-known, highly rigorous analytical computation methods which become too involved when applied to complete aircraft for one to perform manually, these groups have, within the last three-to-six years, achieved some remarkable successes in predicting the aerodynamic characteristics of complex geometric shapes.

It is the intention of the present work

- to review analytical and experimental developments in aerodynamics of the past 32 years, in particular those of the National Aeronautics and Space Administration,

- to identify those of special pertinance to the design of light aircraft and

- to develop from these easy-to-use design procedures.

Of necessity these procedures will involve digital computer programs. This approach follows that employed in earlier works in this series. Reference 1, for example, provides detailed computer programs for the prediction of point and path performance assuming that the lift, drag, and thrust characteristics are known. References 2 and 3 give programs for the calculation of stability derivatives and aircraft motions given the vehicle's geometric and inertial characteristics. Thus with these and the present work the reader can specify the aircraft geometry, mass distribution, and thrust applied to the air and expect to obtain the vehicle's performance and its handling qualities. He can then vary the geometry, etc. in a systematic fashion and find the shape giving the most satisfactory combination of performance and handling qualities.

While the availability of these programs will certainly be of great assistance in the overall design task, it should be noted that many areas of aircraft configuration design have not been treated in detail or have not been programmed for computer solution in the work to date. These include large excursions in the motions about an equilibrium position, performance in the horizontal plane, takeoff and landing, aerodynamic characteristics at high angles of attack and/or with deflected flaps, flight in turbulent air, calculation of stick and rudder forces and deflections, propeller slipstream effects, adequate representations of thrust horsepower and fuel

flow, and the effects of specific stability augmentation systems. It is the authors' ultimate intention to treat all of these problems in the manner of the programs included in the present work. They would, however, be pleased to receive suggestions from readers and users of the work as to the priority with which the problems should be attacked.

The present work departs from the practice of previous works in this series in that the computer programs presented are usually modifications (generally simplifications) of elaborate programs in use at government facilities rather than original efforts. This was done to take advantage of the rather substantial effort which went into the preparation of these programs. Each program which was used has shown good agreement with experiment in at least a limited number of cases. Such a practice also has a number of disadvantages:

1. The available documentation is usually very sketchy and frequently inconsistent with the program statements and/or logic. As a result it is very difficult to determine in detail the method on which the program is based and the validity and/or applicability of the methods.

2. The programs usually contain many more options than are needed for the present purposes. It is often difficult to unravel the program to the point that these unneeded options can be removed successfully.

3. The programs are usually written to take advantage of the characteristics of a particular machine which limits their transferability to other machines.

4. In every case the programs are written for very large machines. Smaller machines generally have insufficient storage capacity even to compile the programs. In order to use them on smaller machines one must devise a means of splitting a program into several parts or employing a form of virtual storage.

The present work represents an effort at overcoming these disadvantages. It begins with a review of the literature on the estimation of lift and drag characteristics of wings, wing-bodies, and complete aircraft configurations. Among those treated in this discussion are a group of government reports which describe computer programs for performing various portions of this estimation task in a rapid but accurate manner. Several of these programs appeared to offer a sufficient reduction in the cost of estimating the aerodynamic characteristics of new or modified designs that it seemed desirable to adapt them for use with light aircraft, the computer capabilities of this industry, and as an instructional device for fledgling designers. For these reasons, those portions of the programs dealing with the effects of flap deflections have been removed. The modified programs are therefore more applicable to the higher speed portions of the flight profile. Studies are currently underway of means for including the computation of these effects with reasonable additional computer requirements.

In the next section of the work the theoretical bases of the recommended programs are discussed starting from first principles. It should be emphasized that the methods described are not always exactly those used by the computer programs. The approach to the problem is <u>usually</u> the same but the details are frequently quite different. This has been done because, as noted above, the details of the methods actually used are obscure, at least to the present authors, and because a different treatment was regarded as being easier for those approaching the area for the first time to understand.

Following this discussion is a review of the changes in the programs, instructions for their use, and some sample results. Included also are appendices providing locally-written computer programs found useful for producing analytical check cases, simple approximate solutions to more general computations, or extensions of the range of the major programs to other speed regimes.

The present work is intended to serve several needs. Its primary function is to provide the practicing light aircraft designer with a powerful tool for reducing the engineering labor needed to develop a new airplane or revise an existing one. Hopefully, it is written at such a level and in sufficient depth that the user will be able to gain an understanding of the limitations imposed on the attainable accuracy by the choice of physical and mathematical models as well as an appreciation for the new capabilities provided by the programs and instructions for their use. By keeping the mathematical sophistication required for comprehension to a minimum and by emphasizing physical descriptions of the means by which flows over aircraft are represented, it is hoped that undergraduate aeronautical engineering students will also find the work both helpful and illuminating. It seems unfortunate that because of time limitations, a lack of technical maturity on the student's part, and a reluctance on many educators' part to depart from traditional practice, flight vehicle design is still taught largely as a semi-empirical art rather than as the near-science which it has lately become. Perhaps with the aid of these more powerful less time-consuming tools the student can now successfully complete more realistic design problems during his undergraduate education.

LITERATURE REVIEW AND THEORETICAL

BASIS OF COMPUTER PROGRAMS

LITERATURE REVIEW

INTRODUCTION

Given the task of creating an entirely new airplane, the designer will usually seek to devise first a wing geometry and, ultimately, a whole airplane geometry that

1. provides the required lift

2. has suitable stall characteristics

3. has minimum drag for good performance

4. has good stability and control characteristics

5. meets structural requirements

6. is easy to build.

He will usually select a configuration that satisfies the last two objectives reasonably well and then attempt to determine how well the configuration meets the other objectives. He recognizes that he need not calculate the aerodynamic forces acting on the vehicle with great accuracy in order to determine the flying qualities. On the other hand, if he is to predict the craft's performance with reasonable accuracy, he must know the lift and drag as precisely as possible.

From the viewpoint of designers active during the early years of this century the analysis process was very ill-defined. One did not then even know how much wing he should provide or what shape to make it in order to insure that his aircraft would fly. Being able to estimate how fast or how far his craft might go seemed a matter of secondary concern to the more urgent problem of how much lift is associated with a particular geometry. A systematic study of this problem would seem to begin with consideration of the lift developed by a slice or section out of the wing. Modeling the problem in this fashion has the advantage that one need consider only flow in two dimensions rather than in three, a great mathematical simplification. Further it would seem reasonable to assume that the fluid is inviscid if for no other reason than to take advantage of the extensive analytical studies (particularly those of Helmholtz (Ref. 4) and Kirchhoff (Ref. 5)) that had been carried out for this case during the nineteenth century. These studies had been successful at explaining several experimental facts and present far less mathematical difficulty than one would encounter working the more general equations for the flow of a viscous fluid formulated by Navier and by Stokes about 1840. A good account of much of this work may be found in Lamb (Ref. 6).

The immensity of the problem facing engineers in 1900 trying to devise a rational means of calculating wing lift can be better appreciated when

6

one realizes that in the contemporary view lift was the force reacting to
the change in the momentum of the airstream striking the inclined lower
surface of wing. Such a force would be proportional to $\sin^2 \alpha$ where α is
the angle by which the lower surface is inclined to the wind. If one were
to assume that a wing is flying at fifty miles an hour with $\alpha = 6°$, then
it could develop about 0.0635 pounds of lift per square foot of surface,
according to this theory. Since it was then impossible to build a wing
lighter than this weight, many scientists confidently predicted that man
would never fly. More preceptive individuals noted however that the
flight of gliders could not be explained by such small values of lift
and therefore something must be wrong with the theory.

THE AIRFOIL IN INVISCID FLOW

Lord Rayleigh had shown in 1878 that the swerving flight of a "cut"
tennis ball could be explained at least in general terms by comparing it to
the case of a cylinder placed in an inviscid uniform stream. By superposing
a circulatory flow upon the cylinder, the cylinder developed a force normal
to the direction of the uniform stream, directly proportional to the strength
of the circulatory flow. This result along with the earlier work of Helmholtz
and Kirchhoff was known to the German mathematician M. W. Kutta who was
interested in why cambered airfoils produce lift at $\alpha = 0$. In a 1902 paper
(Ref. 7) he studied a thin airfoil formed by a circular arc. He concluded
that the only reasonable assumption one could make in view of what was
known physically was that the flow velocity over the upper surface was
equal to that over the lower surface at the trailing edge. The flow would
therefore leave the surface smoothly at finite velocity. He was willing
to accept the idea of an infinite velocity at the sharp leading edge, a
situation studied by Helmholtz, in order to obtain an approximate solution
for the lift. Von Kármán (Ref. 8) gives a highly readable account of this
early work.

Joukowski (Ref. 9), working independently along somewhat parallel
lines, was able to obtain exact solutions for a certain class of airfoils
in inviscid flow. He first showed that when a cylindrical body of arbitrary
cross-section moves with velocity, V, in a fluid whose density is ρ and
there is a circulation of the magnitude, Γ, around the body, a force is
produced equal to the product $\rho V \Gamma$ per unit length of the cylinder. The
direction of the force is normal both to the velocity, V, and the axis of
the cylinder. Joukowski also assumed the flow to leave the airfoil smoothly
at the trailing edge. By means of this hypothesis the whole problem of
lift becomes purely mathematical: one has only to determine the amount of
circulation so that for zero vertex angle at the trailing edge the velocity
of the flow leaving the upper surface is equal to the flow leaving the lower
surface. If the tangents to the upper and lower surfaces form a finite
angle, the trailing edge is a stagnation point.

Joukowski then found a transformation, $\zeta = z + C^2/z$, by which a circle
in the z-plane becomes an airfoil in the ζ-plane. See the following sketch.

$$\zeta = \xi + i\eta$$
$$z = x + iy$$
According to the transformation, a point represented by $z = x + iy$ in the x,y plane is moved to a different location in the ξ,η plane. In the process, all the other points in the plane are moved in such a way that the figure of a circle in the x,y plane becomes an airfoil in the ξ,η plane. Under Joukowski's transform the shape of the airfoil may be changed to a considerable extent by moving the center of the circle (originally at O) to some other location M while keeping the point at which the circle crosses the x-axis in the left half-plane at B. To see how this happens it is instructive to carry out a sample calculation.

The general equation of a circle is of course

$$(x - x_1)^2 + (y - y_1)^2 = a^2$$

where
$$x_1 = a \cos \beta - C = \frac{a^2 - C^2 - m^2}{2C}$$

$$y_1 = a \sin \beta$$

in the notation of the sketch. For simplicity one may assume that in this calculation $\beta = 0$. Then

$$[x - (a - C)]^2 + y^2 = a^2$$

or
$$y = \sqrt{2(a - C)x + 2aC - C^2 - x^2} \quad .$$

8

Now
$$\zeta = x + iy + \frac{C^2}{x + iy}$$

$$= x + iy + C^2 \left(\frac{x - iy}{x^2 + y^2} \right)$$

$$= x \left(1 + \frac{C^2}{x^2 + y^2} \right) + iy \left(1 - \frac{C^2}{x^2 + y^2} \right).$$

Substituting values for $x^2 + y^2$ and y into this expresion yields

$$\zeta = x \left(1 + \frac{C^2}{2aC - C^2 + 2x(a - C)} \right)$$

$$+ i \left(1 - \frac{C^2}{2aC - C^2 + 2x(a - C)} \right) \sqrt{2(a - C)x + 2aC - C^2 - x^2}.$$

Since a and C are arbitrary numbers, choosing x completely specifies the value of ζ. For example, let C = 1 and a = 1.1. For this special case the previous equation becomes

$$\zeta = x \left(1 + \frac{1}{1.2 + 0.2x} \right) + i \left(1 - \frac{1}{1.2 + 0.2x} \right) \sqrt{1.2 + 0.2x - x^2}.$$

The equation is easily evaluated and the results presented in tabular form. The table below may be extended to determine the shape of the resulting figure more accurately, if desired.

x	ξ	η
1.2	2.035	0.
1.	1.707	+.1855
1.	1.707	-.1855
0.5	0.885	+.236
0.5	0.885	-.236
0.	0.	+.182
0.	0.	-.182
-1.	-2.	0.

Even from this limited set of numbers, however, it is apparent that for these values of a and C the circle <u>maps</u> into a symmetrical airfoil-like figure of high thickness-to-chord ratio. Moving M to the right increases airfoil thickness while moving M in the y-direction adds camber to the airfoil. Note that the airfoil chord is approximately 4C. Note also that point A becomes the leading edge of the mean camber line and point B the trailing edge of the airfoil under the transformation. When the angle of attack is changed, the flow strikes the airfoil from a different direction. To represent this situation, the strength of the circulation must be changed so that as far as the flow over the cylinder in the x-y plane is concerned the forward stagnation point has moved to some new location obtained by rotating the line MA through an angle α, α being positive when A moves down (y becomes negative). The location of the rear stagnation point must, for reasons pointed out in the next chapter, remain fixed during this operation.

Since the transformation is conformal, the fluid velocity and pressure which exist at any point on the surface of the cylinder can be related quantitatively, as indicated below, to those which exist at the corresponding point on the airfoil. Integration of these pressures in the direction normal to the free stream velocity then gives the airfoil lift (which is also the same as the lift produced by the generating cylinder).

For the cylinder, the surface velocity components are given by

$$u = V[\cos \alpha(1 - \cos 2\theta) + \sin \alpha \sin 2\theta] + \frac{\Gamma y}{2\pi a^2}$$

$$v = V[\cos \alpha \sin 2\theta - \sin \alpha(1 - \cos 2\theta)] - \frac{\Gamma x}{2\pi a^2}$$

while the surface pressures are given by

$$P_{CIRCLE} = P_{STAGNATION} - \frac{\rho}{2}\left(u^2 + v^2\right) \quad .$$

Here θ is the angular location of the point of interest on the surface measured from the negative x-axis. Hence $x = a \cos \theta$ and $y = a \sin \theta$. One may use these values in the procedure outlined above to find that location on the airfoil corresponding to θ. The velocity on the airfoil surface is simply the velocity at the equivalent point on the circle times $|dz/d\zeta|$. From the transform

$$\left|\frac{dz}{d\zeta}\right| = \left|\frac{1}{d\zeta/dz}\right| = \left|\frac{1}{1 - C^2/z^2}\right| = \left|\frac{z}{z - C^2/z}\right|$$

thus the airfoil surface pressure is given by

$$P_{AIRFOIL} = P_{STAGNATION} - \frac{\rho}{2}\left(u^2 + v^2\right)\left|\frac{z}{z - C^2/z}\right|^2 \quad .$$

It is interesting to note that while the theory places no limit on the magnitude of Γ, a value greater than $\Gamma = 2\pi Va$ means that the front and rear stagnation points have come together and are moving away from the circle along the ray $\theta = -\pi/2$, clearly a physically impossible situation since it would mean a strong cyclonic flow was present about the airfoil. In actual cases Γ seldom exceeds $\pi Va/4$.

The Joukowski transform technique was a great step forward in analyzing the lift of airfoils. It gives the correct variation of lift with angle of attack and predicts lift values which are very close to measured values at the same angles of attack. Unfortunately the Joukowski transform techniques also had a number of disadvantages:

1. It is an inverse technique, that is, one does not know beforehand precisely what the airfoil will look like. As a result it is difficult to use the technique to estimate the characteristics of a given airfoil.

2. It leads always to an airfoil with a cusp at the trailing edge. This is impractical structurally.

3. It leads to airfoils which have their minimum pressure point very far forward. Consequently, they have thick boundary layers, and therefore higher drag and lower maximum lift values than airfoils with the minimum pressure point further aft.

4. Being an inviscid theory, it cannot be used to estimate either lift characteristics near stall or drag values.

5. It is tedious to determine the ordinates of the airfoil accurately.

These deficiencies were soon recognized and many investigators set about devising more general transforms which could be used to represent a greater variety of airfoils, in particular those with finite trailing edge angles. Kármán and Trefftz (Ref. 10), von Mises (Ref. 11), Müller (Ref. 12), and Theodorsen (Ref. 13) were among the leaders in this effort, which by 1932 had reached the point where one could determine the lift characteristics of a great variety of airfoils. The great effort required to complete a calculation, however, discouraged thoughts of a further generalization in the transform technique. The following outline of Theodorsen's method will indicate the labor required.

The transform or mapping function is built up in two stages; in the first the airfoil profile in the z-plane is mapped into a contour in the ζ'-plane through the use of the Joukowski transformation

$$z = \zeta' + \frac{C^2}{\zeta'} \quad .$$

It is desirable that the contour in the ζ'-plane be as close to a circle as possible; for this reason the axes in the z-plane should be chosen with a view toward producing that result. This means that the airfoil should be distributed as near like an ellipse as possible with respect to the axes in the z-plane.

The second stage consists of <u>finding</u> a mapping function which will transform the near-circle in the ζ'-plane to an exact circle in the ζ-plane. Theodorsen used the transform

$$\zeta' = \zeta \exp\left(\sum_{n=1}^{\infty} \frac{C_n}{\zeta^n}\right) \quad ,$$

where the coefficients C_n, complex in general, have to be determined.

A point on the near or pseudo circle in the ζ'-plane is given by

$$\zeta' = C\, e^{\psi(\theta)}\, e^{i\theta} \quad .$$

The factor $e^{\psi(\theta)}$ determines how much the contour in the ζ'-plane departs from that of a circle. The relationship between points on the airfoil and points

11

on the pseudo-circle is given by the equations

$$x = 2C \cosh \psi \cos \theta$$

$$y = 2C \sinh \psi \sin \theta .$$

These two equations can be put into the form

$$2 \sin^2 \theta = P + \left[P^2 + \left(\frac{y}{C} \right)^2 \right]^{1/2}$$

$$2 \sin^2 \psi(\theta) = -P + \left[P^2 + \left(\frac{y}{C} \right)^2 \right]^{1/2} ,$$

where

$$P = 1 - \left(\frac{x}{2C} \right)^2 - \left(\frac{y}{2C} \right)^2 ,$$

which establishes the function $\psi(\theta)$.

Theodorsen describes a point on the exact circle in the ζ-plane by the equation

$$\zeta = Ce^{\psi_0}e^{i\phi} = Re^{i\phi}$$

where ψ_0 is a constant not yet determined. R is, of course, also a constant. The relationship between points on the pseudo-circle and those on the exact circle is given by

$$\frac{Ce^{\psi(\theta)}e^{i\theta}}{Ce^{\psi_0}e^{i\theta}} = \frac{\zeta'}{\zeta} = \exp \left(\sum_{n=1}^{\infty} \frac{C_n}{\zeta^n} \right) .$$

Setting

$$\frac{C_n}{\zeta^n} = \frac{A_n + iB_n}{\zeta^n} = \frac{A_n + iB_n}{R^n} e^{-in\phi}$$

and equating real and imaginary parts one obtains

$$\psi - \psi_0 = \sum_{n=1}^{\infty} \frac{1}{R^n} (A_n \cos n\phi + B_n \sin n\phi)$$

$$\theta - \phi = \sum_{n=1}^{\infty} \frac{1}{R^n} (B_n \cos n\phi - A_n \sin n\phi) .$$

From these it follows that

12

$$\psi_0 = \frac{1}{2\pi} \int_0^{2\pi} \psi(\phi) d\phi$$

$$\frac{A_n}{R^n} = \frac{1}{\pi} \int_0^{2\pi} \psi(\phi) \cos n\phi \, d\phi$$

$$\frac{B_n}{R^n} = \frac{1}{\pi} \int_0^{2\pi} \psi(\phi) \sin n\phi \, d\phi \quad .$$

The foregoing equations define ψ_0, A_n, and B_n in terms of $\psi(\phi)$ or, equivalently, $\theta(\phi)$. Since $\psi(\theta)$ is usually not easily extracted and when it has been it is not a simple form, the evaluation of the various coefficients is best handled numerically or by a combination of graphical constructions, approximations, and iterations. Theodorsen's original method followed the second course. The original paper may be consulted for details. To use the method today one would employ numerical techniques.

Once the process has been completed by whichever means are employed, one then has the pressures and velocities at each point on the airfoil surface in terms of those at the equivalent point on the exact circle.

Analyses of the lift characteristics of various Joukowski airfoils in the meantime revealed that the thickness contributed little to the lift. It therefore seemed to some that if airfoils for which one had difficulty finding appropriate conformal transforms could be characterized by their mean camber lines only, then perhaps one would have a relatively simple, yet direct method of evaluating the lift and pressure distribution of arbitrary airfoils. Such an approach is obviously most appropriate when the actual airfoils are thin. These ideas were developed in the early 1920's by Munk (Ref. 14), Birnbaum (Ref. 15), and Glauert (Ref. 16).

In Glauert's conception the airfoil is replaced by its mean camber line which he assumed, never lies very far from the chord line. For this reason he felt justified in making the approximation that the velocities over the airfoil could be represented by a continuous distribution of vortices (or a sheet of vorticity)* lying along the chord line. The variation in vorticity with chord location is not known initially. The velocity induced at point x' on the chord of the airfoil due to the vortex sheet is given by

$$v(x') = \int_0^c \frac{\gamma dx}{2\pi(x - x')} \quad ,$$

---

* The reader unfamiliar with the theoretical basis of the concept is referred to the next section of the present work or to Reference 17 for complete mathematical details.

where γ is the vortex strength per unit length. This induced velocity is actually calculated for a point on the chord but, according to Glauert's approximation, may be taken to be the same as the induced velocity at the corresponding point of the airfoil itself.* Since the resultant of the free stream velocity and the induced velocity adjacent to the airfoil must be parallel to the surface at each point of the airfoil and since the flow angularities are small, one may write this statement as

$$\alpha + \frac{v}{V} = \frac{dy}{dx} ,$$

where dy/dx is the slope of the mean camber line at x'. It will be seen that these two equations are sufficient to provide a complete solution of the problem in terms of the shape of the curved line which represents the airfoil. The solution is obtained as $\gamma(x)$. Then according to Joukowski's theorem

$$L = \int_0^c \rho V \gamma \, dx$$

$$M = \int_0^c \rho V \gamma x \, dx \quad .$$

The method Glauert employed to find $\gamma(x)$ is instructive because most subsequent calculative procedures use refinements of the same idea. Glauert first changed the independent variable x to θ according to the transformation

$$x = \frac{c}{2} (1 - \cos \theta) \quad .$$

He assumed that he could represent γ by a sine series in θ:

$$\gamma = 2V \left\{ A_0 \cot \theta/2 + \sum_{n=1}^{\infty} A_n \sin n\theta \right\} \quad .$$

Hence

$$\gamma dx = cV \left\{ A_0(1 + \cos \theta) + \sum_{n=1}^{\infty} A_n \sin n\theta \sin \theta \right\} d\theta \quad ,$$

then

$$v(x') = \frac{V}{\pi} \int_0^\pi \frac{A_0(1 + \cos \theta) + \frac{1}{2} \sum_{n=1}^{\infty} A_n \{\cos (n - 1)\theta - \cos (n + 1)\theta\}}{\cos \theta' - \cos \theta} d\theta$$

---

* Karamcheti (Ref. 17) presents a very detailed discussion of the relation of this approximation to the exact formulation.

14

$$= V \left\{ - A_0 + \frac{1}{2} \sum_{n=1}^{\infty} A_n \frac{\sin (n + 1)\theta' - \sin (n - 1)\theta'}{\sin \theta'} \right\}$$

$$= V \left\{ - A_0 + \sum_{n=1}^{\infty} A_n \cos n\theta' \right\} .$$

Substituting of this result in the second of the two original equations gives

$$\frac{dy}{dx} = \alpha - A_0 + \sum_{n=1}^{\infty} A_n \cos n\theta' .$$

According to the theory of Fourier series the coefficients A_n are determined from the shape of the airfoil by evaluating the integrals

$$\alpha - A_0 = \frac{1}{\pi} \int_0^\pi \frac{dy}{dx} d\theta$$

$$A_n = \frac{2}{\pi} \int_0^\pi \frac{dy}{dx} \cos n\theta \, d\theta$$

where dy/dx now is the slope of the surface at any x between 0 and c as a function of θ. The integral can, of course, be evaluated piecewise if the functional form changes as θ goes from 0 to π.

Glauert showed that one need find only A_0, A_1, and A_2 in order to determine C_L and C_{M_O}. Note that

$$\frac{L}{\frac{1}{2}\rho V^2 c} = C_L = \frac{2}{\rho c V^2} \int_0^\pi \rho c V^2 \left\{ A_0 (1 + \cos \theta) + \sum_{n=1}^{\infty} A_n \sin n\theta \sin \theta \right\} d\theta$$

$$= 2\pi (\dot{A}_0 + \tfrac{1}{2} A_1)$$

and similarly that

$$C_{M_O} = \frac{\pi}{2} (A_0 + A_1 - \tfrac{1}{2} A_2) = \frac{\pi}{4} (A_2 - A_1) - \tfrac{1}{4} C_L .$$

He also showed that

$$A_0 + \tfrac{1}{2} A_1 - \alpha = - \frac{1}{\pi} \int_0^\pi \frac{dy}{dx} (1 - \cos \theta) d\theta = \frac{2}{\pi} \int_0^\pi \frac{y}{c} \frac{d\theta}{1 + \cos \theta} ,$$

thus

$$C_L = 2\pi \left(\alpha + \frac{2}{\pi} \int_0^\pi \frac{y}{c} \frac{d\theta}{1 + \cos \theta} \right) .$$

15

Since Glauert also showed that

$$\int_0^\pi \frac{y}{c} \cos \theta \, d\theta = \frac{\pi}{4} (\alpha - A_0 - \tfrac{1}{2}A_2) \, ,$$

$$C_{M_O} = 2 \left(\int_0^\pi \frac{y}{c} \cos \theta \, d\theta - \tfrac{1}{2} \int_0^\pi \frac{y}{c} \frac{d\theta}{1 + \cos \theta} \right) - \tfrac{1}{4}C_L \, .$$

Values of C_L and C_{M_O} computed by this method Glauert found to be "in close agreement with experimental determinations of these quantities." The method can be seen to be considerably simpler to use than the transform technique. During the 1930's when designers sought to reduce wing drag by eliminating external bracing, they were forced by structural considerations to abandon the very thin airfoils they had been using until that time. They found that in order to predict the lift and moment characteristics of the newer and thicker airfoil sections that were then becoming the vogue, more elaborate analytical methods or extensive wind tunnel testing were necessary. One of these analytical methods took the following tack. Since the sum of solutions to the Laplace equation (the equation describing inviscid, incompressible flow) is also a solution, one can describe a thick, cambered airfoil at angle of attack by superimposing solutions for a curved line (Glauert's method), a flat plate at angle of attack (also represented by a vortex sheet), and a thick symmetrical airfoil at $\alpha = 0$ (using a distribution of sources along the chord line). An example of such a built-up solution is given by Karamcheti (Ref. 17). Reference 18 provides an exposition of both the thin airfoil and Theodorsen approaches and indicates how these techniques were used to guide the very significant series of experimental investigations carried out during the 1930's by the NACA.

These investigations sought to measure in considerable detail aerodynamic characteristics of several general families of airfoils. Since these data were obtained in well-calibrated wind tunnels at flight Reynolds numbers and presented valid drag data as well, designers came to regard NACA TR-824, "A Summary of Airfoil Data," (Ref. 19) and its forerunners as their primary data source. It has only been within the last 20 years or so that interest in improved analytical methods has been rekindled. This revival perhaps can be attributed to the simultaneous occurance of

1. recent, sharp escalation in the cost of making models and conducting tests,

2. the desire to optimize certain aspects of airfoil behavior and to investigate the characteristics of unconventional airfoils,

3. the appearance of the large digital computer which made it possible to consider the use of what had previously been rather laborious methods on a routine basis.

16

One of the first and most widely used methods of the current revival is that described by J. Weber (Refs. 20, 21). In the earlier of the two papers she treated the case of a symmetrical two-dimensional airfoil at angle of attack. By transforming an airfoil into a slit, she was able to show that the source distribution which she used to represent the thickness at zero lift can be placed along the chord line rather than on the surface with little error, provided the airfoil is no thicker than about 10% of the chord. With that assumption and the superposition of a vortex distribution on a flat plate at angle of attack, Weber obtained the equation

$$V(x,z) = \frac{V_o}{\sqrt{1 + (\frac{dz}{dx})^2}} \left\{ \cos \alpha \left[1 + \frac{1}{\pi} \int_0^1 \frac{dz}{dx} \frac{dx'}{x - x'} \right] \right.$$

$$\left. \pm \sin \alpha \sqrt{\frac{1 - x}{x}} \left[1 + \frac{1}{\pi} \int_0^1 \left(\frac{dz}{dx} - \frac{2z(x')}{1 - (1 - 2x')^2} \right) \frac{dx'}{x - x'} \right] \right\} .$$

The positive sign holds for the upper surface, the negative sign for the lower surface. $V(x,z)$ is the velocity along the airfoil surface. The pressure coefficients along the surface are given by

$$C_p = 1 - \left(\frac{V(x,z)}{V_o} \right)^2 .$$

The most attractive feature of the method is Weber's technique for finding a numerical value of $V(x,z)$. She begins by making the following definitions

$$S^{(1)}(x) = \frac{1}{\pi} \int_0^1 \frac{dz}{dx'} \frac{dx'}{x - x'}$$

$$S^{(2)}(x) = \frac{dz}{dx}$$

$$S^{(3)}(x) = \frac{1}{\pi} \int_0^1 \left[\frac{dz}{dx} - \frac{2z(x')}{1 - (1 - 2x')^2} \right] \frac{dx'}{x - x'} .$$

She then evaluates these quantities at specific points, x_ν, along the chord using the representation

$$S^{(1)}(x_\nu) = \sum_{\mu=1}^{N-1} S_{\mu\nu}^{(1)} z_\mu$$

$$S^{(2)}(x_\nu) = \sum_{\mu=1}^{N-1} S_{\mu\nu}^{(2)} z_\mu$$

$$S^{(3)}(x_\nu) = \sum_{\mu=1}^{N-1} S_{\mu\nu}^{(3)} z_\mu + S_{N\nu}^{(3)} \sqrt{\frac{\rho}{2c}} \quad .$$

The coefficients $S_{\mu\nu}^{(1)}$, $S_{\mu\nu}^{(2)}$, $S_{\mu\nu}^{(3)}$ are independent of airfoil shape and Weber gives tables of their values. N is the number of points used to approximate the airfoil (she gives tables for 8, 16, and 32 points). Point #1 is always at the trailing edge. ρ is the leading edge radius and c is the chord length. Weber also gives a table for finding x_ν corresponding to a given value of ν. These are the chordwise stations at which the pressure is calculated. z_μ is the airfoil ordinate corresponding to the chord location given by

$$x_\mu = \tfrac{1}{2}\left(1 + \cos\frac{\mu\pi}{N}\right)$$

where $1 < \mu < N-1$. It will be seen that with the aid of the tables of universal coefficients $S_{\mu\nu}^{(1)}$, $S_{\mu\nu}^{(2)}$, $S_{\mu\nu}^{(3)}$ the pressure computation is carried out very easily using a desk calculator.

A significant feature of Weber's method is her retention of the factor $1/\sqrt{1 + (dz/dx)^2}$ which materially improves the accuracy of the pressure computation near the leading edge. (See Appendix F.)

Weber extended her approach to treat cambered airfoils in a second paper (Ref. 21). She showed that two additional terms are required in the expression for pressure to account for camber:

$$c_p = 1 - \frac{\{\cos\alpha\,[1 + S^{(1)}(x) \pm S^{(4)}(x)] \pm \sin\alpha\,\sqrt{(1-x)/x}\,[1 + S^{(3)}(x)]\}^2}{1 + [S^{(2)}(x) \pm S^{(5)}(x)]^2}$$

where

$$S^{(5)}(x) = \sum_{\mu=1}^{N-1} S_{\mu\nu}^{(5)} z_{c_\mu} = \left(\frac{dz_c}{dx}\right)_{x_\nu}$$

$$S^{(4)}(x) = \sum_{\mu=1}^{N-1} S_{\mu\nu}^{(4)} z_{c_\mu} = \frac{\Gamma(x_\nu)}{2V_o} \quad .$$

The subscript "c" refers to the camber line. Weber gives tables for $S_{\mu\nu}^{(4)}$ and $S_{\mu\nu}^{(5)}$ and also provides some second order corrections to aid in predicting the pressure in the nose regions more accurately.

18

Comparisons between Weber's results and exact theory for Joukowski airfoils indicate that her method predicts pressures which are low by about 1%. Maximum camber must be less than about 4% of chord and thickness less than 10% of chord to obtain results of this accuracy, however.

The success of Weber's approach and its obvious adaptability to computer solution (see for example Reference 22) seems to have served as a spur to the development of more exact airfoil representation schemes which are practical only if carried out by digital computer. The method of Hess and Smith (Ref. 23) is among the best known of these developments. In this method the non-lifting airfoil surface is replaced by a source sheet with strength $\sigma(s)$ where s is the distance measured along the airfoil surface. The sum of the velocity induced by the source sheet and the free stream velocity is forced to satisfy the condition that its component normal to the airfoil surface at each value of s is zero. This statement is written mathematically as a Fredholm integral equation of the second kind:

$$2\pi\ \sigma(s)\ +\ \oint \sigma(s')\ \ell n\ r(s,s')ds'\ =\ F(s)$$

where $r(s,s')$ is the distance between the point of interest, s, and any other point on the surface, s'; $\sigma(s')$ represent the source strength at points other than s; $\sigma(s)$ is the source strength at s; and $F(s)$ represents the component of the free stream velocity normal to the surface at s. The left side of the equation then represents the component of the velocity induced by the source sheet which is normal to the surface. Note that for a given airfoil in a stream of known speed the unknown quantity is $\sigma(s')$ which occurs under the integral sign.

To solve this equation Hess and Smith make several approximations:

1. the contour of the airfoil can be represented by N straight line segments,

2. $\sigma(s')$ is constant over each segment,

3. the integral is evaluated at only one point—generally the mid-point—of each segment.

This leads to a system of N simultaneous linear equations which can be solved to find σ on each segment. For good accuracy, N must be large, particularly in regions of high curvature. Knowing σ one can then find the tangential component of velocity from which one can compute the surface pressure.

To treat the lifting airfoil, Hess and Smith in effect superpose a vortex sheet of suitable strength so that the total flow satisfies the local tangency condition as well as the Kutta condition at the trailing edge.

Martensen (Ref. 24) chose a different approach. He represented the airfoil by a vortex sheet on its surface. By requiring that the strength

19

of the vortex sheet be identical to the velocity distribution on the
surface of the airfoil, Martensen was able to show that in the interior of
a closed vortex sheet the velocity is everywhere zero. Thus on the
inner side of the vortex sheet the net tangential velocity which is a
sum of that due to free stream and that due to the vortex sheet is zero, or

$$\frac{\Gamma(s)}{2} - \frac{1}{2\pi} \frac{\partial}{\partial n} \oint \Gamma(s') \ln r(s,s')ds' = V_\infty \left(\frac{dx}{ds} \cos \alpha + \frac{dy}{ds} \sin \alpha \right).$$

This equation has almost exactly the same form as that formulated by
Hess and Smith.

To solve the equation Martensen chose, as did Hess and Smith, to
replace the integral by a summation. As a result he also ended up solving
a system of simultaneous equations. An equation expressing the Kutta
condition is required to complete the formulation. Martensen's method
while giving the velocity distribution on the surface as the solution
to the system of equations does not give good results for very thin
airfoils. The reason is that when the upper and lower surface control
points are very close together, the vortices located there induce strong
tangential velocities on each other. While this induced velocity
actually decays very rapidly for points in the neighborhood of the control
point, the method of approximating the integral which Martensen used
assumes it to be a constant. Jacob (Ref. 25) used a different limiting
approximation which improves the results but at the cost of restricting
one's freedom in distributing the control points on the airfoil surface.

If an inviscid fluid flow is.everywhere parallel to the surface of
a closed body then the surface of the body can be represented by a
streamline on which the stream function, ψ, is constant. Oellers (Ref. 26)
used this idea to write

$$\psi = V_\infty y(s) \cos \alpha - V_\infty x(s) \sin \alpha - \frac{1}{2\pi} \oint \Gamma(s') \ln r(s,s')ds' .$$

To solve this equation for ψ and $\Gamma(s')$, the integral is approximated by
a summation of the type used by Hess and Smith.

Chen (Ref. 27) made a very detailed comparison of the three foregoing
methods. He found that when applied to airfoils for which analytical
expressions for the pressure distribution are known, the Hess-Smith method
always gives the correct value of circulation generated by the airfoil.
On the other hand the computed surface velocity was found to be very
sensitive to the coordinates of the control points. A tiny error in the
input coordinates can produce a wavy behavior of large amplitude in the
computed surface velocity, more so than is reasonable physically. Chen
also tried approximating Martensen's integral in the same way Hess and
Smith approximated theirs. He found that the resulting circulation was
smaller than that found by Hess and Smith because the integration is
carried out along straight line segments rather than curves. This also
leads to some difficulties in the numerical computation because the

20

matrix of coefficients is ill-conditioned. Even after curvature effects are taken into account, the circulation computed by the Martensen-Jacob method, although larger, is still slightly smaller than that obtained by the Hess-Smith method. On the other hand, because it is a vortex sheet and tangential velocities which are considered by Martensen and Jacob, the computed results are not very sensitive to inaccuracies in the values of the input coordinates.

Chen prefers Oellers' method, primarily because it leads to fewer computational difficulties. Since it is an integral representation, no surface slopes must be computed, a process which always causes some loss in accuracy. Secondly, because the kernel of the integral equation is simpler in this formulation, the computing time required is generally less.

Several improvements in the transform approach to predicting airfoil characteristics have also appeared in recent years. Lighthill (Ref. 28) chose to specify the desired velocity distribution about the airfoil in closed form. Sato (Ref. 29) extended this approach to permit a velocity distribution of any kind to be specified. As worked out by Sato, the velocity distribution is assumed in such a way that front and rear stagnation points can be treated separately. A well-behaved function $g(\theta)$ takes up the velocity distribution everywhere with the exception of the stagnation points and three constants which are imbedded. The constants are determined by $g(\theta)$, the fact that the airfoil is a closed curve, and the fact that the flow field at infinity is uniform. A set of initial values must be given to the three constants in order to obtain $g(\theta)$ from the specified velocity distribution. This $g(\theta)$ is then used to obtain a new set of values for the constants which will give a closed curve as the airfoil geometry. The process is repeated iteratively until the before and after constant values match. In this way Sato's method always guarantees an airfoil geometry giving the desired velocity distribution. Because of the repetitive nature of many of its steps and the need for piecewise integration, it is best done on a digital computer.

THE AIRFOIL IN VISCOUS FLOW

It was of course recognized that all of these approaches would give somewhat optimistic predictions of airfoil lift and no prediction at all of airfoil drag. It was therefore just a matter of time until efforts would be made to attempt to account for the effects of viscosity at least so far as the lift produced by an airfoil is concerned. Powell (Ref. 30) was one of the first to attack the problem in a fairly rigorous fashion. He modified the airfoil geometry in two ways to account for the effects of boundary layer displacement of the inviscid flow. To the airfoil thickness distribution (symmetrical about the mean camber line) he added the total displacement thickness evenly distributed between upper and lower surfaces. He recognized, however, that the displacement thickness is not the same in the two surfaces, being thicker

on the upper surface. He chose to account for this fact by reflexing the trailing edge, adding $\frac{1}{2}(\delta^*_{upper} - \delta^*_{lower})$ to the ordinates of the mean camber line. Because the airfoil did not then physically close at $x = c$, he chose to set the upper and lower pseudo-surface velocities equal at $x = c$ as a replacement for the Kutta condition. He then employed Weber's method to predict the surface pressures. Powell assumed in his computation that $\delta^*(x)$ was available a priori. He also discussed the problem of "closing" the pseudo-airfoil in the wake as a means of finding reasonable surface slopes at $x = c$.

Apparently Powell's paper served as a source of inspiration for the work reported in Reference 31. Although the sketchy nature of the discussion in the report makes it difficult to ascertain precisely the heritage of the approach used or even its particulars, detailed examination of the computer program indicates that the authors (of the Lockheed Georgia Company) actually employed a combination of methods (vortex distribution on surface of a cambered airfoil plus a vortex distribution on a symmetrical airfoil) along with the idea discussed by Powell of modifying camber and thickness separately to account for boundary layer thickness. This represents somewhat of a departure from an earlier version of the computer program (Ref. 32) which is said to be based on Van Dyke's inviscid method (Ref. 33) and earlier British work on viscous corrections which was also considered by Powell. Van Dyke offered a way of treating thicker airfoils by transferring the surface tangency condition to the chord line with a Taylor series expansion. In other respects his approach is equivalent to Weber's.

The significant feature of the Lockheed program is its provision for arriving at the pseudo-airfoil shape in an iterative fashion. The program uses the inviscid pressure distribution and a fairly crude boundary layer computation to obtain the initial estimate of the displacement thickness. The displacement thickness is then used to get a new inviscid pressure distribution. The process is continued for five iterations until the pressure distribution used to compute the displacement thickness is virtually the same as that which one gets after adding the displacement thickness to the airfoil geometry. Computations of skin friction, transition of the boundary layer from laminar to turbulent flow, and location of the separation point are made at the same time. Program output is therefore airfoil lift, drag, and pitching moment as a function of angle of attack. It can also account for variations in free stream Mach number.

The program, which forms the basis of the modified version given herewith, was found, when compared with experimental results, (see for example Reference 52) to:

1.   over-estimate the lift curve slope by 5% to 8%,

2.   give very accurate estimates for the surface pressures except in the neighborhood of large suction peaks or incipicent separation,

22

3. give rather poor estimates of section drag, errors of 30% to 50% being common at low-to-moderate angles of attack; in particular the integration of the inviscid pressures in the drag direction is frequently not zero.

Despite these difficulties, the success of the program and its inherent rigor makes it apparent that with improvements in the boundary layer computation method and in the numerical procedures used an accurate and reliable means of estimating all the aerodynamics characteristics of airfoils at subsonic speeds is at hand. Reference 31 is the basis for the presentation in the next chapter of a theory for the prediction of lift, drag, and moment characteristics of two-dimensional airfoils.

COMPRESSIBILITY

To complete the discussion of developments in theoretical means for predicting the inviscid characteristics of light plane airfoils it is necessary to mention the effect of changes in Mach number. Although non-jet powered aircraft are not likely to reach speeds such that a local sonic point will exist on the airfoil, many do experience sufficiently high speeds to distort the M = 0 pressure distribution significantly. Thus it is desirable to chronicle the efforts which have been made in describing these effects.

Despite the folklore that the speed of sound presented an impregnable barrier to the velocity of flight vehicles, it was recognized quite early by many aeronautical scientists that artillery shells, for example, frequently exceed this speed. One should therefore be able to develop an expression for the pressure forces on a body for situations where the compressibility of the air is not negligible. Studies later showed that by allowing the density to vary in the equations describing the motion of an inviscid fluid but retaining the idea that the airfoil was thin and therefore did not disturb the flow greatly, it was possible to describe the flow over airfoils by the equation

$$\cdot \left(1 - M_\infty^2\right)\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} = 0$$

along with suitable boundary conditions. This equation, however, can be written as

$$\frac{\partial^2(\beta\phi)}{\partial x^2} + \frac{\partial^2(\beta\phi)}{\partial(\beta y)^2} = 0$$

where $\beta^2 = 1 - M_\infty^2$, a constant. The form then is that of the Laplace equation with which hydrodynamicists and early aerodynamicists were already familiar. Consistent with the small disturbance idea is the representation of the pressure coefficient at an arbitrary point on the airfoil surface by

$$C_P = \frac{P_L - P_\infty}{\frac{\rho_\infty}{2} U_\infty^2} = \frac{1}{\frac{\rho_\infty}{2} U_\infty^2} \left[P_{STAG} - \frac{\rho_\infty}{2} (U_\infty + u')^2 - P_{STAG} + \frac{\rho_\infty}{2} U_\infty^2 \right]$$

$$= \frac{2}{\rho_\infty U_\infty^2} \left[-\frac{\rho_\infty}{2} (U_\infty^2 + 2u'U_\infty + u'^2) + \frac{\rho_\infty}{2} U_\infty^2 \right]$$

$$= \frac{2}{\rho_\infty U_\infty^2} \left[-\rho_\infty U_\infty u' - \cancelto{0}{\frac{\rho_\infty}{2} u'^2} \right]$$

$$\cong -\frac{2u'}{U_\infty} \quad .$$

But $u' = \beta \frac{\partial \phi}{\partial x}$ and thus

$$C_P = -\frac{2\beta}{U_\infty} \frac{\partial \phi}{\partial x} \quad .$$

For the case where $\beta = 1$ (incompressible flow),

$$C_P = -\frac{2}{U_\infty} \frac{\partial \phi}{\partial x} \quad .$$

Thus,

$$(C_P)_{COMPRESSIBLE} = \frac{C_{P_{INCOMP}}}{\sqrt{1 - M_\infty^2}} \quad .$$

This simple relation was advanced about 1928 by Glauert and by Prandtl independently. It provides a good prediction of experimental results for local Mach numbers over the airfoil less than critical. It fails at higher Mach numbers because for rigor, the equation describing the flow must then contain an additional, non-linear term. This also makes it impossible to compare exactly the same airfoil at two different Mach numbers. Nevertheless, the fact that the Prandtl-Glauert formula permits one to find the pressure distribution over airfoils with reasonable accuracy for all Mach numbers less than that where the flow first becomes sonic merely by knowing the M = 0 distribution led to a very serious search for parameters which can be used to determine when the flow over an airfoil at one Mach number is similar to that over a second airfoil at another Mach number and hence will have the same pressure distribution.

One of the most successful efforts in this direction was the formula

$$C_P = \frac{C_{P_{INC}}}{\sqrt{1 - M_\infty^2} + \frac{M_\infty^2}{\sqrt{1 - M_\infty^2} + 1} \left(\frac{C_{P_{INC}}}{2} \right)}$$

24

proposed by Kármán and Tsien in 1939. (Quoted in Reference 56.) Although not strictly applicable to the flow over the same airfoil at different Mach numbers, it has been used in this way with good results. A good discussion of the theoretical basis for comparing flows over bodies at one Mach number with flows over the same or related bodies at different Mach numbers is given in Chapter 10 of the text by Liepmann and Roshko (Ref. 57).

EXTENSION TO THREE DIMENSIONS

The conceptual basis for expanding an airfoil section laterally into a finite wing can be traced to an 1894 paper by F. W. Lancaster. He elaborated these views in a book (Ref. 34) published in 1907. The mathematical expression of these ideas in a convenient form, however, seems to have originated with Prandtl (Ref. 35). He took a very simplified view of the wing, arguing that because the lift curve slope of all airfoils is nearly the same and because one cannot in any event determine viscous effects from an inviscid theory why not, then, for purposes of determining the effect of planform geometry or twist, represent the wing by just a line located at about the airfoil aerodynamic center. By placing a circulation about this line whose strength varies with the angle of attack of the wing, one can obtain a linear lift curve (C_L versus α) of the correct magnitude. Since such a vortex must either close or extend to infinity, Prandtl assumed that the vortex leaves each wing tip and extends, parallel to the fuselage, to some point very far downstream at which it closes; this can be considered to be at infinity for all practical purposes. Such a flow pattern is then consistent with the vortices observed leaving the tips of lifting wings. By superposing a series of vortices of different strengths and spans but assuming that they all "roll up" into one on leaving the tips, one can represent a rather arbitrary spanwise lift distribution.

Glauert (Ref. 16b) points out that the flow induced by this vortex system is normal to the span and to the direction of the aircraft's motion and is directed downwards in general. This downward flow velocity, w, is small compared with the flight velocity, U, but has the effect of reducing the angle with which the wing meets the oncoming flow, α. The reduction in angle of attack is given by w/U. Since w varies over the span, the induced angle of attack also varies over the span. Further, since the lift is defined as the force normal to the flow direction, the presence of an induced flow angle w/U causes the lift force to tilt backwards, giving a component in the direction of the drag force. This induced drag,

$$D_i = \frac{w}{U} L$$

is an **inviscid** effect resulting from the finite extent of the wing span. It may be noted that the work done on the fluid by the induced drag appears as the kinetic energy of the trailing vortices.

In the lifting line theory, the characteristics of a monoplane airfoil are determined by first finding w and hence the effective angle of attack at each point along the span, then finding the corresponding two-dimensional lift and drag, and finally, integrating across the span. The first step in this process is determining w in terms of the strength of the trailing vortices. Between the points y and y + dy on the span, the circulation Γ can be assumed to fall by an amount $-(d\Gamma/dy)dy$ and hence a trailing vortex of this strength springs from the element of span dy. There is therefore a sheet of trailing vortices extending across the span and the normal induced velocity, w, at any point y_1 on the span contains contributions from all the trailing vortices in this sheet. At y_1, therefore,

$$w(y_1) = \int_{-b/2}^{-b/2} \frac{-\frac{d\Gamma}{dy}\, dy}{4\pi(y - y_1)} \quad .$$

It can also be shown that the circulation around a section of any wing (airfoil) is

$$\Gamma = \tfrac{1}{2} C_L cU = \tfrac{1}{2} C_{L_\alpha} (\alpha - w/U)\, U \quad .$$

Although C_{L_α} actually varies slightly with airfoil geometry it is usually taken to be a constant. This equation, in conjunction with the preceding one, makes it possible to determine the circulation and w for any wing in terms of the local values of c and α. Note, however, that the first of these two equations is an integral equation because one of the unknowns, Γ, appears under the integral sign. This fact is responsible for much of the difficulty incurred in solving the wing lift problem because, in contrast to differential equations, few techniques exist for solving integral equations.

The technique which Glauert (Ref. 16b) suggested for solving the two equations proceeds as follows:

Call
$$y = -\frac{b}{2} \cos \theta$$

and
$$\Gamma = 2bU \sum_{n=1}^{\infty} A_n \sin n\theta \quad .$$

Then
$$w(\theta_1) = \frac{U}{\pi} \int_0^\pi \frac{\Sigma n A_n \cos n\theta}{\cos \theta - \cos \theta_1}\, d\theta = U \sum n A_n \frac{\sin n\theta_1}{\sin \theta_1}$$

from which it may be seen that at any point along the span

$$w \sin \theta = U \sum n A_n \sin n\theta \quad .$$

The second equation connecting Γ and w becomes in this notation

$$2bU \sum A_n \sin n\theta = \tfrac{1}{2} C_{L_\alpha} cU \left\{ \alpha - \frac{\Sigma n A_n \sin n\theta}{\sin \theta} \right\} \ .$$

Letting $\mu = (C_{L_\alpha} c)/(4b)$ one can write this as

$$\sum A_n \sin n\theta \sin \theta = \mu\alpha \sin \theta - \mu \sum n A_n \sin n\theta$$

or

$$\sum A_n \sin n\theta \, (\mu n + \sin \theta) = \mu\alpha \sin \theta \ .$$

In general it is to be expected that μ and α are functions of θ. The problem now is determining the values of the coefficients A_n which will satisfy the foregoing equation at every value of θ along the span of the particular wing in question.

In passing one may note that since

$$L = C_L \frac{\rho}{2} S U^2 = \int_{-b/2}^{b/2} b^2 \rho U^2 \, (\Sigma A_n \sin n\theta) \sin \theta \, d\theta$$

$$= \pi b^2 \frac{\rho}{2} U^2 A_1 \ ,$$

then

$$A_1 = \frac{C_L S}{\pi b^2} = \frac{C_L}{\pi AR} \ .$$

From this result it appears that the wing lift is determined by the value of A_1 and that the other coefficients in the series for the circulation, Γ, modify the shape of the spanwise lift distribution without altering the total lift.

The general procedure for obtaining the coefficients is to write as many equations as coefficients one desires to evaluate, each equation for a different value of θ, and solve the resulting system for the coefficient values. For example, the system

$$A_1\sin \theta_1(\mu_1 + \sin \theta_1) + A_3\sin 3\theta_1(3\mu_1 + \sin \theta_1) + A_5\sin 5\theta_1(5\mu_1 + \sin \theta_1)$$

$$+ A_7\sin 7\theta_1(7\mu_1 + \sin \theta_1) = \mu_1\alpha_1\sin \theta_1$$

$$A_1\sin \theta_2(\mu_2 + \sin \theta_2) + A_3\sin 3\theta_2 \, (3\mu_2 + \sin \theta_2) + A_5\sin 5\theta_2(5\mu_2 + \sin \theta_2)$$

$$+ A_7\sin 7\theta_2(7\mu_2 + \sin \theta_2) = \mu_2\alpha_2 \sin \theta_2$$

$$A_1\sin\theta_3(\mu_3 + \sin\theta_3) + A_3\sin 3\theta_3(3\mu_3 + \sin\theta_3) + A_5\sin 5\theta_3(5\mu_3 + \sin\theta_3)$$
$$+ A_7\sin 7\theta_3(7\mu_3 + \sin\theta_3) = \mu_3\alpha_3 \sin\theta_3$$

$$A_1\sin\theta_4(\mu_4 + \sin\theta_4) + A_3\sin 3\theta_4(3\mu_4 + \sin\theta_4) + A_5\sin 5\theta_4(5\mu_4 + \sin\theta_4)$$
$$+ A_7\sin 7\theta_4(7\mu_4 + \sin\theta_4) = \mu_4\alpha_4 \sin\theta_4$$

can easily be solved for A_1, A_3, A_5, and A_7 by algebraic techniques since the values of θ_1, θ_2, θ_3, θ_4, μ_1, μ_2, μ_3, μ_4, etc. are known from the wing geometry. The value of A_1 becomes independent of n only when n is large.

Only odd coefficients occur in the series because the wing is assumed to be symmetric about its mid-span point.

The induced drag is found easily once the A_n's are known. Since

$$D_i = \int_{-b/2}^{b/2} \frac{w}{U} L\, dy = \int_{-b/2}^{b/2} \rho w\Gamma\, dy = \int_{-b/2}^{b/2} \rho U^2 b^2 (\sum nA_n \sin n\theta)(\sum A_n \sin n\theta)d\theta,$$

$$D_i = \pi b^2 \frac{\rho}{2} U^2 \sum nA_n^2 .$$

Since A_1 is independent of the planform shape, it follows that the induced drag will be a minimum when the other coefficients in the series are zero. The circulation for such a condition is then represented by

$$\Gamma = 2bU \frac{C_L}{\pi AR} \sin\theta = 2bU \frac{C_L}{\pi AR} \sqrt{1 - \cos^2\theta} = 2bU \frac{C_L}{\pi AR} \sqrt{1 - 4y^2/b^2}$$

or the equation of an ellipse. An elliptical span-wise distribution of circulation (lift) can be obtained in practice by an elliptical variation of chord in the spanwise direction or by combinations of taper and twist.

During preliminary design one of the things one seeks to establish, at least approximately, is the relationship between aircraft attitude and lift developed. This entails finding the effect of the finite wing span on the slope of the lift curve. For infinite aspect ratio of course it is about 2π per radian for all airfoils. The lifting-line theory, however, indicates that for an elliptical lift distribution—the most efficient type—there is a reduction in the effective angle of attack of $C_L/\pi AR$. To develop the same lift, the geometric angle of attack must then be $\alpha_{2D} + C_L/\pi AR$. The geometric angle of attack for finite-span wings can also be written

$$\alpha_{2D}\left(1 + \frac{C_{L\alpha 2D}}{\pi AR}\right) \simeq \alpha_{2D}\left(1 + \frac{2}{AR}\right) = \alpha_{3D} .$$

28

Since $C_{L_{\alpha 2D}}\alpha_{2D} = C_{L_{\alpha 3D}}\alpha_{3D}$ when the finite span wing develops the same lift as the infinite span wing, the three-dimensional lift-curve slope is

$$C_{L_{\alpha 3D}} = \frac{2\pi}{1 + \frac{2}{AR}} \quad \text{per radian.}$$

The conclusion drawn from lifting line theory that an elliptical spanwise aerodynamic loading leads to minimum induced drag has been of particular interest to the designers of large aircraft. Since the performance gains resulting from minimum induced drag can be significant for such aircraft, designers have sought to devise methods capable of treating complex planforms more accurately and accounting for inviscid, non-planar effects (wing fences, end plates, engine pylons, etc.) in determining the lift distribution. The latter area has been of more than academic interest since the appearance of jet transports with pylon-mounted engines and boundary layer control fences. The computer program described by Lundry (Ref. 55) uses a transform technique to map the non-planar configuration into a type of lifting line and then computes the distribution of twist and camber necessary to minimize the induced drag.

Many other significant features of the aerodynamic characteristics of wings have been deduced using the lifting-line approach. This theory has its limits, however. Obviously it does not treat well the case where, because of sweep, there is a substantial spanwise flow component, nor is a single lifting line an adequate representation of a wing when the ratio of span to chord is not large. These deficiencies were recognized quite early, but because of the complexity of the generalization from lifting line to lifting surface and the use of high aspect ratio unswept wings until after World War II, solution techniques were long in developing. In 1950 Multhopp (Ref. 60) employed a generalization of the scheme above to make one of the first successful attacks on the problem.

The complexity one must contend with is easily seen in the expression for the local angle of attack (Ref. 43) at a point on the wing

$$\alpha(x_1,y_1) = -\frac{1}{8\pi} \fint_{-b/2}^{b/2} \frac{dy}{(y_1 - y)^2} \int_{x=x_{\ell.e.}}^{x=x_{t.e.}} \Delta C_p(x,y) \left[1 + \frac{x_1 - x}{\sqrt{(x_1-x)^2 + (y_1-y)^2}} \right] dx$$

where ΔC_p is the unknown load distribution and the bar through the integral sign denotes the principal value.

As in the lifting line theory, the unknown loading function is usually approximated by a series:

$$C_p(\xi,\eta) = \frac{2b}{c(\eta)} \sum_{r=0}^{N-1} a_r(\eta) h_r(X)$$

$$\text{with} \quad h_r(X) = \frac{2}{\pi} \frac{\cos[\frac{\psi}{2}(2r+1)]}{\sin(\psi/2)} \;; \quad \xi = \frac{2x}{b} \;; \quad \eta = \frac{2y}{b} \;; \quad X = \frac{x - x_{\ell.e.}}{c} = \tfrac{1}{2}(1 - \cos\psi);$$

$$\psi = \cos^{-1}(1 - 2X) \qquad\qquad \theta = \cos^{-1}(\eta)$$

$$a_r(\eta) = \frac{2}{m+1} \sum_{n=1}^{m} a_{rn} \sum_{\mu=1}^{m} \sin\mu\theta \sin\frac{\mu n\pi}{m+1}$$

This approach in effect replaces the unknown $\Delta C_p(x,y)$ by mN unknown coefficients A_{rn}. The problem is then to calculate A_{rn} by satisfying the boundary condition $\alpha(x_1,y_1)$ at suitable points distributed over the planform. The main numerical difficulty lies in determining the double integral due to each term in the respective loading.

Reference 43 discusses three methods of carrying out the integration which are of comparable accuracy and difficulty. The details of one of these, including the computer program (in Algol 60), is given in Reference 61. In the later work, the theory has been extended to treat slowly oscillating wings. Reference 41 makes some detailed appraisals of the accuracy of this and other methods developed in Europe. A similar approach for the non-oscillating case with the computer program given in FORTRAN is presented in Reference 39. Further details are discussed in Reference 44. A FORTRAN program of slightly different approach is given by Lamar in Reference 59. The effects on accuracy of certain assumptions for the form of the pressure distribution, the number of points at which the boundary conditions are satisfied, and the location of these points is discussed in Reference 38. Wagner, in Reference 47, gives a good summary of the present state of development of true lifting surface theory. He is particularly careful to distinguish this approach from the vortex lattice or other "finite element" approaches.

Because one seems compelled to employ a large system of simultaneous equations to approximate the lifting surface integral equation satisfactorily and because the choice of points at which the boundary condition is satisfied, the method of integration, and the complexity of the planform all effect to the accuracy of the results, investigators quickly began to search for alternate lifting surface methods. Although called by a variety of names, the most popular alternate is an extension of the idealized single horseshoe vortex representation of a wing given by Glauert (Ref. 16b). By dividing the wing surface into a finite number of flat rectangular panels, placing such a horseshoe vortex on each, and summing the contribution of all the vortices to the flow over a control point in each panel, one obtains a system of relatively simple equations which, when solved for the individual

vortex strengths, has been found to give remarkably good estimates of the pressure distribution over the wing. Reference 37 describes such an approach—called here a vortex lattice—and supplies a FORTRAN program for computing the lift and moment distribution and overall lift and moment characteristics of rather complex wings. This particular program can accept a maximum number of horseshoe vortices on the left side of the plane of symmetry of 120. Within this limit, the number of horseshoe vortices in any chordwise row may vary from 1 to 20 and the number of chordwise rows may vary from 1 to 50. It can treat wings with dihedral and/or sweep.

Reference 40 describes another perhaps more restricted computer-based approach while Reference 42 is a systematic mathematical study of the characteristics of the method and various solution techniques. Current work at the Boeing Company (Ref. 58) seems intended to reduce computation time and increase accuracy by using overlapping (both spanwise and chordwise) continuous distributions of vorticity over a set of panels on a paneled wing. The basic distributions are independent and each satisfies all the boundary conditions required of the final solution. Boundary conditions are satisfied in a least square error sense. Excellent results have been obtained thus far and consideration is now being given to including an automatic paneling routine in the program so that the user need only specify the wing geometry and the accuracy with which he wishes to calculate the downwash in order for the program to select, on an iterative basis, sufficient panels to satisfy this requirement.

All of these lifting surface and vortex-lattice theories suffer from twin faults: they are applicable only to planar wings, wings without thickness which lie entirely in the x-y plane, and they do not include the effects of viscosity. One interesting way of circumventing these problems for unswept, moderate-to-high aspect ratio wings is given in Reference 36. There, two dimensional data—obtained either from wind tunnel test or theoretical calculations which include the effects of thickness and viscosity—are extended to three-dimensions by using lifting-line theory to determine the effective local angle of attack at each point along the span, looking up the two-dimensional characteristics corresponding to that local angle of attack, and integrating the results in the spanwise direction. This method forms the basis of the discussion in the next chapter on extending the theory for predicting two-dimensional aerodynamic characteristics to treat complete wings.

TREATMENT OF VISCOUS EFFECTS: DRAG

Despite the fact that much of the aerodynamic behavior of an airplane can be deduced by considering air to be an inviscid fluid, one very important characteristic, its resistance to continued motion, arises directly from the viscosity of the air and necessitates the installation of a power plant and a store of fuel to operate that power plant. Unfortunately, adequate theoretical descriptions of this characteristic are very much more difficult to provide than are descriptions of the aircraft's lifting behavior. For this reason early designers relied almost exclusively on correlations of experimentally-determined drag with body shape and surface condition during the

preliminary design phase and on wind tunnel and flight tests of the actual
configuration during the final stages of development. This procedure is still
widely used. Reference 53 is an up-to-date compilation of the most widely
accepted correlations along with procedures for using them to estimate th
drag of complete subsonic aircraft. A similar approach is employed in
Reference 62.

Analytical determination of the drag of bodies evolved from the work of
Prandtl, who in 1904 proposed that the effects of viscosity could be considered
to be confined to a thin layer of fluid immediately adjacent to the body sur-
face (*i.e.*, a boundary layer). Such an assumption permits a considerable
simplification to be made in the equations describing fluid motion in this
region. Outside this region one can use the classical inviscid analysis.
Other investigators then began to develop methods for solving the boundary
layer equations, first for simple configurations such as flat plates and
later for curved two-dimensional bodies. One of the more versatile techniques
has been programmed for computer solution (Ref. 63). Although the technique
treats compressible flows with heat transfer, the flow will be taken here to
be incompressible and non-heat-conducting in order to describe the approach
as simply as possible.

If one begins with the conventional momentum integral equation (equation
44 in the next chapter),

$$\frac{d\theta}{dx} + \frac{du_e}{dx}\left(\frac{2\theta + \delta^*}{u_e}\right) = \frac{\nu}{u_e^2}\left(\frac{\partial u}{\partial y}\right)_{wall} \quad ,$$

and makes the following definitions

$$\ell \equiv \frac{\theta}{u_e}\left(\frac{\partial u}{\partial y}\right)_w \quad ,$$

$$-n \equiv \frac{\theta^2}{\nu}\frac{du_e}{dx} \quad ,$$

$$H \equiv \frac{\delta^*}{\theta} \quad ,$$

then this equation can be written

$$-u_e\frac{d}{dx}\left(\frac{n}{\frac{du_e}{dx}}\right) = 2[n(H + 2) + \ell] = N$$

Correlation of N against n for a number of exact theoretical solutions
of the boundary layer equations indicated to Cohen and Reshotko (Ref. 64)
that one could take

32

$$N = A + Bn$$

where A and B are constants for flows with zero or favorable pressure gradients. Under these circumstances the equation can be integrated to yield

$$n = -Au_e^{-B} \frac{du_e}{dx} \int_0^X u_e^{B-1} dx$$

A = 0.44 and B = 5.5. Then,

$$\theta = \left(\frac{-n\nu}{\frac{du_e}{dx}} \right)^{1/2} .$$

Since exact theoretical solutions of the boundary layer equations give a unique correlation between n and ℓ, this can be used to find $(\partial u/\partial y)_w$. Then one may use

$$A + Bn = 2 \left[n \left(\frac{\delta^*}{\theta} + 2 \right) + \ell \right]$$

to find δ^*.

The solution for the turbulent boundary layer case is obtained from a variant of the momentum integral analysis with experimental skin friction correlations. Transition is determined from a variant of the Schlichting Ulrich (sixth order polynominal representation of the velocity distribution) laminar boundary layer stability analysis.

Comparisons between predicted and measured values of δ^* and θ on an NACA 0012 airfoil were quite good, except in the immediate neighborhood of the transition point. It is to be expected, therefore, that predicted values of skin friction drag would also be quite good. To find the total drag on the airfoil, however, it would be necessary to find the change in the pressure distribution over the airfoil resulting from the presence of the boundary layer displacement thickness and add this to the skin friction drag or integrate completely across the wake to find the overall change in the momentum of the flow caused by the passage of the airfoil. Schlichting (Ref. 65) describes a method, based on the latter idea, which was developed by Squire and Young in 1938. The drag force per unit length of span represented by the momentum defect in the wake far downstream of the airfoil is

$$\frac{D}{b} = \int_{y=-\infty}^{y=+\infty} \rho u \, (u_\infty - u) \, dy$$

from which

$$C_D = \frac{D}{b \, \frac{\rho}{2} \, cu_\infty^2} = \frac{2}{c} \int_{y=-\infty}^{y=+\infty} \frac{u}{u_\infty} \left(1 - \frac{u}{u_\infty} \right) dy = \frac{2\theta_\infty}{c} .$$

The problem, then, is to evaluate θ_∞ in terms of the boundary layer characteristics over the airfoil.

The momentum integral equation of boundary layer theory is of course also valid in the wake behind a body. In the wake, however, the shearing stress at the wall is zero so that the equation for this circumstance becomes

$$\frac{d\theta}{dx} + \frac{du_e}{dx}\left(\frac{2\theta + \delta^*}{u_e}\right) = 0 \ .$$

x now denotes the distance from the trailing edge of the body measured along the wake centerline. The foregoing equation can also be written as

$$\frac{1}{\theta}\frac{d\theta}{dx} = -\left(\frac{2 + H}{u_e}\right)\frac{du_e}{dx} = -\left(2 + H\right)\frac{u_\infty}{u_e}\frac{d(u_e/u_\infty)}{dx}$$

$$= -\left(2 + H\right)\frac{d}{dx}\left(\ln \frac{u_e}{u_\infty}\right) \ .$$

Integration by parts of this equation along x from the trailing edge of the body (station 1) to a station very far downstream in the wake results in

$$\ln \theta \Big|_\infty^1 = -(H + 2)\ln \frac{u_e}{u_\infty}\Big|_\infty^1 + \int_\infty^1 \ln \frac{u_e}{u_\infty}\frac{dH}{dx}\ dx \ .$$

At the downstream station $u_e = u_\infty$ and

$$\frac{\delta^*}{\theta} = \frac{\displaystyle\int\left(1 - \frac{u_e}{u_\infty}\right)dy}{\displaystyle\int\frac{u_e}{u_\infty}\left(1 - \frac{u_e}{u_\infty}\right)dy} = 1$$

thus,

$$\ln (\theta_1/\theta_\infty) + (H_1 + 2)\ln (u_{e_1}/u_\infty) = \int_{H=1}^{H=H_1} \ln \frac{u_e}{u_\infty}\ dH$$

or

$$\theta_\infty = \theta_1 \ln\left(\frac{u_{e_1}}{u_\infty}\right)^{H_1 + 2} \exp\left(\int_1^{H_1} \ln \frac{u_\infty}{u_e}\ dH\right) \ .$$

Now, if the integral on the right hand side and u_{e_1}/u_∞ can be evaluated, one has the required explicit relationship between θ_∞ and θ_1. From an analysis of experimental data H. B. Squire proposed that one could assume

$$\frac{\ln (u_\infty/u_e)}{H - 1} = \frac{\ln (u_\infty/u_{e_1})}{H_1 - 1} = \text{constant} \ .$$

34

Hence,

$$\ln (u_\infty/u_e) = \text{constant } (H - 1)$$

$$\int_1^{H_1} \ln \frac{u_\infty}{u_e} \, dH = \int_1^{H_1} (H - 1) \left[\frac{\ln (u_\infty/u_e)}{H_1 - 1} \right] dH = \frac{\ln (u_\infty/u_{e_1})}{H_1 - 1} \left(\frac{H^2}{2} - H \right)_1^{H_1}$$

$$= \left(\ln \frac{u_\infty}{u_{e_1}} \right) \left(\frac{H_1 - 1}{2} \right) \quad ;$$

with this result

$$\theta_\infty = \theta_1 \left(\frac{u_{e_1}}{u_\infty} \right)^{H_1 + 2} \left(\frac{u_\infty}{u_{e_1}} \right)^{\frac{H_1 - 1}{2}} = \theta_1 \left(\frac{u_{e_1}}{u_\infty} \right)^{\frac{H_1 + 5}{2}} .$$

A typical value of H_1 is 1.4. For this value

$$\theta_\infty = \theta_1 \left(\frac{u_{e_1}}{u_\infty} \right)^{3.2}$$

and thus

$$C_D = \frac{2\theta_1}{c} \left(\frac{u_{e_1}}{u_\infty} \right)^{3.2} .$$

To find C_D, then, one must know the value of the potential velocity (velocity outside the boundary layer) at the trailing edge and the value of the momentum thickness at the same place. One attempt to be more explicit is reported by Schlichting. Using relations for a flat plate H. B. Helmbold obtained

$$C_D = \frac{0.074}{R_e^{\frac{1}{2}}} \left\{ \int_{x_u/c}^1 \left(\frac{u_e}{u_\infty} \right)^{3.5} d\left(\frac{x}{c} \right) + 62.5 \, R_e^{\frac{1}{4}} \left(\frac{\theta_t}{c} \right)^{5/4} \left(\frac{u_{e_t}}{u_\infty} \right)^{3.75} \right\}^{0.8}$$

for the drag due to the one surface of a wing. The subscript "t" refers to the point of transition from laminar to turbulent flow.

The method of Squire and Young can be extended fairly simply to axisymmetric bodies and was so done by Young in 1939. (ARC R&M 1947)

Cebeci, Mosinskis, and Smith (Ref. 54) studied the possibility of improving the estimation of the drag of two-dimensional and axisymmetric bodies by improving the laminar and turbulent boundary layer methods used as inputs to the Squire and Young method. They also sought the effect of better identification of the location of the transition region. They concluded that the total drag coefficients of two-dimensional bodies such as airfoils can with such improved techniques be calculated very accurately for $\alpha \leq 6°$. For higher angles of attack "use of the Squire-Young formula introduces an error into the drag calculations. . .since the Squire-Young formula is applicable only to a symmetrical wake." It would seem, however, that this

restriction could be removed without excessive difficulty. They also found that by improving the theoretical turbulent boundary layer methods they could match 57 experimental values with an rms error of 2.9%

The total-drag coefficient of axisymmetric bodies, they found, can be calculated less accurately than the total drag coefficient of two-dimensional bodies. "The calculations show a great sensitivity to the choice of tail end location on the body and to the use of inviscid pressure distributions in the drag calculations." For more general three-dimensional bodies such as aircraft fuselages there are unfortunately no quasi-rigorous analytical methods now available and one must resort to techniques based on rather gross approximations or to correlations of experimental results.

The reader has no doubt observed by this time that a detailed discussion of ways to calculate the drag of bodies ultimately comes to a consideration of methods for solving the boundary layer equations. Even the simplest case of steady, two-dimensional, incompressible, laminar flow involves a non-linear partial differential equation for which a general closed-form solution is impossible. This is the reason for the proliferation of solution techniques one sees in the literature. Some of these involve a great deal of insight into the problem and others employ rather sophisticated mathematical techniques. For these reasons it seems appropriate not to discuss the various methods in detail here but rather to direct the reader to Reference 65 which is probably the best single source of information on the rationale behind the various solution techniques.

FUSELAGE CONTRIBUTIONS TO LIFT, DRAG, AND MOMENT

The isolated fuselage is generally a body with a plane of symmetry rather than an axis of symmetry. This situation effectively precludes accurate calculations of its lift and drag by relatively simple, closed-form methods. Thus, until recently, it was the practice to rely on the guidance provided by a few classical approximate theoretical treatments and determine the detailed lift and drag characteristics experimentally.

Sir Horace Lamb (Ref. 6) for example was able to find an exact expression for the potential about an ellipsoid with three unequal axes. The problem was treated somewhat more completely by Munk (Ref. 66) who was interested in its application to determining the aerodynamic characteristics of airship hulls. Timman (Ref. 49) extended the analysis to include flows with velocity components along two axes simultaneously. He then calculated the streamline patterns for such a case. From these one can get the inviscid pressure distribution over the surface. This could then serve as the basis of a boundary layer calculation. Timman in fact had previously developed a boundary layer computation method for such a body and Reference 49 was intended to supply the potential field needed to begin the calculation.

A 1941 paper by Hans Multhopp (Ref. 51) provided a quantum jump in theoretical understanding of the fuselage contribution to airframe lift and moment. The essence of his arguments are contained in the following exerpts taken from a translation of that paper.

36

One notoriously neglected phase in the aerodynamics of aircraft is that of the fuselage. This is due, in the first instance, to the fact that the fuselage considered by itself is a comparatively simple structure the effects of which are apparently readily perceived. But its real effects come into evidence only in combination with other parts of the aircraft, especially with the wing; hence it becomes necessary to evolve a fuselage theory which includes this mutual interference.

The search for mathematically exact solutions for such interference problems is exceedingly bothersome throughout, as it would entail the development of a three-dimensional potential theory with very arbitrary boundary coditions; a problem to which hardly more than a few proofs of existance could be adduced.

****

For the present task the performance mechanics are, in general, excluded, since drag problems usually must be left to experimental research.

****

Before proceeding to the analysis of the interference of the fuselage with the other parts of the airplane, a brief discussion of the phenomena observed on the fuselage, in the absence of all other airplane parts, is necessary.

On analyzing the conditions in frictionless parallel flow the first result is the total absence of resultant forces on the fuselage; the pressure distribution over the body merely affords free moments. These free moments are of some significance since they are proportional to the angle of attack of the fuselage and hence enter the stability quantities. The sign of these moments is such that the stability about the normal axis is lowered by the action of these free moments. On an axially symmetrical fuselage the free moment in flow along the fuselage axis is, of course, zero; on unsymmetrical fuselage forms or by appendages the axis for zero moment can be located at any other place. The free moment is produced by negative pressure on the upper side of the bow and on the lower side of the stern and positive pressure at the lower side of the bow and on the upper side of the stern. (See the figure at the top of the next page.)

The free moments can be computed in various ways. If time and patience are no object, a field of singularities substituting for the fuselage may be built up by means of potential theory methods.* But for the task in hand Munk's method is much more suitable. He simply determined the asympototic value for very slender fuselage forms and then added a correction factor dependent on the slenderness ratio, which he obtained by a comparison with the values of easily and accurately computable forms.

---

*   This is, in fact, just what is done in Reference 23; the computer makes it possible to be impatient and still accomplish the task quickly and accurately.
According to Munk, the unstable moment of a very slender body of revolution is

$$\frac{1}{q} \frac{dM}{d\alpha} = -2 \text{ vol.} \text{ ,}$$

the effect of finite fuselage length being accounted for by the correction factor $(K_2 - K_1)$ which depends on the slenderness ratio ℓ/D. (See the accompanying sketch.) In this representation K_2 is the air volume in ratio
to the fuselage volume by transverse motion of the fuselage and K_1 *that by longitudinal fuselage motion. For other than axially symmetrical surfaces it is*

$$\frac{1}{q}\frac{dM_R}{d\alpha} = -\frac{\pi}{2}(K_2 - K_1)\int_0^{\ell} b_R^2\, dx.\ {}^{**}$$

This is all that the consideration of the potential theory supplies concerning a single fuselage. But the actual behavior of the fuselage is not described by the potential flow alone. As soon as the flow past the fuselage ceases to be perfectly symmetrical, boundary-layer material accumulates more on one side than on the other and the flow conditions are altered. This results in additional forces at the fuselage and so becomes an appreciable factor in the moment balance of the fuselage. The point of application of the induced frictional lift or cross force is of course proportionally far aft at the fuselage.

As the dependence of frictional lift on angle of attack is strongly suggestive of a very similar course on wings of very small aspect ratio, its correlation suggests itself. For a wing of very small aspect ratio we get approximately for $\alpha = 0$:

$$\frac{1}{q}\frac{dA}{d\alpha} = \frac{\pi b^2}{2}\ {}^{***},$$

---

*   The air volume depends upon the local air velocity which is found from an exact solution to the flow over an ellipsoid. (See Reference 66, Division C.) The formula for computing K_1 is given (Ref. 66) as

$$K_1 = \frac{2\left(\dfrac{1-e^2}{e^3}\right)\left[\frac{1}{2}\log\dfrac{1+e}{1-e} - e\right]}{2 - 2\left(\dfrac{1-e^2}{e^3}\right)\left[\frac{1}{2}\log\dfrac{1+e}{1-e} - e\right]}$$

where $e = \sqrt{1 - (a^2/b^2)}$ and a = the half axis and b = the largest radius of the ellipsoid.

**   The notation is that of the original paper. While somewhat different from present usage in the United States, its meaning, when taken in context, should be reasonably clear.

***   Assume a circular streamtube with diameter b equal to the wing span. The lifting force which the fluid applies to the wing results in a deflection of the streamtube according to Newton's Second Law of Motion:

$$L = \left[\rho V\left(\frac{\pi b^2}{4}\right)\right] V \sin \varepsilon$$

where ε is the deflection angle of the streamtube. For small aspect ratios the wing chord is comparatively long. Thus the flow inclination seen by most of the wing is ε. Hence for such situations one can take

a result readily derivable by means of certain momentum considerations which is in good agreement with the available test data for such wings. However, the conventional fuselage has no sharp sides; hence a temporarily unknown measure that denotes the width of the separating boundary layer substitutes for the width b. In place of it we correlate the lift to the maximum fuselage width b_R and introduce a form factor f, the exact determination of which might be a profitable field of experimental research; presumably it depends, above everything else, on the cross-sectional form of the fuselage, on its solidity, and on the location of appendages. Hence we put

$$\frac{1}{q} \frac{dA_R}{d\alpha} = \frac{\pi}{2} f b_R^2 .$$

The foregoing appraisal of the moments of the fuselage in free stream fails, because the flow pattern of the wings causes a very substantial variation of the flow at the fuselage. To begin with, the previously described frictional lift of the fuselage is not likely to exist, since the wing orientates the flow along the wing chord and even far aft of it with the result that no appreciable flow component transverse to the fuselage exists in the real zone of formation of the frictional lift. Hence there is some justification in assuming that the theoretically anticipated moments will afterward actually occur.

First of all the fuselage with wing differs from the fuselage alone in that the fuselage takes up a very substantial proportion of the lifting

---

***continued $\qquad\qquad\qquad$ $\alpha \approx \epsilon$.

For small angles of attack the lift may then be written

$$L = \frac{\pi}{2} b^2 \frac{\rho V^2}{2} \alpha$$

from which

$$\frac{1}{q} \frac{dL}{d\alpha} = \frac{\pi}{2} b^2 .$$

Note that Multhopp uses the symbol A to designate lift. This result can also be obtained from the general expression for the dependence of lift-curve slope on aspect ratio (sweep angle and Mach number = zero):

$$C_{L_\alpha} = \frac{2\pi AR}{2 + \sqrt{4 + AR^2}}$$

when AR→0 this expression becomes

$$C_{L_\alpha} = \frac{2\pi AR}{4} = \frac{2\pi b^2}{4S} = \frac{\pi}{2} \frac{b^2}{S} .$$

Then $\qquad\qquad\qquad$ $L = C_{L_\alpha} \alpha q S$

and $\qquad\qquad\qquad$ $\frac{1}{q} \frac{dL}{d\alpha} = \frac{\pi}{2} b^2 .$

40

forces ordinarily carried by the wing section in its place. The point of application of the aerodynamic forces at the fuselage directly due to the circulation of the wing, is located at the same place as on the substitute wing section; separating this air force distribution for the moment leaves only a free moment which is solved from a simple momentum consideration.

Next, the fuselage is assumed to be sufficiently long, so that, after fixing a reference plane at right angles to the flow direction that meets the fuselage at distance x from the nose, the integral over the pressure distribution of the fuselage portion ahead of the reference plane equals the vertical momentum passing through this area in unit time. Then, with β^* as the angle in yaw in the reference plane, that is, the angle which the flow would form with the fuselage axis if the fuselage were non-existent, and b_R as the fuselage width at this point, the lift of the thus segregated fuselage portion is:

$$\int_0^x \frac{dA_R}{dx}\, dx = \rho V^2 \beta\, \frac{\pi}{4}\, b_R^2 \ .$$

For, if the fuselage is long enough, the flow at right angles to the fuselage axis may be approximated to two-dimensional, and for the flow at right angles to an elliptic cylinder the comprised air volume, that is, the integral

$$\int \rho (v_n - v_{n_\infty})\, df = \rho v_{n_\infty}\, \frac{\pi}{4}\, b_R^2 = \rho v \beta\, \frac{\pi}{4}\, b_R^2$$

is (v_n and v_{n_∞} being the components at right angles to the cylinder axis) independent of the axes ratio of the ellipse. (Note the sketch below.)
Since this formula holds true even for a cylinder degenerated to a flat plate, its approximate use for all cross-section forms appears justified.

---

* β is the angle the flow direction makes with the fuselage axis. If these vectors lie in the x-z plane then β is the angle of attack.

Differentiation with respect to x then affords:

$$\frac{1}{q}\frac{dA}{dx} = \frac{\pi}{2}\frac{d}{dx}\left(\beta\, b_R^2\right)$$

(The air load distribution along the typical fuselage is shown in the figure below)

■ **FROM FUSELAGE MOMENTS**

□ **FROM FUSELAGE LIFT**

-- **TOTAL VARIATION**
By reason of the disappearance of b_R *the so computed total fuselage lift is zero at both its ends, hence gives the desired free moments additionally supplied by the fuselage. This free moment is for any reference point*

$$\frac{M_R}{q} = \frac{\pi}{2}\int_0^\ell \frac{d}{dx}\left(\beta\, b_R^2\right)x\,dx$$

and, after partial integration:

$$\frac{M_R}{q} = -\frac{\pi}{2}\int_0^\ell \beta\, b_R^2\,dx$$

For surfaces of revolution on which the flow is not disturbed by the presence of the wing, we get, because β = *constant*

$$\frac{M_R}{q\beta} = -\frac{\pi}{2}\int_0^\ell D^2\,dx = -2\,vol.$$

42

or the same result as Munk's for the free moments of airship hulls. It then might be advisable to apply a correction factor to these free fuselage moments on Munk's pattern, containing the effect of the finite fuselage length, except for the difficulty of not quite knowing what slenderness ratio to apply. The reduction relative to the theoretical value is primarily due to the fact that the flow at the fuselage ends still varies somewhat from the assumed two-dimensional pattern; and while the rear end contributes almost nothing to the free fuselage moment, the portions of the fuselage directly before the wing, which certainly are not encompassed by this reduction through the effect of the finite length, contribute very large amounts. Hence the actual value for the correction factor is likely to be far closer to 1 than Munk's quantity $(K_2 - K_1)$.

The presence of the wing is allowed for by relating β *to the wing circulation. The change of the moment with the angle of attack is:*

$$\frac{1}{q}\frac{dM_R}{d\alpha} = -\frac{\pi}{2}\int_0^{\ell} b_R^2 \frac{d\beta}{d\alpha}\, dx \ .$$

The change of the yawed flow with the angle of attack $d\beta/d\alpha$ *is expressed as follows: The flow in the region of the wing is practically parallel to the wing chord; hence* $d\beta/d\alpha = 0$. *Behind the wing the downwash reduces the yawed flow; at the fuselage stern in the vicinity of stabilizer and elevator there is obtained:*

$$\frac{d\beta}{d\alpha} = 1 - \frac{d\alpha_W}{d\alpha}\ .$$

(This is depicted graphically in the accompanying sketch.)
It is sufficiently exact, when assuming that $d\beta/d\alpha$ *rises linearly from the wing trailing edge to this value. Before the wing* $d\beta/d\alpha$ *is always greater than 1 because of the prevalent upwash.* (This variation is shown in the graph below.)

$$\frac{\overline{d\beta}}{d\alpha} = \frac{1}{x} \int_0^x \frac{d\beta}{d\alpha} dx$$

$$\frac{d\beta}{d\alpha}$$

$$\frac{x}{t}$$
For the determination of the fuselage effect on the lift distribution of the wing the flow transverse to the fuselage was assumed to be two-dimensional; then all the mathematical difficulties which the fuselage of itself would entail, can be removed by a conformal transformation of the fuselage cross section to a vertical slit. Then the calculation of the lift distribution for a wing-fuselage combination reduces to that of an equivalent wing, wherein the fuselage effect is represented by a change in chord distribution and also, to some extent, in the angle-of-attack distribution. Then the conventional methods of computing the lift distribution of a wing are fully applicable. Multhopp's transform forms the basis of the method discussed in detail in the next chapter for extending two-dimensional airfoil characteristics to three-dimensional wings. For that reason it will not be discussed further here.

As mentioned earlier, modern treatments of the fuselage contribution to airplane lift, drag, and moments usually represent the flow displacement caused by the presence of the fuselage through source distributions either on the fuselage surface (Ref. 23) or along the fuselage axis (Ref. 48). The three-dimensional source distribution (Ref. 23) can of course be extended to include the wing, etc. A means to account for lift, such as

44

a distribution of horseshoe vortices, must then be added and, finally, a consistent boundary layer computation must be included in order to complete the calculation. This is, all told, a very complex procedure. Some details of these treatments are given in the next chapter.

It should be noted that the treatment of the fuselage as a body surrounded by a boundary layer is tenable only so long as the angle of attack does not get very large. Reference 68 points out that when a thin cone exceeds an angle of attack of 8° or so vortices begin to be shed from the edges in the streamwise direction resulting in a larger-than-expected normal force coefficient.

Cebeci, Mosinskis, and Smith (Ref. 109) obtained some interesting results from their efforts to predict the drag coefficients of axisymmetric bodies. Their procedure took the following course:

1. Calculate the inviscid pressure distribution on the body using a distribution of sources technique (Ref. 23).

2. Consider the aft end of the body to occur at that longitudinal station where the pressure coefficient first returns to zero. Note that the inviscid source distribution method will always yield a stagnation point at the aft end. The point at which $C_p = 0$ is therefore located somewhat upstream. For the fineness ratio 4-10 bodies which they studied, this point occurs at roughly 90% of the length. Bodies with blunt trailing edges such as ellipsoids and airship hulls were found experimentally to have separated boundary layers aft of the 85%-90% point so that the assumption of $C_p = 0$ in this region is fairly reasonable. Some boundary layer separation also occurs on bodies which taper slowly to a point because the boundary layer cannot withstand a pressure rise to a stagnation value. Again, the assumption of separation at about the 90% or 95% point is probably reasonable although the ratio of boundary layer thickness to body radius at separation (used as indicated below) is different than for bodies with blunter trailing edges. Data presented in the paper indicates a pressure coefficient of about +0.1 in the separated flow region.

3. Calculate the boundary layer displacement thickness and momentum thickness at the point taken to be the trailing edge. When the body radius is expected to be large compared with the displacement thickness, a two-dimensional value for the momentum thickness is found to give better results.

4. Then use Granville's formula (Ref. 111)

$$C_D = \frac{4 r_o \theta_{2-D}}{R_o^2} \left(\frac{u_e}{u_\infty} \right)^{[7(\frac{\delta^*}{\theta} + 2) + 3]/8}$$

45

to determine the total drag of the body. In this formula r_o is the radius of the body at the tail "end", R_o is the maximum radius, u_e is the flow velocity outside the boundary layer at the tail end of the body, and u_∞ is the free stream velocity. If the "end" is chosen to be that point at which $C_p = 0$, then $u_e/u_\infty = 1.0$.

For a fineness ratio 4.0 body (similar to an ellipsoid but having the tail end modified to come to a point) the method gave excellent agreement with experimental results up to a Reynolds Number of about 6 million. Above this value, the prediction was about 20% low. The skin friction drag constituted about 90% of the total drag in this case. For the fineness ratio 7.0 body (same contour) the agreement with experiment was excellent for all Reynolds Numbers and the skin friction consititutes virtually all the drag.

The airship hull (fineness ratio = 4.2) predictions agreed very well with experimental results for all Reynolds numbers. Skin friction was again about 90% of the total drag and flow separation occurred at about 90% of the length.

Cebeci, Mosinskis, and Smith comment that their studies showed a great sensitivity to the effective end location on the body to be used in the drag formulas and to the inviscid pressure distribution used in the drag calculations. They note also that the two-dimensional analog of Granville's formula really applies only to the case where the wake is symmetrical with respect to the body chord. This condition is not satisfied for $\alpha > 6°$. Thus, a similar situation can be expected to prevail for axisymmetric bodies.

It would seem reasonable to expect that one might someday develop a version of Granville's formula for asymmetric bodies more representative of aircraft fuselages. To do this, however, it will be necessary to solve the three-dimensional boundary layer equations for the body in question and to develop a proper averaging method for final average values of θ_{2-D}, r_o, R_o, u_e/u_∞, and δ^*/θ. Such bodies also require more careful scrutiny for the presence of and locations of flow separations. In a recent paper Cebeci, Mosinskis, and Smith (Ref. 109) address this problem for <u>axisymmetric</u> bodies. Using a finite difference method of numerically solving the axisymmetric boundary layer equations which included tranverse curvature effects, they were able to predict the location of separation with less than 1% error. Their two-dimensional calculations also gave excellent results for separation on airfoils at high angles of attack. It should, perhaps, be pointed out at this point that finite difference techniques for solving the boundary layer equations take on the order of twenty times the computer time that are required for the less accurate momentum integral technique described in some detail in the next chapter.

A very recent analytical effort to describe the drag-producing separated flow behind bodies of revolution is described by Marshall and Deffenbaugh (Ref. 117). They first treat three-dimensional steady separation as equivalent to two-dimensional unsteady flow. This assumption, a heuristic one, is suggested primarily by experimental data. They then describe the two-dimensional unsteady wake by a distribution of inviscid point vortices superimposed on the un-

46

separated potential flow solution, suitably modified by diffusive effects. Their
argument for following this tack is the way the wake is observed to develop with
time. The object of this approach is to avoid solving the complete Navier-Stokes
equations for the separated flow field by a laborious and lengthy finite-dif-
ference technique. Instead, one pieces together by computer an ensemble of
relatively well-known solutions for sub-flow fields which together form the whole.
This is essentially the approach followed by the present work although it dif-
fers in details. Marshall and Deffenbaugh include a computer program listing
and user instructions in their report. They also compared results obtained by
their method with experimental data. For a prolate spheroid C_n agreed with
experiment for $\alpha \le 10°$. C_m agreed well for $\alpha \le 20°$. No drag computations were
presented, however.

INTERFERENCE EFFECTS

The flow at the junction of a wing and a fuselage is not that which
one would obtain by combining the flows about isolated wings and fuselages.
The flow about the wing modifies or influences the fuselage flow and vice
versa. Hence the name interference effects. Küchemann and Weber (Ref. 64)
provide two relatively simple means of determining the effect of the junction
on the inviscid pressure distribution: (a) Ring vortices are placed on the
surface of the body and their strengths are determined from the condition
that their induced radial velocities are proportional to the slope of the
wing-body junction in the streamwise direction; (b) A fictitious body,
obtained by subtracting the wing thickness inside the body from the given
body thickness, is considered and is replaced by a source distribution
along the body centerline. Applied with care to situations which the models
represent reasonably well, the methods give results for the interference
velocities which agree well with experiment.

With the advent of the computer, computation of the three-dimensional
potential field can be carried out on a fairly routine basis. Loeve
(Ref. 50) describes a computer program for the calculation of subsonic flow
about wing-body combinations. A three-dimensional distribution of sources
on the surface of the wing and the body is used to represent the disturbance
to the free stream caused by the presence of the non-lifting wing-body
combination. The source strengths are so adjusted that the flow is always
everywhere parallel to the surface of the wing-body. To treat the effects
of lift, a system of horseshoe vortices is placed on the camber line of
the wing.

The superposition of the flow due to sources located on the surface
of a wing-body combination is also discussed by Hess and Faulkner (Ref. 46)
who give some examples obtained through the aid of a computer program.

Success at treating the wing-body combination would naturally lead one
to attempt a method for the determination of the inviscid pressure distribution
on complete aircraft. The problem becomes tractable by considering the
aircraft surface to consist of a finite number of panels (hence the name
sometimes applied: finite element technique). As reported by Carmichel
(Ref. 48), the computer program being used at the NASA/AMES Center represents

(a) body thickness by line sources,

(b) body lift by line doublets,

(c) wing thickness by constant source panels,

(d) wing lift by constant pressure panels, and

(e) wing-body inteference by constant pressure panels.

These finite element methods can be considered a "brute force" approach, in that if one is willing to expend the computer time, the accuracy of the computation can generally be improved by using more and smaller elements. Ultimately, limitations in machine accuracy and in the numerical methods used provide a bound for the accuracy which can be obtained.

A recent correlation of wing-body lift interference effects in provided by Reference 67. Five effects are noted: (1) body upwash on the local angle of the wing; (2) local body flow parameters such as dynamic pressure on the wing characteristics; (3) lift carry-over from the wing to the body; (4) wing upwash on the body ahead of the wing; (5) wing lifting vortices on the body behind the wing. The correlation provided in the paper suggests that one may find the lift on a wing-body combination as follows: (1) Find the lift-curve slope of the wing from

$$C_{L_\alpha} = \frac{2\pi AR}{2 + \sqrt{4 + AR^2\beta^2(1 + \tan^2 \Delta/\beta^2)}}$$

where $\beta^2 = 1 - M^2$ and Δ is the sweep angle of the maximum thickness point on the wing. Aspect ratio here is based on exposed wing area, *i.e.* that part away from the fuselage. C_L is then based on the same area. (2) Multiply C_{L_α} thus found by an interference factor, F, given graphically in the paper. The present authors have determined that for M < 0.8 this curve can be fit by the equation

$$F = 1 + 2\left(\frac{d}{b}\right) + 24\left(\frac{d}{b}\right)^4$$

where d = body diameter and b = wing span. Working through the numbers shows that most of the effect is lift carry over from the wing. Most of the remainder can be accounted for with Multhopp's transform. (See next section.)

The fact that viscous effects have been excluded from all of these computations tends to compromise their accuracy or applicability somewhat. To use them successfully, one must first be sure that no flow separations are present such as at wing-body junctions.

In addition to the effect on lift, wing-body interference also complicate the estimation of drag since the boundary layer flow around wing-body junctions, for example, is subject to an external pressure distribution which is the resultant of all the effects listed above. It is not surprising then

48

that interference drag at subsonic speeds is usually evaluated experimentally or from correlations of data on similar configurations. A "brute force" means of accounting for viscosity in evaluating interference effects, however, would seem to follow from the methods used to calculate the viscous pressure distributions on airfoils (Ref. 31).

UNIFIED ANALYTICAL TREATMENTS OF WING-BODY CHARACTERISTICS

By 1962 (Ref. 83) the potential flow about a three-dimensional, non-lifting body had been determined quite successfully through the expedient of representing the surface by an ensemble of connecting plane quadrilaterals, placing on each a source of undetermined strength, and then finding the source strengths by requiring that the total flow produced by the interaction of all the sources and the free stream be parallel to a point on each of the quadrilaterals. A rather large number of "panels" was found to be necessary to obtain results which agreed well with closed form analytical solutions for simple bodies. In addition one had to keep the areas of all panels nearly the same. Despite the very significant amount of computer time required for even the simplest of such computations, the prospect of being able to extend the scheme to include wings, other protuberances and/or lift and thereby treat entire practical configurations at one time was unusually attractive to industry researchers. As a result there are now a number of numerical methods and associated computer programs for treating all or part of the wing-body problem. Among these one may cite References 84, 85, 86, 87, 88, and 89. The differences among the various methods cited lie principally in the numerical procedures employed. Indeed, since these bear so heavily on the economic practicality of the methods, it is not surprising to find a paper (Ref. 93) dealing entirely with this facet of the prediction procedure. Finally, the review article by Widnall (Ref. 90) is quite helpful in distinguishing among the approaches to these and other aspects of the problem used by 19 other authors.

The use of such calculation procedures to examine other aerodynamic characteristics (stability derivatives for example) of complete configurations is discussed in References 91 and 92. Here also the procedures are useful for determining only those contributions to the parameter values which do not depend significantly upon viscous effects. The ability to integrate the determination of these effects into the procedures in a rational yet computationally-manageable way seems to be a skill yet to be learned.

A THEORY FOR THE PREDICTION OF LIFT, DRAG, AND PITCHING

MOMENT OF LIGHT AIRCRAFT WINGS

INTRODUCTION

One of the fundamental tasks in aircraft design is the estimation of the forces which the air will exert on the vehicle during flight so that the structure may be made appropriately strong, the wings may be made sufficiently large to carry the desired load, and the engine may have sufficient power to propel the vehicle at the desired speed. Because no two masses may occupy the same space at the same time, the airplane must move air out of its way temporarily as it flies. To move air one must exert a force on it. Even the mere "sliding" of the air over the skin of the aircraft requires that one exert a force to overcome the friction.

To represent these phenomena quantitatively we consider a fictitious cube through which the air is moving. The cube is fixed to the airplane. Now in general, the velocity of the air moving across one face of the cube does not have to be the same as that moving across the opposite face. Thus we say that in any one of the three principal directions there is a net flux of mass across the cube boundaries given by

$$\rho \frac{\partial u_i}{\partial x_i}$$

where ρ represents the density of the fluid; u, the velocity; x, the length of the cube; and i indicates that it applies to any one of the three principal directions.

We assert that for the purpose of this analysis the volume occupied by a given mass of fluid always stays the same. As a result, if more net mass flows into the cube in one direction more must flow out in another direction. A mathematical statement of this concept is

$$\rho \frac{\partial u}{\partial x} + \rho \frac{\partial v}{\partial y} + \rho \frac{\partial w}{\partial z} = 0 \quad . \tag{1}$$

Newton's Second Law of Motion states in effect that the force required to change the direction of a mass, *i.e.* move it out of the way, is equal to the product of its mass and its acceleration. This force can be assumed to have three components, *i.e.* one along each principal axis, so that we should write three mathematical statements or equations to describe the complete picture:

$$F_1 = ma_1$$

$$F_2 = ma_2 \tag{2}$$

$$F_3 = ma_3$$

Now, acceleration is a time rate of change of velocity. But if the velocity crossing one face of the cube is different from that crossing an opposite face _at the same time_ there has been a change in velocity with distance. The product of this change with distance and the velocity at any point in the cube is also an acceleration. For acceleration along x, one may write

$$a_1 = \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} \quad . \qquad (3)$$

For the time being we will ignore the force applied to the airplane (and therefore also to the air, according to Newton's Third Law) by the air sliding over the skin. We note that air is caused to move by a pressure difference. In fact, the greater the pressure difference _per unit distance_ the greater will be the force which causes the air to move. Thus, according to Equations (2) and (3) we write

$$-\frac{\partial P}{\partial x} = \rho \left[\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} \right]$$

$$-\frac{\partial P}{\partial y} = \rho \left[\frac{\partial v}{\partial t} + v \frac{\partial v}{\partial y} + u \frac{\partial v}{\partial x} + w \frac{\partial v}{\partial z} \right] \qquad (4)$$

$$-\frac{\partial P}{\partial z} = \rho \left[\frac{\partial w}{\partial t} + w \frac{\partial w}{\partial z} + u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} \right] \quad .$$

At this point we will assume that the aircraft velocity is steady—unchanging in time—and that the speed of the air flowing over the airplane depends only upon _its position with respect to the aircraft_. This assumption permits us to ignore terms of the type $\partial u/\partial t$ and to write Equation (4) as follows

$$-\frac{\partial P}{\partial x} = \rho \left[u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} \right]$$

$$-\frac{\partial P}{\partial y} = \rho \left[v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} + u \frac{\partial v}{\partial x} \right] \qquad (5)$$

$$-\frac{\partial P}{\partial z} = \rho \left[w \frac{\partial w}{\partial z} + u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} \right] .$$

We will need these equations later to relate the pressure forces on wings and fuselages to the velocity of the air moving around them.

Let us now examine the imaginary cube through which we assume the air to be flowing. Consider one face as shown in the sketch below:
By assuming that the air slides over the surface of the airplane without applying any force to it we have in effect assumed that the air has no way of transmitting shearing forces to itself or to solid bodies with which it comes in contact. The measure of this shearing action is the viscosity of the fluid. We have assumed therefore that air is <u>inviscid</u>. Since we have no way of causing one fluid cube to shear against another it is reasonable to conclude that there is no way a fluid cube can be caused to rotate. From the sketch we see that a mathematical statement of this conclusion is

$$u \, dx + \left(v + \frac{\partial v}{\partial x} \, dx\right) dy - \left(u + \frac{\partial u}{\partial y} \, dy\right) dx - v \, dy = 0 \tag{6}$$

Simplifying the equation, one has

$$\frac{\partial v}{\partial x} \, dxdy - \frac{\partial u}{\partial y} \, dxdy = 0$$

or

$$\frac{\partial u}{\partial y} - \frac{\partial v}{\partial x} = 0 \quad . \tag{7}$$

Similar expressions can be obtained for the other five faces of the cube.

We move now to consider the consequences of the condition represented by Equation (7). A general differential $d\phi$ can be written

$$d\phi = u \, dx + v \, dy + w \, dz \quad . \tag{8}$$

Since

$$d\phi = \frac{\partial \phi}{\partial x} \, dx + \frac{\partial \phi}{\partial y} \, dy + \frac{\partial \phi}{\partial z} \, dz \quad , \tag{9}$$

$$u = \frac{\partial \phi}{\partial x} \, , \quad v = \frac{\partial \phi}{\partial y} \, , \quad w = \frac{\partial \phi}{\partial z} \quad . \tag{10}$$

But

$$\frac{\partial^2 \phi}{\partial x \partial y} = \frac{\partial^2 \phi}{\partial y \partial x} \quad .$$

Therefore

$$\frac{\partial u}{\partial y} = \frac{\partial v}{\partial x} \, , \quad \frac{\partial v}{\partial w} = \frac{\partial w}{\partial y} \, , \quad \frac{\partial w}{\partial x} = \frac{\partial u}{\partial z} \quad . \tag{11}$$

Consequently, requiring that the fluid be irrotational means that $d\phi$ is an exact differential. The integral of an exact differential is independent of the path of integration and depends only on the value of the function at the two end points. We say then that for an irrotational fluid a function ϕ, called a velocity potential, exists such that its partial derivatives represent the components of the fluid velocity. See Equation (10).

Using this result in Equation (1) one may write

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} = 0 \tag{12}$$

52

This partial differential equation is called the Laplace Equation and is one of the most studied in the mathematical literature. Note that there is only one dependent variable. Thus if one can find a function ϕ which satisfies the equation and the boundary conditions he should be able to find the velocity around a body represented by the boundary conditions. Note that since the Laplace Equation is linear, a sum of solutions is also a solution. We shall make use of this fact to represent complex bodies as a sum of simple solutions.

For the calculation of the lift and drag of aircraft wings we will restrict our attention for the time being to flow in a plane aligned with the airstream. Therefore we take $w = 0$ and ignore derivatives with respect to z. We postulate that a function

$$\phi = \frac{\Gamma}{2\pi} \tan^{-1} \frac{y}{x} \quad , \tag{13}$$

where Γ is a constant, is a solution of the equation

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0 \quad . \tag{14}$$

Now

$$\frac{\partial \phi}{\partial x} = - \frac{\Gamma}{2\pi} \frac{y}{x^2 + y^2} \tag{15}$$

$$\frac{\partial \phi}{\partial y} = \frac{\Gamma}{2\pi} \frac{x}{x^2 + y^2} \quad , $$

hence

$$\frac{\partial^2 \phi}{\partial x^2} = - \frac{\Gamma}{2\pi} \frac{y(-2x)}{(x^2 + y^2)^2} \tag{16}$$

$$\frac{\partial^2 \phi}{\partial y^2} = \frac{\Gamma}{2\pi} \frac{x(-2y)}{(x^2 + y^2)^2} \quad . $$

The sum of the two equations in (16) is seen to equal zero and thus Equation (13) is a solution of Equation (14). The figure below depicts this function.

— Lines of constant velocity

--- Lines of equal value of velocity potential
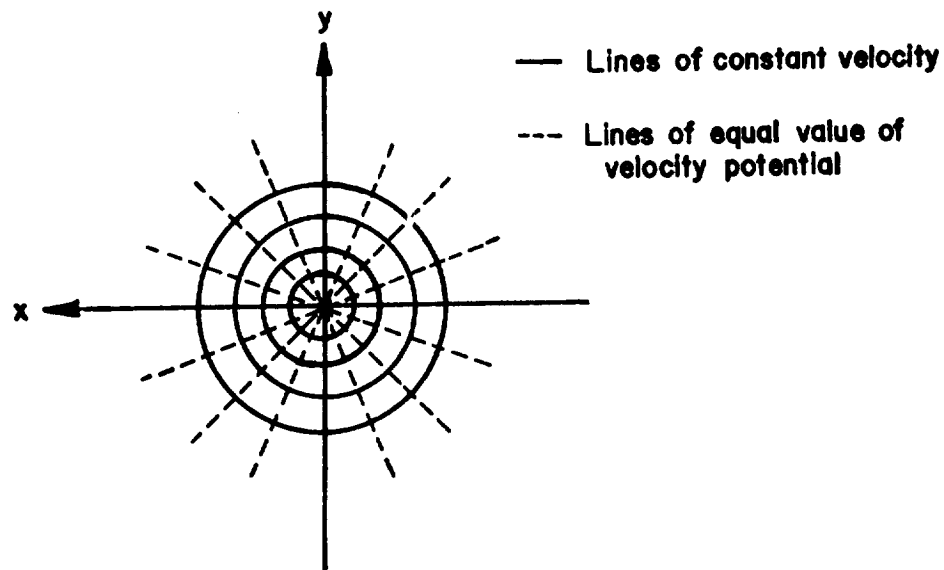

For a given value of Γ the velocity decreases as $1/(x^2 + y^2)^{\frac{1}{2}}$. This type of flow is called a vortex. It is irrotational. The quantity Γ is called the vortex strength.

If the vortex is not located at the origin the expression for the potential becomes

$$\phi = \frac{\Gamma}{2\pi} \tan^{-1} \frac{y - y_0}{x - x_0} \tag{17}$$

where (x_0, y_0) is the location of the center of the vortex. Corresponding expressions for the velocity components are

$$u = - \frac{\Gamma}{2\pi} \frac{y - y_0}{(x - x_0)^2 + (y - y_0)^2}$$

$$v = \frac{\Gamma}{2\pi} \frac{x - x_0}{(x - x_0)^2 + (y - y_0)^2} \quad . \tag{18}$$

Now suppose we place a number of vortices in a plane and ask what is the velocity induced at a point (x, y). We should be able to assume that the vortices may all be treated separately and that their contributions at a point may be summed to find the net velocity. We write therefore

$$\bar{u} = - \frac{1}{2\pi} \sum_{N=1}^{k} \frac{(y - y_{0_N}) \Gamma_N}{(x - x_{0_N})^2 + (y - y_{0_N})^2}$$

$$\bar{v} = \frac{1}{2\pi} \sum_{N=1}^{k} \frac{(x - x_{0_N}) \Gamma_N}{(x - x_{0_N})^2 + (y - y_{0_N})^2} \tag{19}$$

where k is the total number of vortices.

REPRESENTATION OF AN AIRFOIL IN TWO-DIMENSIONAL FLOW

Consider then the possibility of placing the vortices on the perimeter of an airfoil. If we can choose the strength of each vortex properly we should be able to make the net flow velocity along the airfoil surface satisfy, at least approximately, the boundary condition that the flow be parallel to the airfoil surface. To do this it is necessary to consider in addition the contribution of the free stream to the total flow picture. The velocity potential for a uniform stream is readily shown to be

$$\phi = -Vx \quad . \tag{20}$$

Hence, the effect of the free stream is to add a velocity V to $\bar{u}$. The boundary condition may then be stated as

$$\tan^{-1} \left(\frac{\bar{v}}{V + \bar{u}} \right) = \tan^{-1} \left(\frac{dy}{dx} \right)_{wing} - \alpha$$

54

or

$$\frac{\overline{v}}{V + \overline{u}} = \left(\frac{dy}{dx}\right)_{wing} - \tan \alpha \qquad (21)$$

where α is the angle of attack of the wing chord line.

$\left(\dfrac{dy}{dx}\right)_{wing}$ is the slope of the wing surface (measured relative to the axis system) at the point where the boundary condition is to be satisfied. The use of this notation follows from the concept of describing the surface by the equation $y = f(x)$. The local value of the tangent to this curve is of course given by $dy/dx|_x$.

In Equations (19) Γ_N, the vortex strength at each of the k points, is unknown and must be found by applying the boundary condition k times, that is, by writing k equations. Since we can accomodate no more than k values of the surface slope, one usually depicts the airfoil as consisting of straight line segments connecting the vortex centers. For this reason one usually desires k to be large in order to describe thick or cambered airfoils accurately.

The concept for representing airfoils and the significance of the various symbols used in the text is illustrated in the sketches below.

PHYSICAL AIRFOIL SHAPE

Note that each vortex on the entire airfoil contributes its share to the net velocity which is produced at each M. Note also that we have chosen to bound each line segment by a vortex. This choice facilitates the description of point M in terms of the vortex locations as may be seen in the analysis below. We could have chosen instead to represent the airfoil by a group of line segments, locate a vortex at the 1/4 point, say, and satisfy the boundary condition at the 3/4 point on each line segment. Such a procedure requires that one first find the equation of each line segment and then locate the vortex and the control point (point where boundary condition is satisfied) on it.

Let us call the right-hand side of Equation (21) B_M, the tangent of the required flow angle at point M. M has coordinates (x, y). Let us also call

$$\frac{(y_M - y_{O_N})}{(x_M - x_{O_N})^2 + (y_M - y_{O_N})^2} = a_{MN} \tag{22}$$

$$\frac{(x_M - x_{O_N})}{(x_M - x_{O_N})^2 + (y_M - y_{O_N})^2} = b_{MN} \quad , \tag{23}$$

then

$$
\begin{aligned}
B_1 &= \frac{b_{11}\Gamma_1 + b_{12}\Gamma_2 + \cdots b_{1N}\Gamma_N + \cdots b_{1k}\Gamma_k}{V + a_{11}\Gamma_1 + a_{12}\Gamma_2 + \cdots a_{1N}\Gamma_N + \cdots a_{1k}\Gamma_k} \\
\cdot & \\
\cdot & \\
\cdot & \\
\cdot & \\
B_k &= \frac{b_{k1}\Gamma_1 + b_{k2}\Gamma_2 + \cdots b_{kN}\Gamma_N + \cdots b_{kk}\Gamma_k}{V + a_{k1}\Gamma_1 + a_{k2}\Gamma_2 + \cdots a_{kN}\Gamma_N + \cdots a_{kk}\Gamma_k}
\end{aligned}
\tag{24}
$$

represents the system of equations which must be solved to find all the Γ's.

To evaluate a_{MN} and b_{MN} in Equation (24) we need to locate points M in relation to $(x_O, y_O)_N$. For convenience we will choose M halfway between successive values of $(x_O, y_O)_N$. Now the line which extends from x_{O1}, y_{O1} to x_{O2}, y_{O2} is described by

$$y = y_{O_1} + \left[\frac{y_{O_2} - y_{O_1}}{x_{O_2} - x_{O_1}}\right](x - x_{O_1}) \quad . \tag{25}$$

If we let

$$x = x_{O_1} + \frac{x_{O_2} - x_{O_1}}{2} \quad ,$$

then

$$y = y_{O_1} + \frac{y_{O_2} - y_{O_1}}{2} \quad . \tag{26}$$

By generalizing Equation (26) to

$$x_M = x_{O_N} + \tfrac{1}{2} (x_{O_{N+1}} - x_{O_N})$$

$$y_M = y_{O_N} + \tfrac{1}{2} (y_{O_{N+1}} - y_{O_N}) \quad , \tag{27}$$

we can find the coordinates of all except one of the points where the boundary conditions must be matched.

The reason one boundary value cannot be found by this procedure is that by tracing line segments between successive points we draw what can be termed an open polygon. Such a polygon has one less line segment than points. For example, if one numbers four arbitrary points and draws line segments from pt. one to pt. two, from pt. two to pt. three, and then from pt. three to pt. four, he will have only three line segments connecting the four points. As a result, the maximum value of M is therefore $k - 1$. Note that if $N = k$ there is no $k + 1$ point. We can resolve this difficulty by closing the polygon and giving one point two names, $i.e.$ $N = 1$ and $N = k$. While this step does not provide us with an extra line segment at which to match the boundary condition, it does permit one to invoke the physics of the problem to reduce the number of unknown Γ_N's by one and thereby obtain a determinant system.

At this point the question is sure to arise in the mind of the uninitiated reader, why could not one simply locate one vortex and one control point on each line segment? The system is then completely determinant and there is no need to worry about finding another constraint. Unfortunately, such an approach encounters difficulties satisfying our present view of the physical situation. Consider for example the fact that with such a mathematical model we know the flow to be parallel to the line segments only at the control points. We do not know what the direction or magnitude of the resultant flow is anywhere else. The flow could very well cross the airfoil "surface". In particular we must be concerned about the situation at the trailing edge. Now we call one boundary for a quantity of flow a streamline. Far from the airfoil, or course, the streamlines are parallel. As the flow approaches the airfoil one streamline marks the exact line above which all the flow moves over the upper surface of the airfoil and below which all the flow moves over the lower surface of the airfoil. This line is called the stagnation streamline because at the point where it intersects the airfoil surface the flow velocity is exactly zero or stagnant.

The flow in the immediate neighborhood of this line obviously cannot move into the surface and it splits, half of it moves up and half down along the surface at this point with a net velocity of zero. Now, there must be another point of this type on the lee side of the airfoil where the flow around the airfoil comes together and leaves the surface. Where is this point located? Note the accompanying sketch.
Point A here is the forward stagnation point. It would seem reasonable to
locate B such that the distance the flow would have to travel between A
and B over upper surface would be equal to the distance from A to B using
a lower surface route. For low drag, airfoils usually have trailing edges,
S, with very small radii of curvature. If the stream is to remain attached
to the surface and flow smoothly around this sharp corner, then it must
change direction very rapidly. This means there must then be portions of
this region where the velocity is very high and, according to Equation 31,
where the pressure is very low.

If the fluid experiences no frictional forces, the kinetic energy of
its motion at S is just sufficient to drive it to the stagnation point B.
Viscous forces, which are present in the actual case, retard this motion
so that the fluid does not quite reach B but stops somewhere on the way.
In fact, anytime the fluid does not quite reach B whether because of
viscosity or not a counter flow is set up (see sketch below) as some

fluid seeks to move from the high pressure area at B to the low pressure
area at S. This tends to separate the flow coming around S from the
upper surface. The action of these two flows creates a vortex. This
vortex, which is formed along the whole trailing edge of the airfoil,
is unstable and separates from the trailing edge. It is carried along
by the general motion.

According to Helmholtz's theorem, vortex cores are closed figures.
Thus there must be a net circulatory flow around the entire airfoil in
the clockwise direction which is attached (at infinity) to the vortex
shed off the trailing edge (see following sketch). Incidently, this
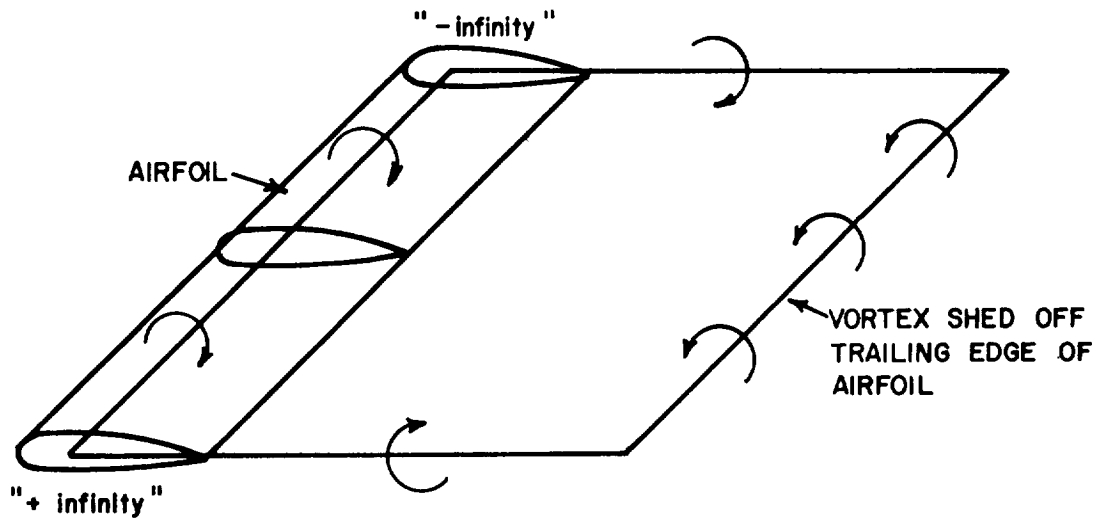

flow pattern can be seen in photographs taken of an airfoil just as it is
set into motion. The flow is made visible by inserting the airfoil verti-
cally into stagnant water on which finely ground aluminum powder is
floating. Such a vortex is shed everytime there is a change in lift.

Simultaneously with the vortex shedding process and the creation of
a net clockwise circulation around the airfoil itself, the stagnation point
B is displaced until it resides approximately at S. The fluid then no
longer moves around the trailing edge but flows off tangentially with
equal velocity at both sides. The assumption that the flow will leave the
trailing edge smoothly was put forward independently by Kutta and Joukowski.
It is the salient point in the theory of lift because it determines the
magnitude of the circulation. By means of this hypothesis the whole problem
of lift becomes purely mathematical: one has only to determine the amount
of circulation so that the velocity of the flow leaving the upper surface
at the trailing edge is equal to that of the flow leaving the lower
surface. The rule stated in this way applies to wings with zero vertex
angle. If tangents to the upper and lower surfaces form a finite angle,
the trailing edge is a stagnation point. Most airfoils with which we
will be concerned have finite trailing edge angles; according to the Kutta-
Joukowski hypothesis the flow velocity and hence the circulation at the
trailing edge of these airfoils is zero. If we locate the first of the
vortex filaments describing the airfoil at the trailing edge and require
that the net velocity at this point be zero, we must also choose the
strength of the vortex filament at that point to be zero since the velocity
at the core of a vortex is infinite. At first thought one would simply
take $\Gamma_1 = \Gamma_k = 0$ but this would mean that there is one more equation in
(24) than is necessary, something we know is not true. To skirt this
mathematical problem we take

$$\Gamma_1 = -\Gamma_k \ .$$

<div align="right">(28)</div>

Obviously, if we have two vortices located at the same point with equal and opposite strengths the sum of those strengths (which is what we would see physically) is zero. Through this device we satisfy the requirement that a stagnation point will always exist at point 1. Simply saying that $\Gamma_1 = \Gamma_k$ does not insure that Γ_1 will come out to be zero even if point 1 is at the trailing edge. Finally, with these constraints Equations (24) now read

$$B_1 = \frac{1}{V}\left[(b_{11} - B_1 A_{11})\Gamma_1 + (b_{12} - B_1 A_{12})\Gamma_2 + \cdots (b_{1N} - A_{1N}B_1)\Gamma_N + \right.$$

$$\left. \cdots (B_1 a_{1k} - b_{1k})\Gamma_1 \right] \tag{29}$$

$$B_{k-1} = \frac{1}{V}\left[(b_{(k-1)1} - B_{k-1}a_{(k-1)1})\Gamma_1 + (b_{(k-1)2} - B_{k-1}a_{(k-1)2})\Gamma_2 + \right.$$

$$\left. \cdots (b_{(k-1)N} - B_{k-1}a_{(k-1)N})\Gamma_N + \cdots (B_{k-1}a_{(k-1)k} - b_{(k-1)k})\Gamma_1 \right]$$

Equations (29) contain $k - 1$ distinct values of Γ_N and $k - 1$ values of B_M so that the system is solvable for all $k - 1$ values of Γ_N. Admittedly, when k is a large number this is a task which is practical only when one is able to use a digital computer with sufficient storage (memory) to carry out the solution process. Generally, the process should be one able to accommodate a system of 65 or more simultaneous algebraic equations. The most favored method for solution of such large systems is a generalization of Cramer's Rule, familiar to college algebra students as a technique for solving systems of 3 or 4 simultaneous algebraic equations. Fortunately, the nature of the matrix form of this large system is such that the solution is less difficult than one might expect to encounter for systems of this size. Those readers interested in the mathematical details of the numerical methods one might employ for this purpose are referred to texts and papers on matrix algebra and in particular to papers on matrix inversion techniques. Since these techniques are not elementary (they are, fortunately, usually available as standard computer library programs) and since their details are not crucial to an understanding of the physical reasoning used to formulate Equations (29), they will not be discussed here.

A cautionary note regarding Equations (29) should, perhaps, be injected at this point. In their formulation, it was assumed that the coordinates of the vortex centers were measured from a fixed reference. Therefore, when the angle of attack changes, the locations of the vortex centers as well as the coordinates of the center of the connecting line segments change. In other words, a_{MN} and b_{MN} depend for their values upon the airfoil angle of attack. On the other hand, the local airfoil slope, $((dy)/(dx))_{wing}$ can be taken as constant for all α since the term $\tan \alpha$ is substracted from the slope to calculate the boundary condition, Equation (21). An alternate formulation considers the airfoil to be fixed and the flow to rotate as α changes. The left hand side of Equation (21) will then read

$$\frac{\overline{v} + V \sin \alpha}{\overline{u} + V \cos \alpha}$$

while the right hand side will no longer have the term $\tan \alpha$.

62

In addition to the necessity of locating two vortex filaments at the trailing edge as discussed above, there is a second geometrical aspect which should be considered in choosing the locations of the other vortex filaments by which one represents the airfoil. This aspect is the surface curvature. Obviously, the line segments between filaments must be more numerous in regions of high curvature if one is to describe the surface accurately. Thus, for most airfoils the preponderance of points should be located near the leading edge. One can quantify this procedure by specifying that the distance from the line segment to the surface should never exceed a fixed, small percentage of the airfoil chord (distance from leading to trailing edge). The orientation of the local surface to the stream also has an effect on the vortex filament spacing. Surfaces nearly parallel to the free stream can be represented more accurately with a few filaments than surfaces with large inclinations.*

The solution of Equation (29) is k values of Γ_N with $\Gamma_1 = -\Gamma_k$. Now that we have these values we ask how we may use them to find what is really of interest to us: the local pressures on the surface of the airfoil. We begin by considering how one might write a two-dimensional version of Equations (5) in a coordinate system with one axis tangent to stream line and the other normal to it. In such a coordinate system (5) reduces to

$$- \frac{\partial P}{\partial s} = \rho \tilde{u} \frac{\partial \tilde{u}}{\partial s} \tag{30}$$

where $\tilde{u}$ is the total fluid velocity and s is the distance along the streamline. Equation (30) is easily integrated to yield

$$P_s = P + \tfrac{1}{2} \rho \tilde{u}^2 . \tag{31}$$

P_s is the stagnation pressure along a streamline, that is, the pressure which would exist if the fluid were brought to rest. It is usually assumed that the disturbances produced by the airfoil decay to zero at great distances upstream and downstream of the airfoil, *i.e.* at these stations. If the flow is uniform then the stagnation pressure must be the same along all streamlines. Since there is no mechanism in an irrotational, incompressible, inviscid flow by which the stagnation pressure can change, P_s is then the same on all streamlines throughout the flow field. It is easily evaluated since P_∞, ρ, and V are known in a given flow.

---

* One might postulate that by representing both the boundary on which parallel flow is to be required and the vortex strength explicitly by continuous functions of the surface coordinates with continuous derivatives everywhere, the intervals over which these functions are fitted can be significantly larger, for equal accuracy, than the straight line segments (with their delta-function-like circulation strengths) used in the present approach. Larger segments, of course, means fewer (although perhaps more complex) equations to solve. Hess (Refs. 81, 82) studied this question at some length. He begins with the implicit assumption that one would always wish to represent the distribution of vorticity over the airfoil surface as a continuous distribution. The strength of the vorticity

over any segment of the airfoil surface is then an integral of the vortex strength per unit length over that segment. Since this integral equation usually cannot be solved in general, one usually seeks to find approximate means of solution. Hess states that "the most straightforward means of evaluating the integral is by means of a quadrature formula that replaces the integral by a weighted sum of values of the integrand evaluated at certain points. That is, the effect of a continuous singularity distribution is approximated by a sum of concentrated point singularities...This is not a satisfactory procedure. The basic difficulty is that the velocity approaches infinity more rapidly in the neighborhood of a point singularity than it does near a finite-strength singularity distribution on an arc of a curve. Thus the spacing of the quadrature points must be small compared to all physical dimensions of the boundary. This is not practical for airfoils which are often quite thin." Near the trailing edge, particularly, the problem is quite difficult. "Adjacent to the corner the ratio of the normal distance between two points to the spacing between them is approximately the sine of the trailing edge angle, no matter how many points are used."
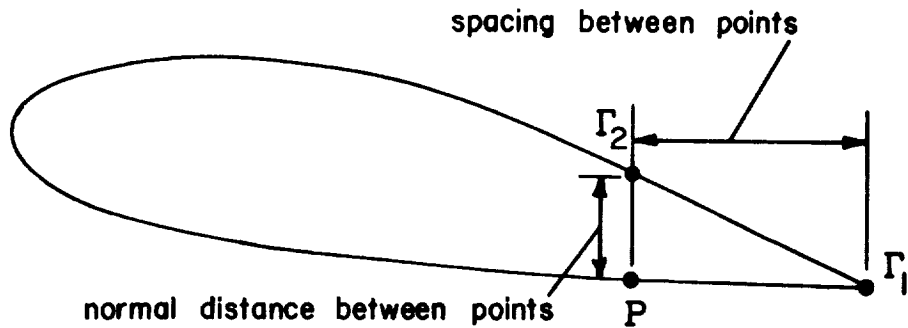

As a result, the velocity at P on the lower surface of the airfoil in the sketch above is dominated by the contribution from Γ_2, whereas in the integral representation the contribution from vorticity at some distance from Γ_2 will still be significant.

To illustrate these concepts consider the following example. Take two flat plates which join at an angle of 3°.
Place vortices Γ_1 and Γ_2 10 units apart as shown and assume $\Gamma_1 = \Gamma_2$. Now Γ_2 induces a velocity which is parallel to the lower plate at P which has a magnitude equal to $(\Gamma/2\pi)(1.91)$ while Γ_1 induces a velocity at P which is normal to the plate and has a magnitude equal to $(\Gamma/2\pi)(0.1)$.

The integral representation for constant vortex strength per unit length is given by

$$V \approx \frac{1}{2\pi} \int_0^{10} \frac{\Gamma}{10} \left[\ln \sqrt{1.002742\ x^2 - .05483\ x + .2742} \right] dx$$

$$\approx \frac{\Gamma}{2\pi} \left(1.37 \right) \ .$$

Note that in this example the magnitude of the induced velocity at P is, as stated by Hess, less for a continuous distribution of vorticity than for a distribution of concentrated point singularities. It would appear, therefore, that the use of continuous distributions of vorticity would lead to less "wavy" flows in the neighborhood of airfoil surfaces and is therefore desirable.

Hess systematically investigated the effectiveness of higher order approximations of the integral equation, including the use of curved surface elements and parabolically-varying vorticity. He found that the approach using flat elements with constant singularity is mathematically consistent as is the next higher-order approach with parabolic elements and linearly-varying singularity strength. The popular approach based on flat elements with linearly-varying singularity strength he shows to be mathematically inconsistent. Hess concludes that "(1) the higher order solutions give very little increase in accuracy for the important case of exterior flow about a convex body; (2) for bodies with substantial concave regions and for interior flows in ducts, the use of parabolic elements and linear varying singularity can give a dramatic increase in accuracy; and (3) the use of still higher order solutions leads to a rather small additional gain in accuracy."

The results which Hess obtained for the surface velocity on a semi-infinite body whose forward portion is a semi-circle concave to the flow has a particular bearing on the question of whether the use of higher order solutions can lead to shorter computational times for equal accuracy. Using 36 curved elements with linearly-varying source strengths he was able to recover the values given by the analytical solution. Even with five times that number of straight elements with constant source strengths—and, more importantly, one hundred times the computing time—he was not able to recover the correct values. The results were qualitatively correct but were quantitatively in error, particularly on the centerline.

Hess also studied the use of the various solutions on a highly cambered Kármán-Trefftz airfoil for which an analytical solution is known. Since the lower surface of this airfoil is concave, use of the higher order method was found to be necessary in order to obtain good agreement with the analytical result.

The implications of Hess's work, so far as the prediction of airfoil characteristics is concerned, are (1) for conventional airfoils little reduction in computational time—for the same accuracy—can be achieved by using fewer curved elements and linearly-varying singularity strengths, (2) for unconventional airfoils—airfoils with concave areas on their lower surfaces—use of the higher order solution will yield substantial improvements in accuracy for a given computational time.

Now the velocity along a streamline is given by

$$\sqrt{(V + \overline{u})^2 + \overline{v}^2} = \widetilde{u} \tag{32}$$

so that the fluid pressure which acts normal to the airfoil surface at point (x, y) is simply

$$P = P_\infty + \tfrac{1}{2}\rho V^2 - \tfrac{1}{2}[(\overline{u} + V)^2 + \overline{v}^2]$$

or

$$P = P_\infty - \tfrac{1}{2}\rho[\overline{u}^2 + \overline{v}^2 + 2\overline{u}V] \quad . \tag{33}$$

Note that we have used all of the Γ_N found from a solution of (29) to determine $\overline{u}$ and $\overline{v}$ at a set of points (x, y) according to Equations (10). It may be well to note here that requiring the flow generated by the system of vortices to be parallel to the surface at the mid-segment points does not guarentee that it is also parallel to the surface everywhere. Thus it is prudent to select x,y for the pressure computation to be those same mid-segment points. Pressures at points inbetween are probably best found from a third order polynomial fit to four successive calculated values.

The net lift on the airfoil is obtained by integrating the components of the pressure which are normal to the free stream direction over the entire surface of the airfoil. Mathematically, this process can be expressed by

$$L = \cos\alpha \oint P(x) \cos\left[\tan^{-1}\left(\frac{dy}{dx}\Big|_x\right)\right] dx - \sin\alpha \oint P(x) \sin\left[\tan^{-1}\left(\frac{dy}{dx}\Big|_x\right)\right] dx \quad . \tag{34}$$

The lift coefficient is then $L/\tfrac{1}{2}\rho V^2 c$.

To perhaps aid the reader in grasping some of the foregoing concepts, we will digress momentarily from the main thrust of our argument, retrace some of our steps and approach the calculation of airfoil lift from a slightly different direction. We will employ for this purpose the analysis given by von Kármán and Burgers in Volume II of the six volume set, Aerodynamic Theory, edited by W. F. Durand, (Julius Springer, 1935). Equations (19) when expressed in polar coordinates become

$$v_r = \sum_{N=1}^{k} \frac{\Gamma_N}{2\pi} \frac{r_{O_N}\sin(\theta - \theta_{O_N})}{r^2 + r_{O_N}^2 - 2r\,r_{O_N}\cos(\theta - \theta_{O_N})}$$

$$v_\theta = -\sum_{N=1}^{k} \frac{\Gamma_N}{2\pi} \frac{r - r_{O_N}\cos(\theta - \theta_{O_N})}{r^2 + r_{O_N}^2 - 2r\,r_{O_N}\cos(\theta - \theta_{O_N})} \quad .$$

In these expressions it is assumed that the positive sign of the circulation corresponds to a clockwise rotation of the fluid and that the nose of the airfoil points to the left into the oncoming stream. v_θ is positive in the counterclockwise direction. We now expand the velocities in a series containing decreasing powers of r. These series are convergent so long

as r is greater than any of the values $r_1, r_2, \ldots, r_n$, that is, so long as the point where we wish to compute the velocity components is further from the origin than any point on the airfoil surface. Under these conditions, the first term in the denominator of each series above is dominant and one may write

$$v_r = \frac{1}{r^2} \sum_{N=1}^{k} \frac{\Gamma_N}{2\pi} r_{0N} \sin(\theta - \theta_{0N}) + \text{higher terms}$$

$$v_\theta = -\frac{1}{r} \sum_{N=1}^{k} \frac{\Gamma_N}{2\pi} - \frac{1}{r^2} \sum_{N=1}^{k} \frac{\Gamma_N}{2\pi} r_{0N} \cos(\theta - \theta_{0N}) + \text{higher terms}.$$

We now assume a uniform and parallel fluid motion with velocity component V_x and V_y to be superimposed on the flow produced by the vortex filaments. We apply to the fluid within a circle of radius $r = K$ the theorem that the difference between the fluid momentum entering the circle and that leaving it is equal to the resultant of the forces acting on the fluid. The forces involved are (a) the pressure distributed along the circle and (b) the forces acting between the vortices and the fluid. The theorem may therefore be stated thus:

Resultant of forces = Resultant of pressures − Change in momentum

or

$$F_x = -\oint P \cos\theta \, ds - \rho \oint W_n W_x \, ds$$

$$F_y = -\oint P \sin\theta \, ds - \rho \oint W_n W_y \, ds$$

where F_x, F_y are the resultant forces in the x and y directions, θ locates the element ds and

$$W_n = V_x \cos\theta + V_y \sin\theta + v_r$$

$$W_x = V_x + v_r \cos\theta - v_\theta \sin\theta$$

$$W_y = V_y + v_r \sin\theta + v_\theta \cos\theta.$$

Then

$$F_x = -K \int_0^{2\pi} P \cos\theta \, d\theta - \rho K \int_0^{2\pi} (V_x \cos\theta + V_y \sin\theta + v_r)$$

$$\cdot (V_x + v_r \cos\theta + v_\theta \sin\theta) d\theta$$

$$F_y = -K \int_0^{2\pi} P \sin\theta \, d\theta - \rho K \int_0^{2\pi} (V_x \cos\theta + V_y \sin\theta + v_r)$$

$$\cdot (V_y + v_r \sin\theta + v_\theta \cos\theta) d\theta$$

$$P = P_\infty + \tfrac{1}{2}\rho(V_x^2 + V_y^2) - \tfrac{1}{2}\rho(V_x + v_r \cos\theta - v_\theta \sin\theta)^2$$

$$- \tfrac{1}{2}\rho(V_y + v_r \sin\theta + v_\theta \cos\theta)^2$$

$$= P_\infty - \tfrac{1}{2}\rho(v_r^2 + v_\theta^2 + 2v_r[V_x \cos\theta + V_y \sin\theta]$$

$$+ 2v_\theta[V_y \cos\theta - V_x \sin\theta])$$

If K is large, then $v_r \to 0$ and $v \to -\dfrac{1}{K} \displaystyle\sum_{N=1}^{k} \dfrac{\Gamma_N}{2\pi}$.

Further, the integral from 0 to 2π of $\sin\theta$, $\cos\theta$, and $\sin\theta\cos\theta$ are all zero so that in computing F_x and F_y one need do only

$$F_x = K \int_0^{2\pi} \frac{\rho}{2} 2\, v_\theta V_y \cos^2\theta\, d\theta + K\rho \int_0^{2\pi} v_\theta V_y \sin^2\theta\, d\theta$$

$$F_y = -K \int_0^{2\pi} \frac{\rho}{2} 2\, v_\theta V_x \sin^2\theta\, d\theta - \rho K \int_0^{2\pi} v_\theta V_x \cos^2\theta\, d\theta$$

which become

$$F_x = K\rho\, 2\pi\, v_\theta V_y$$

$$F_y = -K\rho\, 2\pi\, v_\theta V_x$$

Then with $v_\theta = -\dfrac{1}{K} \displaystyle\sum_{N=1}^{k} \dfrac{\Gamma_N}{2\pi}$ we have

$$F_x = -\rho V_y \sum_{N=1}^{k} \Gamma_N$$

$$F_y = \rho V_x \sum_{N=1}^{k} \Gamma_N$$

In the case where the fluid motion is parallel to the x-axis we see that $V_x = V$ and $V_y = 0$ so that the resultant force or lift,

$\rho V \displaystyle\sum_{N=1}^{k} \Gamma_N$, is normal to the direction of the stream. Since Joukowski

found that the lift of an airfoil is $\rho V\Gamma$, it is evident that the net circulation about the airfoil is the sum of the individual vortex filament strengths.

A simplified form of Equation (34) can also be used to show an interesting relationship between the vortex filament strengths and the surface velocities. Since

$$P(x) = P_\infty - \frac{\rho}{2} [\overline{u^2} + \overline{v^2} + 2\overline{uv}]$$

we could take for $\alpha = 0$ and an airfoil surface made up of straight line segments

$$L = \int P(x) \left(\frac{\Delta x}{\Delta s} \right)_x dx \;,$$

where $\left(\dfrac{\Delta x}{\Delta s} \right)_x$ represents the cosine of the angle formed by a particular

line segment and the chord line. If we are willing to say that this cosine is always near unity then we may ignore the v-component in the velocity and also $\overline{u}^2$ in comparison with $2\overline{u}V$. With these approximations we have for the lift

$$L = \oint \left[P_\infty - \frac{\rho}{2} (2\overline{u}V) \right]_x (\Delta x)_x \, dx \;.$$

Since we are discussing a surface made up of line segments $(\Delta x)_x$ and we assume that the pressure is constant over each line segment, the integral is readily approximated by a series:

$$L = \sum_x \rho V \overline{u}_x (\Delta x)_{x_{upper}} + \sum_x \rho V \overline{u}_x (\Delta x)_{x_{lower}} \;.$$

Note that $\oint P_\infty \, dx = 0$. From a comparison between this expression for the

lift and that in terms of the vortex filament strengths where

$$L = \rho V \sum_N \Gamma_N$$

we see that

$$\overline{u}_x = \frac{\Gamma_x}{(\Delta x)_x} \;.$$

In other words, the velocity induced along a segment of the airfoil surface is equal to the vorticity per unit length existing over that segment.

Some comments concerning the results of the procedure leading to (34) are appropriate at this point. First, it must be recalled that the procedure considers air to be an inviscid, incompressible fluid. Thus, there is no dissipative mechanism available to produce a drag. Hence, the integral of the streamwise components of the pressure force on the airfoil must, if the calculation has been carried out accurately and correctly, be zero, or in mathematical terms,

$$\sin \alpha \oint P(x) \cos \left[\tan^{-1} \left(\frac{dy}{dx}\Big|_x \right) \right] dx$$

$$+ \cos \alpha \oint P(x) \sin \left[\tan^{-1} \left(\frac{dy}{dx}\Big|_x \right) \right] dx \leqq 0.00005 \;. \tag{35}$$

Carrying out the procedure indicated by Equation (35) is an excellent way to check the accuracy and validity of the method used to obtain a numerical result for Equation (34).

A second anomaly resulting from the use of an inviscid theory is that one cannot predict the approach of the phenomenon pilots call "stall." Physically, stall is characterized by a loss of lift and a sharp increase

70

In drag as the wing's angle of incidence to the stream is increased. Thus an airfoil exhibits a maximum lift coefficient just prior to stall. It usually occurs at angles of incidence to the airstream (α) in the neighborhood of $16°$ to $20°$. The inviscid theory, on the other hand, will predict maximum lift at $\alpha \to 45°$. Despite this deficiency, the inviscid theory will generally give quite satisfactory predictions of lift for $\alpha < 6°$ or $8°$.

TREATMENT OF VISCOUS EFFECTS

It should be evident from the previous comments that to be able to make a realistic estimation of aircraft performance one must find some means to consider in the calculations the property by which air is able to resist the motion of aircraft and propellors: viscosity. It has been known for a long time that inclusion of this property in the equations describing fluid motion makes them (a) non-linear, (b) higher order, (c) consider energy transport, and, consequently, a pressure-density-temperature relation—factors which make them virtually insolvable in general. In one of the greatest contributions to the analytical description of physical reality, Ludwig Prandtl argued in 1904 that for most practical applications one could consider the effects of viscosity to be confined to a thin layer of the fluid immediately adjacent to the airfoil surface which he called the boundary layer. Prandtl argued that the remainder of the flow field can be treated quite adequately by retaining the fiction that the fluid is inviscid. If we assume that we have an acceptable method to calculate the lift on an airfoil-like body we must ask ourselves how can we include this viscous boundary layer in the treatment and what are its effects.

The concept of viscosity means that there is a transport or communication of the momentum of the fluid in one layer to the fluid in the adjacent layer. Whereas in inviscid theory we assumed that the fluid layer immediately adjacent to the surface of a flat plate has the same velocity as that far from the surface, we recognize that the stationary character of the surface must be known to the fluid immediately adjacent to it. This fluid cannot be moving very rapidly with respect to the surface because the molecules lose a significant portion of their tangential momentum in striking the stationary surface. This change in momentum appears as a frictional force on the surface. The layers outside the one closest to the surface, however, continually feed in additional momentum so that the net result is the development of a gradation in fluid velocity from the surface to the edge of the boundary layer. At the surface the velocity relative to the surface is zero. At the outer edge of the boundary layer the velocity is equal to that in the inviscid flow. See the following sketch.

Shown on the sketch is a graph of the variation of fluid velocity with height above a solid surface. u_e is the inviscid free stream velocity. A similar graph can be constructed at each streamwise location along the surface. Generally, the height over which the fluid velocity moves from zero to the inviscid free stream value, the distance labeled δ on the graph, increases as one goes downstream.
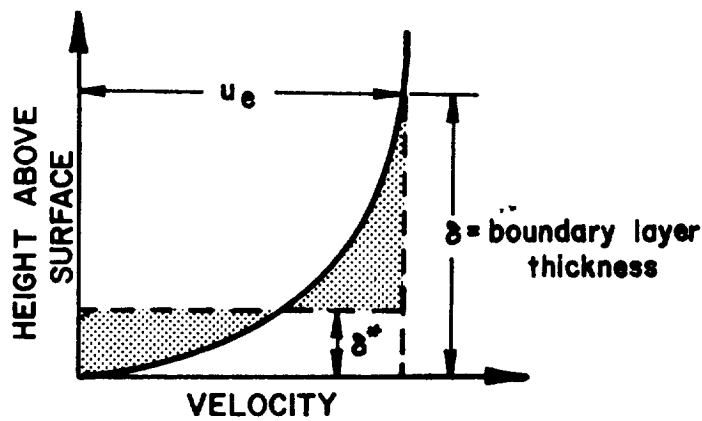

Looking at the sketch one notes that the two cross-hatched areas are approximately equal. This suggests that one could say, for purposes of modeling, that all of the fluid mass in the boundary layer is really concentrated in a region of uniform velocity u_e extending from δ^* outward to δ and that the region from the surface to δ^* could be considered part of the body since in this model there is no fluid in it. It would seem then that a way of accounting for some of the effects of viscosity is to determine δ^*, add this value to the airfoil ordinates, and recompute the lift values by inviscid theory based on this modified shape. As we shall see, this is an iterative process since the value of δ^* depends upon the value of the surface pressures.

Because of the existence of the boundary layer and its accompanying viscous dissipation, the flow in the immediate area of the trailing edge has a lower stagnation pressure than that at the leading edge. Since the pressure just aft of the airfoil must be about the same throughout a plane normal to the stream, there will be a region formed by the confluence of the two surface boundary layers where the fluid velocity will be less than free stream. This is called a wake, that is, a region where the fluid is relatively static with respect to the airfoil. Wakes tend ultimately to diffuse and disappear downstream. A wake exists whether or not the boundary layer(s) separate from the airfoil. The wake is of course much thicker if there is separation.

Another way of looking at the effect of a wake is to note that in moving over an obstruction the fluid velocity increases in proportion to the vertical displacement of the obstruction at the particular streamwise location. As the velocity goes up, the pressure must come down, according to Equation (31). Then, having passed the peak of the obstruction, the fluid begins to decelerate and the pressure begins to rise. Now, the effect of the wake coming off the trailing edge of the airfoil is to prevent the inviscid flow from returning all the way to its orginal free stream value. See the sketch below. Consequently, the pressure at the beginning of this wake region, point "a" on the sketch, is substantially lower than stagnation pressure. Since the streamlines are essentially straight downstream of point "a" it means the flow is more or less uniform and the pressure over

72
the entire airfoil aft of point "a" is approximately constant at the low value that exists at point "a". An integral of the surface pressures in the streamwise direction is now not zero. There is a finite drag, called in this case the form drag since it is dependent for its value on the form or shape of the body.

To accomodate this situation within the bounds of our inviscid theory we can proceed as follows: take as our body shape the airfoil plus δ^* up to x = c. At x = c, assume the body continues to extend downstream by an amount equal to

$$\left(\delta^* \middle/ \frac{dy}{dx} \right)_{x=c} ,$$

the projections from the two surfaces coming together in a point at this location. By this device we artificially create the sharp trailing edge we must have to satisfy the condition $\Gamma_1 = -\Gamma_k$. Γ_1 and Γ_k of course are then placed at this ficticious trailing edge point. Next we compute the pressures as a function of x (to x = c only) in the conventional manner and then employ (34) to obtain the lift and (35) to obtain the form drag. In essence then, we apply the pressures computed with the perturbed shape (geometric plus displacement thickness, δ^*) to the actual physical airfoil shape at the same chordwise station. There is of course some error involved in this procedure because the shape of the pseudo-body aft of x = c may cause the inviscid flow to decelerate somewhat more quickly than is actually the case and some of this effect will be apparent in the pressures calculated for points just upstream of the corners. In other words, it will tend to make the computed drag somewhat lower than it actually is. This effect is not serious as long as the wake is small compared with the airfoil thickness. Unfortunately, the model is not readily amenable to more sophisticated treatments of the wake effect* and the problem of accuracy is probably best

---

* Other schemes for treating the trailing edge condition which come to mind include (1) replacing the Kutta condition by the requirement that the vorticity shed into the wake from upper and lower surfaces be the same (2) extending the airfoil as a thin sheet along the wake centerline with the local curvature determined from considerations of the velocity distribution in the

73

wake according to viscous theory and the fact that the change in the fluid momentum in the y-direction in the upwash and downwash (aft of the airfoil) fields must equal the airfoil lift. One may also consider the superposition of a vortex distribution related in some predetermined way to that found above which will make the integral of the pressures over the pseudo-airfoil in the drag direction equal to zero.

Callaghan and Beatty (Ref. 69) in their treatment represent the displacement thickness with a source near the trailing edge. The pseudo-body then never closes and the source strength must be chosen to yield the proper wake thickness.

The very interesting approach used by Bhateley and McWhirter (Ref. 80) to treat this problem is in some respects quite similar. They do not employ the Kutta condition and, in addition, locate a source of undetermined strength within the airfoil. They must therefore supply two additional boundary conditions to obtain a solvable system. These are obtained by specifying two pseudo airfoil surface points just behind the trailing edge on both the upper and lower surfaces. The condition of continued tangential flow to the last surface element is satisfied at these pseudo boundary points. This type of analysis permits them to treat with good accuracy airfoils with slightly blunted trailing edges. These configurations are currently of increasing popularity because they can yield higher lift coefficients for the same angle of attack than the same airfoils with sharp trailing edges.

Bhateley and McWhirter further apply this concept to airfoils with partially separated boundary layers. Thus they are able to predict the variations in C_ℓ, C_d, and C_m with α up to α_{STALL} quite accurately. In their method the conditions of tangential flow are satisfied only on that part of the body having attached flow. If the boundary layer calculations indicate that the lower surface flow will separate, this fact is ignored and the displacement thickness is computed in the usual fashion. The two additional corner points are generated: one very close to the separation point on the upper surface and the other at the trailing edge on the lower surface of the pseudo body. The condition of continued tangency of the lower surface flow at the additional boundary point is satisfied. In specifying the additional boundary point aft of the separation point on the upper surface the user must select, based on experience, other analysis, etc., the direction of the flow leaving the upper surface. No pressures are calculated in the separated flow region. The pressure distribution downstream of the separation point is assumed constant and equal to that value of the pressure obtained by linear interpolation of the last two boundary point pressures prior to the separation point.

74

In this treatment, the separation point on the upper surface is considered to be the upper trailing edge point of a blunt trailing edge airfoil. It is easily seen, then, that the trailing edge thickness (and the source strength responsible for it) of the pseudo airfoil grows rapidly as α_{STALL} is approached. The pseudo airfoil begins to take on the appearance of a blunt body. Blunt bodies, of course, are known to have relatively high drag and relatively low lift so that it is easily seen how this approach can be used to account for the change in airfoil behavior from a low drag, high lift, relatively wake-free body at moderate angles of attack to a high drag, low lift, large wake body at high angles of attack.

The success of such a technique is, of course, highly dependent upon the accuracy with which one can predict the location of the boundary layer separation point on the airfoil. For this purpose Bhateley and McWhirter use a finite difference method in place of the momentum integral method discussed here. Studies conducted by colleagues of the present authors indicate that the momentum integral technique predicts increasingly more rearward separation locations (compared with predictions of the finite difference technique) as the angle of attack increases. Thus the lift predictions will be too large and the drag predictions too small at higher angles of attack compared with those obtained using a finite difference approach. On the other hand, the finite difference technique was found to require 20 times the computing time needed by the momentum integral technique.

The considerable success enjoyed by Bhateley and McWhirter in predicting the pressure distributions on airfoils at high angles of attack however seems to be more a function of the boundary layer routine they use than because they use an embedded source and two off-body tangency conditions. One can obtain similar results, for example, by replacing the Kutta condition by a requirement that the pressures at the upper surface and lower surface separation points and all points inbetween over the aft portion of the airfoil be the same, provided one does not then wish to construct a new pseudo body and compute from this a new potential solution. The source and two off-body tangency conditions are needed to determine the shape of the pseudo body aft of the separation point and thus to determine the potential flow about the pseudo body.

For airfoils with sharp trailing edges (and no boundary layer) Bhateley and McWhirter chose the Kutta condition in one of two forms: the flow 10^{-5} chord lengths behind the trailing edge is constrained to move in a direction which is an average of the airfoil surface slopes at the trailing edge or the net vorticity at the trailing edge is required to be zero.

handled for the present in a semi-empirical fashion, with the correction expected to be a function of angle of attack.

There is in addition to the form drag what is termed skin friction or shear drag, drag that is due directly to the sliding of the air over the airfoil surface. For well-streamlined shapes this accounts for perhaps 80% of the total drag. Reverting to our concept of momentum transport across layers of fluid as the drag mechanism, it is reasonable to postulate that the skin friction drag is proportional to the change in fluid velocity with distance from the surface. This may be expressed mathematically as

$$D_f = \mu A \left.\frac{du}{dy}\right|_{y=0} \tag{36}$$

where A is the surface area and μ is the coefficient of viscosity, a property of the particular fluid which usually varies with temperature. A very accurate relation for air is that due to Sutherland:

$$\mu = \mu_{ref} \left(\frac{T}{T_{ref}}\right)^{3/2} \frac{T_{ref} + 198}{T + 198} \ . \tag{37}$$

The values for temperature, T, should be given in °R. For $T_{ref} = 519°R$, $\mu_{ref} = 373 \times 10^{-9}$ slugs/ft-secs.

---

* CONTINUED

The potential solution employed by Bhateley and McWhirter represents the airfoil surface by straight line segments and the vorticity distribution by linear variations between values at the corner points. This seems a bit strange in view of Hess's comment in Reference 82.

The troublesome trailing edge condition has also been the subject of several recent, extended, theoretical investigations. Spence (Ref. 70) presents a very graphic explanation of the problems and argues that because of the presence of a viscous wake the circulation around the airfoil should be multiplied by the factor

$$1 - \left(\frac{C_D}{4\pi}\right)\left(\ell n \frac{4}{C_D}\right) \ .$$

For a typical two-dimensional value of $C_D \approx 0.01$ this factor is about .995. Riley and Stewartson (Ref. 71) in examining the flow in the neighborhood of airfoil trailing edges conclude that if the angle of attack is small and the trailing edge angle is less than $1/Re^{\frac{1}{4}}$ then the flow will be maintained, without separation, up to the trailing edge. This is obviously a necessary condition for treating the effects of the viscous wake in a more general way since it establishes the point at which the flow leaves the surface although not necessarily the angle at which it leaves or its radius of curvature.

76

It is apparent from an examination of (36) that the problem in evaluating D_f (and δ^* for that matter) comes in finding

$$\left.\frac{du}{dy}\right|_{y=0}$$

as a function of position on the airfoil surface. One would like to integrate the local value of D_f over the total wetted surface to find the total skin friction drag. Several things complicate the problem:

1. The thickness of the boundary layer can be shown to depend upon the local Reynolds number, $\rho V_x/\mu$.

2. The character of the boundary layer—whether it flows in well-defined layers or lamina, or whether it flows in a more disorderly or turbulent fashion which one can only represent rather approximately—is also dependent upon the local Reynolds number <u>and</u> the condition of the surface. Further, the boundary layer may change from laminar to turbulent during the course of its travel over the airfoil.

3. The thickness of either a laminar or turbulent boundary layer depends upon the nature of the pressures outside the boundary layer. If the pressures are such that the flow tends to accelerate (high pressure upstream and lower pressure downstream) then the boundary layer grows very slowly. If the reverse is true (decelerating flow) the boundary layer grows rapidly. It may .even separate from the surface entirely.

The analysis of two-dimensional boundary layer flows to find $\delta^*(x)$ and $C_f(x)$ where $C_f = D_f/\frac{1}{2}\rho V^2$(unit area) is considerably simplified if we are willing to assume (1) the flow is incompressible, (2) there is no heat transfer from the surface to the flow, (3) the boundary layer is laminar, and (4) the pressure across the boundary layer is constant. With these assumptions the mass conservation Equation (1) has the same form as in the inviscid analysis. The x-momentum Equation (5) has a viscous stress term

$$\mu \frac{\partial^2 u}{\partial y^2}$$

added to it while the y-momentum equation reduces to $\partial P/\partial y = 0$. Thus the equations for this analysis are written

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{38}$$

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{1}{\rho} \frac{\partial P}{\partial x} + \nu \frac{\partial^2 u}{\partial y^2} \quad .$$

Since $\partial P/\partial y = 0$, we can use the relationship between pressure and velocity in the free stream just outside the boundary layer to express

$$-\frac{1}{\rho} \frac{\partial P}{\partial x} \text{ as } u_e \frac{\partial u_e}{\partial x} \quad .$$

See for example Equation (30). With this, (38) becomes

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0$$

<div align="right">(39)</div>

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = u_e \frac{\partial u_e}{\partial x} + v \frac{\partial^2 u}{\partial y^2} \ .$$

Now if we multiply the first equation of (39) by $(u_e - u)$ and subtract from this the second equation we obtain

$$\frac{\partial}{\partial x}\left[u(u_e - u)\right] + \frac{\partial}{\partial y}\left[v(u_e - u)\right] + \left(u_e - u\right)\frac{\partial u_e}{\partial x} + v \frac{\partial u_e}{\partial y} = -v \frac{\partial^2 u}{\partial y^2} \ . \quad (40)$$

The term $\partial u_e/\partial y = 0$ because u_e does not change in the y-direction in the boundary layer. If we now define

$$\delta^* = \int_0^\delta \left(1 - \frac{u}{u_e}\right) dy \ ,$$

<div align="right">(41)</div>

$$\theta = \int_0^\delta \frac{u}{u_e}\left(1 - \frac{u}{u_e}\right) dy$$

and rewrite (40) as

$$\frac{\partial}{\partial x}\left[u_e^2 \left(\frac{u}{u_e}\left[1 - \frac{u}{u_e}\right]\right)\right] + \frac{\partial}{\partial y}\left[v\,(u_e - u)\right] + u_e\left(1 - \frac{u}{u_e}\right)\frac{\partial u_e}{\partial x} = -v \frac{\partial^2 u}{\partial y^2}$$

or

$$\frac{\partial}{\partial x}\left[u_e^2 \frac{\partial \theta}{\partial y}\right] + \frac{\partial}{\partial y}\left[v\,(u_e - u)\right] + u_e \frac{\partial \delta^*}{\partial y}\frac{\partial u_e}{\partial x} = -v \frac{\partial^2 u}{\partial y^2} \ , \quad (42)$$

we can integrate with respect to y to obtain

$$\frac{\partial}{\partial x}\left[u_e^2\, \theta\right] + \int_0^\delta \left\{\frac{\partial}{\partial y}\left[v\,(u_e - u)\right]\right\} dy + u_e\, \delta^* \frac{\partial u_e}{\partial x} = v \left.\frac{\partial u}{\partial y}\right|_{y=0}. \quad (43)$$

Note that

$$\int_0^\delta v \frac{\partial^2 u}{\partial y^2} dy = v \left[\left.\cancel{\frac{\partial u}{\partial y}}^{\,0}\right|_{y=\delta} - \left.\frac{\partial u}{\partial y}\right|_{y=0}\right]$$

and by the first equation of (39)

78

$$\int_0^\delta \left\{ \frac{\partial}{\partial y} \left[v \left(u_e - u \right) \right] \right\} dy = \int_0^\delta \left\{ - \left(u_e - u \right) \frac{\partial u}{\partial x} + v \frac{\partial u_e}{\partial y} - v \frac{\partial u}{\partial y} \right\} dy$$

$$= \int_0^\delta \left\{ - \left(u_e - u \right) \frac{\partial u}{\partial x} + \frac{\partial u}{\partial y} \int_0^\delta \frac{\partial u}{\partial x} \, dy \right\} dy$$

$$= \int_0^\delta \left\{ - \left(u_e - u \right) \frac{\partial u}{\partial x} \right\} dy + \int_0^\delta \left(u_e - u \right) \frac{\partial u}{\partial x} \, dy = 0.$$

Thus (43) is

$$\frac{d\theta}{dx} + \frac{2\theta + \delta^*}{u_e} \frac{du_e}{dx} = \frac{\nu}{u_e^2} \frac{\partial u}{\partial y}\bigg|_{y=0} . \tag{44}$$

We should note that (44) is only an approximate description of boundary layer flow because the process of integration used to obtain (43) in effect smooths out local departures from mean values. Further, although we intuitively understand what we mean by the outer edge of the boundary layer, the fact is we have never defined this value of y precisely. The approximate method, however, gives results which are within a few percent of those obtained with exact solutions in the few cases where the latter are known. For this reason and the ease with which it is applied to airfoil-like bodies, we shall find this approximate technique extremely useful. Empirical corrections to improve the agreement with experiment can be applied at the conclusion of the calculation if desired.

To complete the solution of (44), that is to find $\delta^*(x)$ and $\mu \frac{\partial u}{\partial y}\big|_{y=0}$ (x) which we need to calculate the form drag and the skin friction drag respectively, we need an expression for u(y). We shall assume, following Pohlhausen, that we can represent this function by the polynomial

$$\frac{u}{u_e} = A\eta + B\eta^2 + C\eta^3 + D\eta^4 \tag{45}$$

where $\eta = y/\delta$. We choose this polynomial because it is the lowest order polynomial which can represent the essential character of what we know of boundary layer flow and is the highest order polynomial for which we can easily evaluate the constants. The constants are found from the boundary conditions:

$$\text{at} \quad y = 0, \quad u = 0; \quad \frac{dp}{dx} = -\rho u_e \frac{du_e}{dx}$$

$$y = \delta, \quad u = u_e; \quad \frac{\partial u}{\partial y} = 0; \quad \frac{\partial^2 u}{\partial y^2} = 0 . \tag{46}$$

The result is that

$$A = 2 + \frac{1}{6} \frac{\delta^2}{\nu} \frac{du_e}{dx} ; \qquad B = -\frac{1}{2} \frac{\delta^2}{\nu} \frac{du_e}{dx}$$

$$C = -2 + \frac{1}{2} \frac{\delta^2}{\nu} \frac{du_e}{dx} ; \qquad D = 1 - \frac{1}{6} \frac{\delta^2}{\nu} \frac{du_e}{dx} . \tag{47}$$

79

Substitution of (47) into (45) yields

$$\frac{u}{u_e} = 2\eta - 2\eta^3 + \eta^4 + \frac{1}{6}\frac{\delta^2}{\nu}\frac{du_e}{dx}\left(\eta - 3\eta^2 + 3\eta^3 - \eta^4\right)$$

or

$$\frac{u}{u_e} = \left[2 + \frac{1}{6}\frac{\delta^2}{\nu}\frac{du_e}{dx}\right]\eta - \frac{1}{2}\frac{\delta^2}{\nu}\frac{du_e}{dx}\eta^2 - \left[2 - \frac{1}{2}\frac{\delta^2}{\nu}\frac{du_e}{dx}\right]\eta^3 + \left[1 - \frac{1}{6}\frac{\delta^2}{\nu}\frac{du_e}{dx}\right]\eta^4.$$

$$(48)$$

du_e/dx of course is found from the potential, or inviscid, solution. Equation (48) may be substituted into (41) to obtain

$$\delta^* = \delta\left[\frac{3}{10} - \frac{1}{120}\frac{\delta^2}{\nu}\frac{du_e}{dx}\right]$$

$$(49)$$

$$\theta = \delta\left[\frac{37}{315} - \frac{1}{945}\frac{\delta^2}{\nu}\frac{du_e}{dx} - \frac{1}{9072}\left(\frac{\delta^2}{\nu}\frac{du_e}{dx}\right)^2\right].$$

The local shearing stress on the surface, $\mu\left.\frac{\partial u}{\partial y}\right|_{y=0}$, is simply

$$\frac{\mu u_e}{\delta}\left[2 + \frac{1}{6}\frac{\delta^2}{\nu}\frac{du_e}{dx}\right].$$

$$(50)$$

To complete the numerical evaluation of δ^* and the shearing stress, $\tau_{y=0}$, we substitute (49) and (50) into (44) to obtain

$$\frac{37}{315}\frac{d\delta}{dx} - \frac{3\delta^2}{945\,\nu}\frac{du_e}{dx}\frac{d\delta}{dx} - \frac{5\delta^4}{9072\,\nu^2}\left(\frac{du_e}{dx}\right)^2\frac{d\delta}{dx} - \frac{1}{945}\frac{\delta^2}{\nu}\frac{d^2u_e}{dx^2} - \frac{2\delta^4}{9072\,\nu^2}\frac{du_e}{dx}\frac{d^2u_e}{dx^2}$$

$$+ \frac{2\delta}{u_e}\left[\frac{37}{315} - \frac{1}{945}\frac{\delta^2}{\nu}\frac{du_e}{dx} - \frac{1}{9072}\left(\frac{\delta^2}{\nu}\frac{du_e}{dx}\right)^2\right]\frac{du_e}{dx} + \frac{\delta}{u_e}\left[\frac{3}{10} - \frac{1}{120}\frac{\delta^2}{\nu}\frac{du_e}{dx}\right]\frac{du_e}{dx}$$

$$= \frac{\mu}{\rho u_e\delta}\left[2 + \frac{1}{6}\frac{\delta^2}{\nu}\frac{du_e}{dx}\right]$$

or

$$\left[\frac{37}{315} - \frac{3\delta^2}{945\,\nu}\frac{du_e}{dx} - \frac{5\delta^4}{9072\,\nu^2}\left(\frac{du_e}{dx}\right)^2\right]\frac{d\delta}{dx} - \frac{1}{945}\frac{\delta^2}{\nu}\frac{d^2u_e}{dx^2} - \frac{2\delta^4}{9072\,\nu^2}\frac{du_e}{dx}\frac{d^2u_e}{dx^2}$$

$$+ \frac{2\delta}{u_e}\left[\frac{37}{315} - \frac{1}{945}\frac{\delta^2}{\nu}\frac{du_e}{dx} - \frac{1}{9072}\left(\frac{\delta^2}{\nu}\frac{du_e}{dx}\right)^2\right]\frac{du_e}{dx} + \frac{\delta}{u_e}\left[\frac{3}{10} - \frac{1}{120}\frac{\delta^2}{\nu}\frac{du_e}{dx}\right]\frac{du_e}{dx}$$

$$= \frac{\mu}{\rho u_e\delta}\left[2 + \frac{1}{6}\frac{\delta^2}{\nu}\frac{du_e}{dx}\right].$$

$$(51)$$

Equation (51) is a highly non-linear first-order ordinary differential equation
with δ the dependent variable and x the independent variable. Note that u_e,
du_e/dx, d^2u_e/dx^2 must all be supplied as data from the external, or potential,
solution and the value of each of these quantities depends upon the particular
value of x. The equation may be solved by predicting $d\delta/dx$, solving the
resultant polynomial for δ and then checking to be sure that the predicted
value of $d\delta/dx$ is sufficiently close to that found. If not, the process is
repeated until sufficient accuracy is achieved. In the interests of speed
and accuracy the solution is best obtained on a digital computer. The solution
will be in the form of δ for each value of x along the chord for each surface.
By the use of the first equation of (49) and by (50) one can find then $\delta^*(x)$
and $\tau_{y=0}(x)$. Schlichting (Ref. 65) gives the more common evaluation of (51).

As a check on the solution technique one can look at (51) as applied to
a flat plate at zero angle of attack. Under these circumstances (51) reduces
to

$$\frac{37}{315} \frac{d\delta}{dx} = \frac{2\mu}{\rho u_e \delta} .$$

(52)

This has the solution

$$\frac{\delta^2}{2} = \frac{630}{37} \frac{x\mu}{\rho u_e}$$

or

$$\delta = \frac{5.84 \; x}{\sqrt{\frac{\rho u_e x}{\mu}}} = \frac{5.84 \; x}{\sqrt{R_{e_x}}} .$$

(53)

This overestimates the value of δ by about 1.8% compared with more exact
solutions. δ^* is therefore also high by about 1.2%.

The effect of du_e/dx is to reduce δ for a given x when du_e/dx is
positive and increase it when du_e/dx is negative. Both types of behavior
will be present on airfoils. From the leading edge to the crest on the upper
surface of the airfoil du_e/dx will be positive. From the crest aft, du_e/dx
will be negative. The boundary layer will therefore be very thin up to the
crest and will begin to grow rapidly downstream of that point.

If the du_e/dx is sufficiently negative and persists for a sufficient
extent of x it will cause the boundary layer to leave the surface. This
condition is manifest to the pilot as a stall or loss of lift accompanied by
a sharp increase in drag. Usually, the flight Reynolds number, airfoil
geometry, and surface condition are such that the boundary layer becomes
turbulent before separation occurs so that we will postpone our discussion
of how to calculate the aerodynamic characteristics near maximum lift.

Assuming we now have the value of $\delta^*(x)$ as calculated above, how do we
use it to correct the surface pressure values obtained from the inviscid
computation? By adding $\delta^*_{upper \; surface}$ to the actual upper surface
ordinates and $\delta^*_{lower \; surface}$ to the actual lower surface ordinates we
obtain a new fatter airfoil. We submit these new ordinates to the inviscid
computation procedure and obtain a new pressure distribution. If du_e/dx

is substantially different from what we used to compute $\delta^*(x)$ we must use the new values of du_e/dx in a predictor-corrector scheme to compute a new $\delta^*(x)$. The process must be repeated until the values of du_e/dx obtained from the inviscid computation agree with what we used in computing $\delta^*(x)$. Generally, as speed and aircraft size increase, fewer iterations will be required to achieve satisfactory agreement because the boundary layer will be proportionately thinner.

As we have noted there are a number of things which can cause a laminar boundary layer to become turbulent: existence of a large Reynolds number, surface roughness, and to some degree the sign on du_e/dx. Because wings on light aircraft will usually experience a turbulent boundary layer on at least some portion of their surfaces it is necessary to examine how the procedure to calculate δ^* and $\tau_{y=0}$ are altered for this conditon and how one determines when to change from laminar to a turbulent calculation. It should be recognized at the outset that turbulent motion is a very complex phenomenon, never successfully treated in a completely analytical fashion. It is necessary therefore to employ rather crude analytical models or semi-empirical correlations in order to retain the usual equations of motion (38) as the describing equations of the fluid behavior. Following this approach we observe that Equation (44) may also be used to represent turbulent boundary layer flow provided we use a suitable relation for skin friction in place of

$$\mu \left.\frac{\partial u}{\partial y}\right|_{y=0}$$

and a consistent expression for $u(y)$. One empirical formula for $\tau_{y=0}$ which finds considerable use is that due to Ludwieg and Tillmann (as quoted in Ref. 65):

$$\tau_{y=0} = \frac{\rho u_e^2 \left(0.123 \times 10^{-0.678 \frac{\delta^*}{\theta}}\right)}{\left(\frac{u_e \theta}{\nu}\right)^{0.268}} \quad . \tag{54}$$

The relation for the velocity profile commonly used in related studies is

$$\frac{u}{u_e} = \left(\frac{y}{\delta}\right)^{\frac{1}{n}} \quad , \tag{55}$$

where n is between 4 and 6, but is usually taken to be the latter value.

The use of (54) in (44) still leaves the equation non-integrable because an explicit relation between δ^* and θ has not been given. This could be developed from the definitions of θ and δ^*, (41) and (55), or the problem skirted by proceeding as follows: Multiply the second equation of (39) by u and then integrate with respect to y. We obtain what might be termed an energy integral equation

$$\frac{1}{u_e^3} \frac{d}{dx}\left[u_e^3 \delta^{**}\right] = \int_0^\delta \frac{\tau_{y=0}}{\rho u_e^2} \frac{\partial}{\partial y}\left(\frac{u}{u_e}\right) dy \quad , \tag{56}$$

82

analogous to the momentum integral Equation (44). The name of course refers to the fact that momentum times velocity has the units of energy. Note that

$$\delta^{**} = \int_0^\delta \frac{u}{u_e}\left(i - \frac{u^2}{u_e^2}\right) dy \quad .$$

(57)

It has been found experimentally that there exists a unique relationship between δ^*/θ and δ^{**}/θ which can be expressed as

$$\frac{\delta^{**}}{\theta} = \frac{1.269\frac{\delta^*}{\theta}}{\frac{\delta^*}{\theta} - 0.379} \quad .$$

(58)

Experiments have also led to the conclusion that

$$\int_0^\delta \frac{\tau_{y=0}}{\rho u_e^2}\frac{\partial}{\partial y}\left(\frac{u}{u_e}\right) dy = \frac{0.56 \times 10^{-2}}{\left(\frac{u_e\theta}{\nu}\right)^{1/6}} \quad .$$

(59)

Substitution of these experimental results, (58) and (59), into (56) yields

$$\frac{1}{u_e^3}\frac{d}{dx}\left[\frac{1.269\, u_e^3\frac{\delta^*}{\theta}\theta}{\frac{\delta^*}{\theta} - 0.379}\right] = \frac{0.56 \times 10^{-2}}{\left(\frac{u_e\theta}{\nu}\right)^{1/6}}$$

(60)

while (54) substituted into (44) gives

$$\frac{d\theta}{dx} + \frac{2\theta + \delta^*}{u_e}\frac{du_e}{dx} = \frac{0.123 \times 10^{-0.678\frac{\delta^*}{\theta}}}{\left(\frac{u_e\theta}{\nu}\right)^{0.268}} \quad .$$

(61)

Simultaneous solutions of (60) and (61) will yield $\delta^*(x)$ and $\theta(x)$. When these results are substituted into (54) one has $\tau_{y=0}(x)$. The skin friction drag is then computed by integrating $\tau_{y=0}(x)$ over both surfaces:

$$D_f = \left[\int_0^c \tau_{y=0}(x)\, dx\right]_{\text{upper surface}} + \left[\int_0^c \tau_{y=0}(x)\, dx\right]_{\text{lower surface}} \quad .$$

(62)

The dimensions of D_f are force per unit span. As noted previously, at low angles of attack, the drag as computed by (62) should be about 4 times that found by (35). As α increases, the form drag tends to predominate. The total drag of course is the sum of the drags calculated from (35) and (62).

The correct expression for $\tau_{y=0}$ in (62) depends, as has been indicated, on whether the boundary layer is laminar or turbulent or some combination thereof. Generally one would expect that the boundary layer is laminar over the forward

portion of the wing and then changes—goes through what is called transition—to a turbulent boundary layer. Thus, Equation (50) would give the correct expression for $\tau_{y=0}$ upstream of the transition point and (54) gives the correct expression for $\tau_{y=0}$ downstream of this point. Since the boundary layer already has a finite thickness at the transition point, one chooses as a starting point for the turbulent calculation that point which will give the same δ at the transition point as the laminar solution beginning at the leading edge. The laminar values of $\tau_{y=0}$ and δ^* are used up to transition and the turbulent values downstream. They are approximately the same at transition.

The beginning of transition has been found to occur at a Reynolds number between 3×10^5 and 4×10^6. This is a very substantial range. As a point of reference consider that the Reynolds number per foot of chord for a airplane flying at 200 ft/sec at sea level is 1.275×10^6. Transition could, according to this criterion, occur anywhere from 4" from the nose to 3 ft from the nose. Since the chord for most light aircraft is at least 4 ft, the boundary layer on the aft portion of the wing will always be turbulent. Whether the transition begins 4" from the nose or 3 ft from the nose depends upon such things as surface roughness, free stream turbulence, and du_e/dx. The latter influence, however, is the only one which can be determined *a priori*, that is, before the wing is built and flown under particular conditions. It is, therefore, the only one we will attempt to evaluate.

A laminar boundary layer is said to be unstable—that is, it tends to become turbulent—when a velocity disturbance in this boundary layer can grow. Tollmein was able to show that a necessary and sufficient condition for neutral stability of disturbances in laminar boundary layers is the existence of a point of inflection in the boundary layer's velocity profile, $u(y)$.

Using a sixth order polynomial to represent the velocity profile, Schlichting and Ulrich were able to plot a relationship between the value of $u_e\delta^*/\nu$ for which an inflection point exists and $\delta^2 du_e/\nu dx$. With this plot one can take the values of δ, δ^*, u_e, du_e/dx, and ν and determine whether or not the boundary layer is unstable. The precise distance between the onset of transition and the point of neutral stability as determined above depends upon the rate of amplification of disturbances in the boundary layer and consequently upon du_e/dx in that region. It has been found that plotting experimental data on a graph where

$$\left(\frac{u_e\theta}{\nu}\right)_{transition} - \left(\frac{u_e\theta}{\nu}\right)_{neutral \ stability}$$

is the ordinate and

$$\frac{\int_{x_{n.s.}}^{x_{tr}} \frac{\theta^2}{\nu} \frac{du_e}{dx} dx}{x_{tr} - x_{n.s.}}$$

84

is the abscissa leads to excellent correlation of the data. For a laminar boundary layer we know θ, u_e, du_e/dx, and $(\theta^2/\nu)(du_e/dx)$ as functions of x. We also know $(u_e\theta/\nu)_{n.s.}$ because we know the relationship between θ and δ^*. Marching downstream of the neutral stability point we can easily find a $u_e\theta/\nu$ and an $x_{tr} - x_{n.s.}$ for each point. The other data then permits us to locate a point on the graph for each value of x. The first point which falls on or above the data correlation is taken as the x-location for which transition has taken place.

In addition to the change in δ^* and $\tau_{y=0}$ as one goes from laminar to turbulent boundary layer another type of behavior associated with boundary layer flows which significantly affects the lift, drag and moment characteristics of the airfoil in boundary layer separation is usually identified by the disappearance of the local skin friction, *i.e.* when

$$\frac{du}{dy}\bigg|_{y=0} = 0 \ .$$

The geometry of very thin airfoils is such that regions of laminar separation or separation followed by reattachment confined to the front half of the airfoil are possible at moderate angles of attack. However, light aircraft operating at moderate Mach numbers can be expected to employ airfoils of 12% or greater thickness for which this type of phenomenon is not to be expected. The separation characteristic of thick airfoils is a turbulent separation from the region of the trailing edge. Thus, if one terminates the calculation of δ^* and $\tau_{y=0}$ at that angle of attack for which $\tau_{y=0} = 0$ over a significant portion of the airfoil, he is reasonably assured of having closely approached $C_{L_{max}}$. This is about the most one could expect of the procedure outlined above.

Perhaps it would now be appropriate to review briefly and comment upon the procedure for estimating the aerodynamic characteristics of airfoils as developed up to this point.

1. We first locate the vortex filaments, taking care that we space them sufficiently close together to represent the surface accurately. This is particularly important in regions of high curvature and/or regions where the surface slope is significantly different from the free stream flow direction.

2. Equations (29) are then solved for a particular angle of attack to obtain the values of all Γ_N. These values are then substituted into (19) to obtain the net induced velocities and the surface pressures computed from (33).

3. The lift and drag are evaluated by (34) and (35). The drag at this point should be zero.

4. $u_e(x)$ is evaluated from (32) for both surfaces. Data smoothing procedures are employed to insure that the results represent physical reality as closely as possible with as few inflection points as possible. du_e/dx and d^2u_e/dx^2 are then calculated numerically.

5. $\delta(x)$ for both surfaces is then found from a solution to (57). $\delta^*(x)$ is obtained from (49) and $\tau_{y=0}$ from (50).

6. The location of transition is identified and the turbulent boundary layer computation begun using (60) and (61) and then (54). At the conclusion of this process one has complete values of $\delta^*(x)$ and $\tau_{y=0}(x)$ for both surfaces.

7. $\delta^*(x)$ is then added to the physical ordinates of the airfoil along with artificial trailing edge found by extending the chord

$$\delta^*(c)\bigg/\frac{dy}{dx}\bigg|_{x=c} .$$

8. The previous seven steps are then repeated for the new ordinates.

9. The new value of du_e/dx is compared with the value obtained from step 4. If they differ by more than a few percent, we modify our estimates of $\delta^*(x)$ according whether du_e/dx seems to favor larger or smaller values of δ^*.

10. The process is repeated until the final value of du_e/dx would give the same $\delta^*(x)$ as used in the inviscid calculation. Obviously, care must be taken to insure that adequate precision is maintained during such an extensive series of computations, else the resulting numbers are meaningless.

11. The procedure is valid for a Mach number of zero. Since most light aircraft operate at Mach numbers not far above zero, the simple Prandtl-Ghauert correction to the pressures for Mach number effects is usually quite adequate:

$$P_x = P_\infty + \frac{(P_x - P_\infty)_{M=0}}{\sqrt{1 - M_\infty^2}} . \tag{63}$$

12. The corrected pressure is then applied to the physical boundaries of the airfoil to obtain the lift and form drag according to (34) and (35). The skin friction drag is computed with (62) using the most updated value of $\tau_{y=0}(x)$.

13. The pitching moment about the leading edge can be computed by integrating the product of the pressure forces and the distance from the nose

$$M = \oint P(x) \ x \ \cos\left[\tan^{-1}\frac{dy}{dx}\bigg|_x\right]dx + \oint P(x) \ y \ \sin\left[\tan^{-1}\frac{dy}{dx}\bigg|_x\right]dx. \tag{64}$$

There will also be a small contribution to the moment from the skin friction forces but these are (a) generally in the chordwise direction and (b) the moment generated by the friction on the upper surface opposes that generated by the friction on the lower surface. As a result the net contribution is generally small enough to neglect.

EXTENSION TO THREE DIMENSIONS: THE FINITE WING

The theoretical procedure described above provides a means for estimating the aerodynamic characteristics of a section of an infinite wing. Real wings, of course, have to have ends and frequently, for reasons that will become apparent as the discussion proceeds, are tapered, twisted, and change airfoil sections with changes in span locations.

Some means must therefore be found to account for such influences in determining the aerodynamic characteristics of complete wings. The principal considerations in wing design are (1) low drag for good performance, (2) light weight with adequate strength for good payload capacity, and (3) fairly simple structure with few changes in shape for low cost in manufacturing. We shall be concerned here with means for calculating the lift, drag and moments of wings which we will assume satisfy the latter two criteria. We will also limit our consideration to unswept wings of moderate-to-high span-to-chord (aspect) ratio. Further, in order to keep the computation to a reasonable length we would like the technique we employ to use as much of the previous result as possible. In order to do so we ask the question, what are the effects of ends, twist, and taper? If an untapered wing has the same airfoil over its entire span then it would seem reasonable to conclude that, at least near the center, twisting the wing has the effect of changing the local angle of attack. It will be recalled that the two-dimensional calculation is carried out for specific angle of attack. Generally, both lift and drag increase with increasing angle of attack. Twist will therefore change the local lift and drag values.

The existence of a wing tip permits high pressure air from the lower surface of the wing to flow up around the tip to the low pressure regions on the upper surface. The result is that the lift in the tip regions is reduced and a vortex filament is created. This filament begins near the tip and extends downstream in a plane parallel to the fuselage. The fact that in theory vortices must be closed or infinite led to the thought that since a vortex is actually observed extending rearward from the tip regions of lifting wings, some sort of vortex system must also extend from tip to tip. If this is true, perhaps one could actually represent such a wing by a series of "horseshoe"-like vortices which "roll up" in the tip regions to form a single vortex extending to infinity. A series of horseshoe vortices with different strengths would enable one to represent a variety of lift distributions on a wing. If the wing has a moderate-to-high aspect ratio, little or no sweep, and moderate dihedral then it would seem that one could take the various vortex filaments as being co-linear with little error. Such an assumption, the so-called lifting-line theory of Prandtl, obviously leads to fewer mathematical difficulties than having to consider a chord-wise lattice of vortices or a lifting surface. Because most light aircraft wings meet the criteria for applicability of the lifting line theory and because we intend to use the theory only to modify our 2-dimensional results, we expect the procedure to give us accurate results.

It will be observed that a horseshoe system with the trailing vortex's velocity moving inboard over the upper surface and outboard under the lower surface induces an upwash component ahead of the wing and a downwash component behind the wing. This combination of upwash ahead and downwash

behind the wing is, in effect, a change in local angle of attack in so far as the flow facing a section of wing is concerned. The finite span of the wing can therefore be thought of as producing the same effect as does geometric twist. For consistency it would seem to be convenient to attempt to represent the effects of taper also as a change in local angle of attack. If we are successful in this endeavor, we have reduced the entire procedure for calculating the lift, drag, and moment characteristics of complete wings to one of (1) finding the effective local angle of attack by the lifting line theory, (2) determining the two-dimensional or section characteristics corresponding to these effective local values of α by reference to equations or tables computed by the methods discussed above, and then (3) integrating these section characteristics over the entire wing area to average the values.

In current designs, wings are not free entities but are attached to large structures such as fuselages. It is important, therefore, to model the fuselage-wing junction region in such a manner that the effects of its presence can be handled within the framework of a method to calculate finite wing characteristics. We do this by mathematically transforming this region of the fuselage into a part of the wing. Other examples of the use of mathematical transformations to simplify the analysis of complex problems are well known. Problems involving flow through pipes, structural analysis of tubes, etc. become much simpler when transformed from Cartesian or rectangular coordinates to cylindrical coordinates. Differential equations become algebraic when transformed from the time domain to the frequency domain. Complex shapes, such as airfoils, can be transformed into circles about which the flow behavior is well known. The flow at any point about an airfoil can then be found by locating the equivalent point on the circle.

Generally, in selecting a transformation we seek one which either simplifies the mathematical representation of a physical situation or, as in the present case, distorts a complex shape into a simpler shape for which the physical phenomena are well understood and easily analyzed. We then go through an _inverse_ transform to find how the well-understood behavior distorts in going back to the original physical situation. Devising a suitable transform is usually a trial and error process, guided by experience, skill, and to some extent, luck. Certain mathematical requirements must also be met, dependent upon the framework in which the transform is used. The transform used here was devised by H. Multhopp (Ref. 51).

The thought processes followed by Multhopp in devising the transform shown below for elliptical cross-section fuselages probably included these elements: Under the Joukowski transform,

$$\zeta = z + \frac{c^2}{z} \quad ,$$

a circle in the z-plane with its center at the origin transforms to a flat plate along the ξ-axis in the ζ-plane for positive values of c^2. If one takes $c^2 = -1$, then

88

$$\zeta = \xi + i\eta = x + iy - \frac{1}{x + iy}$$

$$= x + iy - \frac{x - iy}{x^2 + y^2}$$

$$= x\left(1 - \frac{1}{x^2 + y^2}\right) + iy\left(1 + \frac{1}{x^2 + y^2}\right)$$

and the circle (of radius 1.0) transforms into a flat plate along the η-axis in the ζ-plane. From this result one concludes that a similar transform, suitably modified to account for elliptical fuselages and variable placement of the wing with respect to the origin, should produce the requisite figure.

Consider also the ellipse shown in the sketch below:
The properties of an ellipse are such that

$$A^2 - B^2 = e^2 \quad,$$

$$\frac{x^2}{A^2} + \frac{y^2}{B^2} = 1 \quad,$$

and

$$\overline{F_1 P} + \overline{F_2 P} = 2A \quad.$$

From the last statement it follows that

$$2A = \sqrt{y^2 + (h - e)^2} + \sqrt{y^2 + (h + e)^2}$$

from which one can obtain

$$A^2 = y^2 + h^2 + e^2$$

or

$$B^2 = y^2 + h^2 \quad .$$

For points <u>outside</u> the ellipse we can generalize this by writing

$$a^2 = y^2 + h^2 + e^2$$

$$b^2 = y^2 + h^2$$

$$e^2 = a^2 - b^2 \quad .$$

It has been a feature of textbooks on hydrodynamics for some years to show that the equation for mapping an ellipse in the ω-plane into a circle of radius $\frac{1}{2}(A + B)$ in the z-plane is

$$z = \tfrac{1}{2} (\omega + \sqrt{\omega^2 - e^2}) \quad .$$

Thus to map the ellipse into a flat plate we write

$$\zeta = z + \frac{\tfrac{1}{4}(A + B)^2}{z} = \tfrac{1}{2} (\omega + \sqrt{\omega^2 - e^2}) + \frac{\tfrac{1}{2}(A + B)^2(\omega - \sqrt{\omega^2 - e^2})}{\omega^2 - \omega^2 + e^2}$$

$$= \frac{(A^2 - B^2)}{2e^2} \left(\omega + \sqrt{\omega^2 - e^2}\right) + \frac{(A + B)^2}{2e^2} \left(\omega - \sqrt{\omega^2 - e^2}\right)$$

$$= \left(\frac{A^2 - B^2}{2e^2} + \frac{A^2 + 2AB + B^2}{2e^2}\right)\omega + \left(\frac{A^2 - B^2}{2e^2} + \frac{A^2 + 2AB + B^2}{2e^2}\right)(\sqrt{\omega^2 - e^2})$$

$$= \left(\frac{2A^2 + 2AB}{2e^2}\right)\omega + \left(\frac{-2AB - B^2}{2e^2}\right)\sqrt{\omega^2 - e^2}$$

$$= \frac{A}{A - B}\, \omega - \frac{B}{A - B}\sqrt{\omega^2 - e^2}$$

which is the form employed by Multhopp.

The figure below shows how the trace of the wing-fuselage combination in the y-z plane transforms from the physical u-plane to the $\bar{u}$-plane according to the relation

$$\bar{u} = \frac{1}{A' - B'} \left[A'u - B'\sqrt{u^2 - A'^2 + B'^2}\right] \quad . \tag{65}$$

u - plane

ū - plane
We use this transformation because it changes an elliptical fuselage into a thin vertical line which then provides no resistance to the vertical or induced component of flow over the wing. As we noted above, it is these vertical components which determine the magnitude of the local angle of attack. In essence, then, the transform distributes the flow components due to the fuselage over the span of the distorted wing. A similar transformation $\overline{u} = u + R^2/u$ is used for circular fuselages. More complex shapes can be handled in the same fashion through the use of a suitable transform. By writing u and $\overline{u}$ as complex variables

$$u = z + iy = a \cos \psi + ib \sin \psi$$

$$\overline{u}' = \overline{z} + i\overline{y}$$

(66)

and making the following definitions

$$a = \tfrac{1}{2}\left[\sqrt{y^2 + (h - e')^2} + \sqrt{y^2 + (h + e')^2}\right]$$

$$b = \sqrt{a^2 - e'^2}$$

(67)

$$e = \sqrt{A'^2 - B'^2} = \sqrt{a^2 - b^2}$$

91

then

$$\overline{u} = \frac{1}{A' - B'} \left[A'u - B'\sqrt{u^2 - e'^2} \right]$$

$$= \frac{1}{A' - B'} \left[A'u - B'\sqrt{u^2 - a^2 + b^2} \right] . \tag{68}$$

But

$$u^2 - a^2 + b^2 = a^2 \cos^2 \psi - b^2 \sin^2 \psi + 2abi \sin \psi \cos \psi - a^2 + b^2$$

$$= a^2(\cos^2 \psi - 1) - b^2(\sin^2 \psi - 1) + 2abi \sin \psi \cos \psi$$

$$= a^2 \sin^2 \psi + b^2 \cos^2 \psi + 2abi \sin \psi \cos \psi \tag{69}$$

$$= (b \cos \psi + ia \sin \psi)^2$$

therefore,

$$\overline{u} = \frac{1}{A' - B'} \left[A'u - B'(b \cos \psi + ia \sin \psi) \right]$$

$$= \frac{1}{A' - B'} \left[A'z + iA'y - B'b \cos \psi - iB'a \sin \psi \right] \tag{70}$$

$$= \frac{1}{A' - B'} \left[(A'z - B'b \cos \psi) + i(A'y - B'a \sin \psi) \right] = \overline{z} + i\overline{y} .$$

Comparing real and imaginary parts, one finds that

$$\overline{y} = \frac{1}{A' - B'} \left[A'y - B'a \sin \psi \right] . \tag{71}$$

Since

$$y = b \sin \psi = \sqrt{a^2 - e'^2} \sin \psi$$

then

$$\sin \psi = \frac{y}{\sqrt{a^2 - e'^2}} .$$

One may therefore write for $\overline{y}$

$$\overline{y} = \frac{y}{A' - B'} \left[A' - B' \frac{a}{\sqrt{a^2 - e'^2}} \right] . \tag{72}$$

This relationship determines how points along the span in the physical or u-plane transform into the $\overline{u}$-plane.

92

We seek now to find how the flow in the neighborhood of the fuselage influences the flow direction and magnitude at each station along the wing's span. The real part of $d\bar{u}/du$ in effect distributes the vertical components of the fuselage flow along the wing. If α_B is the fuselage angle of attack in the $\bar{u}$-plane then the induced* upwash along the span is given by

$$\Delta\alpha(y) = \left[R \frac{d\bar{u}}{du} - 1 \right] \alpha_B \quad . \tag{73}$$

Because of the nature of the transformation α_B will have the same value in either plane.

Now
$$\frac{d\bar{u}}{du} = \frac{1}{A' - B'} \left[A' - \frac{B'u}{\sqrt{u^2 - e'^2}} \right]. \tag{74}$$

The real part of $d\bar{u}/du$ is, of course, its vertical component:

$$\frac{d\bar{u}}{du} = \frac{1}{A' - B'} \left[A' - B' \frac{a \cos\psi + ib \sin\psi}{b \cos\psi + ia \sin\psi} \right]$$

$$= \frac{1}{A' - B'} \left[A' - B' \frac{(a \cos\psi + ib \sin\psi)(b \cos\psi - ia \sin\psi)}{(b \cos\psi + ia \sin\psi)(b \cos\psi - ia \sin\psi)} \right]$$

$$\therefore \quad R \frac{d\bar{u}}{du} = \frac{1}{A' - B'} \left[A' - B' \frac{ab(\cos^2\psi + \sin^2\psi)}{b^2 \cos^2\psi + a^2 \sin^2\psi} \right]$$

$$= \frac{1}{A' - B'} \left[A' - B' \frac{ab}{b^2 \left(1 - \frac{y^2}{b^2} + \frac{a^2 y^2}{b^2} \right)} \right] \tag{75}$$

$$= \frac{1}{A' - B'} \left[A' - B' \frac{\frac{a}{\sqrt{a^2 - e'^2}}}{1 + \frac{e'^2 y^2}{(a^2 + e'^2)^2}} \right] \quad .$$

If the wing is very thick at its junction with the fuselage then the actual $\Delta\alpha$ obtained is less than that predicted by (73). It has been suggested that one should therefore reduce (73) by a factor T, taken as constant across the wing span, which is the ratio of the body cross-sectional area above and below the wing to the total frontal area of the body. The area of the

---

* The amount by which the flow angularity exceeds that due to geometric inclination.

elliptical fuselage is of course $\pi A'B'$. The segment of the fuselage which represents a continuation of the wing has an area of approximately $2y_0 t_{root}$. Thus

$$T = 1 - \frac{2 \; y_0 \; t_{root}}{\pi A'B'} \qquad (76)$$

and a more general expression for (73) is

$$\Delta\alpha(y) = T \; \alpha_B \left[\frac{R}{} \frac{d\overline{u}}{du} - 1 \right] \; . \qquad (77)$$

We could also have written (77) as

$$\Delta\alpha(y) = \alpha_B \left[\left(\frac{R}{} \frac{d\overline{u}}{du} \right)_T - 1 \right] \qquad (78)$$

if we had known how to write

$$\left(\frac{R}{} \frac{d\overline{u}}{du} \right)_T$$

explicitly. However, by comparing (77) and (78) we find that as a first approximation

$$\left(\frac{R}{} \frac{d\overline{u}}{du} \right)_T = 1 + T \left[\frac{R}{} \frac{d\overline{u}}{du} - 1 \right] \; . \qquad (79)$$

In addition to the flow angularity induced along the wing by the presence of a fuselage there is also a flow angle (a downwash) induced by the lift associated with a finite wing. This angle in the $\overline{u}$-plane is written $\overline{\alpha}_i(\overline{y})$. We seek now to transform this angle into the u-plane so that we may see more easily its influence on the actual lift and drag of the local airfoil section. We note that the induced angle in the $\overline{u}$-plane multiplied by the real part of the change in $\overline{u}$ for a given change in u is just the induced angle in the u-plane. Thus for thick airfoils

$$\alpha_i(y) = \overline{\alpha}_i(\overline{y}) \left[\frac{R}{} \frac{d\overline{u}}{du} \right]_T \; . \qquad (80)$$

This angle is negative in the usual sense. The geometric angle of attack of the wing can be given in terms of the angle of attack at the root and the twist relative to the root angle as a function of span: $\alpha_e(y) = \alpha_R + \epsilon(y)$. To the geometric angle we must add flow angularities due to body upwash, α_B, and due to wing lift, α_i. The result is that for thick wings the effective section angle of attack in the physical plane is given by

$$\alpha_e(y) = \alpha_R + \epsilon(y) + \left[\alpha_B - \overline{\alpha}_i(\overline{y}) \right] \left[1 + \left(1 - \frac{2 \; y_0 \; t_{root}}{\pi A'B'} \right) \right.$$
$$\left. \cdot \left(\frac{1}{A' - B'} \left\{ A' - B' \frac{\dfrac{a}{\sqrt{a^2 - e'^2}}}{1 + \dfrac{e'^2 \; y^2}{(a^2 - e'^2)^2}} \right\} \right) - 1 \right] \qquad (81)$$

94

with

$$a = \frac{1}{2} \left[\sqrt{y^2 + (h - A'^2 - B'^2)^2} + \sqrt{y^2 + (h + A'^2 - B'^2)^2} \right]$$

and

$$e = \sqrt{A'^2 - e'^2} \quad .$$

Note that with the exception of $\overline{\alpha}_i(\overline{y})$ all the quantities in (81) can be determined from the geometry of the design.

For the evaluation of $\overline{\alpha}_i(\overline{y})$ we employ a variant of the technique used to determine the inviscid velocity distribution about an airfoil section. Consider the sketch below.
Recall also that we had indicated previously that we would represent a wing by a group of horseshoe-like vortices which physically "roll-up" at the tips to form single trailing vortices. Thus the circulation Γ will vary along the span, being symmetrical about the point 0 and falling to zero at the tips. Between the point y and y + dy on the span the circulation decreases by an amount

$$- \frac{d\Gamma}{dy} dy \quad .$$

Ideally, a trailing vortex of this strength springs from the element of span dy. There is therefore a sheet of trailing vortices extending across the span and the induced velocity normal to the free stream velocity must be obtained as the sum of the effects of all trailing vortices in this sheet.

To determine the form of the expression giving the sum of the effects of all trailing vortices consider first the case of a wing represented by a single horseshoe vortex. We see from Equation (15) that the velocity induced by a vortex at a point depends upon the distance from the point to the filament. In the following sketch the distance from P to the wing filament is PM. Now in Equations (15) the total velocity, $\sqrt{u^2 + v^2}$, is normal to the line, $\sqrt{x^2 + y^2}$, connecting the filament to the point at which one desires to know the velocity. One could therefore write

$$\sqrt{u^2 + v^2} = \frac{\Gamma}{2\pi\sqrt{x^2 + y^2}} \quad . \tag{82}$$

It seems reasonable to conclude that at any point the velocity induced by a semi-infinite vortex filament is half that induced by an infinite vortex. Let us ask then what is the velocity induced at a point by a small segment of a vortex filament. We know that the velocity depends upon the distance from the segment to the point. If we call $x^2 + y^2 = r^2$, then this distance from the vortex segment at A' is $r/\sin \theta_1$ where θ_1 is the angle PA'M in the sketch below.

Substitution of this expression for distance into an expression for the velocity induced at a point, say in the XOZ plane, by a segment of a semi-infinite vortex can be seen to yield

$$dV = \frac{\Gamma \sin \theta}{4\pi r} d\theta \quad . \tag{83}$$

Integration of (83) gives

$$V_1 = \frac{\Gamma}{4\pi} \left[- \cos \theta \, \Big|_{\theta_1}^{\pi/2} \right] = \frac{\Gamma}{4\pi} \cos \theta_1 \quad . \tag{84}$$

Calculation of the contribution to the velocity from the part of the filament beyond O yields

$$V_2 = \frac{\Gamma}{4\pi} \cos \theta_2 \tag{85}$$

so that the total induced velocity is given by

$$V = \frac{\Gamma}{4\pi} (\cos \theta_1 + \cos \theta_2) \quad . \tag{86}$$

In the notation of the sketch, the downwash velocity at point P (normal to PM) may be written
$$V = \frac{\Gamma}{4\pi PM} \left[\cos PA'A + \cos PAA' \right].$$ (87)

If we now assume that point P is located along the span at, say, y_1, then the distance from y_1 to any other point is $y_1 - y$. Further, if Γ is variable along y then

$$\Gamma = \int_{-b/2}^{b/2} \frac{d\Gamma}{dy} \, dy.$$

One may therefore write the induced velocity at some point y_1 along the span as

$$V \, \alpha_i(y_1) = \frac{1}{4\pi} \int_{-b/2}^{b/2} \frac{\frac{d\Gamma}{dy} \, dy}{y_1 - y} \quad .$$

In the $\bar{u}$-plane this is simply

$$\bar{\alpha}_i(\bar{y}_1) = \frac{1}{4\pi V} \int_{-b/2}^{b/2} \frac{\frac{d\Gamma}{dy} \, d\bar{y}}{\bar{y}_1 - \bar{y}} \quad .$$ (88)

If $\bar{\alpha}_i(\bar{y}_1)$ is to be in degrees, we multiply the right hand side of (88) by $180/\pi$.

Unfortunately the circulation Γ about an airfoil is not readily measured nor is it a quantity which is easily thought of in physical terms. More commonly, the characteristic of an airfoil is stated in terms of its lift coefficient, a quantity easily measured and important in aerodynamic and structural design. It can be shown on analytical grounds (Ref. 9) that the lift per unit span of a wing is $\rho V\Gamma$ where ρ is the air density. The lift coefficient is therefore

$$C_\ell = \frac{\rho V\Gamma}{\frac{1}{2}\rho V^2 c} = \frac{2\Gamma}{Vc} \quad ;$$

hence

$$\Gamma = \tfrac{1}{2} C_\ell Vc \quad .$$ (89)

Because both C_ℓ and c can vary as functions of y we put

$$\frac{d\Gamma}{dy} = \frac{V}{2} \frac{d(C_\ell c)}{dy}$$

or in non-dimensional form

$$\frac{d\Gamma}{dy} = \frac{Vb}{2} \frac{d\left(\frac{C_\ell c}{b}\right)}{dy} \qquad (90)$$

with (90), (88) becomes

$$\overline{\alpha}_i(\overline{y}_1) = \frac{180\overline{b}}{8\pi^2} \int_{-\overline{b}/2}^{\overline{b}/2} \frac{\left[\frac{d\left(\frac{C_\ell \overline{c}}{\overline{b}}\right)}{d\overline{y}}\right]}{\overline{y}_1 - \overline{y}} \, d\overline{y} \quad . \qquad (91)$$

where $\overline{\alpha}_i(\overline{y}_1)$, is now in degrees.

We note that the transformation (65) is an analytic function (and therefore conformal). It does not, however, affect geometric quantities in the chord-wise direction so that $\overline{c} = c$. Wing twist is also not affected, nor does the transformation affect quantities such as the local value of the circulation, Γ. In other words, the circulation or lift that exists at y in the u-plane is the same circulation or lift that exists at $\overline{y}$ in the $\overline{u}$-plane:

$$C_\ell(y)c = \overline{C}_\ell(\overline{y})\overline{c} \quad . \qquad (92)$$

The key to the evaluation of Equation (81) is therefore a suitable expression for $C_\ell(y)c$, the spanwise lift distribution. Unfortunately we do not know *a priori* what it is. We do know from the two-dimensional values calculated previously and the problem geometry what lift we would obtain if $\overline{\alpha}_i(\overline{y})$ could be neglected. We have only to find $\alpha_e(y)$ and the corresponding C_ℓ comes from the two-dimensional data. We can assume some modification to the local angle of attack for 3-dimensional effects and see if our calculated value of $\overline{\alpha}_i(\overline{y})$ is equal to the assumed value. If not, we can modify our assumption until it is. What we seem to require then is a systematic procedure for doing this.

Let us represent $C_\ell(y)c/b$ by a series,

$$\frac{C_\ell(y)c}{\overline{b}} = \sum_{n=1}^{\infty} A_n \sin\left[n \cos^{-1}\left(\frac{-2\overline{y}}{\overline{b}}\right)\right] \qquad (93)$$

and call $\overline{\theta} = \cos^{-1}(2\overline{y}/\overline{b})$. Then (91) could be written

$$\overline{\alpha}_i(\overline{y}_1) = \frac{180}{4\pi^2} \int_0^{\pi} \frac{\sum_{n=1}^{\infty} n A_n \cos n\overline{\theta}}{\cos \overline{\theta} - \cos \overline{\theta}_1} \, d\overline{\theta} \quad . \qquad (94)$$

Since it can be shown that

$$\int_0^{\pi} \frac{\cos n\theta}{\cos \theta - \cos \phi} \, d\theta = \pi \frac{\sin n\phi}{\sin \phi} \qquad (95)$$

98

$$\overline{\alpha}_i(\overline{y}_1) = \frac{180}{4\pi} \left[\frac{\displaystyle\sum_{n=1}^{\infty} n\, A_n \sin n\overline{\theta}_1}{\sin \overline{\theta}_1} \right] . \tag{96}$$

To proceed with the evaluation of (96) one returns for the moment to (93). Let us assume that we can adequately represent the lift at each of m evenly spaced points along the span with a finite series of r - 1 terms. m and r we assume are related by $\overline{\theta} = m\pi/r$ and m = 1, 2,...,r - 1. In other words, we divide the range $0 \le \overline{\theta} \le \pi$ into r intervals. Over each interval, the lift is a constant which we can represent by a finite series, the number of terms of which being also the number of points at which we calculate the lift. Thus, to use a large number of terms in the series to represent the lift in each interval, it is necessary to take a large number of intervals. The lift in each interval is written

$$\left(\frac{C_\ell(y)c}{b} \right)_m = \sum_{n=1}^{r-1} A_n \sin n\, \frac{m\pi}{r} \tag{97}$$

for which

$$A_n = \frac{2}{r} \sum_{m=1}^{r-1} \left(\frac{C_\ell c}{b} \right)_m \sin n\, \frac{m\pi}{r} . \tag{98}$$

Substitution of this result into (96) yields

$$\overline{\alpha}_i(\overline{y}_1) = \frac{180}{4\pi \sin \overline{\theta}_1} \left\{ \sum_{n=1}^{\infty} n \left[\frac{2}{r} \sum_{m=1}^{r-1} \left(\frac{C_\ell c}{b} \right)_m \sin n\, \frac{m\pi}{r} \right] \sin n\overline{\theta}_1 \right\} . \tag{99}$$

It will be readily recalled that

$$\sin \alpha \sin \beta = \tfrac{1}{2} [\cos (\alpha-\beta) - \cos (\alpha+\beta)] \quad ;$$

with this identity (99) is

$$\overline{\alpha}_i(\overline{y}_1) = \frac{180}{4\pi r \sin \overline{\theta}_1} \left\{ \sum_{m=1}^{r-1} \left(\frac{C_\ell c}{b} \right)_m \sum_{n=1}^{r-1} n \left[\cos n \left(\overline{\theta}_1 - \frac{m\pi}{r} \right) - \cos n \left(\overline{\theta}_1 + \frac{m\pi}{r} \right) \right] \right\} \tag{100}$$

where we have chosen to terminate the infinite series in (99) at r - 1 terms for computational convenience.

We choose to evaluate the induced angle of attack at the same points along the span at which we are required to find C_ℓ. To accomplish this we put $\overline{\theta}_1 = k\pi/r$. if we define

$$\beta_{mk} = \frac{180}{4\pi r \, \sin \frac{k\pi}{r}} \sum_{n=1}^{r-1} n \left[\cos n \frac{(k-m)\pi}{r} - \cos n \frac{(k+m)\pi}{r} \right] \qquad (101)$$

then

$$\bar{\alpha}_i(\bar{y}_1) = \bar{\alpha}_{ik} = \sum_{m=1}^{r-1} \left(\frac{c_{\ell}c}{b} \right)_m \beta_{mk} \qquad (102)$$

Now if $k = m$

$$\beta_{mk} = \frac{180}{4\pi r \, \sin \frac{k\pi}{r}} \sum_{n=1}^{r-1} n \left[1 - \cos \frac{2kn\pi}{r} \right] \qquad (103)$$

The sum of the series is not easily found but can be shown by evalauting series of varying numbers of terms to be $r^2/2$; hence

$$\beta_{mk} = \frac{180r}{8\pi \, \sin \frac{k\pi}{r}} \qquad (104)$$

for

$$k = m \qquad .$$

If $k + m$ is even (and $k \neq m$) then β_{mk} contains terms such as

$$1 \left[\cos 1 \left(\frac{1-3}{4} \right) \pi - \cos 1 \left(\frac{1+3}{4} \right) \pi \right]$$
$$+ 2 \left[\cos 2 \left(\frac{-2}{4} \right) \pi - \cos 2\pi \right]$$
$$+ 3 \left[\cos 3 \left(\frac{-2}{4} \right) \pi - \cos 3\pi \right] = 0$$

which always sum to zero. In a similar fashion one can show that when $k + m$ is odd

$$\beta_{mk} = \frac{180}{4\pi r \, \sin \frac{k\pi}{r}} \left[\frac{1}{1 - \cos \frac{(k+m)\pi}{r}} - \frac{1}{1 - \cos \frac{(k-m)\pi}{r}} \right] \qquad (105)$$

Note that the value of β_{mk} depends only on the number of spanwise stations used and is independent of wing aspect ratio or taper ratio.

The perceptive reader will note that (102) really does not supply us with more information regarding the spanwise variation of $\bar{\alpha}_i(\bar{y}_1)$ than we had previously. It does, however, provide us with the physical and geometric

100

tools we need to work out a successful iterative procedure for finding the correct value of $C_\ell c/\overline{b}$ as a function of span. That this is true will become apparent as we proceed. First, let us write (81) as

$$\alpha_e(y) = \alpha_k - \frac{R}{} \frac{d\overline{u}}{du} \sum_{m=1}^{r-1} \left(\frac{C_\ell c}{\overline{b}} \right)_m \beta_{mk} \; . \tag{106}$$

As a first approximation we will assume that the variation of lift coefficient with angle of attack, C_{ℓ_α}, at any spanwise location, k, is constant. Then by writing

$$\alpha_e \left(C_{\ell_\alpha} \frac{c}{\overline{b}} \right)_k = \left(\frac{C_\ell c}{\overline{b}} \right)_k + \Delta_k \tag{107}$$

we can define Δ_k as the amount that must be added to the initial estimate for $(C_\ell c/\overline{b})$ in order to obtain a new value which includes in it effects from other portions of the wing. A second iteration is formed as follows:

$$\left\{ \alpha_k - \frac{R}{} \frac{d\overline{u}}{du} \sum_{m=1}^{r-1} \left[\left(\frac{C_\ell c}{\overline{b}} \right) + \Delta' \right]_m \beta_{mk} \right\} \left(C_{\ell_\alpha} \frac{c}{\overline{b}} \right)_k = \left(\frac{C_\ell c}{\overline{b}} \right)_k + \Delta'_k \; . \tag{108}$$

Subtraction of (108) from (107) yields

$$\left(C_{\ell_\alpha} \frac{c}{b} \right)_k \left(\frac{R}{} \frac{d\overline{u}}{du} \right)_k \sum_{m=1}^{r-1} \Delta'_m \beta_{mk} = \Delta_k - \Delta'_k \; . \tag{109}$$

If we define

$$\left(\frac{C_{\ell_\alpha} c}{\overline{b}} \right)_K \left(\frac{R}{} \frac{d\overline{u}}{du} \right)_k \frac{180r}{8\pi \sin \frac{k\pi}{r}} = G_{kk} \; , \tag{110}$$

then Equation (109) could be written as

$$\Delta'_k + G_{kk} \Delta'_k + \left[\sum_{m=1}^{r-1} \Delta'_m \beta_{mk} \right]_{k \neq m} \left(\frac{C_{\ell_\alpha} c}{\overline{b}} \right)_k \left(\frac{R}{} \frac{d\overline{u}}{du} \right)_k = \Delta_k \; . \tag{111}$$

Dividing by G_{kk} yields

$$\left(1 + \frac{1}{G_{kk}} \right) \Delta'_k + \left[\sum_{m=1}^{r-1} \frac{\beta_{mk}}{\beta_{kk}} \Delta'_k \right]_{k \neq m} = \frac{\Delta_k}{G_{kk}} \; . \tag{112}$$

Equation (112) represents r/2 simultaneous equations which may be represented in matrix form as

101

$$\left[G_{ij} \right] \left\{ \Delta_i' \right\} = \frac{1}{G_{kk}} \left\{ \Delta_i \right\} \tag{113}$$

where $\left[G_{ij} \right]$ is a matrix with all the principal diagonal elements equal to $(1 + 1/G_{kk})$ and the other elements are β_{mk}/β_{kk}. The values to be added to one set of approximate values to obtain a better approximation are therefore given by

$$\left\{ \Delta_i' \right\} = \left[G_{ij} \right]^{-1} \frac{1}{G_{kk}} \left\{ \Delta_i \right\} \quad . \tag{114}$$

As a first approximation to the distribution of lift on the wing we use the expression (Ref. 36)

$$\frac{C_{\ell} c}{b} = C_{\ell} \left(\frac{AR}{AR + 1.8} \right) \left(\frac{c}{c_R} \right) \left(\frac{c_R}{b} \right) \left(\frac{b}{b} \right) \left[\frac{1}{2} + (1 + \lambda) \sqrt{1 - \left(\frac{2\overline{y}}{b} \right)^2} \right] \tag{115}$$

which, as can be seen, contains a simple aspect ratio correction and a simple taper ratio correction to a typical elliptical lift distribution. Here, AR is the aspect ratio, (b^2/wing area), c_R is the root chord, and λ is the taper ratio or the ratio of the tip chord to the root chord. The value of C_{ℓ} on the right-hand side of this equation comes from the two-dimensional data corresponding to the local geometric angle of attack.

Now the flow in the tip regions and its effect on the overall wing characteristics is particularly difficult to determine quantitatively. The more inboard sections of a finite wing are influenced by the downwash generated by the horseshoe vortex system and the upwash due to the fuselage so that the primary effect there is a change in effective angle of attack. In the tip region, on the other hand, there is a substantial spanwise flow which detracts from the flow moving chordwise; consequently, the tip region is able to generate less lift than one would normally expect for a given free stream velocity. This of course reduces the total lift of the wing somewhat. To accommodate this loss in lift within the idea of using two-dimensional data at an appropriate angle of attack, we modify α_e as given by (81) to read (Ref. 36)

$$\alpha_e' = \frac{\left[(\alpha_e - \alpha_{Z.L.})(1 - \sqrt{1 + 4/AR^2}) \right]}{\sqrt{1 + \dfrac{4}{AR^2}}} \quad . \tag{116}$$

We then use α_e' to look up the 3-dimensional value of the section lift coefficient from the 2-dimensional data.

If $C_{\ell} c/\overline{b}$ computed in this fashion is not sufficiently close to the initial estimate of $C_{\ell} c/\overline{b}$ than a correction given by (114) is added. The process is repeated until satisfactory agreement is obtained.

102

When a satisfactory lift distribution has finally been obtained, one can employ the same section data to find the profile drag and moment coefficient at each station along the wing. The local induced drag is simply a product of the lift and the induced angle of attack at that point. The overall force and moment coefficients are obtained by integrating the local values over the span. If one uses Simpson's rule for this integration, explicit relations for the lift, drag, and pitching moment can be obtained:

$$C_L = \left(\frac{\overline{b}}{b}\right)^2 \text{ AR} \sum_{m=1}^{r-1} \left(\frac{C_\ell c}{\overline{b}}\right)_m \left[\frac{\pi}{6r}\left(3 - (-1)^m\right) \sin\frac{m\pi}{r}\right] \tag{117}$$

$$C_{D_i} = \frac{\pi}{180}\left(\frac{\overline{b}}{b}\right)^2 \text{ AR} \sum_{m=1}^{r-1} \left[\left(\frac{C_\ell c}{\overline{b}}\right)\alpha_i\right]_m \left[\frac{\pi}{6r}\left(3 - (-1)^m\right) \sin\frac{m\pi}{r}\right] \tag{118}$$

$$C_{D_o} = \left(\frac{\overline{b}}{b}\right)^2 \text{ AR} \sum_{m=1}^{r-1} \left(\frac{C_{d_o} c}{\overline{b}}\right)_m \left[\frac{\pi}{6r}\left(3 - (-1)^m\right) \sin\frac{m\pi}{r}\right] \tag{119}$$

$$C_m = \frac{\text{AR}\,\overline{b}}{b^2 c'} \sum_{m=1}^{r-1} \left(C_m c^2\right) \left[\frac{\pi}{6r}\left(3 - (-1)^m\right) \sin\frac{m\pi}{r}\right] \tag{120}$$

where

$$C_m = C_{m_{c/4}} - \frac{x}{c}\left[C_\ell \cos(\alpha_B - \alpha_i) + C_{d_o} \sin(\alpha_B - \alpha_i)\right]$$

$$- \frac{z}{c}\left[C_\ell \sin(\alpha_B - \alpha_i) - C_{d_o} \sin(\alpha_B - \alpha_i)\right] \tag{121}$$

and c' is the mean aerodynamic chord. Note that this integration is somewhat analogous to the process represented by

$$\frac{1}{bc'} \int_{-b/2}^{b/2} C_\ell c \, dy \ .$$

Since the computation of $(C_\ell c/\overline{b})$ has really been carried out in the $\overline{u}$-plane so far as the wing span is concerned we must multiply our result by $\overline{b}/b$ to transform it to the physical plane. AR is just b/c' and the average (aerodynamic not geometric) value of c over the span is c'. The term in brackets is the multiplier employed by Simpson's Rule. It is seen therefore that C_L is in fact an average over the span in the physical plane.

103

CONCLUDING REMARKS

The totality of procedures described in this section for computing the aerodynamic characteristics of complete wings can be seen to be capable—at least in principle—of a very accurate representation of physical reality. The vortex filament distribution approach to determining the inviscid pressure distribution on airfoil sections leads in the limit of a multitude of filaments and high computational accuracy to very good results. The application of the lifting line concept to the correction of section characteristics for finite span effects also can yield very reliable results, provided the number of spanwise stations at which the characteristics are computed is large, computational accuracy is maintained, and the underlying assumptions of the lifting-line theory are not violated by the planform it is supposed to represent.

The approach used here has two principal advantages, insofar as the computation of light aircraft wing aerodynamic characteristics is concerned, when compared with the finite element or vortex lattice approach which has been discussed prominently in the literature of late:

(1) three-dimensional drag data is obtained,

(2) the computational time for an equally accurate potential solution is far less since, in effect, the spanwise integration of vorticity is replaced by a single integration along the lifting line. This, of course, is made possible by restricting the interest to unswept, moderate-to-high aspect ratio wings in subsonic flow.

The computation of the effects of fluid viscosity is the least rigorous and least accurate of the procedures. So long as the boundary layer is laminar and the wing surface smooth one could expect to obtain very acceptable drag and boundary layer displacement effects by successive refinement of the psuedo-airfoil shape using a more general polynomial for u/u_e if necessary. Laminar boundary layer methods inherently more accurate than the momentum integral technique are also available as computer programs and could be included if desired, at the cost, however, of greatly increased computer time. The local characteristics during boundary layer transition and for turbulent boundary layers are here computed by what may be termed state of the art techniques—not completely rigorous, but about as reliable as any available. The procedure is therefore expected to be less accurate as the need for a precise knowledge of boundary layer behavior increases—at high angles of attack or in the presence of surface irregularities.

Finally, we should mention that to translate these concepts into useful design tools we must also employ sound, efficient computational procedures. Although a treatment of the rationale behind the choice of one numerical method over another for a particular computation is beyond the scope of the present discussion, it must be emphasized that such decisions can be crucial both economically and technically. For this reason it is to be expected that the major improvements which occur in the procedure presented in this work, at least in the immediate future, will likely be in the area of computational effectiveness.

104

A THEORY FOR THE PREDICTION OF LIFT, DRAG, AND PITCHING MOMENT OF LIGHT AIRCRAFT FUSELAGES

INVISCID FLOW OVER FUSELAGES

In the preceding discussion we were concerned with a means of predicting the lift, drag, and moment characterisitcs of wings. An airplane, however, contains other parts which contribute to the overall aerodynamic force and moment experienced by the vehicle. Most notable of these is the fuselage. The fuselage contributes to the overall drag for two reasons: it has a large surface area against which the air can "rub" and in order to provide a finite volume in which to carry a useful payload it must move air "out of the way." It can also contribute some amount to the lift in addition to that provided by the bridging action between the two wings. This effect is usually significant only at high angles of attack. If the fuselage produces contributions to the lift and drag, then it is also likely to affect the pitching moment.

Because the fuselage is usually not a body of revolution but rather a three-dimensional body with a plane of symmetry its proper analytical representation is more difficult than that of an airfoil. In the case of an airfoil we were able to represent the surface by a series of line vortices. Because a vortex must either be closed or extend to infinity, the only vortex we can use to represent three-dimensional bodies is a ring. To be sure the ring can be contorted, but it must close. The geometric problems associated with describing such a ring leads us to ask whether there is another flow function for describing the inviscid flow about fuselages which may be easier to use. The point source is an elementary flow which can be described quite easily mathematically. The potential at the point (x, y, z) due to a source at (ξ, η, ζ) is given by

$$\phi = \frac{-q}{4\pi} \frac{1}{[(x - \xi)^2 + (y - \eta)^2 + (z - \zeta)^2]^{1/2}} \qquad (122)$$

where q is called the source strength. The components of the velocity associated with a source flow are then

$$u = \frac{q}{4\pi} \frac{(x - \xi)}{[(x - \xi)^2 + (y - \eta)^2 + (z - \zeta)^2]^{3/2}} \qquad (123)$$

$$v = \frac{q}{4\pi} \frac{(y - \eta)}{[(x - \xi)^2 + (y - \eta)^2 + (z - \zeta)^2]^{3/2}} \qquad (124)$$

$$w = \frac{q}{4\pi} \frac{(z - \zeta)}{[(x - \xi)^2 + (y - \eta)^2 + (z - \zeta)^2]^{3/2}} . \qquad (125)$$

105

That this flow is irrotational and satisfies the Laplace Equation is easily verified.

Physically, the three-dimensional source is a point from which fluid emanates in straight lines in all directions. The quantity of fluid emanating from the point depends upon the value of q. By placing a source in a uniform stream one in effect displaces the streamlines in the uniform stream because of local additions to the mass flow. By distributing sources in space and using a different strength for each source it is possible to cause the streamline pattern of the flow to simulate the shape of the windward side of complex bodies quite satisfactorily. To represent a closed body it is necessary to withdraw the mass added by the sources so that the streamlines can return to their original positions downstream of the body. We do this by means of a distribution of sources with negative values of the source strength, or sinks. Hence, the net source strength when integrated over a closed body is zero.

A source flow is also a flow which inherently cannot create a net circulation about a body. Consequently, it cannot be used to represent a situation where lift is present. Such situations can be simulated by a combination of sources, horseshoe vortices, and a uniform stream. Even though a distribution of sources in a uniform stream by itself cannot represent a lifting body, it is suitable for determining the inviscid pressure distribution on a non-lifting body. Then by adding a boundary layer one can determine both the form and friction drag of such bodies.

The technique by which such a calculation is carried out is very similar to that which we employed to determine the aerodynamic characteristics of airfoils. We begin by considering the body surface to be made up of a number of connected plane quadrilaterals. As the number of quadrilaterals approaches infinity, the polygon becomes the body identically. On each plane quadrilateral we place a source of undetermined strength. We require that the flow induced on any one quadrilateral through the interaction of all the sources with the uniform stream be parallel to the quadrilateral surface or that the flow velocity normal to the quadrilateral be zero. This gives us sufficient boundary conditions to write a determinant system of equations, one for each quadrilateral, which we can then solve to find the individual source strengths.

The total velocity induced at a point on the body surface by a series of sources distributed over the body can, following (19), be written

$$\bar{u} = \frac{1}{4\pi} \sum_{N=1}^{k} \frac{q_N(x - \xi_N)}{[(x - \xi_N)^2 + (y - \eta_N)^2 + (z - \zeta_N)^2]^{3/2}}$$

$$\bar{v} = \frac{1}{4\pi} \sum_{N=1}^{k} \frac{q_N(y - \eta_N)}{[(x - \xi_N)^2 + (y - \eta_N)^2 + (z - \zeta_N)^2]^{3/2}} \tag{126}$$

$$\bar{w} = \frac{1}{4\pi} \sum_{N=1}^{k} \frac{q_N(z - \zeta_N)}{[(x - \xi_N)^2 + (y - \eta_N)^2 + (z - \zeta_N)^2]^{3/2}} .$$

To complete the formulation of the equations, we must include the effects of the free stream velocity at (x, y, z) and define the normal to the surface at (x, y, z) so as to be able to state the requirement that the net flow be parallel to the surface. The free stream velocity just adds a term V_∞ to the u-component.

The surface in which the point (x, y, z) lies can, in general, be defined by the equation $a'x + b'y + c'z + d' = 0$. Each quadrilateral composing the fuselage will have a different range of values for x, y, and z as well as for a', b', c', and d'. The values of the coefficients a', b', c', and d' for a particular quadrilateral are found by solving for them from the system of equations

$$a'x_1 + b'y_1 + c'z_1 + d' = 0$$

$$a'x_2 + b'y_2 + c'z_2 + d' = 0$$

$$a'x_3 + b'y_3 + c'z_3 + d' = 0 \qquad\qquad (127)$$

$$a'x_4 + b'y_4 + c'z_4 + d' = 0$$

where (x_1, y_1, z_1), (x_2, y_2, z_2), (x_3, y_3, z_3) and (x_4, y_4, z_4) are four points all of which lie in the same plane. One can use for these points the four corners of the quadrilateral. One can also rewrite the equation for a plane surface in the form

$$\frac{a'}{\sqrt{a'^2+b'^2+c'^2}}x + \frac{b'}{\sqrt{a'^2+b'^2+c'^2}}y + \frac{c'}{\sqrt{a'^2+b'^2+c'^2}}z + \frac{d'}{\sqrt{a'^2+b'^2+c'^2}} = 0 .$$

Then the quantities

$$a = \frac{a}{\sqrt{a'^2 + b'^2 + c'^2}} , \quad b = \frac{b'}{\sqrt{a'^2 + b'^2 + c'^2}} , \quad c = \frac{c'}{\sqrt{a'^2 + b'^2 + c'^2}}$$

are what are called the direction cosines of the normal to the plane $ax + by + cz + d = 0$. The reason for this may be seen from the sketch below. If we draw a line from point P normal to the plane in which it lies then $a = \cos \gamma_1$, $b = \cos \gamma_2$, and $c = \cos \gamma_3$. a', b', and c' are called direction numbers. The plane through point $P(x_p, y_p, z_p)$ whose normal has direction numbers a', b', and c' is the graph of the equation $a'(x - x_p) + b'(y - y_p) + c'(z - z_p) = 0$. From this discussion we see that direction numbers and direction cosines are proportional.
The requirements that there be no flow normal to the surface is satisfied when

$$(\bar{u} + V_\infty)a + \bar{v}b + \bar{w}c = 0 \qquad (128)$$

at one point on each quadrilateral. That this is true is easily seen if one writes the velocity as a vector, $(\bar{u} + V_\infty)\vec{i} + \bar{v}\vec{j} + \bar{w}\vec{k} = \vec{V}$, and the normal as a vector, $a\vec{i} + b\vec{j} + c\vec{k} = \vec{N}$. The scalar or dot product of two vectors is the product of their magnitudes times the cosine of the angle between them. Thus if $\vec{V}\cdot\vec{N} = 0$ the two vectors are at right angles to one another. But $\vec{V}\cdot\vec{N} = (\bar{u} + V_\infty)a + \bar{v}b + \bar{w}c$. When this is zero the flow is parallel to the surface.

It will be recalled that in the two-dimensional case of the airfoil one could as easily chose the condition that the flow must be parallel to the surface as the condition that the flow velocity normal to that surface must be zero. They are equivalent statements and offer similar mathematical problems.* In the three-dimensional case, however, one does not know *a priori* the direction of the flow parallel to the surface. For this reason, a single, fixed-value boundary condition becomes difficult to specify. Requiring that the velocity normal to the surface be zero on the other hand, removes this difficulty.

---

* It has been pointed out by Chen (Ref. 27) that specifying that the tangent of the flow angle be the same as the local angle of the surface makes the solution less sensitive to errors in the coordinates of the surface than requiring that the flow velocity normal to the surface be zero.

While perhaps not evident in the discussion above there is a problem in relating points on the body surface to the coefficients of (127). Simply stated it is that the four points on the body surface closest to x, y, z do not necessarily lie in the same plane. In fact, it would be most remarkable if they did. Further, if the four corner points on any quadrilateral are "adjusted" so that they are in fact coplanar then the edges of that quadrilateral will not necessarily be colinear with the edges of adjacent quadrilaterals. The effect then is to represent the body by an ensemble of planar "scales," similar to those of a fish, rather than by something that resembles a wire gridwork. In the limit, however, as the number of quadrilaterals becomes very large, the two models become the same thing.

How then to resolve the dilema? Forming triangular panels from three adjacent surface points insures that the three points are coplanar but, as one may readily observe, it also doubles the number of panels one needs to cover a given area. Since the computational time required to solve for the source strength on each panel varies approximately as the number of panels squared, one does not take such a step lightly. On the other hand if one is willing to "adjust" the corner points of a quadrilateral to make them coplanar, how should he proceed to insure that the calculated normal is nearly the same as the true normal to the body at x, y, z. One way which has been suggested (Ref. 23) approaches the problem by writing, first of all, equations for the two diagonals of the quadrilateral. This is straightforward since the two opposite corner points of a quadrilateral define a straight line uniquely. Now, if one is willing to say that these two lines are essentially coplanar, then the crossproduct of their vector representations is the normal to the quadrilateral. For example, the equation describing a line through points $P_1(x_1, y_1, z_1)$ and $P_2(x_2, y_2, z_2)$

$$\frac{x - x_1}{x_2 - x_1} = \frac{y - y_1}{y_2 - y_1} = \frac{z - z_1}{z_2 - z_1} \tag{129}$$

while the equations describing a line through points $P_3(x_3, y_3, z_3)$ and $P_4(x_4, y_4, z_4)$ are

$$\frac{x - x_3}{x_4 - x_3} = \frac{y - y_3}{y_4 - y_3} = \frac{z - z_3}{z_4 - z_3} \quad . \tag{130}$$

The various points and lines are depicted on the sketch below.

109
Now, the point at which the two lines have the same values of x and y (that is, the point at which they cross one another) is found by solving the two equations simultaneously to obtain

$$y = \frac{(x_1 - x_3) - y_1(x_2 - x_1)/(y_2 - y_1) + y_3(x_4 - x_3)/(y_4 - y_3)}{\dfrac{x_4 - x_3}{y_4 - y_3} - \dfrac{x_2 - x_1}{y_2 - y_1}}$$

$$x = x_1 - y_1 \left(\frac{x_2 - x_1}{y_2 - y_1} \right)$$

$$+ \left(\frac{x_2 - x_1}{y_2 - y_1} \right) \left[\frac{(x_1 - x_3) - y_1(x_2 - x_1)/(y_2 - y_1) + y_3(x_4 - x_3)/(y_4 - y_3)}{\dfrac{x_4 - x_3}{y_4 - y_3} - \dfrac{x_2 - x_1}{y_2 - y_1}} \right] .$$

(131)

z is then found from

$$z = (y - y_3) \left(\frac{z_4 - z_3}{y_4 - y_3} \right)$$

$$\text{or} \qquad z = (y - y_1) \left(\frac{z_2 - z_1}{y_2 - y_1} \right) .$$

(132)

A vector beginning at $P(x,y,z)$ and terminating at $P_2(x_2, y_2, z_2)$ is represented by

$$\vec{A} = (x_2 - x)\vec{i} + (y_2 - y)\vec{j} + (z_2 - z)\vec{k}$$

(133)

while that beginning at $P(x,y,z)$ and terminating at $P_4(x_4, y_4, z_4)$ is represented by

$$\vec{B} = (x_4 - x)\vec{i} + (y_4 - y)\vec{j} + (z_4 - z)\vec{k} .$$

(134)

The vector which is normal to the plane defined by $\vec{A}$ and $\vec{B}$ is then

$$\vec{A} \times \vec{B} = (x_2 - x)(y_4 - y)\vec{k} - (x_2 - x)(z_4 - z)\vec{j}$$

$$+ (y_2 - y)(z_4 - z)\vec{i} - (y_2 - y)(x_4 - x)\vec{k}$$

$$+ (z_2 - z)(x_4 - x)\vec{j} - (z_2 - z)(y_4 - y)\vec{i}$$

(135)

$$\vec{A} \times \vec{B} = [(y_2 - y)(z_4 - z) - (z_2 - z)(y_4 - y)]\vec{i}$$

$$+ [(z_2 - z)(x_4 - x) - (x_2 - x)(z_4 - z)]\vec{j}$$

$$+ [(x_2 - x)(y_4 - y) - (y_2 - y)(x_4 - x)]\vec{k}$$

110

The condition that the flow be parallel to the surface is then satisfied when

$$\vec{V} \cdot (\vec{A} \times \vec{B}) = 0$$

or $(\bar{u} + V_\infty)\left[(y_2 - y)(z_4 - z) - (z_2 - z)(y_4 - y)\right] + \bar{v}\left[(z_2 - z)(x_4 - x)\right.$

$$\left. - (x_2 - x)(z_4 - z)\right] + \bar{w}\left[(x_2 - x)(y_4 - y) - (y_2 - y)(x_4 - x)\right] = 0.$$

(136)

For simplicity we will define the terms in brackets as $\bar{a}$, $\bar{b}$, and $\bar{c}$ respectively. Note that one must exercise care in choosing the labels for the points so that the normal $(\vec{A} \times \vec{B})$ is always outward.

We have now found a means to represent the boundary condition of no flow across the surface of the body in terms of the coordinates of the corner points of the quadrilaterals making up the body.
The system of equations one must then solve to find the individual source strengths is

$$\left(V_\infty + \frac{1}{4\pi} \sum_{N=1}^{k} \frac{q_N(x_1 - \xi_N)}{[(x_1 - \xi_N)^2 + (y_1 - \eta_N)^2 + (z_1 - \zeta_N)^2]^{3/2}}\right) \bar{a}_1$$

$$+ \frac{\bar{b}_1}{4\pi} \sum_{N=1}^{k} \frac{q_N(y_1 - \eta_N)}{[(x_1 - \xi_N)^2 + (y_1 - \eta_N)^2 + (z_1 - \zeta_N)^2]^{3/2}}$$

$$+ \frac{\bar{c}_1}{4\pi} \sum_{N=1}^{k} \frac{q_N(z_1 - \zeta_N)}{[(x_1 - \xi_N)^2 + (y_1 - \eta_N)^2 + (z_1 - \zeta_N)^2]^{3/2}} = 0$$

$$\vdots$$

(137)

$$\left(V_\infty + \frac{1}{4\pi} \sum_{N=1}^{k} \frac{q_N(x_k - \xi_N)}{[(x_k - \xi_N)^2 + (y_k - \eta_N)^2 + (z_k - \zeta_N)^2]^{3/2}}\right) \bar{a}_k$$

$$+ \frac{\bar{b}_k}{4\pi} \sum_{N=1}^{k} \frac{q_N(y_k - \eta_N)}{[(x_k - \xi_N)^2 + (y_k - \eta_N)^2 + (z_k - \zeta_N)^2]^{3/2}}$$

$$+ \frac{\bar{c}_k}{4\pi} \sum_{N=1}^{k} \frac{q_N(z_k - \zeta_N)}{[(x_k - \xi_N)^2 + (y_k - \eta_N)^2 + (z_k - \zeta_N)^2]^{3/2}} = 0 \quad .$$

111

In these equations k = the number of quadrilaterals by which the surface is represented. x_k, y_k, z_k is the point on each quadrilateral at which the boundary condition is satisfied and ξ_k, η_k, ζ_k is the point on each quadrilateral at which the source is located. Not making these points coincident will usually lead to less waviness in the surface pressures and velocities. If we choose to separate the source point from the point at which the boundary condition is satisfied, *i.e.*, the point at which the normal is computed, then we need to write an equation for a <u>plane</u> quadrilateral having its normal identical with that given by (135) and its corner points located at the same x and y locations but with slightly different z values. We need to do this in order to locate the source approximately on the surface in a known relationship to the corner points and to P(x,y,z). From Equation (127) we see that since $\bar{a}$, $\bar{b}$, and $\bar{c}$ are now the direction numbers of the normal to the plane, picking one value of z, say z_1 as lying on the physical surface permits one to solve for the other value of z and for d. If we choose to locate the source point at 1/3 the quadrilateral chord then the x-coordinate of the source point is given by

$$\tfrac{1}{2}\left[x_1 + \frac{x_4 - x_1}{3} + x_3 + \frac{x_2 - x_3}{3} \right] = \xi_k \,.$$ (138)

The y-coordinate is given by

$$\tfrac{1}{2}\left[y_3 + \frac{y_2 - y_3}{3} + y_1 + \frac{y_4 - y_1}{3} \right] = \eta_k \,.$$ (139)

The z-coordinate is then determined from the equation of that particular quadrilateral. If one wishes to move the point at which the boundary condition is satisfied to some other, fixed point along the quadrilateral chord, he could follow a similar procedure.

The source strengths, q_N, are then found by solving the rather large system of Equations (137) simultaneously. Given these values one can then find local velocity components from (126). The local pressure on the fuselage is then given by

$$P = P_\infty + \tfrac{1}{2}\rho\left[V_\infty^2 - (V_\infty + \bar{u})^2 - \bar{v}^2 - \bar{w}^2 \right] \,.$$ (140)

Obviously, to obtain a reasonably accurate picture of the surface pressures, the number of quadrilaterals with which the surface is represented must be very large, particularly if the fuselage shape deviates significantly from that of a streamlined body. As was the case in the analysis of two-dimensional bodies (airfoils), conventional practice usually represents the potential by a constant source strength over the entire surface of a particular panel rather than by a point source as is done here. Use of the continuous distribution, it will be recalled, usually results in less waviness in the computed surface streamline. This streamline of course is required by our formulation to be parallel with the physical surface only at one point on each panel.

Because of the very large number of panels usually required to achieve reasonably accurate descriptions of the surface pressures on fuselage-like bodies, the opportunity to save substantial amounts of computer time or storage through the use of sophisticated numerical or mathematical procedures exists. Every program for performing such computations that the present authors have examined in detail (three at this writing) either carries out the calculation in pieces, takes advantage of the special character of the coefficient matrix in performing the inversion, recognizes that panels far away from the one on which the boundary condition is satisfied contribute little to the flow and therefore can be represented more approximately with no loss in accuracy, or uses line sources to represent all or part of the fuselage. Line sources, of course, can be used to greatly simplify the formulation of the problem, but unfortunately they can describe only slender fuselages adequately. A detailed discussion of the advantages and disadvantages of the various computation techniques is beyond the scope of the present work. This activity is mentioned merely to indicate to the reader that reducing the cost and complexity of the computations has already received considerable intelligent attention and is likely to be the subject of further intensive study in the near future.

By treating the fuselage as an isolated body, we have assumed implicitly that the fuselage is flying at such an inclination to the stream that it generates no lift other than by providing a bridge between the two halves of the wing. We shall also assume that the effect of the entire fuselage on the wing lift is adequately treated by the method of the previous section. Further, we shall assume that for purposes of finding the fuselage drag we can treat the fuselage as a free body, adding the wing-body interference effects later as an empirical or semi-empirical correction. These assumptions leave us with the necessity of determining only the boundary layer displacement and skin friction effects. In subsequent sections we shall examine some of the rationale for these assumptions and determine in a general way the conditions for which they are reasonable.

VISCOUS FLOW OVER FUSELAGES

The problem of determining the characteristics of a boundary layer flowing over a general, three-dimensional body is one of great fundamental interest. Unfortunately, the only known solutions are for axisymmetric bodies or other special cases. It is known, however, that if the body cross-sectional area and volume do not change rapidly in the streamwise direction and if there is no significant pressure gradient in the cross flow direction, then the boundary layer behaves in much the same way as it would on a two-dimensional body subject to the same history of pressure gradients in the streamwise direction. If we are willing to accept the restrictions and errors inherent in assuming that the three-dimensional boundary layer can be treated through such a concept, then we may use the techniques of the previous section to determine δ^* and $\tau_{y=0}$ along the

body streamlines[†]. One can obtain a reasonable estimate of the circumferential variation of δ^* and $\tau_{y=0}$ at any axial station by calculating δ^* and $\tau_{y=0}$ along a series of these lines approximately equally spaced in the circumferential direction.

A new pseudo-surface can then be constructed by smoothing these displacements from the original surface and a new inviscid pressure distribution can then be calculated. This process for determining the fuselage drag follows essentially the same path as that employed earlier for determining airfoil drag except that the pressures and viscous shear must be integrated over appropriate <u>areas</u> rather than line segments. We will examine the process in somewhat more <u>detail</u> a little later.

One may argue with considerable justification that if the use of a two-dimensional-boundary-layer-along-streamlines procedure gives results which compare well with experimental values for a group of fuselages, then it should be regarded as satisfactory for engineering purposes on this basis alone. However, since it is not exceedingly difficult to determine—to a fair degree of approximation—the conditions under which the additional terms in the three-dimensional boundary layer equations are small compared with the two-dimensional-along-streamlines terms, we shall now make this determination in order to identify those cases where the results obtained by the procedure may be suspect.

We begin by choosing to represent the fuselage locally by a section of a prolate spheroid with its major axis aligned with the local streamline and its center always in the x-z plane. The figures below depict this concept.

---

† Formally, two adjacent streamlines form the boundaries of the flow of a given quantity of fluid. The position of these lines on a body can be determined from the magnitude and direction of the flow over the surface.

The solutions of equations (126) give us the magnitude and direction of the flow velocity at one point on each panel. If we observe a group of panels, as in the sketch below,

116
and place, at the point on each where the boundary condition is satisfied, a vector whose direction is the flow direction at that point and whose length is proportional to the flow magnitude, then we may employ the method of isoclines (Ref. 107, page 97) to sketch the streamlines. The streamlines, after all, represent the trajectories of given masses of fluid as they travel over the surface of the body. For computational purposes, however, it is preferable to describe these streamlines in a more analytical fashion. Consider the section of the surface shown in the sketch below:
From the magnitudes of the surface velocity components we know the direction of the flow at a, b, c, and d. Let us assume that this direction is constant across the panel (as shown by the dashed line). The quantity of flow that moves between b and c depends upon the distance between b and c and the average velocity between b and c. Since the quantity of fluid between two streamlines is always constant, the appearance of converging streamlines means that the flow velocity is increasing as the flow moves from left to right. If we assume that the fluid velocity at a given x-station between two streamlines can be considered to be constant, with a value between that along line 1-4 and that along line 3-6 at the same x-station, then the position of the streamline continuing to the right from point 2 will be related to points 4 and 6 as $\left(\dfrac{\text{line } 2\text{-}3}{\text{line } 1\text{-}3}\right) = \left(\dfrac{\text{line } 5\text{-}6}{\text{line } 4\text{-}6}\right)$. This insures that the quantity of fluid between 2 and 3 is the same as between 5 and 6. Further the magnitude of the velocity at 5 is that at 2 times $\left(\dfrac{\text{line } 1\text{-}3}{\text{line } 4\text{-}6}\right)$. Since we know the coordinates of the corner points on each planar panel as well as those of points a, b, c, and d in terms of the original reference axes, we may describe the line segment from 2-5 in this reference system without undue difficulty. We can do the same for other similar line segments and so relate the streamlines over the body to one another in an analytical fashion. The equation for any particular streamline will change of course as it crosses a panel boundary.

We recognize that the assumptions we made with regard to the velocity between streamlines and the straightness of streamlines across panels are true only in the limit of vanishing panel size. However, since we will generally employ more than 400 panels to represent a fuselage such assumptions should not introduce significant error in practice.

Having identified the location of the streamlines in this manner we proceed to orient the prolate spheriod by which we represent a section of the surface of the fuselage.

$$\text{Let } \lambda = \tan^{-1}\left[\frac{z_{n+1} - z_{n-1}}{x_{n+1} - x_{n-1}}\right] \tag{141}$$

be the inclination of the streamline and z_{n+1}, x_{n+1} are the z and x coordinates of a point on the streamline just immediately downstream of the point of interest. z_{n-1} and x_{n-1} are then the coordinates of the point immediately upstream of the point of interest. λ defined in this fashion also represents the angle which the major axis of the spheroid makes with the original x-axis, as noted in one of the foregoing sketches.

This method of determining how the major axis should be oriented in order that it lie parallel to a streamline becomes indeterminant when the streamline is near the top or bottom of the fuselage. Indeterminacy occurs because

changes in flow direction are no longer confined principally to the x-z reference plane. For example, crossflow over the top of the fuselage may be evident only as a point in the x-z plane. The condition can be rectified by rotating ones viewpoint so that the changes in flow direction occur almost entirely in a plane normal to the direction of view. However, to illustrate the concept of fitting an arbitrary fuselage-like body locally by a prolate spheroid, we need work only with streamlines lying in a plane parallel to the x-z reference plane.

The equation for a prolate spheroid at the origin reads

$$\left(\frac{x}{b}\right)^2 + \left(\frac{y}{a}\right)^2 + \left(\frac{z}{a}\right)^2 = 1 \tag{142}$$

If, however, the origin is translated and the body rotated, both events taking place only in the x-z plane, the equation becomes

$$Ax^2 + By^2 + Cz^2 + Dxz + Ex + Fz + G = 0 \tag{143}$$

where

$$C = (a^2 \sin^2 \lambda + b^2 \cos^2 \lambda)$$

$$B = b^2$$

$$A = (a^2 \cos^2 \lambda + b^2 \sin^2 \lambda)$$

$$D = 2(b^2 - a^2)\sin \lambda \cos \lambda \tag{144}$$

$$F = 2x_1(b^2 - a^2)\sin \lambda \cos \lambda - 2z_1(b^2 \cos^2 \lambda + a^2 \sin^2 \lambda)$$

$$E = 2z_1(b^2 - a^2)\sin \lambda \cos \lambda - 2x_1(b^2 \sin^2 \lambda + a^2 \cos^2 \lambda)$$

$$G = 2x_1 z_1(b^2 - a^2)\sin \lambda \cos \lambda + (b^2 x_1^2 + a^2 z_1^2)\sin^2 \lambda$$

$$+ (a^2 x_1^2 + b^2 z_1^2)\cos^2 \lambda - a^2 b^2$$

Since we have chosen to specify λ according to (141) and since the body cross-section in the original y-z plane is a circle, the number of unknown constant values is really only four: a, b, x_1, and z_1. We therefore rearrange the equation as follows:

$$a^2(h_1 + h_2 \, x_1 + h_3 \, z_1 + h_4 \, x_1 \, z_1 + h_5 \, x_1^2 + h_6 \, z_1^2)$$

$$+ \, b^2(h_7 + h_8 \, x_1 + h_9 \, z_1 + h_{10} \, x_1 \, z_1 + h_{11} \, x_1^2 + h_{12} \, z_1^2) = a^2 b^2 \qquad (145)$$

In this form

$$h_1 = z^2 \sin^2 \lambda + x^2 \cos^2 \lambda - 2xz \sin \lambda \cos \lambda$$

$$h_2 = - \, 2x \cos^2 \lambda + 2z \sin \lambda \cos \lambda$$

$$h_3 = + \, 2x \sin \lambda \cos \lambda - 2z \sin^2 \lambda$$

$$h_4 = - \, 2\sin \lambda \cos \lambda$$

$$h_5 = \cos^2 \lambda$$

$$h_6 = \sin^2 \lambda \qquad\qquad (146)$$

$$h_7 = z^2 \cos^2 \lambda + y^2 + x^2 \sin^2 \lambda + 2xz \sin \lambda \cos \lambda$$

$$h_8 = - \, 2x \sin^2 \lambda - 2z \cos \lambda \sin \lambda$$

$$h_9 = - \, 2x \sin \lambda \cos \lambda - 2z \cos^2 \lambda$$

$$h_{10} = 2\sin \lambda \cos \lambda$$

$$h_{11} = \sin^2 \lambda$$

$$h_{12} = \cos^2 \lambda$$

This equation we then fit to the fuselage surface at four points (A, B, C, D in sketch) to evaluate a, b, x_1, and z_1. We do this by choosing two points on the streamline of interest, one on either side of the point of interest, and one point on each of the adjacent streamlines as close to the point of interest as possible. We have then a system of four non-linear algebraic equations which we must solve to find a, b, x_1, and z_1. The equations are non-linear because they contain products of the unknowns, e.g., x_1^2, $x_1 z_1$.

One method of solution for such a system of four equations is an adaptation of Newton's method for finding the roots of a single equation. In Newton's method one makes an initial estimate for the value of a root. If the estimate is reasonably close, the procedure yields a second approximation which is closer to the correct value. The procedure is repeated until the desired degree of accuracy is achieved. The generalization to a system of

120

four equations is outlined in Ref. 100, page 105. It is of course a numerical procedure of some length and is therefore best done on a computer.

Having found a and b for the particular prolate spheroid which represents the surface at the point of interest we ask how we might describe in orthogonal coordinates the length of a line along the surface of the spheroid. We wish to do this because the expression for the line element provides us with a means of characterizing the space (prolate spheroidal in this case). We may then use the boundary layer equations written in general curvilinear coordinates with the local values of the space inserted to evaluate the effects of body curvature on the values one might obtain for τ_w and δ^* using a momentum integral formulation.

Consider the figure below:

$$x = b \sin \theta$$
$$y = a \cos \theta$$
We recognize that the distance along the perimeter is given by

$$ds_1 = \sqrt{a^2 \cos^2 \theta + b^2 \sin^2 \theta}\; d\theta \, , \qquad\qquad (147)$$

while if we rotate the figure about its x-axis the circumferential displacement of P is given by

$$ds_2 = a \cos \theta \, d\phi \; . \tag{148}$$

Thus, we can describe the distance traveled along the surface by the change in the values of two coordinates, θ and ϕ:

$$ds^2 = \{a^2 \cos^2 \theta + b^2 \sin^2 \theta\} \, d\theta^2 + a^2 \cos^2 \theta \, d\phi^2 \tag{149}$$

By specifying λ in the manner which we did we have virtually required that the major axis of the ellipsoid be parallel to the projection of the streamline in the x-z reference plane. In addition, by evaluating a and b in the manner described we have almost assured that the streamline is a section of the curve

$$\frac{\bar{x}^2}{b^2 \left[1 - \frac{\bar{z}^2}{a^2}\right]} + \frac{\bar{y}^2}{a^2 \left[1 - \frac{\bar{z}^2}{a^2}\right]} = 1 \; , \tag{150}$$

where $\bar{z}$ may be treated as a constant. In other words, the streamline of interest is still an ellipse but may not be in the meridional plane. It will, however, lie parallel to this plane. The element of distance traveled along the surface in the streamwise direction now becomes

$$d\bar{s}_1 = \sqrt{a^2 \left(1 - \frac{\bar{z}^2}{a^2}\right) \cos^2 \bar{\theta} + b^2 \left(1 - \frac{\bar{z}^2}{a^2}\right) \sin^2 \bar{\theta}} \; d\bar{\theta} \tag{151}$$

while the distance in the crossflow direction is given by

$$d\bar{s}_2 = \sqrt{\bar{z}^2 + a^2 \left(1 - \frac{\bar{z}^2}{a^2}\right) \cos^2 \bar{\theta}} \; d\bar{\phi} \tag{152}$$

$\bar{\theta}$ is a displacement about the z-axis in the plane z = constant while $\bar{\phi}$ is a displacement about the x-axis in the plane x = constant. In terms of these

coordinates, the element of distance along the surface is given by

$$d\bar{s}^2 = \left[a^2 \left(1 - \frac{\bar{z}^2}{a^2} \right) \cos^2 \bar{\theta} + b^2 \left(1 - \frac{\bar{z}^2}{a^2} \right) \sin^2 \bar{\theta} \right] d\bar{\theta}^2$$

$$+ \left[\bar{z}^2 + a^2 \left(1 - \frac{\bar{z}^2}{a^2} \right) \cos^2 \bar{\theta} \right] d\bar{\phi}^2 \tag{153}$$

or

$$d\bar{s}^2 = g_1^2 \, d\bar{\theta}^2 + g_2^2 \, d\bar{\phi}^2 \ . \tag{154}$$

For purposes of practical calculation we must still evaluate $\bar{z}$, $\bar{\theta}$, and $\bar{\phi}$, in terms of the original body coordinates. The transformation equations for these quantities we can show to be

$$\bar{z} = (z - z_1)\cos \lambda + (x - x_1)\sin \lambda \tag{155}$$

$$\bar{\theta} = \tan^{-1} \left(\frac{(x - x_1)\cos \lambda - (z - z_1)\sin \lambda}{y} \right) \tag{156}$$

$$\bar{\phi} = \tan^{-1} \left(\frac{\bar{z}}{y} \right) \tag{157}$$

We now have the tools we need to describe streamwise and crossflow coordinates locally on the body in terms of the coordinates of points on the body surface as well as to write the boundary layer equations in this curvilinear coordinate system. We will not go through the derivation of the boundary layer equations in a general curvilinear coordinate system; rather we will employ those given for this case by Cebeci et al. (Ref. 99), rewritten in the present notation:

$$\frac{1}{g_1} \frac{\partial u_{\bar{\theta}}}{\partial \bar{\theta}} + \frac{\partial u_n}{\partial n} + \frac{1}{g_2} \overset{\textcircled{1}}{\frac{\partial u_{\bar{\phi}}}{\partial \bar{\phi}}} + \frac{u_{\bar{\theta}}}{g_1 g_2} \overset{\textcircled{2}}{\frac{\partial g_2}{\partial \bar{\theta}}} = 0$$

$$\frac{u_{\bar{\theta}}}{g_1} \frac{\partial u_{\bar{\theta}}}{\partial \bar{\theta}} + u_n \frac{\partial u_{\bar{\theta}}}{\partial n} + \frac{u_{\bar{\phi}}}{g_2} \overset{\textcircled{3}}{\frac{\partial u_{\bar{\theta}}}{\partial \bar{\phi}}} - \frac{u_{\bar{\phi}}^2}{g_1 g_2} \overset{\textcircled{4}}{\frac{\partial g_2}{\partial \bar{\theta}}} = - \frac{1}{\rho g_1} \frac{\partial P}{\partial \bar{\theta}} + \nu \frac{\partial^2 u_{\bar{\theta}}}{\partial n^2}$$

$$\frac{u_\theta}{g_1}\frac{\partial u_{\bar\phi}}{\partial \bar\theta} + u_n \frac{\partial u_{\bar\phi}}{\partial n} + \frac{u_{\bar\phi}}{g_2}\frac{\partial u_{\bar\phi}}{\partial \bar\phi} + \frac{u_{\bar\theta}u_{\bar\phi}}{g_1 g_2}\frac{\partial g_2}{\partial \bar\theta} = -\frac{1}{\rho g_2}\frac{\partial P}{\partial \bar\phi} + \nu \frac{\partial^2 u_{\bar\phi}}{\partial n^2} \qquad (158)$$

The velocities and directions are defined in the sketch below:

Point of interest on body surface
In these equations

$$\frac{\partial g_2}{\partial \bar\theta} = -\frac{\frac{1}{2}a^2\left(1-\frac{\bar z^2}{a^2}\right)\sin^2\bar\theta}{\sqrt{\bar z^2 + a^2\left(1-\frac{\bar z^2}{a^2}\right)\cos^2\bar\theta}} \cdot \qquad (159)$$

Despite the apparent generality of this form of the boundary layer equations we are still forced to assume when using them that the inviscid streamlines are displaced only in the n-direction by the presence of the boundary layer. We must do this in order that the metrics (g_1, g_2) we compute at a point on the surface apply vertically through the boundary layer.

The differences between the two-dimensional boundary layer equations developed earlier and the present three-dimensional treatment lie in the four numbered terms and the third equation. We note that if the circumferential variation in pressures at a given x-station along the body is small compared with the change in pressures in the streamwise direction, then there is no significant force available to produce a crossflow. Since this term, $\frac{\partial P}{\partial \bar{\phi}} \frac{1}{\rho g_2}$, must, because of the basis on which the equation was written, be at least as large in magnitude as any term in the equation, we are justified in ignoring the third equation whenever $\frac{\partial P}{\partial \bar{\phi}} \ll \frac{\partial P}{\partial \bar{\theta}}$.

We now need to find the conditions under which the other four terms may be ignored. Unfortunately we cannot demonstrate these easily in a rigorous fashion. But we will observe that if $\partial P/\partial \bar{\phi}$ is small then it is not likely that $u_{\bar{\phi}}$ will be large; in fact, it will probably be no more than about 1/10 as large as $u_{\bar{\theta}}$. In that event, term number (4) is probably small compared with terms on the right hand side of the equation. Again, if $\partial P/\partial \bar{\phi}$ is small we would not expect $u_{\bar{\theta}}$ to change substantially from one $\bar{\phi}$ value to another (for the same $\bar{\theta}$). This, combined with the small value of $u_{\bar{\phi}}$, means that term (3) probably is also quite small. By the same argument we can ignore term (1). Term (2), however, is not small in regions of large changes in body curvature, i.e., near the nose or the tail of the spheroid. $(\bar{\theta} \rightarrow \pm 90°)$. It is this term which accounts for the spreading of the flow as it moves straight downstream from the nose over the increasing surface area of the body.

It would appear, then, that as long as one observed the criteria

$$1. \quad \frac{\partial P}{\partial \bar{\phi}} \ll \frac{\partial P}{\partial \bar{\theta}}$$

and

$$2. \quad \bar{\theta} < \left| \frac{0.9\pi}{2} \right| \tag{160}$$

the use of a two-dimensional boundary layer calculation along streamlines would be a reasonable way of determining δ^* and τ_w.

By choosing a sufficient number of streamlines we can insure that at least one streamline will cross each panel somewhere near its center. The solution of the boundary layer equation along that streamline will then give us τ_w and δ^*

125

near the centroid of each panel. Because of the very great amount of work involved in successively modifying the body shape to account for displacement thickness effects, we will for the present, adopt the policy of using the first calculation of τ_w as the final value.

We could modify the body shape to account for displacement effects by adding

$$\delta^* = \frac{\bar{a}}{\sqrt{\bar{a}^2 + \bar{b}^2 + \bar{c}^2}} \qquad (161)$$

to the x-dimension of all point on the panel

$$\delta^* = \frac{\bar{b}}{\sqrt{\bar{a}^2 + \bar{b}^2 + \bar{c}^2}} \qquad (162)$$

to the y-dimension and

$$\delta^* = \frac{\bar{c}}{\sqrt{\bar{a}^2 + \bar{b}^2 + \bar{c}^2}} \qquad (163)$$

to the z-dimension, $\bar{a}$, $\bar{b}$, and $\bar{c}$ are given by equation (136).

However, the displacement thickness over the forward part of the body is usually small and the use made of this information on the rear part of the body in our drag calculations, as outlined below, is rather approximate. In these circumstances recomputation of the entire body contour does not appear to be warranted.

It must be constantly borne in mind that the approach used here for determining the pressures and velocities over the body surface is an inviscid one. As such, it always places a stagnation point at the downstream end of a closed body. As a result, the computation always leads to a prediction of rear stagnation pressures at the aft end of the body in what is physically a wake region. See the sketch below. The pressures in this wake are generally less than atmospheric immediately aft of the body and rise to the free stream value some distance downstream. The relatively low pressure exerted on that portion of the body's geometry opposite the high pressure stagnation region near the nose is the principal source of the force acting in the direction of the flow which we call form drag or pressure drag. Bodies producing extensive regions of flow separation will therefore have large pressure drags. It is apparent, therefore, that we must represent the wake effects with reasonable accuracy if we are to make meaningful drag computations.

BODY IN INVISCID FLOW
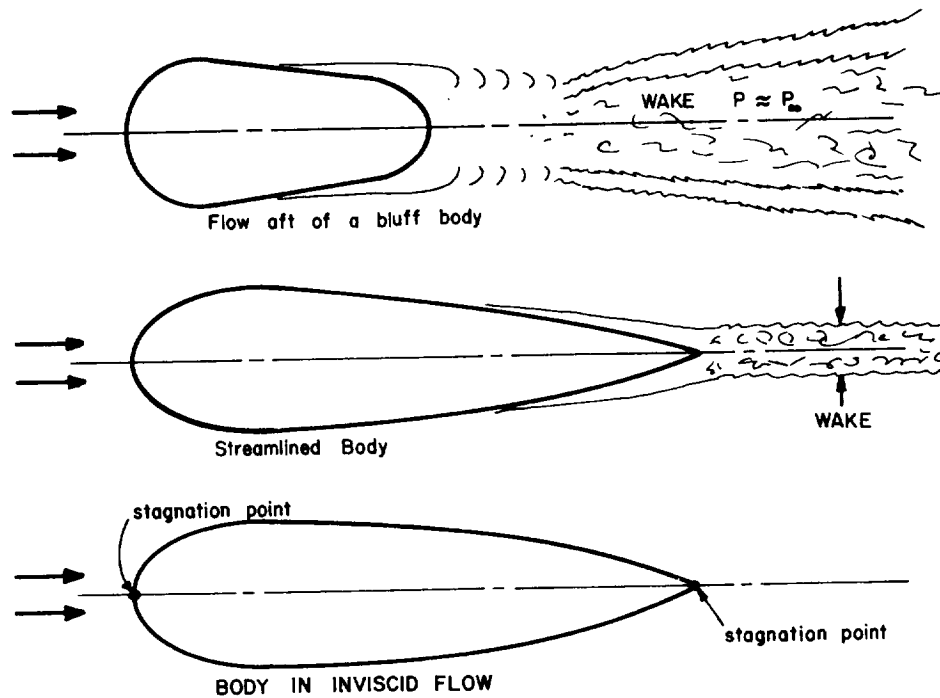

How to include such a representation within the framework of our procedure for determining the inviscid flow field is the hurdle we must clear. Since the wake is a region of "dead" air relative to the body it seems reasonable to represent it by assuming it to be part of the physical body for purposes of calculating the inviscid flow field. Then, by assigning quadrilaterals to the surface of this wake-body which are of approximately the same area as those on the physical body, one can redo the inviscid computation to find the pressures on the wake-body. See the sketch below. The pressures on those panels of the wake-body which lie immediately above equivalent panels (quadrilaterals) on the physical body are then applied to the panels on the physical body along the normals to the physical body. The forces acting on the physical body are summed to find a lift and a drag. Since the pressures on the upstream portion of the wake-body will, if its contours are properly chosen, be less than those on the rear of the physical body according to the inviscid flow computation, the integration of forces will indicate a net drag on the body. Note that the total number of panels considered in the analysis is greater when the wake-body is present.

127
Pressures computed on panels a', b', c', and d' by the inviscid source distribution are applied to panels a, b, c, and d on the physical body before the integration of forces in the axial direction is carried out. Since these pressures are lower than those computed by source distribution on the physical body, a net drag is obtained on integration.

Some difficulty arises in attempting to specify the contours of the wake-body *a priori*. If the contours are significantly concave, the inviscid flow model will always produce a decelerating flow in these regions and, hence, rising pressures. The computed pressure drag will then be less than that actually present. Further, the boundary layer model used cannot predict the location of the actual flow separation point. Thus, there is some ambiguity in locating the upstream origin of the wake-body as well as how it should fair into the physical body.

Consider, however, the drag data (Ref. 112) for airship hulls with geometries given in the following table.

x/ℓ	$2y/t$	x/ℓ	$2y/t$	x/ℓ	$2y/t$
0	0	.150	.887	.600	.885
0.0125	.2	.200	.947	.700	.790
.0250	.335	.250	.982	.800	.665
.050	.526	.300	.998	.900	.493
.0750	.658	.350	.999	.950	.362
.100	.758	.400	.990	.980	.225
.125	.835	.500	.950	1.000	0

128
Note that the minimum combined skin friction and pressure drags occur at a fineness ratio of 2.1. The drag coefficient rises steeply for blunter bodies. It is thus, unlikely that fuselages will be blunter than a fineness ratio of 2 to 3. Calculations of the skin friction drag over a 3 to 1.0 ellipsoid (see sketch below) compared with the total measured drag indicate that the pressure

129
drag generated by such a body is about 25 percent of the total. As the
fineness ratio increases this fraction of course decreases. The total drag
is thus not particularly sensitive to small errors in determining the pres-
sure drag on streamlined bodies. Let us, therefore, arbitrarily assume that
the wake-body always begins at about the 0.9ℓ point on the physical body. We
will also assume that we can determine the initial surface slope of the wake-
body from our calculation of the displacement thickness as indicated in the
sketch below:
The wake-body surface we will gradually fair, via an exponential function, to
a point sufficiently far downstream that the surface of the wake-body can be
paneled with an even number of sets of panels in the streamwise direction.
The panel areas are to be the same size as those on the physical body. It
will be recognized that for thin wakes the termination point of the wake-body
with this scheme is of necessity very far downstream. For thicker wakes, the
termination point will be somewhat further upstream. The sketch below shows
how the 3 to 1.0 ellipsoid appears with a wake-body appended.

130
The reader will recognize that an ellipsoid of revolution is one of the simplest bodies possible. Because the procedure outlined above gives reasonable results in such cases, does not mean that it will necessarily give reasonable results for more complex bodies, if applied in an arbitrary and capricious fashion. More complex bodies—of which light aircraft fuselages are excellant examples—can produce local separations as the flow rounds the cowling or encounters the windscreen and more general separations in the area aft of the cabin, for example. None of these situations can really be treated properly by the boundary layer theory employed. All one can do is insure that the fuselage geometry is adequately presented to the inviscid flow field computation and that when boundary layer computations indicate that separation is imminent, force the flow to continue attached (for computational purposes) until a more favorable pressure gradient is encountered. Sometimes these measures will yield acceptable results, sometimes not. The user must in most cases examine the results with caution and in detail, relying on past experience and experimental evidence to determine whether they are reliable. It is unfortunate that the requirement for the exercise of such substantial engineering judgement in this procedure has not yet been eased. However, in defense of this situation one may point out that in contrast to other aspects of the prediction of aerodynamic characteristics of complete configurations, the estimation of fuselage drag in a rigorous analytical fashion is now in its infancy and undergoing considerable flux. The method related herein was assembled by the present writers in the absence of suitable techniques in the literature. With the intense activity in the field, however, it would be surprising indeed if it were not soon superceded by methods more easily applied and using more accurate boundary layer models.

We have discussed above the methods by which we find the pressure and skin friction on individual panels or quadrilaterals. To determine the lift, drag, and pitching moment of the entire body we begin by finding first the component in either the z (lift) direction or the x (drag) direction, of the pressure on each panel. A product of this pressure component and the panel area (assuming of course that the pressure determined for a particular point on the panel exists everywhere on that panel) gives the force contributed by the panel to the total body force along either the z or x-axis. The pressure on a panel is exerted parallel to the normal to the panel. Thus, the component of the pressure in the z-direction is given by

$$P_{z_i} = P_i \left(\frac{\bar{c}}{\sqrt{\bar{a}^2 + \bar{b}^2 + \bar{c}^2}} \right)_i \qquad (164)$$

while the component in the x-direction is

131

$$P_{x_i} = P_i \left(\frac{\bar{a}}{\sqrt{\bar{a}^2 + \bar{b}^2 + \bar{c}^2}} \right)_i \qquad (165)$$

Formally, then, the lift is simply

$$L = \sum_{i=1}^{k} P_{z_i} A_i \qquad (166)$$

where k is the number of panels on the body and A_i is the area of the ith panel. The pressure drag is

$$D_p = \sum_{i=1}^{k} P_{x_i} A_i \ . \qquad (167)$$

The pitching moment is easily seen to be

$$M = \sum_{i=1}^{k} P_{z_i} (x_o - x_i) A_i \ , \qquad (168)$$

where x_o is the moment reference point and x_i is the x-coordinate of the ith panel.

If we call γ_x, γ_y, and γ_z the direction cosines of the streamlines over the body, then the x-component of the skin friction on each panel, when summed over all panels on the body, becomes the skin friction drag:

$$D_f = \sum_{i=1}^{k} \tau_{w_i} \gamma_{x_i} A_i \ . \qquad (169)$$

Skin friction contributions to the lift and pitching moment can be found in an analogous fashion. The total fuselage drag is the sum of the pressure drag and the skin friction drag, i.e.,

$$D = D_f + D_p \ . \qquad (170)$$

132

CONCLUDING REMARKS

In our determination of the lift, drag, and moment characteristics of light aircraft fuselages we have generally employed a procedure which is characterized by the following steps:

1. Represent the surface of the isolated fuselage by a number of quadrilaterals or four-sided panels.

2. In effect move all four corners of the panel into the same plane through the procedure which determines the direction of the normal.

3. Place a source of undetermined strength on each panel and require that the velocity induced by all sources plus that due to the free stream in the direction normal to the surface of each panel be zero.

4. Solve the resulting system of equations for the source strengths.

5. Compute the velocity over the body surface. From this, determine streamlines and surface pressures.

6. Perform two-dimensional, momentum-integral-type boundary layer computations along streamlines to find local values of τ_w and δ^*.

7. Integrate τ_w over the surface to find the skin friction drag of the isolated fuselage.

8. Modify the body shape by attaching a wake-body toward the trailing edge and enlarging, if desired, the remainder of the body to account for displacement thickness effects.

9. Compute a new set of source strengths and surface pressures corresponding to the wake-body shape.

10. Integrate the surface pressures to find the lift, pressure drag, and pitching moment of the fuselage.

This procedure of course applies only to an isolated fuselage and does not account for flow interactions between the fuselage and the wing or tail plane. These are discussed in the following chapter. The procedure also does not account for the effects on drag of small protuberances such as extended landing gear. A suggested means of tying together the results of the various computations in this, the previous chapter, and the chapter on interactions, along with empirical results for small protuberances, is presented in the chapter on Lift and Drag Estimation of Complete Configurations.

We should mention also that the method developed here applies only to fuselages so inclined as to have minimum circumferential pressure gradients. This was done, it will be recalled, to permit the use of a simple boundary layer computation procedure along streamlines. With the need for many panels to adequately represent the body and the desire to have at least one streamline go through each panel near its centroid, the number of boundary layer calculations required to accomplish this is very substantial. In essence we are substituting a large number of two-dimensional computations which we know how to do for a smaller number, perhaps, of difficult and involved three-dimensional computations with which we have had little experience as yet. For this reason and the very large computer capacity required even for such an approach, we have not considered the case of flow approaching the fuselage with a vertical or sidewise component. The reader will recognize that because the formulation of our problem is linear, the effects of such components can be superimposed on the effects of the axial component. To include one of these components, however, is the equivalent, computationally, of repeating the problem. Considering only an axial onset flow limits the applicability of our treatment to cases where the fuselage angle of attack is always near zero, i.e., near cruise. We cannot, therefore, take adequate advantage of the ability of the wing program to yield reliable results up to C_L's of about 0.8 except to account for variations in wing incidence angle. It is to be expected, however, that such restrictions will be relaxed through the use of improved methods which should be available from the major airframe manufacturers within the next few years.

134

INTERFERENCE EFFECTS

In our previous discussion we mentioned that while we perform most of our aerodynamic calculations on isolated fuselages and wings we did realize that when these components are joined together to form practical configurations there are interactions between them not accounted for by the treatment of isolated components. We intimated that we would approach these interaction effects largely on an empirical basis. As may become evident from the discussion below, we are virtually forced to take this approach by the complexity of the problem.

WING-TAIL INTERFERENCE

An aircraft's horizontal tail plane is flying in a very non-uniform flow field at least compared with the one seen by the main wing. In developing lift, the main wing imparts a downward component to the flow over it, a component which is not uniform across the span. Further, the wake produced by the main wing is a sheet-like region of low dynamic pressure which diffuses slowly as it moves downstream. These phenomena make it difficult to determine the orientation and magnitude of the flow striking the tailplane. Ferrari in Ref. 98 describes the situation aptly:

"For wings of aspect ratio greater than 4.0 and sweep angles of less than 30°, the wings' system of bound vortices may be taken to be compressed into one single vortex, the axis of which is normal to the plane of symmetry and passes through the mean aerodynamic center of the lifting surface. The single vortex has a circulation that is variable in strength along the span; a trailing vortex sheet is shed across the whole breadth of this bound vortex core. The actual shape of the vortex sheet is rather difficult to specify inasmuch as it depends upon the particular velocities induced by the vortex system at the points occupied by the trailing vortex sheet.

The problem is complicated even more seriously because the trailing band of vortices is unstable. As a result of this instability the band tends to roll up at the edges in such a way that two distinct vortical corelike nuclei of appreciable size are formed, which are characterized by equal and opposite amounts of circulation....the complete rolling up of the vortices is accomplished only at a certain distance behind the rear edge of the wing, which may be calculated from the relationship $0.56 \frac{b}{2} \frac{AR}{C_L}$ *"* where the symbol AR denotes aspect ratio and b is the wing span.

For most cases of interest however *"the region of the vortex sheet which stands nearest to the stabilizer...is not yet involved in the roll-up phenomena."*

The usual way to treat the problem of determining the direction and magnitude of the flow approaching the stabilizer is to assume first of all that the wake is non-existent. This enables one to use an extension of the lifting line theory (as we shall do below) to find the flow angle anywhere in the downwash field. The effect of the wake is then added in a semi-empirical fashion.

Referring now to the figure following equation (82) we may, as we did in obtaining equation (87), write an expression for the downwash component of the flow velocity at any point aft of the wing, which includes contributions from the bound vortex (that running along the wing span) and the two trailing vortices:

$$w = \frac{\Gamma}{4\pi} \left\{ \frac{-x}{x^2 + z^2} \left[\frac{y + b/2}{\sqrt{x^2 + z^2 + (y + b/2)^2}} - \frac{y - b/2}{\sqrt{x^2 + z^2 + (y - b/2)^2}} \right] \right.$$

$$- \frac{y - b/2}{z^2 + (y - b/2)^2} \left[1 - \frac{x}{\sqrt{x^2 + z^2 + (y - b/2)^2}} \right] \qquad (171)$$

$$\left. + \frac{y + b/2}{z^2 + (y + b/2)^2} \left[1 - \frac{x}{\sqrt{x^2 + z^2 + (y + b/2)^2}} \right] \right\}$$

Positive z-direction is downward and positive x-direction is upstream. The other components of the induced velocity are

$$u = \frac{\Gamma}{4\pi} \frac{z}{x^2 + z^2} \left\{ \frac{y + b/2}{\sqrt{x^2 + z^2 + (y + b/2)^2}} - \frac{y - b/2}{\sqrt{x^2 + z^2 + (y - b/2)^2}} \right\} \qquad (172)$$

$$v = \frac{\Gamma}{4\pi} \frac{z}{z^2 + (y - b/2)^2} \left\{ 1 - \frac{x}{\sqrt{x^2 + z^2 + (y - b/2)^2}} \right\}$$

$$- \frac{\Gamma}{4\pi} \frac{z}{z^2 + (y + b/2)^2} \left\{ 1 - \frac{x}{\sqrt{x^2 + z^2 + (y + b/2)^2}} \right\} . \qquad (173)$$

The foregoing expressions give the velocity components induced by a single horseshoe vortex. In the usual case where it is necessary to represent

136

the actual distribution of circulation by superimposing a number of simple horseshoe vortices, the induced velocity components are calculated by replacing Γ by $d\Gamma/d\eta$ and $b/2$ by η in (171, 172, and 173) and the integrating the resulting expressions from $\eta = 0$ to $\eta = b/2$. $\Gamma(\eta)$ is known beforehand from the procedure which determines the three-dimensional lift distribution on the wing. Since this integration must be carried out for each point of interest, the mapping of the flow direction and magnitude in the region near the tail is a laborious process. The flow direction in the x-z plane is found from the expression

$$\varepsilon = \sin^{-1}\left[\frac{w}{V + u}\right] , \qquad (174)$$

while the magnitude is given by

$$\sqrt{w^2 + (V + u)^2} . \qquad (175)$$

If the stabilizer is placed about three chord-lengths behind an aspect ratio 6.0 wing, it will be found that the downward angle will be about $2SC_L/\pi b^2$ radians. For $C_L = 0.6$ this is $3.64°$.

The center of the vortex sheet describes a path in an x-z plane which can be found by integrating ε with respect to x from the trailing edge of the wing rearward. Ferrari gives an expression, developed from experimental data, for the vertical displacement of this vortex sheet center which occurs because of the influence of the wake:

$$\Delta z = -\frac{1}{2} C_s \sin \alpha , \qquad (176)$$

where C_s represents the length of separated flow over the airfoil (primarily the upper surface). The semi-thickness of the airfoil wake he states as

$$z_{wake} = 1.38 \ c \ C_{d_o}^{\frac{1}{2}} \left[\frac{x}{c} + 0.15\right]^{\frac{1}{2}} , \qquad (177)$$

where C_d is the profile drag coefficient applying to the airfoil section located at the spanwise station at which the wake's behavior is being investigated. The magnitude of the velocity along the wake centerline Ferrari gives as

$$u_{w_c} = V\sqrt{1 - \frac{2.42\left[C_{d_o}\right]^{\frac{1}{2}}}{\frac{x}{c} + 0.3}} \qquad (178)$$

137

while the distribution of velocity vertically through the wake is

$$u_w = V \sqrt{1 - \frac{2.42 \left[C_{d_o} \right]^{\frac{1}{2}}}{\frac{x}{c} + 0.3} \cos^2 \left(\frac{\pi \tilde{z}}{z_{wake}} \right)} \tag{179}$$

$\tilde{z}$ is to be measured from the wake centerline and $\tilde{z}/z_{wake} \leq 1/2$.

To summarize the procedure related above, we described the trace of the center of the vortex sheet shed by the wing in x-z plane at any value of y by an integration with respect to x of equation (174). Since this is an inviscid theory, we apply empirical corrections to account for viscosity effects. The actual wake centerline is displaced from the value given by the integration of (174) by an amount Δz from (176). The actual magnitude of the flow velocity across the wake is given by (179) rather than (175). Outside the wake region, the magnitude of the flow velocity is given by (175). The magnitude given by (175) should also be used in place of V in (179). These relationships are depicted in the figure below:

SECTION A-A

138
From the foregoing we have sufficient information to develop at least a semi-quantitative view of the disturbance which the wing produces in the flow field approaching the horizontal tail plane. With this view we can then proceed to calculate with reasonable accuracy the aerodynamic characteristics of this surface considering it to be a portion of a complete airframe. We do this by employing the theory for a complete wing in the presence of a fuselage developed in the previous chapter but substituting local values of $(\alpha - \epsilon)$ for α and u_w for V (if the tail plane is flying in the wing wake). Such a procedure ignores the presence of a thick boundary layer over the aft portion of the fuselage, the disturbance to the flow field caused by the vertical stabilizer, and the confluence of the body flow immediately downstream of the stabilizer. Since a thick boundary layer tends to smooth out disturbances and since it tends to make the fuselage appear to the flow to be longer and less rapidly varying in area than it actually is, it seems reasonable to conclude that for most configurations in cruise flight the effects ignored are small.

LIFT OF AN ISOLATED FUSELAGE

It was pointed out in the discussion of the literature that a fuselage at angle of attack in inviscid flow should experience no net lift. Any lift generated is a result of viscous effects. In principle we could obtain the correct result by extending our treatment of forces on an isolated fuselage as presented in the previous chapter to include a vertical component in the onset flow and a boundary layer computation method which accepts circumferential pressure gradients and expanding flows. (It is of course possible that bodies of unusual shape will also generate lift in much the same way that wings do but we have not as yet added planar vortices to our treatment of the pressures on the fuselage to account for this.) Unfortunately, the procedure would assuredly be very lengthy. Since it is desirable in design work to have an indication of the relative importance of certain effects so that we know how precisely we will have to evaluate them, we would like to have a simpler means for establishing the magnitude of the fuselage lift and for identifying its source physically. One such means follows from the argument given below.

A very long circular cylinder whose axis is at angle α with the oncoming flow has a flow about it which can be thought of as being made up of two non-interacting parts: first, an axial flow which cannot affect the lift although it does result in a skin friction drag; second, a crossflow which exhibits the same characteristics as the flow over a cylinder placed normal to a stream of velocity $V \sin \alpha$. For Reynolds numbers between 4×10^2 and 2×10^5 one finds from experiments (Ref. 65) that the drag coefficient of a cylinder normal to a stream is always about 1.1. This is, of course, a result of the separation of the flow from the cylinder near the 90° points and the creation of a large low pressure wake on the lee side. If the cross flow Reynolds number lies within this range, one would expect that a long, isolated cylinder will experience a force normal to its axis given by

$$N = 1.1 \frac{\rho}{2} (V^2 \sin^2 \alpha) \ell d \ . \tag{180}$$

ℓ is the length of the cylinder and d is its diameter. The force normal to the stream direction is then

$$L = N \cos \alpha \ . \tag{181}$$

Normalizing this force by the usual $1/2 \ \rho V^2 \ d\ell$ gives

$$C_L = 1.1 \sin^2 \alpha \cos \alpha \ . \tag{182}$$

Most fuselages are not very long circular cylinders but have instead a nose which, even for the flow model assumed, i.e., noninteracting axial and crossflow components, experience an inviscid lift force. Usually, this force would be balanced by an equal and opposite force on the tail in inviscid flow, resulting in the development of a pitching moment but no net lift. If, however, the body is cut off so that the flow separates from the base and forms a viscous wake, the body appears to the inviscid flow to extend downstream for some distance at essentially constant diameter. The balancing force is then not developed and we are left with a net lift which is said to be potential or inviscid in origin. Following Ref. 101, we shall show how this arises.

We recall that the potential for the crossflow at station x on an infinite circular cylinder in cylindrical coordinates is written

$$\phi = - V \sin \alpha \left(r + \frac{a^2}{r} \right) \cos \theta \tag{183}$$

where a is the radius of the cylinder at station x, r is the radial coordinate, and θ is the angular coordinate measured from the forward stagnation point. The crossflow may also change in time as the flow moves along the axis of the cylinder so that the appropriate form of the Bernoulli equation giving the relation between pressure and velocity along a streamline is

$$\frac{P}{\rho} = - \frac{\partial \phi}{\partial t} - \frac{1}{2} \left[\left[\frac{\partial \phi}{\partial r} \right]^2 + \left[\frac{\partial \phi}{r \partial \theta} \right]^2 \right] + c \ . \tag{184}$$

The three partial derivatives are given by

140

$$\frac{\partial \phi}{\partial t} = -V \sin \alpha \, \frac{\cos \theta}{r} \, 2a \, \frac{da}{dt} = -V \sin \alpha \cos \theta \, \frac{2a}{r} \frac{da}{dx} \frac{dx}{dt}$$

$$\frac{\partial \phi}{\partial r} = -V \sin \alpha \, (1 - \frac{a^2}{r^2}) \cos \theta \; . \qquad (185)$$

$$\frac{\partial \phi}{r \partial \theta} = + \frac{V \sin \alpha}{r} (r + \frac{a^2}{r^2}) \sin \theta$$

Inserting these values into the Bernoulli Equation yields

$$\frac{P}{\rho} = 2V^2 \sin \alpha \cos \alpha \, \frac{da}{dx} \frac{a}{r} \cos \theta - \frac{V^2 \sin^2 \alpha}{2} \left\{ \cos^2 \theta \left(1 - \frac{a^2}{r^2} \right)^2 \right.$$

$$\left. + \left(1 + \frac{a^2}{r^2} \right) \sin^2 \theta \right\} + c \qquad (186)$$

As $r \to \infty$, we must assume that P becomes P_∞, the freestream value at infinity; hence

$$c = \frac{P_\infty}{\rho} + \frac{V^2 \sin^2 \alpha}{2} \; . \qquad (187)$$

On the surface of the cylinder $r = a$. At this location the pressure is, accordingly,

$$\frac{P}{\rho} = 2V^2 \sin \alpha \cos \alpha \, \frac{da}{dx} \cos \theta - \frac{V^2 \sin^2 \alpha}{2} \left[4 \sin^2 \theta \right] + \frac{P_\infty}{\rho} + \frac{V^2 \sin^2 \alpha}{2}$$

$$= 2V^2 \sin \alpha \cos \alpha \, \frac{da}{dx} \cos \theta + \frac{V^2 \sin^2 \alpha}{2} \left[1 - 4 \sin^2 \theta \right] + \frac{P_\infty}{\rho} \qquad (188)$$

The force exerted by the crossflow, per unit length, on the cylinder is, as may be seen in the sketch below,

Cross Flow → | Normal Force →
$$\frac{N}{\ell} = \int_0^{2\pi} P \ a \cos \theta \ d\theta \ = \frac{\rho V^2}{2} \left[\int_0^{2\pi} 2 \ a \ \sin 2 \ \alpha \ \frac{da}{dx} \cos^2 \theta \ d\theta \right.$$

$$\left. + \sin^2 \alpha \int_0^{2\pi} a(1 - 4 \sin^2 \theta) \cos \theta \ d\theta \right] + a \int_0^{2\pi} P_\infty \cos \theta \ d\theta \ . \tag{189}$$

Since

$$\int_0^{2\pi} \cos \theta \ d\theta = 0 \quad \text{and} \quad \int_0^{\pi} \cos^3 \theta \ d\theta = 0 \ ,$$

$$\frac{N}{\ell} = \frac{\rho V^2}{2} 4 \ a \ \sin 2 \ \alpha \ \frac{da}{dx} \int_0^{\pi} \cos^2 \theta \ d\theta$$

$$= \frac{\rho V^2}{2} 2\pi a \ \frac{da}{dx} \sin 2 \ \alpha \tag{190}$$

In producing a force on the cylinder the inviscid flow is deflected so that the lift is considered to act at an angle $\alpha/2$ from the normal force:

$$\frac{L}{\ell} = \frac{\rho V^2}{2} 2\pi a \ \frac{da}{dx} \sin 2 \ \alpha \ \cos \frac{\alpha}{2} \tag{191}$$

This inviscid lift is developed by the body in addition to the viscous lift described earlier. The total lift is the sum of the two effects. We write therefore

142

$$\frac{L}{\frac{\rho V^2}{2}} = \int_0^\ell \left[2\pi a(x) \; \frac{da}{dx} \; \sin 2\alpha \; \cos \frac{\alpha}{2} + \; 2a(x) \; 1.1 \; \sin^2 \alpha \; \cos \alpha \right] dx \tag{192}$$

If we choose our reference area to be ℓd then

$$C_L = \frac{2}{\ell d} \int_0^\ell \left[\pi a(x) \; \frac{da}{dx} \; \sin 2\alpha \; \cos \frac{\alpha}{2} + 1.1 \; a(x) \; \sin^2 \alpha \; \cos \alpha \right] dx \tag{193}$$

We note with interest that inviscid lift is present only when $\frac{da}{dx} \neq 0$, that is, primarily in the nose region of the body. We can easily make an approximate comparison between the predictions of this theory and experimental results taken on an ogive-cylinder-boattail (ℓ/d = 12.7, d = 5, nose length = 26.25) by assuming that the ogive can be satisfactorily represented by a cone and the boattailing can be ignored. Then da/dx = 0.125, a(x) = 0.125x for x from 0 to 20; da/dx = 0, a(x) = 2.5 for x from 20 to 63.5. With these numbers

$$C_L = \frac{2}{317.5} \left[\pi \sin 2\alpha \; \cos \frac{\alpha}{2} \; \frac{x^2}{128} \Big|_0^{20} + 1.1 \; \sin^2 \alpha \; \cos \alpha \; \left(\frac{x^2}{16} \Big|_0^{20} + 2.5x \Big|_{20}^{63.5} \right) \right] \tag{194}$$

$$C_L = 0.0619 \; \sin 2\alpha \; \cos \frac{\alpha}{2} + 0.573 \; \sin^2 \alpha \; \cos \alpha \tag{195}$$

The table below presents the results obtained with this formula and the comparable experimental data. Other experimental data on bodies of revolution may be found in Ref. 95.

α	C_L Theory	C_L Experiment Ref. 96
4°	.0114	.0108
8°	.0280	.0233
12°	.0494	.0376
16°	.0744	.0536
20°	.1022	.0713

143

Qualitative agreement is seen to be quite good. The lack of quantitative agreement is no doubt a result of our failure to describe the shape of the experimental body with sufficient accuracy since the comparisons with experiment presented in Ref. 101 show good correlations.

To apply this theory properly to isolated fuselages, we can see from the foregoing development that we need to know

(a) the fuselage geometry,

(b) the crossflow drag coefficient at each axial station on the fuselage,

(c) the crossflow potential function at each axial station, and

(d) the extent of the fuselage over which the axial flow is essentially inviscid.

The latter we need in order to determine the axial extent over which we may need to consider potential forces. Frequently this point is taken to be the fuselage station at which the wing intersects the fuselage. The crossflow drag coefficient and crossflow potential function are often difficult to determine for non-circular bodies. We do know, however, that the crossflow drag coefficient for Reynolds numbers in the range 10^2-10^5 is always less than about 1.4. (It has this value for a flat plate normal to the wind.) Since the inviscid lift term in (195) is linear and approximately equal to the viscous term for $\alpha = 12°$, it seems reasonable to conclude that it would seldom be more than 30 percent greater than for the experimental configuration considered here. Thus, for all angles of attack of interest, the lift of an isolated fuselage can be expected to be less than 5 percent as great as the lift of a wing of the same planform area. Under conditions of cruising flight, the fuselage lift is probably around 1 percent of the wing lift. With the uncertainties involved in determining wing-body interference effects of this magnitude, fuselage lift alone can be justifiably ignored.

INTERACTION BETWEEN WING LIFT AND FUSELAGE LIFT

As long as the fuselage is long and thin and either circular or elliptical in cross section and the flow about the wing-body combination can be regarded as inviscid, Multhopp's transform technique discussed earlier adequately describes the effect of wing-body interference on overall lift. These conditions are seldom obtained in practice, however. It is of interest, therefore, to examine what method practicing designers use to describe this effect. Ref. 97 suggests that one assume a linear variation of lift with angle of attack and consider that the effect of the body on the wing lift, the wing on the body lift, and total wing-body lift are as given by the ratios in the following table:

144

body diameter / wing span	L_{WB}/L_W	L_{BW}/L_W	L/L_W
0	1.0	0	1.0
0.05	0.99	0.057	1.047
0.1	0.972	0.1215	1.094
0.15	0.956	0.170	1.127
0.2	0.936	0.224	1.16
0.25	0.907	0.270	1.18
0.30	0.882	0.308	1.19

L_{WB} = wing lift in presence of body

L_{BW} = body lift in presence of wing

L_W = lift of wing without body

L = Total lift

Examining the quantities in the table shows that as the body grows and begins to shield the wing, the wing lift falls off, but not as rapidly as the fuselage diameter increases. This indicates a substantial "bridging" effect and is about what one would predict from the Multhopp theory. The body's contribution to the total lift grows in direct proportion to its diameter. The total wing-body lift for fuselage width-to-span ratios typical of light airplanes is about 10 percent greater than for an isolated wing because of the flow wake existing over the fuselage. On the basis of our previous argument concerning the lift of isolated fuselages, it would appear that the interaction between the wing and the fuselage enhances the fuselage's contribution to the total lift. Experience with the flow over cylinders inclined to a stream (Ref. 102) would indicate that these effects actually are more non-linear with α than would be suggested by the table above. In particular, if $\alpha < 6°$, a common condition, certainly, for cruising flight, the crossflow wake is weaker than would be expected from linear considerations and the total lift under these conditions is probably about the same as for the wing alone or perhaps as small as that given by Multhopp's transform. Thus, it would seem reasonable to ignore lift interaction effects unless boundary layer calculations on the body alone indicate the likelihood of the formation of a wake on the upper side of the fuselage which would grow with small increases in angle of attack.

DRAG INTERACTION EFFECTS

During preliminary design it is usually assumed (Ref. 53) that the drag of wing-body combinations is the sum of the skin friction drag of the body and wing separately times a mutual interference factor plus the form drag of the combination. This mutual interference factor for the Mach numbers of interest in light aircraft is usually taken to be about 1.06 for Reynolds

numbers below 2×10^7 and 0.93 for Reynolds number based on fuselage length above 6×10^7. A light aircraft with a 30' fuselage moving at 150 mph will have a Reynolds number of about 4.5×10^7. Thus for cruise conditions this interaction criterion would suggest that the drag interference effects are small.

Such interference criteria, however, cannot account for interactions which result in locally adverse pressure gradients on the wing or fuselage. These gradients often lead to flow separation (and accompanying high drag) at places like wing-fuselage junctions. Correction of these drag problems is usually relegated to the flight phase of the development program, the process being called "drag cleanup."

146

LIFT AND DRAG OF COMPLETE CONFIGURATIONS

In the preceding chapters we have set forth theoretical methods by which one can determine the aerodynamic characteristics (lift, drag, and pitching moment) of airfoil sections and isolated fuselages at low and moderate angles of attack. We also presented an analytical method, valid for unswept wings at moderate-to-high aspect ratios, for correcting two-dimensional aerodynamic characteristics for the presence of the fuselage, taper, twist, changes in camber, and the finite extent of the wing. In addition, we discussed an analytical means by which one might determine the magnitude and direction of the flow approaching the horizontal tailplane. Further, we were able to show that for low-to-moderate angles of attack the fuselage contribution to the aircraft lift is usually negligible. We also noted the semi-empirical means by which drag interaction effects are frequently treated.

These various methods, interesting as they may be in themselves, remain largely academic exercises for the designer unless he can employ them effectively in the estimation of the lift and drag of complete configurations. It is really only in tasks of this kind that the advantages of more rigorous estimation procedures can be fully appreciated. For many reasons it is not yet practical to attempt to consolidate the various methods into a single computer program, the inner workings of which need not concern the user. It therefore requires some understanding of the basis for the various methods in order to apply them all to the same configuration and obtain useful results. We shall outline below a step-by-step procedure which should accomplish this objective.

1. Select the basis of the force coefficients. Normally we will take the wing planform area, including the portion covered by the fuselage, as the basic area.

2. From the geometry of the wing, including

    (a) airfoil ordinates at several spanwise stations (at least root and tip)
    (b) taper
    (c) twist
    (d) aspect ratio
    (e) fuselage cross section at wing root and location of wing in relation to fuselage center,

determine the lift, drag, and pitching moment coefficients of the wing and the spanwise variation in circulation. These data come from the methods discussed in the chapter on wing characteristics. The spanwise circulation, it may be noted, is proportional to the final form of the spanwise variation in section

147

lift coefficient for a given α. This information will be used later when we determine the flow conditions approaching the horizontal tailplane. Note also that for good results we should choose flight conditions for which $C_L \leq 0.8$.

3. Determine the drag <u>force</u> on the fuselage using the methods discussed in the chapter on fuselages. The methods will also give fuselage lift and pitching moment. The moment will be of interest if one seeks to perform stability computations at some later time. The lift given by these methods includes both the inviscid and viscous lifts discussed in the chapter on interference but of course does not include wing-body interference effects. This fuselage lift properly can be added to the wing lift; because it should be small compared with the wing lift, its computation can also serve as a check on the fuselage drag computation. If the fuselage lift is large, the fuselage drag values should be suspect.

4. Normalize the fuselage drag <u>force</u> by the wing area and the free-stream dynamic pressure.

5. Compute the magnitude and direction of the flow approaching the horizontal tailplane.

6. With these data, use the methods of (2) above to determine the lift, drag, and pitching moment of the horizontal tailplane.

7. Normalize by the wing area and freestream dynamic pressure.

8. Add the lift coefficients for the wing, fuselage, and horizontal tailplane together to obtain an overall lift coefficient. Do the same for drag and moment coefficients.

9. Multiply the total drag coefficient by a factor ranging from 1.06 at low Reynolds numbers ($< 2 \times 10^7$) to 0.93 at high Reynolds numbers ($< 6 \times 10^7$). Reynolds number is based on fuselage length.

10. Add in drag increments for protuberances as in Ref. 2 (C_{D_π} method) and for those interference effects which experience or test data indicates may be greater than normal. The C_{D_π} method is summarized below.

Protuberances such as handles, hinges, antennas, cover plates, etc., impose additional drag on the aircraft but their effects are not readily treated within the analytical framework discussed earlier. It has been common to account for such effects in the following manner:

The drag produced by some element of the aircraft can be written

$$D_e = C_{D_e} q S_w$$

148

where C_{D_e} represents the drag coefficient of the element based on the wing area. It is, however, difficult to estimate the drag coefficient of many protuberances in terms of the wing area. These estimates are frequently made by comparing the protuberance with some simple shape which has been tested frequently. For example, the drag of a vertical antenna wire would be estimated by considering the wire to be a cylinder normal to a uniform stream. For most Reynolds numbers, the drag coefficient of such cylinders is given in classic texts as 1.2-1.3 based on a product of the wire diameter and its length. If one calls such a "natural" area A_π and the drag coefficient based upon it C_{D_π}, then D_e is also given by

$$D_e = C_{D_\pi} \, q \, A_\pi \, .$$

In terms of C_{D_π} then,
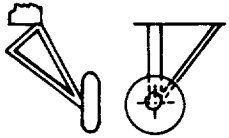

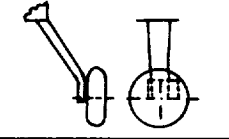

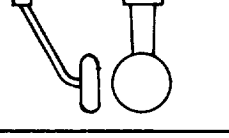

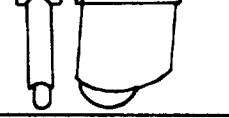

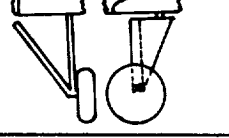

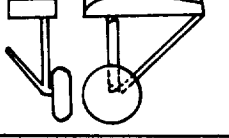

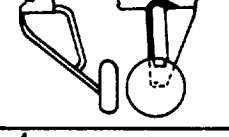

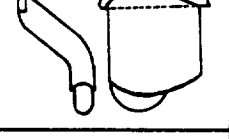

$$C_{D_e} = \frac{C_{D_\pi} A_\pi}{S_w} \, .$$

The net contribution of all protuberances to the total airplane drag coefficient based on the wing area is thus simply

$$C_{D_{Protuberances}} = \frac{\sum_\pi C_{D_\pi} A_\pi}{S_w} \, .$$

The same rationale applies to the contributions to the vehicle drag provided by the fuselage and tail surfaces. The reason for basing all contributions to the overall drag on the wing area is simply one of convenience. The wing area is the basic geometric parameter used in sizing the airplane during preliminary design and is therefore the parameter governing initial estimates of power required and performance.

Given below are C_{D_π} values and the areas upon which they are based for some landing gear designs, nacelles, wing tanks, and wires and struts.

149

2. standard aircraft cable (per foot)	Frontal area	1.4-1.7
3. smooth elliptical wire (per foot)	Frontal area	
fineness ratio 2:1		0.6-0.4
fineness ratio 4:1		.35
fineness ratio 8:1		.3-.2
4. standard streamlined wire (per foot)	Frontal area	.45-.20
5. square wire (per foot)	Frontal area	.16-.20
6. streamlined struts (per foot)	Frontal area	.075-0.10

For smooth round wire of diameter less than ¼ inch, assume two end fittings equivalent to three feet of wire.

For smooth round struts of diamter greater than 5/16 inch, assume two end fittings equivalent to one foot of strut.

For smooth elliptical wire, assume two end fittings equivalent to 10 to 15 feet of wire.

For square wire, assume two end fittings equivalent to two feet of wire.

For streamlined struts, assume two end fittings equivalent to five feet of strut if faired, ten feet if unfaired.

The contribution of the various protuberances to the total aircraft drag coefficient is commonly on the order of 3% to 5%.

PROGRAM FOR THE CALCULATION OF TWO-DIMENSIONAL

AERODYNAMIC COEFFICIENTS

INTRODUCTION

In order to predict the three-dimensional lift and drag characteristics of a general planform, one usually begins with the two-dimensional characteristics of the airfoils which constitute the wing. As noted in the literature review, a computer program which estimates the aerodynamic characteristics of multiple-component airfoils in subsonic, viscous flow already exists (Ref. 31). This program, originally written for NASA Langley under NASA Contract NAS1-9143, has undergone extensive in-house modification at NASA Langley; this modified version is available to the general public. To take advantage of the rather substantial effort which went into the preparation of this program, it was decided to use this NASA program as the basis for developing a suitable—in terms of accuracy and computational requirements—procedure for estimating the two-dimensional lift and drag characteristics of general airfoils.

Since the present report is concerned only with the prediction of characteristics of single-element airfoils and wings, a single element version of the program was obtained from NASA Langley. Although the NASA program was written for the CDC 6600 computer, only slight modification was required in order to use it on the IBM 370-165 computer at N. C. State University. Several airfoils were then investigated at NCSU to determine how well the program prediction of lift, drag, and pitching moment coefficients compared with the experimental data given in Reference 19. After several comparisons it was concluded that in general the predicted lift coefficient was high by 5 to 8 percent for moderately thick airfoils and 8 to 15 percent for very thick airfoils; the drag coefficient was usually high by at least 25% and sometimes as much as 75%. The program as obtained from Langley required 200K (K denotes 1,000 bytes) of core storage and a scratch disk (for matrix inversion use) for an IBM FORTRAN IV H-LEVEL run on the IBM 370-165 computer. The average execution time was 45 to 60 seconds for each airfoil angle of attack (a large portion of this time is input-output time for the scratch disk). Based on the above results the goals for the new program were set as follows:

(1) modify the NASA program to improve the predicted lift and drag coefficients

(2) reduce the size of the program to facilitate its use on smaller computers (∿100K)

(3) reduce the computational time required to evaluate the coefficients of a particular airfoil.

The extent to which the above goals were achieved is summarized below:

(1) a marked improvement in the accuracy of the predicted lift and drag coefficients is evident by perusing Figure 12 through Figure 30

(2) the modified program required only 106K of core storage with no scratch disk required

(3) the computational time required to evaluate the coefficients of
a particular airfoil was reduced to 20 seconds or less.

In the following sections the reader will find a brief explanation of
the theory upon which the program is based, a discussion of the various
changes and modifications implemented in the NASA program, and a comparison
of the predicted lift and drag coefficients (from both the original NASA
program and the NCSU-modified program) with experimentally-determined
coefficients.

GENERAL PROGRAM THEORY

The only practical method currently available for predicting the viscous flow field about an airfoil involves an iterative procedure. The basic steps for this iterative procedure are:

(1) obtain an inviscid flow solution for the basic airfoil

(2) obtain a boundary layer solution based on the inviscid flow solution

(3) construct a modified airfoil by adding the boundary layer displacement thickness to the original airfoil

(4) obtain an inviscid flow solution for the modified airfoil

(5) repeat steps (2) through (4) until some convergence criterion is satisfied, for example, the difference between two successive values of lift coefficient is less than some specified tolerance.

The above steps represent only an outline of the procedure to be used since there are many techniques available for obtaining inviscid and boundary layer flow solutions. For a discussion of many of the available techniques and how they are applied to particular problems, the reader should consult the literature review.

A detailed description of a logical solution procedure is given in the general theory of the previous section. However, for reasons noted in the general introduction, this procedure differs in some details from the method actually employed in the program. Thus, to insure clarity, a brief description of the actual solution procedures used in the modified NCSU program is given below.

It is of utmost importance to choose a solution procedure which can be relied on to converge in most cases. For the problem of the flow field about an airfoil, convergence depends primarily on the manner in which the displacement effects of the boundary layer are treated in the inviscid flow calculations. The program as supplied to NASA chose to model the influence of the boundary layer on the velocity distribution over the actual airfoil as two separate effects. The effect of the boundary layer on the lift is considered to be a modification of the camber line so as to effectively decrease the angle of attack of the airfoil. The change in camber is given by the difference in the magnitude of the upper and lower surface displacement thicknesses as shown in Figure 1.

modified camber line
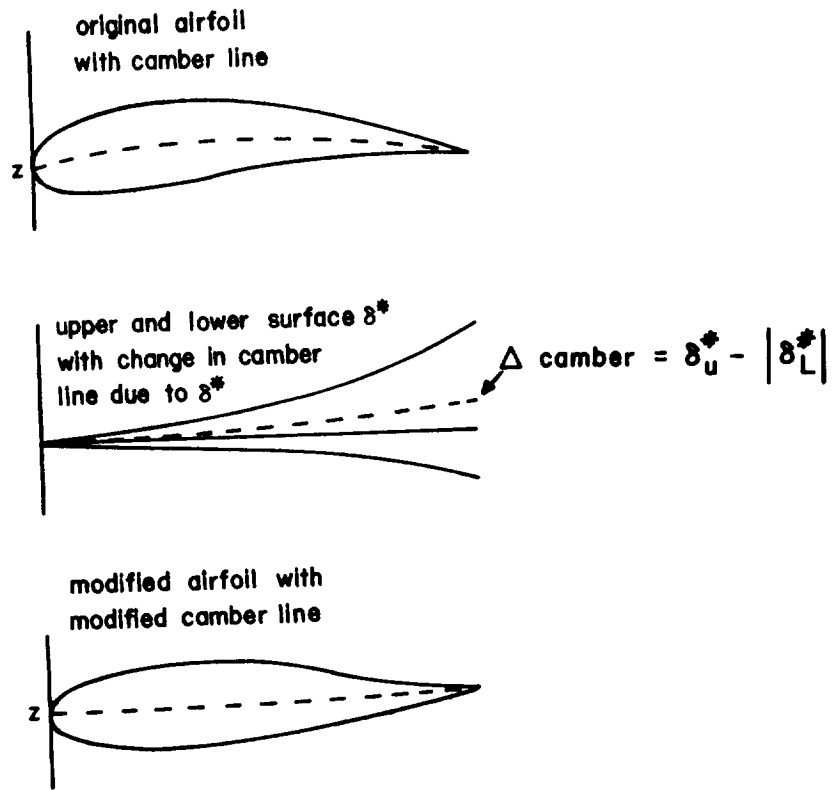

Figure 1.   Modification of camber line due to boundary
layer displacement thickness.

Thickness effects due to the existence of the boundary layer tend to relieve the stagnation condition in the trailing-edge region, giving rise to the pressure or form drag of the airfoil. This effect of the boundary layer on the drag was approximated by the difference of two "thickness" solutions (see Figure 2). The first thickness solution is for a symmetric airfoil at zero angle of attack with the same thickness distribution as the original airfoil plus boundary layer displacement thicknesses. The second thickness solution is also for a symmetric airfoil at zero angle of attack but with the same thickness distribution as the original airfoil. Since superposition is assumed to apply, the velocity distribution over the original airfoil is given by,

$$\left(\frac{V}{V_\infty}\right)_{TOTAL} = \left(\frac{V}{V_\infty}\right)_{CAMBER} + \left(\frac{V}{V_\infty}\right)_{BT+\delta^*} - \left(\frac{V}{V_\infty}\right)_{BT} \quad ,$$

where BT stands for the basic thickness distribution of the original airfoil.

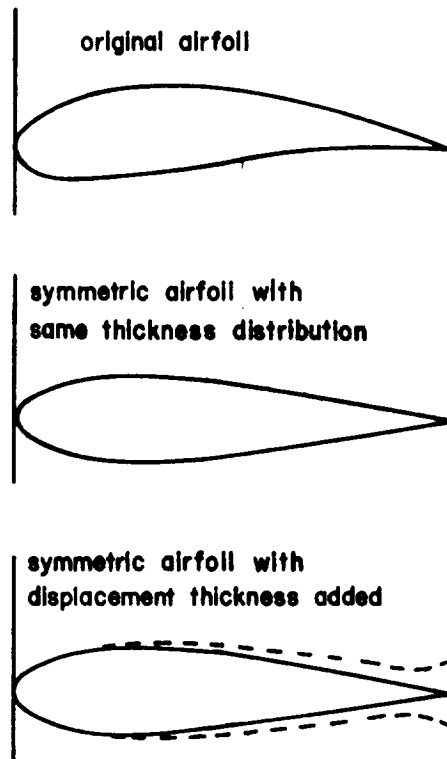

Figure 2.   Thickness effects due to boundary layer
            displacement thickness.

During the initial phase of the investigation, the authors questioned
the necessity of having to use superposition to model the various boundary
layer displacement effects. It seemed that the boundary layer displacement
effect could be modeled by simply adding the displacement thickness to the
original airfoil. However, upon consultation with Mr. Harry L. Morgan, Jr.,
the authors were informed this approach had already been attempted at NASA
Langley but was unsuccessful. Time simply did not permit the authors to
investigate this possible solution procedure further.

The program as originally supplied to NASA Langley used a distributed
vorticity method to calculate inviscid flow solutions. The airfoil was
approximated by a closed polygon, and the distributed vorticity was assumed
to vary linearly along each line segment of this polygon. The sum of the
velocity induced by the distributed vorticity and the free stream velocity
was forced to satisfy the condition that its component normal to the
airfoil surface must be zero at the midpoint of each line segment. NASA
replaced this inviscid solution procedure with a different distributed
vorticity method based on Oeller's work (Ref. 26 and 27).* Using the new

---

*   For the user's convenience, a derivation of the equations for Oeller's
method is given in Appendix G.

158

procedure the airfoil is again approximated by a closed polygon, but the
distributed vorticity is assumed to have a constant value per line segment.
The solution is obtained by requiring that the stream function have the
same constant value at each of the midpoints of the line segments (see
page 405). Consider the two line segments shown in Figure 3. To obtain a
Figure 3. Schematic of control point averaging.

value for the local velocity at the point (i + 1) on the airfoil surface,
it is necessary to use some type of averaging technique on the distributed
vorticities γ_i and γ_{i+1}. The NASA program used an averaging procedure
of the form,

$$\left(\frac{v}{V_\infty}\right)_{i+1} = \tfrac{1}{2} (\gamma_i + \gamma_{i+1}) \quad .$$

Strictly speaking this procedure is correct only if all the line segments
have the same arc length. A somewhat better averaging procedure is obtained
by using the following form,

$$\left(\frac{v}{V_\infty}\right)_{i+1} = (\gamma_i \Delta s_i + \gamma_{i+1} \Delta s_{i+1})/(\Delta s_i + \Delta s_{i+1}) \quad .$$

This improved averaging technique was therefore incorporated into the
NCSU-modified program.

To facilitate the understanding of the remainder of the programming
theory, a program flow chart has been included and is presented in Figure 4.
The remainder of this section will be concerned with the explanation of
this flow chart.

As indicated in the flow chart, the program begins by calling subroutine
READIT. As its name implies READIT is responsible for reading the input
geometry and the ambient conditions. A call is then made to subroutine GEOM
to obtain a set of 65 distributed solution points. A basic thickness
velocity distribution $\left(\frac{v}{V_\infty}\right)_{BT}$ is calculated next using subroutine VOVBT.
This velocity distribution is calculated only once for each airfoil because
it is the basic thickness solution at zero angle of attack. Various arrays
are then initialized and MAIN2 which controls the calculation of the inviscid
flow solution is entered. The camber solution velocity distribution $\left(\frac{v}{V_\infty}\right)_{CAMBER}$

159

is calculated in subroutine CAMBER. For all iterations after the first (zeroth in the program output), the "basic thickness plus displacement thickness" velocity distribution $\left(\dfrac{V}{V_\infty}\right)_{BT+\delta^*}$ is calculated in subroutine VOVBT. The three velocity distributions are combined to give the total velocity distribution for the airfoil, $\left(\dfrac{V}{V_\infty}\right)_{TOTAL}$. Using this velocity distribution subroutine COMPR is called to obtain the compressible pressure coefficients using the Karman-Tsien correction law. The location of the forward stagnation point is obtained from subroutine STAG and subroutine MAIN2 returns control to the mainline.

Subroutine MAIN3 is next entered to control the boundary layer calculations. A call is made to subroutine LAMNA2 to obtain the laminar boundary layer solution for the upper surface. At each point on the airfoil surface subroutine LAMNA2 makes a call to subroutine BLTRAN to see if boundary layer transition has occurred. Control remains in subroutine LAMNA2 until either laminar separation, boundary layer transition, or the end of the surface is encountered. If boundary layer transition has occurred, TURB2 is called to calculate the turbulent boundary layer solution. To insure stability in the computation the last seven boundary layer displacement thicknesses are replaced using a least squares fit obtained from subroutine LSQ*. A calculation for the lower surface boundary layer is performed in a similar manner. The pressure coefficient and skin friction coefficients are integrated over the airfoil in subroutine LOAD, and the various aerodynamic and force coefficients are computed in MAIN3 before control is returned to the mainline. A check is then made to see if five iterations have been completed, a check is made to see if all the angles of attack have been used for the specified Mach number, and a check is made to see if the airfoil has been investigated at each of the specified Mach numbers. Once all the Mach numbers have been investigated, the program returns to subroutine READIT where it attempts to read another data set.

Although this description of the flow chart concludes the General Program Theory section, the reader is reminded that additional aspects of the theory must, of necessity, be discussed in explaining many of the modifications incorporated into the NCSU program. The next section will discuss program modifications of a general nature while later sections will be concerned with modifications of a more specific nature.

161

GENERAL PROGRAM MODIFICATIONS

Many of the changes made in the NASA program may be classified as general programming modifications applicable to the entire program rather than a particular subroutine; these general modifications are discussed below. Throughout the remainder of the text the program obtained from NASA Langley will be referred to as the NASA program while the modified program generated at N. C. State University will be referred to as the NCSU program.

The NASA program was run on the CDC 6600 computer using segmentation to reduce the core requirement. Since segmentation as such is not supported by IBM machines, the segmentation control cards were deleted. The NASA program also contained a PLOT subroutine which was used to plot the pressure coefficients. Inasmuch as plotting software may vary drastically from installation to installation, this subroutine was deleted from the program.

Although only a multi-component version of the program was originally supplied to NASA Langley (Ref. 31), a single element version was produced at NASA by deleting the confluent boundary layer and slot flow subroutines. This single element version was the program made available to N. C. State University. The program as supplied still contained variables in other subroutines which were used only for multi-component calculations and variables which were double subscripted to facilitate multi-component calculations (the second subscript was used to denote the particular component). These unnecessary variables and second subscripts are eliminated in the NCSU version of the program.

In the interest of clean coding, the COMMON statements were aligned and modified so that the Common variables have the same variable name in each of the subroutines in which they appear. Also, whenever possible the NCSU program makes use of Common transfer of information thus eliminating many of the subroutine arguments.

In the NASA program a Mach number extrapolation and smoothing process* was applied to upper and lower surface trailing edge pressure coefficients in subroutine MAIN3 (statements 90 through 99 of NASA program). Since this pressure coefficient modification was found to produce a significant non-zero lift coefficient for a symmetrical airfoil at zero angle of attack, it was deleted in the NCSU program.

The NASA program also allowed the user to specify the total number of solution points desired for the airfoil investigated, up to 100 points. In order to minimize storage, several test cases were investigated to find a minimum value for the number of solution points which would still give valid aerodynamic coefficients. Calculations with 65 points produced

---

* See pages 78 and 79 of Reference 31 for the description of this procedure.

coefficients which were within one or two percent of those predicted
using 100 points; also, less than 65 points showed the trend of producing
a larger percentage difference as the number of points were decreased.
It was therefore decided that 65 solution points were the optimum number,
and the NCSU program specifies the use of 65 solution points.

Several of the unnecessary WRITE and PRINT statements contained in the
NASA program were deleted in the NCSU program to reduce total program
size. To insure compatibility with other installations all input/output
statements were changed to the forms READ(JREAD,C), WRITE(JWRITE,C), and
WRITE(JPUNCH,C) where JREAD, JWRITE, and JPUNCH are the appropriate
input/output numbers and C is some FORMAT statement number. The values
of the input/output unit numbers are assigned by three specification
statements at the beginning of the mainline of the NCSU program (JREAD=1,
JWRITE=3, and JPUNCH=2). For installations having different input/output
unit numbers these specifications may be changed. Only Hollerith field
literal data specifications were permitted in the NCSU program to insure
IBM-CDC machine compatibility.

The maximum number of angles of attack, specified as 5 in the NASA
program, was increased to 10 in the NCSU program. Also, many of the
subroutines contained in the NASA program were combined or deleted in
the NCSU program to make it simpler and more efficient. A table comparing
the subroutines contained in each of the programs is given below.

Table 1. Comparison of subroutines contained in the NASA
program and the NCSU program.

In order to give the user the option of reducing the size of the NASA
program output for a particular airfoil, an IWRITE control parameter was
incorporated into the NCSU program. IWRITE is a program input variable
which should have the value 0, 1, 2, or 3. IWRITE = 0 is the default
write option which basically gives the complete output presented in the
NASA program. An IWRITE of 1, 2, or 3 will yield reduced portions of the
total output with IWRITE = 3 producing the minimum output for each airfoil
tested. An example of the output generated for each of the IWRITE options
is given in Figures A-3, A-4, A-5, and A-6 of Appendix A.

The angle of attack of an airfoil is generally defined as the angle
between the free stream flow direction and the airfoil chord line. The
program must therefore know the location of the chord line of the airfoil
with respect to the x-axis of the reference system in order to calculate
the correct aerodynamic coefficients as a function of angle of attack.
In most cases the location of the chord line is known, and the airfoil
coordinates are referenced with respect to this chord line. However, in
some instances the chord line location may not be precisely defined, thus
requiring the program to calculate a chord line to use as a reference
line for the angle of attack. In general the most logical choice for
the calculated chord line would be the longest line from the midpoint of
the trailing edge to the nose of the airfoil. Thus, the program would
choose line A as the chord line for the airfoil depicted in Figure 5.
Figure 5. Sample airfoil with longest chord line.

Throughout this report a chord line calculated by the program in this manner
will be referred to as the longest chord line. An input control parameter
IALPHA was incorporated into the NCSU program to allow the user to either
specify the airfoil chord line or to allow the program to calculate the
longest chord line.

164

IALPHA = 0 implies that the chord line of the airfoil is parallel to the x-axis of the input reference system of specified airfoil data points. Although it would be more convenient to specify the airfoil coordinates with the chord line as the x-axis of the reference system as shown in Figure 6a, it is only necessary to input the coordinates with the chord line parallel to the x-axis of the reference system as shown in Figure 6b.

(a)   **(b)**
Figure 6.   Location of chord line for IALPHA = 0.

The authors strongly urge that only the convention in Figure 6a be used. As indicated in the User Instructions of Appendix A, a set of lower surface points and a set of upper surface points are read for the airfoil. The upper and lower surface points are defined as those points above and below the specified chord line respectively as indicated in Figure 6. It should also be noted that when calculating the moment coefficient about the nose, the nose point is taken to be the point where the chord line cuts the leading edge of the airfoil. It should be reemphasized that the above discussion applies only to the IALPHA = 0 option.

IALPHA = 1 implies that the chord line of the airfoil is the longest chord line calculated by the program. For this particular option the user may choose any convenient reference line for dividing the airfoil into upper and lower surface input points. The only restriction placed on this reference line is that it must go through the trailing edge midpoint. Again however, the authors strongly recommend that this line be the x-axis of the input reference system as shown in Figure 7. After calculating the longest chord line, the program will then rotate and translate the airfoil coordinates so that the longest chord line lies along the x-axis with the nose of the airfoil at the (0,0) point (see Figure 8). The lift and drag coefficients are then calculated with the angle of attack referenced to this longest chord line, while the moment coefficient about the nose is calculated about the (0,0) point. Similarly the moment coefficient about the quarter-chord is calculated using the point (.25C,0), where C is the length of the longest chord line.
Figure 7.   Example airfoil in reference system
            for IALPHA = 1 option.
Figure 8.   Rotated airfoil after longest chord line
            has been calculated.

In order to make the NCSU airfoil program compatable with the companion program (given in Appendix C) for calculating three-dimensional aerodynamic coefficients, an input IPUNCH control parameter was added.   The control parameter IPUNCH gives the user the option of obtaining punched data (lift, drag, and quarter-chord moment coefficients for each angle of attack) which may be used in the three-dimensional program.   IPUNCH = 1 gives punched output while the default IPUNCH = 0 gives none.

Many comment cards were added throughout the entire program to help explain program theory and logic.   In general, the purpose of each subroutine is defined at the beginning of the subroutine, and also many of the important areas of the program were denoted using these comment cards.

As a final note to the general program modifications the user is strongly advised to read the User Instructions concerned with input data to the NCSU program since it differs in some respects with that of the NASA program.   For example, the input variable RN in the NCSU program denotes the value of the Reynolds number in millions.   It does not denote Reynolds number in millions per foot as it did in the NASA program!!!

166

While many of the revisions of the NASA program could only be classified as general modifications, there were also modifications which were more specific in nature. The revisions which are concerned with airfoil geometry are discussed in the following section.

CHANGES CONCERNING THE AIRFOIL GEOMETRY SPECIFICATION

In order to compute the lift and drag characteristics of any airfoil, the airfoil coordinates must be specified. The NASA program was designed so that 200 points could be used to specify the shape of the airfoil surface. Since most airfoils can be specified adequately using less than 100 points, the size of the NCSU program was reduced by requiring that the airfoil be specified by 100 points or less. These specified points must be distributed about the airfoil in a manner such that if the airfoil were rotated to the longest chord line system there would be no more than 65 upper or lower surface points (where the upper and lower surface points are defined with respect to the longest chord line). The problem of having more than 65 upper or lower surface points after rotation can usually be avoided if the user specifies no more than 50 input points on either surface. However, if more than 65 points are encountered an appropriate error message will be printed in the program output, and execution of that particular airfoil will be terminated.

As noted under general program modifications the aerodynamic coefficients are calculated based on 65 airfoil solution points. However, these 65 solution points are <u>not</u> specified airfoil input points as such; they are a set of points generated <u>from</u> the specified points by a distribution procedure in subroutine GEOM. Only one call is made to subroutine GEOM since the airfoil can be investigated for several angles of attack and/or Mach numbers using the same set of distributed points. The distribution procedure requires many intermediate arrays for computational purposes, but only two arrays containing the coordinates of the distributed airfoil points are required for the remainder of the program computations. The intermediate arrays are therefore equivalenced to other arrays used in later program computations. This equivalencing procedure gives a reduction of the number of large arrays required by the program.

Subroutine GEOM in the NCSU program is a combination of three of the subroutines in the NASA program (subroutines ROTRAN, GEOM, and DISTP). This subroutine first calculates the longest chord line of the airfoil regardless of the IALPHA option used. It then calculates the angle β between this longest chord line and the x-axis of the input reference system (see Figure 9) and rotates and translates the specified input points so that the longest chord line lies on the x-axis with the nose at the (0,0) point. This is done so that a new set of upper and lower surface points defined with respect to the longest chord line will have monotonic increasing values of x. It was decided that the NASA program could be greatly simplified if the x-values of the distributed upper surface points and the x-values of the distributed lower surface points were the same along the longest chord line. Based on this decision the NCSU program was modified so that it would produce 32 upper and 32 lower surface distributed points along with a common leading edge point (*i.e.* the (0,0) point), giving a total of 65 distributed points.

168
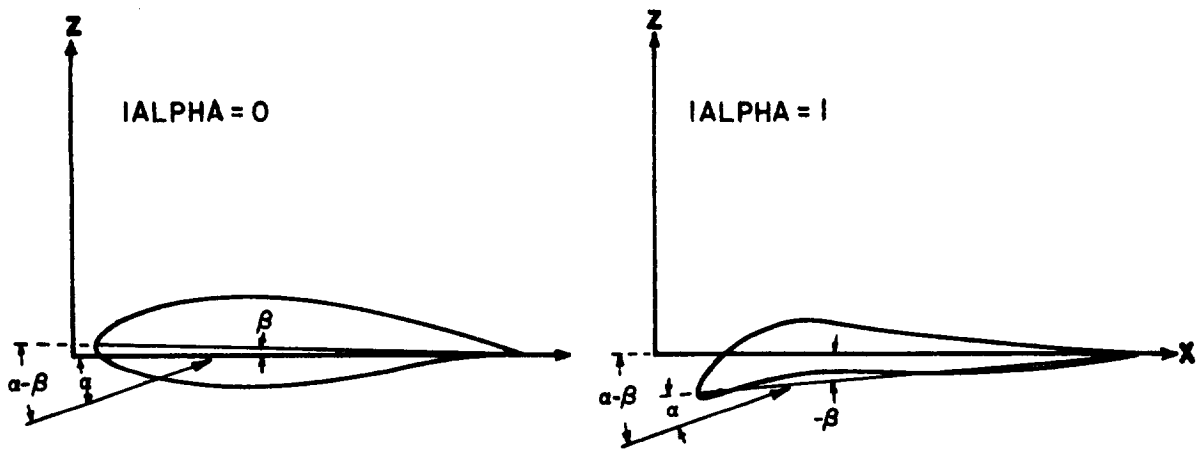

Figure 9.   Reference line for the angle of attack
for both IALPHA options.

The distribution of the points Is made a function of local surface
curvature so that more points are distributed In regions of high curvature.
The distribution procedure Is as follows:

(1) the program uses the upper surface x-values as a longest chord
line scanning array starting with the leading edge point

(2) the curvatures* of both the upper and lower surfaces are computed
at each of these x-values

(3) the absolute value of the curvature for both surfaces are
compared at each x station, and the maximum curvature Is kept

(4) the Integral $SUMA_i = \int_0^{s_i} |K|^{0.25}\, ds$ Is evaluated using the

maximum curvatures at the x stations and the corresponding surface
arc lengths s_i along the upper surface (note that a value of this
Integral Is stored for each s_i station to facilitate backward
Interpolation)

---

* In the nose region the curvature K Is calculated from

$$K = [cz^2 - (cx + b/2)^2]/[z^2 + (cx + b/2)^2]^{3/2}$$

where c and b are taken from a curve fit of the airfoil points of the form

$$z^2 = a + bx + cx^2 \quad .$$

Note that this curve fit gives a slope $dz/dx = (cx + b/2)/z$ which becomes
Infinite when z becomes zero. Because the above curve fit gives an Infinite
slope when z = 0, It obviously cannot be used near the trailing edge of the
airfoil. Therefore, In the trailing edge region the curvature Is calculated
from $K = 2c/[1 + (2cx + b)^2]^{3/2}$, where c and b are taken from a curve fit of
the form $z = a + bx + cx^2$.

169

(5) the maximum value of the integral is divided into 32 equal portions

(6) an s value corresponding to each of these increments is found by backwards interpolation between the s_i array and $SUMA_i$ array

(7) similarly an x value corresponding to the s value is found by backward interpolation

(8) finally corresponding z values for both the upper and lower surfaces are found by backward interpolations.

Although the curve fit formula used in the nose region is designed to approximate an infinite slope, a better value for the curvature integral is achieved when there are more points specified in the nose region of the input data. The better value of the curvature integral will lead to a better set of distributed x's.

In the NASA program the distributed points are rotated and translated back to the reference axis system. For the NCSU program the distributed points remain in the longest chord line system in order to take advantage of the same upper and lower surface x values. For the IALPHA = 1 option the longest chord line system is the ideal system in which to calculate the aerodynamic coefficients. For the IALPHA = 0 option the program calculations are performed using an angle of attack with respect to the longest chord line of $(\alpha - \beta)$ since this corresponds to an angle α with respect to the actual airfoil chord line (refer back to Figure 9).

Following this discussion of the specification of the airfoil geometry, the next two sections present the revisions made to the camber, thickness, and boundary layer solutions of the NASA program.

170

THICKNESS AND CAMBER SOLUTION MODIFICATIONS

It was pointed out in the section on general program theory that the solution for the complete airfoil is a sum of a thickness solution and a camber solution. The modifications which were made in both the thickness and camber solution portions of the NASA program will now be considered.

Subroutine VOVBT is designed to calculate the γ's or surface velocities for a symmetric airfoil with the same thickness distribution as the original airfoil plus boundary layer displacement thickness. Remembering that the upper and lower surface x-arrays are the same in the longest chord line system, the upper surface ordinates of the symmetric airfoil are generated from the following equation,

$$(z_{sym.})_{up} = \tfrac{1}{2}((z_{air})_{up} - (z_{air})_{low}) + \tfrac{1}{2}((\delta^*)_{up} + (\delta^*)_{low}) \ ,$$

for $0 \leq x \leq C$,

where:

z_{air} = original airfoil ordinate
δ^* = boundary layer displacement thickness
C = length of longest chord line.

It also follows that $(z_{sym})_{lower} = -(z_{sym})_{upper}$. Now, once the boundary layer displacement thicknesses have been added, the symmetric airfoil will have a finite trailing edge thickness which is denoted by z_{te}. In the actual physical flow, the wake acts as a displacement body in which the thickness decreases very rapidly from z_{te} to a finite value $z_\infty = \tfrac{1}{2}C_D C$ according to Reference 30, where C_D is the airfoil drag coefficient based on the chord length C. In subroutine VOVBT the wake displacement body of the symmetric airfoil is modeled by:

$$(z_{sym})_{up} = \tfrac{1}{2}[(z_{te} - z_\infty) \ e^{(-6.9XX)} + z_\infty](1.0 - XX)$$

where

$$XX = x/C - 1.0 \quad \text{for} \quad C \leq x \leq 2C.$$

Based on actual measurements given in References 72 and 73 the present authors found that the extrapolation function inside the brackets in the equation above closely approximated the boundary layer displacement thickness of the wake in the trailing edge region. The multiplicative term inside the parentheses is included to close the wake displacement body at x = 2C since the inviscid procedure used for the solution gives best results when applied to closed bodies. The authors feel that this approximation to the wake displacement body gives a better representation of the actual physical flow than does the wake extrapolation procedure in the NASA program while also reducing program size and computation time.

171

Since the thickness solution is calculated only at a zero angle of attack, the flow field about the symmetric airfoil gives an upper surface γ distribution which is simply the negative of the lower surface γ distribution, $i.e.$ $(\gamma_{up})_{x_i} = -(\gamma_{low})_{x_i}$, where x_i denotes a particular x station of the airfoil along the longest chord line. Thus, only the γ's for the upper surface of the symmetric airfoil need to be found.

Subroutine CAMBER is designed to calculate the γ's or surface velocities for an "equivalent" airfoil which has the same thickness distribution as the original airfoil but a modified camber line. This modification is due to the effect of boundary layer displacement thickness on the original airfoil as noted in general program theory. The upper and lower surface ordinates of the "equivalent" airfoil are given by the following equations,

$$(z_{eq})_{up} = (z_{air})_{up} + \tfrac{1}{2}\,\Delta z$$

$$(z_{eq})_{low} = (z_{air})_{low} + \tfrac{1}{2}\,\Delta z$$

where $\qquad \Delta z = (\delta^*)_{up} - (\delta^*)_{low}$.

172

BOUNDARY LAYER MODIFICATIONS

The NASA program contains four subroutines for boundary layer calculations: LAMNA2, BLTRAN, TURB2, and TURB. LAMNA2 performs the laminar boundary layer calculations on the airfoil surfaces. At each point along the airfoil surface, LAMNA2 calls BLTRAN to determine if either transition from laminar to turbulent boundary layer flow or laminar separation has occurred. If transition has occurred, TURB2 calculates the turbulent boundary layer solution over the remainder of the airfoil surface. After the last iteration between the potential and boundary layer flow calculations is performed, an additional turbulent boundary layer calculation is performed using subroutine TURB. This subroutine performs a refined turbulent boundary layer computation to predict the point of turbulent separation.

A brief description of the methods used in LAMNA2 is given in Reference 31, and they are derived in detail in Reference 32. The method for predicting transition used in BLTRAN is described briefly in Reference 31 and derived in detail in Reference 32, while the method for predicting laminar stall is derived in Reference 31. TURB2 uses Goradia's Turbulent Boundary Layer Method which is derived in Reference 31. Goradia's method is designed to remain stable under the influence of extreme gradients, both favorable and adverse, and provide reasonable momentum and displacement thicknesses downstream of the turbulent separation point. TURB uses Nash's Turbulent Boundary Layer Method which is described briefly in Reference 31. Nash's method provides a prediction of the point of turbulent separation, but his method is too sensitive to adverse gradients to be used in the initial iterations.

The NCSU program retains subroutines LAMNA2, BLTRAN, and TURB2. Subroutine TURB (Nash's method) was removed to reduce program size since it played no active part in the iterative process between the potential and boundary layer flow solutions. However, the user should be able to return it to the NCSU program if he so desires.

The three boundary layer subroutines retained in the NCSU program are virtually identical to the original routines in the NASA program except for some coding clean-up performed mainly in the COMMON statements. However, the authors have made two important changes in subroutine LAMNA2:

(1) The NASA program input parameter RN specified the Reynolds number in millions per foot. In the NCSU program, the input parameter RN now specifies the Reynolds number in millions. Since subroutine LAMNA2 requires a value for the Reynolds number in millions per foot, the authors have added a variable RNPFT (equal to RN/CREF) to LAMNA2. This variable is calculated in statement LAM 61 and is used only in statement LAM 62 (see the listing given in Appendix A).

173

(2) The Reynolds number is modified to improve the comparison between calculated and experimental drag coefficients. The modification is justified in the following section of this report (Coefficient Modification). It consists of calculating the boundary layer flow using a Reynolds number which is twice that of the specified Reynolds number. Now the Reynolds number is used only once in LAMNA2 to calculate the kinematic viscosity VO which is then used in all three of the boundary layer subroutines. Increasing the Reynolds number by a factor of two is equivalent to dividing the kinematic viscosity by a factor of two. Therefore, the Reynolds number modification procedure is carried out in statement LAM 65 by dividing the kinematic viscosity by a factor of two.

174

COEFFICIENT MODIFICATION

The various modifications discussed up to this point have resulted in a reduction in both program size and run time. While the authors had hoped that some of the modifications would significantly improve the predicted aerodynamic coefficients, comparison with test results indicated that only slight improvement had been obtained. Since attempts at improving the actual program theory had failed the authors sought to determine whether semi-empirical and empirical corrections might improve the results. The corrections which were incorporated into the program are discussed below.

During the course of the investigation the authors noticed that integration of the pressure coefficients from the inviscid solution gave a non-zero pressure drag. This result was obviously contrary to potential flow theory which says there are no drag forces in inviscid flow. It was first believed that this non-zero pressure drag was the result of round-off and loss of significance in the program computations. Calculations were thus made in both single and double precision arithmetic with various integration procedures to test this hypothesis. The results of these tests demonstrated that the problem was not one of loss of significance in program computations but rather a result of the boundary condition applied at the trailing edge of the airfoil. In true potential flow the Kutta condition requires that a stagnation point be recovered at the trailing edge thus yielding a zero pressure drag. However, the boundary condition employed at the trailing edge in the program's potential flow calculations (subroutines VOVBT and CAMBER) is based on Howarth's criterion that the total flux of vorticity shed into the wake from the upper and lower airfoil surfaces must be zero (References 74 and 75). This condition sometimes referred to as a modified Kutta condition is satisfied by requiring that the upper and lower surface velocities at the trailing edge be equal and thus not necessarily zero as would be the case with a stagnation point at the trailing edge. As a result, a potential flow calculation using this modified Kutta condition yields a velocity distribution which has a non-zero pressure drag.

As discussed in General Program Theory, the superposition technique used in this program implies that the lift forces are represented by the camber solution while the pressure drag due to boundary layer displacement effects is represented by the difference of the two thickness solutions. The difference in the thickness solutions should contain all of the pressure drag; however, because the camber solution is calculated using the modified Kutta condition, it also has an inherent pressure drag. As a result, when the three separate velocity distributions are superimposed, the resulting velocity distribution has, in effect, an "extra" pressure drag in it from the camber solution. The obvious "cure" would be to use a camber solution which has a zero pressure drag. This can be accomplished by using the true Kutta condition as the trailing edge boundary condition for the camber solution while still employing the modified Kutta condition in the two thickness solutions. However, when this procedure was attempted the

175

program's boundary layer routines were unable to cope with the resulting steeply-rising pressure distribution and failed. The next most obvious "cure" would be to try to estimate this "extra" drag and subtract it from the final drag. The authors found that the best way to estimate this "extra" drag was to integrate the pressure coefficients of the inviscid camber solution calculated in the zeroth* iteration which contains no boundary layer effects. A modification was therefore incorporated into the NCSU program to calculate the pressure drag of the zeroth iteration and then subtract this pressure drag from the final predicted drag coefficient.

The modified drag coefficients compared much more favorably with experimental data than did the unmodified coefficients, however they were still a little too large. While computing the aerodynamic coefficients for several airfoil sections, the authors noticed that if the coefficients were calculated using a Reynolds number twice as large as the experimental value an even greater improvement in drag coefficient could be achieved. For example, it was found that if the coefficients of the 23012 airfoil were computed at a Reynolds number of 6,000,000 the predicted drag coefficient compared very well with experimental tests at a Reynolds number of 3,000,000. The trend observed with the 23012 airfoil was also evident in the other airfoils which were investigated; thus, it was decided that a modification would be made so that the aerodynamic coefficients would be calculated using a Reynolds number which is twice that of the specified Reynolds number. This procedure can be justified at least qualitatively by the fact that momentum integral boundary layer methods such as that used here give boundary layer thicknesses which are somewhat large when compared with exact results. Using larger Reynolds numbers tend to reduce the boundary layer thickness.

The effect of both of the modifications discussed above is illustrated in the graph on the following page.

Up to this point none of the modifications have affected the lift coefficients to any extent; they still remained in general 3 to 8 percent too high with the larger errors occurring at the larger angles of attack. For some of the thicker airfoils the lift coefficients may differ from experiment by as much as 10 to 12 percent at high angles of attack. One reason for the large lift coefficients resides in the fact that the effect of the wake on the circulation about the airfoil is not included in the theory. In the actual physical situation the presence of the wake tends to reduce the circulation about the airfoil leading to a reduction of its lift coefficient (Ref. 76). In Reference 77 Spence and Beasley developed an expression which gives the reduction of the lift coefficient due to the wake. This expression, incorporated into the NCSU program, is

$$(C_L)_{\text{with wake}} = (1.0 - 0.214 \sqrt{C_D})(C_L)_{\text{without wake}} \; .$$

In the NASA program the lift and drag coefficients were calculated using the normal axial force coefficients obtained by integrating the pressure and skin friction coefficients over the surface of the airfoil.

---

* In the program the initial or first iteration is referred to as the zeroth iteration.
Figure 10. Effect of each of the drag modifications on
the drag coefficients of the 23012 airfoil at
a Reynolds number of 3.0 million.

In the NCSU program the lift and drag coefficients were calculated in the
same manner and then corrected using the modifications discussed above.
In order to make the normal and axial force coefficients consistent with
these new lift and drag coefficients, the force coefficients were re-
computed using the following relations:

$$C_N = C_L \cos \alpha + C_D \sin \alpha$$

$$C_A = - C_L \sin \alpha + C_D \cos \alpha \quad .$$

It is important to note that while the aerodynamic and force
coefficients can be modified to give values which agree better with
experimental data, a similar correction procedure cannot be applied to
modify the pressure coefficients, and therefore they are printed as
calculated.

The results of these program modifications when applied to the
calculation of the aerodynamic characteristics of a number of airfoils
are discussed in the next section.

177

DISCUSSION OF PROGRAM RESULTS

This section is concerned with quantitative comparisons between the predicted coefficients of both the NASA program and the NCSU program and experimental data (taken for the most part from Ref. 19). In order to obtain generally valid comparisons, fifteen airfoils of various thickness and camber distributions were included in the investigation. The fifteen airfoil contours are depicted in Figure 11. The reader can see by examining Figures 12 through 30 that the lift coefficients predicted by each program are quite similar while the drag coefficients are quite different. (Although the plots show only lift and drag coefficient, the reader is reminded that the normal force, axial force, and moment coefficients for any airfoil investigated may also be obtained from the program if desired.) For most of the airfoils the comparisons are self-explanatory and require little discussion; however, some of the more interesting results warrant individual identification.

In general, the lift and drag coefficients obtained using the NCSU program compare very well with experimental data at the lower angles of attack for airfoils with thickness ratios of less than 18 percent. The drag coefficients for the lower angles of attack are slightly high and therefore conservative. For the higher angles of attack the lift is over-predicted, and the drag coefficient is usually under-predicted, because the boundary layer routines used cannot treat flows with large adverse pressure gradients, separated flows, or large wakes such as are present when the airfoil approaches stall.

For the thicker airfoils (thickness ratios of 18 percent or greater) the lift predicted by the NCSU program is more optimistic than for the thinner airfoils. For example, the 2424 airfoil really has a non-linear lift-curve slope which tends to reduce the lift, but the predicted lift curve slope is quite linear, resulting in the over-prediction of lift. The drag coefficients for the thicker airfoils are also seen to agree less well with experimental data than the drag coefficients of the thinner airfoils.

The NASA program usually gave a slightly higher predicted lift coefficient than did the NCSU program. The predicted drag coefficients for the NASA program, however, are in very poor agreement with experimental data. While the comparisons are generally poor, the NASA program drag coefficients do match experimental data better for the thicker airfoils than for the thinner airfoils.

Neither program does a very good job of predicting the aerodynamic characteristics with leading edge surface roughness as can be seen in the case of the 4412 airfoil (Figure 17). The roughness used in the test condition was approximated in the programs by specifying fixed transition at the leading edge for both the upper and lower surfaces of the airfoil. While both programs did a fairly good job of predicting the lift coefficient at the lower angles of attack, neither program did well for the drag

178

coefficient; the NASA program over-predicted the drag coefficient by 25 to 40 percent while the NCSU program under-predicted the drag by 20 to 40 percent.

The reader will notice that there are no predicted NASA coefficients for the 63_2-615 airfoil (Figure 23). While the NCSU program prediction is very good the NASA program was not able to produce an acceptable set of distributed solution points for this airfoil, and thus no correlation can be shown. In a similar situation, the NCSU program was not able to produce a set of distributed points for the 63_3-618 airfoil until two extra points were added in the nose region to those specified for the airfoil in TR 824 (Ref. 19). The extra points were needed because some of the specified points were extremely close together, leaving a large portion of the airfoil nose with no points to specify its shape. The same procedure was used for the 2424 airfoil whose coefficients are shown in Figures 13 and 14. For the 2424 four extra points were added in the region of the nose. As mentioned above, it is important to specify regions of high airfoil curvature properly. While there were a few exceptions, in most cases the ordinates given in TR 824 were sufficient to define the shape of the airfoil.

The Whitcomb airfoil which is currently being investigated by NASA Langley for possible application to general aviation craft is another airfoil which deserves some special mention. While the drawing of this airfoil in Figure 11 does not show it, the Whitcomb airfoil has its minimum thickness slightly ahead of the trailing edge. While the comparison of the NCSU program with experimental data is good for a Reynolds number of 1.9 million, this unusual trailing edge shape is probably one reason for the poor comparison with the previously unpublished experimental data at a Reynolds number of 9.2 million (Figure 29). The poor comparison at 9.2 million may also be due to the erratic nature of the experimental data at this Reynolds number.

In order to investigate another of the latest airfoil designs, that presented in TN D-7071 (Ref. 52) was investigated using the two computer programs. The airfoil (referred to as the TN D-7071 airfoil) was originally designed to optimize the maximum lift coefficient. Experimental results are given for the pressure coefficients and the lift coefficients in Reference 52, but no drag data is presented. This airfoil was of particular interest because of its unusual shape (see Figure 11) and because the original NASA program was used in Reference 52 for a theoretical correlation with the experimental results. Figure 30 indicates that the lift coefficients for the TN D-7071 airfoil obtained from the NCSU program match the experimental values a little better than do the NASA program values. The drag coefficients for both programs are also included for the sake of completeness even though no experimental drag coefficients are available. Figures 31, 32, and 33 give the pressure distributions over the airfoil for experimental measurement, the NASA program, and the NCSU program for this airfoil at angles of attack of 3.4, 12.4, and 18.7 degrees respectively. These pressure coefficients were included to show that the pressure coefficients obtained from the NCSU program

are still basically the same as those predicted by the NASA program. As indicated in Reference 31 the computed pressure coefficients for conventional airfoils usually compared quite well with experimental data.

In order to study some of the bounds of the computational methods presented herein, an attempt was made to predict the aerodynamic characteristics of the last airfoil shown in Figure 11. This is a very thin, highly cambered airfoil recently tested by Milgram (Ref. 108) over a very wide range in Reynolds Numbers and angles of attack. The very non-linear lift curve and high drag coefficients evident in the experimental data indicate extensive flow separation which changes radically with the changes in angle of attack. Figure 34 compares the predictions with the experimental data. The lift predictions are close to experimental values only for an angle of attack of 2-3°. At large angles of attack where the thin nose of the airfoil points into the wind, more or less, there is extensive separation over the aft portion of the upper surface so that the predicted lift does not materialize. The best that can be said for the drag predictions are that the NCSU program is qualitatively correct but predicts only 25% of the actual drag. This experience leads one to suggest extreme caution in applying the program to airfoils which possess regions of surface concavity. Not only does the boundary layer routine used here fail for what in these circumstances will usually be a separated flow, but the inviscid method also has difficulty with such geometries.

As received from Langley, the program contained a provision to modify both the inviscid and viscous computations of the pressure distribution and aerodynamic force coefficients for the effects of changes in free stream Mach number. This capability was retained although it is expected to be of limited utility for most light aircraft designs. For this reason, the applicability to varied airfoils and the accuracy limits of the routine were not investigated extensively. Plotted in Figure 35 are the results for a 23012 airfoil obtained with the original Langley version and the modified NCSU version. It will be seen that for this case and for $\alpha = 0$, at least, the NCSU version gives qualitatively reasonable lift results for all Mach numbers while the original version is reliable to about $M \simeq 0.50$. The reasons for the apparent superiority of the NCSU version were not examined in detail. No explanation for this behavior can, therefore, be offered. Experimental data for the 23012 airfoil were not at hand for comparison, but one may note that generally the Prandtl-Glauert rule under-predicts the increase in C_L near M_{CR} by about 10%. Thus, the NCSU prediction may yield results quantitatively below those found experimentally for $M > 0.5$. The user should therefore approach results for $M > 0.5$ cautiously.

The results of the drag predictions are shown in Figure 36. The Langley results appear to be completely meaningless. Again, the reason for this is not known. The NCSU predictions, on the other hand, appear to be qualitatively correct for all Mach numbers. Quantitatively, the Squire-Young formula seems to give the more reasonable results for $M > 0.55$.

180

Based on the airfoils investigated the authors conclude that:

(1)   the NCSU program gives about the same pressure distribution over the airfoil as does the NASA program

(2)   the lift coefficients for the NCSU program while still a little too large for some airfoils, compare more favorably with experimental data than do the NASA program coefficients

(3)   the predicted drag coefficients using the NCSU program compare much better with experimental data than the drag coefficients obtained from the NASA program.

EXTENSION TO THREE DIMENSIONS

INTRODUCTION

As elaborated in the theory section of the present work, one may employ lifting line theory to find the effective angle of attack at every point along the span of straight, moderately high-aspect-ratio wings. This effective angle of attack in conjunction with two-dimensional lift and drag data may subsequently be used to calculate three-dimensional lift and drag distributions. Integrating these distributions then gives the perceived lift and drag characteristics of the complete wing. A computer program utilizing this theory to predict stall characteristics of straight wing aircraft presently exists and is published in NASA CR-1646 (Ref. 36). It was selected to serve as the basis of a program for generalizing two-dimensional data to three dimensions in order to take advantage of the very considerable effort which went into its development. The program, however, contains many features which are not needed in the present work. Only that portion of the program pertaining to the prediction of the three-dimensional lift, drag, and pitching moment of a wing-fuselage combination is of immediate interest.

Originally written in FORTRAN IV for the CDC-6600 series computer, the program required substantial changes in order to execute effectively on North Carolina State University's IBM 370-165 machine. A list and discussion of the necessary changes is given on page 223.

The program in its original version was written to predict the angle of attack at which a wing-fuselage combination stalls and to aid the designer of a new or modified aircraft in stall-proofing his flight vehicle. This feature of the program cannot be utilized in the present effort because of the inability of the current two-dimensional program to predict boundary layer separation and therefore section aerodynamic characteristics in the near-stall region adequately. As a result, all portions of the program pertaining to the stalling wing, the iterative calculation of the value of the stall angle of attack, and location of the initial stall point were deleted. The resulting program is therefore applicable only to the linear portion of the lift curve.

Since the two-dimensional program treats only unflapped configurations, that portion of the program concerned with prediction of three-dimensional characteristics of flapped airfoils was deleted. Major reductions were also realized in the storage of airfoil data files. Tables of the two-dimensional aerodynamic characteristics were stored in the form of sets of polynomial coefficients with the Reynolds number inherent in the root and tip data sets in order to reduce input-output time and eliminate the need for nine peripheral storage devices which in the original program were used to store the airfoil data in a detailed table-look-up form. (The tables were constructed from the experimental data in NACA TR 824.)

In this modified form, the NCSU program, called FUNC, operates totally within the machine core. It will produce a three-dimensional table of lift, profile drag, induced drag, total drag and moment coefficients for

nine angles of attack (see Figure C-3) in six seconds with sixty thousand bytes of core, considerably less than the 60 seconds and 104 thousand bytes plus ten peripheral storage devices required by the original program, STALL. The specific changes are discussed in detail below.

The only obvious danger in using this fast and efficient polynomial coefficient technique is that the fit may exceed some tolerable level of error. A least squares routine, FITIT, has been provided to determine the polynomial coefficients. With it the fit error encountered on smooth two-dimensional data, as measured by the average mean square deviation, was normally between 10^{-3} and 10^{-5}, certainly less than three percent of the aerodynamic coefficient value. This may be seen in Figure B-3 which gives the fit coefficients and plots of fitted curves for the various aerodynamic coefficient functions of a 23012 airfoil. Although the fits provided by FITIT have always been within an acceptable tolerance for all runs performed to date, it is suggested that one always check the plot of the curve fit before proceeding to supply FUNC with the fitted data. FITIT performs a run of curve fits for the two-dimensional aerodynamic coefficients at nine angles of attack in eight seconds and fifty-four thousand bytes of core storage.

In order to insure that this fit error and the methods employed in modifying the original program were valid, a test case was run which compared the three-dimensional lift and drag produced by STALL using experimental two-dimensional data and the three-dimensional lift and drag as predicted by FITIT and FUNC using experimental two-dimensional data. The results of the test case is shown in Figure 37. This drag error noted is directly attributable to the inability of FITIT to fit the "drag bucket" of these airfoils using only a fourth degree polynomial. Generally, this routine as used with the two-dimensional predictions of the previous chapter do not encounter these "drag buckets" and, as mentioned earlier, operate with much higher accuracy.

Additional test cases were run to compare the three-dimensional data produced by experiment and that produced by the FITIT-and-FUNC-combination using two-dimensional data supplied from the program of the previous chapter. Results of these tests are reported below. Generally, the errors encountered were less than five percent for lift and eight percent for drag (Figure 38 through Figure 40) when compared with experiment. The experimental data and geometric configuration used in these calculations were taken from Reference 78. A drawing of this planform is given in Figure 41.

In the following the reader will find a brief explanation of the theory upon which the programs are based, and a discussion of the modifications implemented in the NCSU program.

GENERAL PROGRAM THEORY AND OPERATION

The mathematical technique for extending two-dimensional data to three dimensions, presented in detail in the theory section of this report, is performed by a modified version of the program (listed in NASA CR-1646) known as STALL. The following is a description of the basic logic of the modified version, FUNC, and its support program FITIT. FUNC is supplied with two-dimensional data in the form of polynomial coefficients by a special program called FITIT. Two-dimensional data (experimental or calculated by two-dimensional programs in the previous chapter) for a specific airfoil is generally given in the form of tables of lift coefficient versus angle of attack, drag coefficient versus lift coefficient, and pitching moment versus lift coefficient for a given Reynolds number. FITIT is designed to take these tables (see Figure B-2) and produce polynomial coefficients (see Figure B-3) for this specific airfoil by a least squares curve-fitting technique (see Figure 42). The polynomial coefficients are then punched into the form acceptable to FUNC. After sufficient data sets have been generated in this fashion, the execution of FUNC is ready to be initiated.

At this point the perceptive reader might suspect that FITIT should be incorporated as a preliminary routine within the program FUNC. This was not done because: (1) The fits should always be checked for intolerable error; (2) The core requirements of FUNC would probably be extended to an intolerable level; and (3) Once a set of data for a given airfoil is run and polynomial coefficients obtained, the set need not be run again, allowing the engineer to run many geometric variations within FUNC without recalculating these polynomial coefficients each time.

As can be seen by the flow chart in Figure 43 operation of FUNC is initiated by reading in (see Figure C-2) all geometric parameters associated with the configuration under consideration. Appropriate polynomial coefficient data are then read in* and calculation of the geometric quantities associated with the transformation from the u to the $\bar{u}$ plane is initiated. If the option to read in irregular geometric shapes has not been initiated, the program proceeds to calculate the chord, thickness, camber, geometric twist and Reynolds number distributions for a wing with linear taper in both chord and thickness. Next, the multipliers β_{mk} from Equation 105, the multiplier employed in Simpson's rule enclosed in brackets in Equation 117 through Equation 120, and the inverted G matrix of Equation 114 are calculated. At this point the values of body angle of attack are read, the first value selected and a case heading printed. After a first approximation to the lift distribution has been estimated by Equation 115, the basic iterative loop searching for a convergent lift distribution is entered.

---

* Note from Figure C-2 that the thickness ratio of each airfoil data set has been inserted so that FUNC will have explicit knowledge of its value.

The first step in the search for convergence is to calculate the corresponding values of induced angles of attack and determine the effective wing angles of attack in the real plane. Now the equivalent angles of attack from Equation 116 are computed for use with the two-dimensional data. Using the section data, the values of lift coefficient corresponding to these equivalent angles of attack are obtained. If the value of $C_{\ell}c/\bar{b}$ using these values of lift coefficient is not sufficiently close to the initial estimate of $C_{\ell}c/\bar{b}$, the correction factor given by Equation 114 is calculated and added. The process discussed in this paragraph is followed until the calculated values are sufficiently close to the previous values of $C_{\ell}c/\bar{b}$.

Having obtained the lift distribution, section values for the profile drag coefficient, the induced drag coefficient, and the pitching moment coefficient are obtained. These are then integrated using Equation 117 through Equation 120.

At this point in the execution, another value of body angle of attack is assumed and the program reenters the search for the convergent lift distribution associated with this body angle of attack. The program continues in this cycle until a body angle of attack of 99.0 is encountered at which time control is returned to the beginning of the program and the next set of geometric parameters is read.

MODIFICATIONS REQUIRED TO ADAPT THE CDC "STALL" PROGRAM

TO IBM EQUIPMENT

The following changes were necessary in the original program STALL as published in NASA CR-1646 in order to insure effective execution on the NCSU IBM 370-165:

(1) Eliminate the overlay structure by changing programs STALL, ONE, TWO, and THREE into subroutines STALL, ONE, TWO, and THREE.

(2) Run with NOSUBCHK option on Fortran IV G-LEVEL compiler.

(3) Set the variable INNOW equal to zero after logical unit numbers are set in routine MAIN.

(4) Set ATMP (vector) to zero at statement 40 in BRIDGE.

```
40   KGO = 1
     ATMP(1) = XX(1)
     DO 41 J = 2,NP
41   ATMP(J) = 0.0  .
```

(5) Insert the following statement immediately preceeding the statements setting logical unit numbers in MAIN.

```
ACOS(X) = ARCOS(X)
```

(6) Prevent illegal entry into a DO loop in LOOK by inserting at statement 60,

```
60   LOCR = 3
61   IF(REYN-A(LVL,1,LOCR)70,70,610
```

and statements 600 to 620 should read

```
600   GO TO 630
610   LOCR = LOCR+1
      IF(LOCR.LE.MAXC)GO TO 61
611   IE = 1
      GO TO 630
620   REYN = 999.0  .
```

(7) Enclose the variable YY in the argument list of BRIDG in slashes to insure call by name.

GENERAL PROGRAM MODIFICATIONS

It was mentioned in the introduction to this chapter that the original program STALL consisted of approximately 1700 executable statements. This section serves as a guide to the systematic dismantling and conversion of the program to its modified form. The program as supplied to NCSU operated in the overlay mode with a main overlay and three additional overlays of the same sublevel. Since total operation within the core of the IBM 370-165 is less expensive than the time to call in overlays, the program was taken out of the overlay mode and compiled and executed as a unit. Some IBM-CDC incompatibilities noted in the previous section were then removed in order to execute the program on the NCSU 370-165. These changes resulted in a significant reduction in execution time at the expense of increased core requirements. As mentioned previously this trade is quite cost-effective.

A second major modification occurred when portions of the program unneeded for the present investigation were removed. These included all portions associated with stall calculations as well as those portions having to do with flaps. These routines are THREE, MAIN3, and MAIN5. See Table 2. These changes reduced the number of executable statements by 550 to approximately 1150, a substantial reduction.

original and modified programs.

A further major reduction was realized by making the Reynolds number of interest inherent in the two-dimensional data. An in-depth look at what is involved with this assumption may be found in the next section of this chapter. Use of this assumption, however, resulted in a decrease in executable statements by 250 to approximately 900.

Still another reduction was made by changing the location of data storage. In addition to saving a tremendous amount of input-output time by expurgating the nine peripheral storage devices associated with the table look-up procedure and storing the polynomial coefficients within core, the move reduced the number of executable statements by 100 to a remaining 800.

Reductions to the existing less-than-700 executable statements can be attributed to the clean-up of unused variables and to common block reorganization.

CHANGES CONCERNING REYNOLDS NUMBER

In order to locate the two-dimensional value of a given aerodynamic coefficient, say C_ℓ, in the original program, three separate interpolations were made. Linear interpolation was performed first for the required value of Reynolds number, then for thickness ratio, and finally for camber. Because of the amount of data being searched, an investigation into a possible deletion of one of these variables was initiated. Deletion of any one of the variables would cut the number of interpolations by forty percent. Since the present investigation had excluded the stall region because of the inability of the two-dimensional program to predict boundary layer separation effects adequately, a reduction in dependence of the results on Reynolds number was established. Changes in Reynolds number at low angles of attack produce very little variation in lift coefficient and only slight variation in drag coefficient (Ref. 79). These variations were so slight that it was decided to either calculate the two-dimensional characteristics for both tip and root airfoil families at the Reynolds number of the mean aerodynamic chord or, at the most, enter the characteristics at only the root and tip values.

Error encountered by the use of the mean aerodynamic Reynolds number is low because of the averaging effect of the camber interpolation and eventual integration. Error encountered by the use of root and tip families at their respective Reynolds number should be even less since this effort gives the coefficient data an implicit relationship in Reynolds number.

The calculation of the spanwise Reynolds number distribution was left in as a check for the designer. It is suggested that designs using high taper ratios resulting in wide Reynolds number variation employ the root-tip implicit method. Removal of the Reynolds number interpolation allowed the deletion of two routines, ARC and LOOK, from the original program (see Table 2).

226

CHANGES CONCERNING AIRFOIL DATA STORAGE

With the transfer of the Reynolds number to an implicit dependence, half of the minimum data sets were no longer necessary; furthermore, the remaining portions of the data sets could be stored in core, resulting in a substantial reduction in operating time since the comparatively long time required to transfer data from tape or disc files could be eliminated. Adopting this philosophy removed nine external data files, decreased the execution time further, and eliminated approximately 100 executable statements among these being the two routines DAGET and AERDA of the original program.

A further reduction in execute time was realized by storing the two-dimensional data not as tables of points but as polynomial function coefficients and thus eliminating tabular interpolation.*

A schematic diagram of the storage and evaluation procedure is given in Figure 44. Note that for a geometric configuration with root and tip families different, evaluation of any given aerodynamic coefficient has been reduced to four functional evaluations, two thickness interpolations, and one final camber interpolation.

---

* Note from Figure C-2 that the angle of attack versus coefficient of lift polynomial was added in order to predict the angles of zero lift without solving for the zeros of a fourth degree polynomial function.
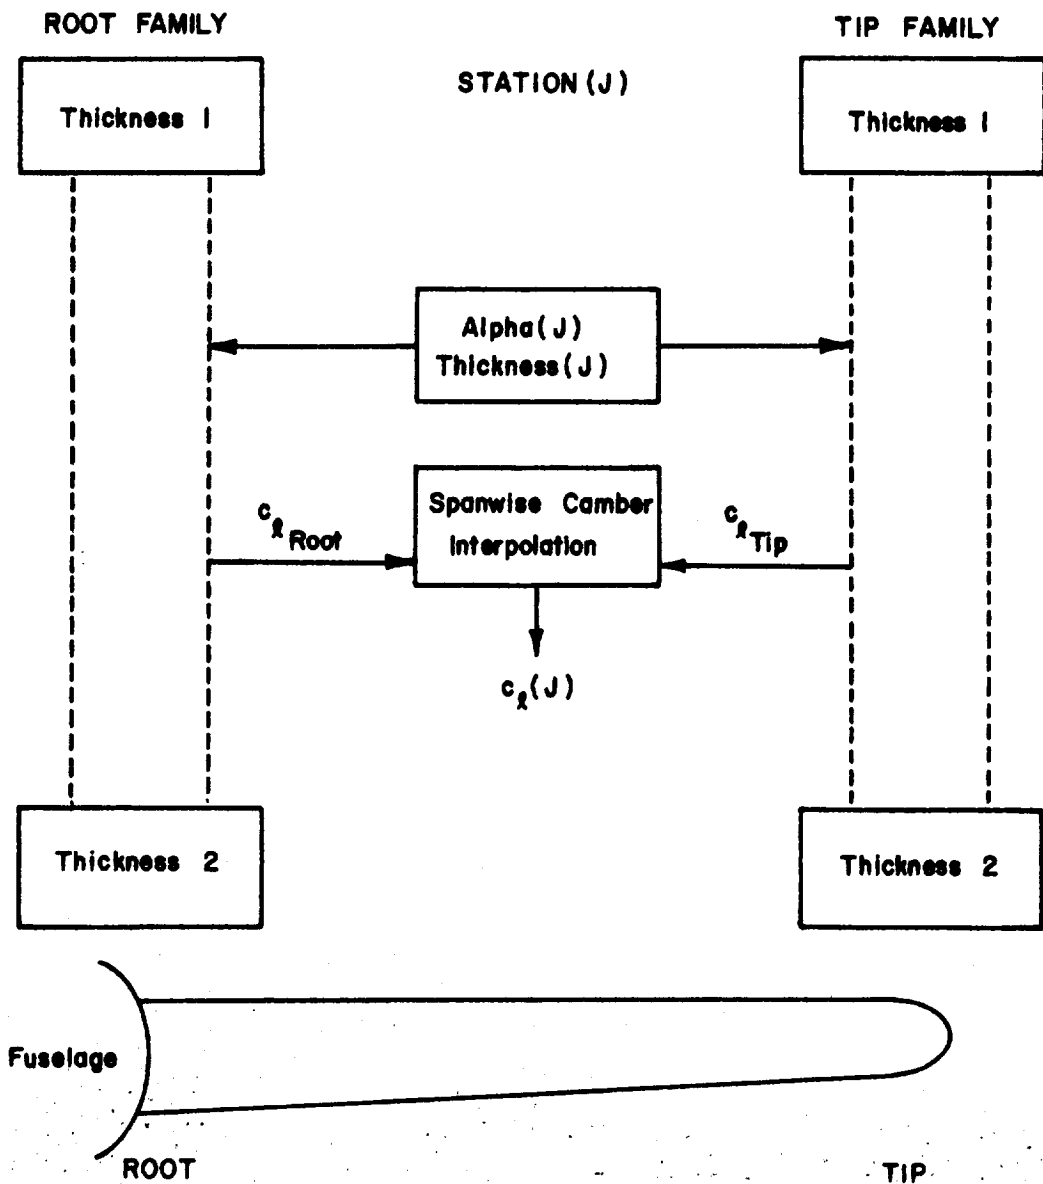

Figure 44. Schematic representation of the modified
data look up procedure.

DISCUSSION OF PROGRAM RESULTS

Results of computations of the three-dimensional lift and drag of a wing using two-dimensional section data as input are shown in Figure 37 for both the reduced NCSU program and for STALL. Agreement with STALL is very good for the lift and quite reasonable for the drag, especially when one considers that drag "buckets" found experimentally on 6-series airfoils and used in STALL cannot be fit satisfactorily with just a fourth order polynomial. This fourth order representation was judged adequate, however, because the airfoil aerodynamic characteristics program inherently predicts relatively smooth drag curves. Since such results were always to be the input to the three-dimensional program, the authors saw no need to increase the program complexity.

A comparison of the results of predictions of the entire computation procedure with experiment is shown in Figures 38, 39, and 40. The lift data for the 6-series airfoils, shown in Figure 38, shows excellent agreement up to a C_L value of 1.2. The drag data is quite acceptable to a C_L value of 0.8. The wing data for the four digit airfoils indicates that, particularly for lift coefficients above 0.4, the viscous effects on these thick airfoils are not properly accounted for. The same behavior is noted for other thick airfoils of the same family. (See Figures 13, 14, and 15.) The prediction is, however, much better on the wing constructed of 230-series airfoils (Figure 40). Here, the lift results agree well with experiment for $C_L < 1.0$ and the drag predictions are in reasonable agreement for $C_L < 0.6$. It seems reasonable to conclude therefore that for $C_L < 1.0$, the program will provide wing lift data as reliable as the two-dimensional data supplied as input. Wing drag predictions made by the program also seem to be as reliable as the section characteristics used as input, at least for $C_L < 0.8$. Thus, for low-to-moderate lift coefficients and moderate-to-high-aspect-ratio, unswept wings this procedure is far simpler computationally and of equal accuracy as compared with the more complex vortex lattice or lifting surface methods.

PROGRAMS FOR THE CALCULATION OF BODY

AERODYNAMIC COEFFICIENTS

INTRODUCTION

The problem of accurately estimating the lift and drag coefficients of arbitrary three-dimensional bodies in a rigorous fashion will certainly be recognized as an extremely difficult task. The word arbitrary, for example, implies that the routine or procedure for estimating these coefficients must be general enough to handle a variety of bodies including bluff ones to be useful to those to whom this work is directed; yet the procedure cannot require an excessively large number of computations. In order to yield the most reasonable solution within the constraints of small computer run times and small computer storage requirements the present authors chose to use the following procedure:

(1) A program to calculate the inviscid flow about arbitrary three-dimensional bodies was obtained from the Naval Ship Research and Development Center at Bethesda, Maryland. One important reason for selecting this program was the fact that it was equipped with the capability of computing on-body streamlines. Another was the fact that it was already limited to bodies alone. Two other programs which the authors acquired in the process of developing this procedure would have required removing the wing characteristics calculation portion of the programs.

(2) The program was reduced in size as much as possible and specialized to calculate the inviscid flow over bodies at zero angles of attack and sideslip. (As received, it permitted one to calculate the inviscid flow field with onset flow components along all three axes.)

(3) The skin friction drag was estimated by applying a two-dimensional boundary layer technique to the on-body streamlines and integrating the resultant wall shear over the body surface.

(4) The viscous form or pressure drag was estimated by considering the body wake to be representable within the framework of an inviscid flow solution in much the same manner as the complete airfoil solution was achieved.

The reasons for choosing this procedure are quite straightforward:

(1) It relies heavily on existing programs or procedures whose applicability and computational problems have been well charted. The time and effort required for program development is thus reduced to a minimum.

(2) The procedure is step-like so that if necessary it can be done in pieces on a small machine with limited storage capacity. In contrast, it would be very difficult to segment an attempt to solve the general three-dimensional Navier-Stokes equations for a complex boundary shape.

232

Theoretical justifications for some of the steps in the procedure are given at length in earlier sections of the present work.

Of course, in order to obtain shorter running times and smaller storage requirements, it has been necessary, as is always the case, to limit flexibility and employ certain assumptions which are not uniformly valid. The restriction to $\alpha = 0$ cases has already been mentioned. In addition, the boundary layer routine used is a two-dimensional one so that stagnation point flows are not well described nor are cases where cross flows are present. Further, the boundary layer procedure does not permit one to consider flow separation, $i.\ e.$, it assumes separation does not exist. Although body wakes are included in the analysis it has been necessary to assume, in the absence of an understanding at the proper criteria, that they all develop according to the same simplified rules. As a result of these limitations, some discretion should be exercised in applying the results of the computation and in selecting cases for computation so that the governing assumptions are not greatly violated.

The discussion below outlines the computational procedure employed. The original program is described in general so as to provide the reader or user with a reference for understanding the modifications made to it. The modifications are then discussed in detail. Also discussed in detail are the locally developed elements of the program, in particular the boundary layer and wake-body computation procedures. We begin with a presentation of a very effective means to identify errors in the input data. The section concludes with a discussion of the results obtained using the program to compute the drag of three bodies: a sphere, a 3:1 prolate spheroid, and a Cessna 182 aircraft fuselage.

233

SPECIFICATION OF INPUT DATA WITH VERIFICATION BY PLOTTING

When calculating the potential flow over a three-dimensional body, one is confronted with the problem of how to specify the shape of the body surface. Obviously, one would like to have an analytical expression for the body surface; however, for general three-dimensional bodies practical analytical representations are usually impossible to obtain. The general practice is therefore to approximate the body surface by a large number of quadrilateral-shaped panels defined by a finite number of points in space; each point is presumably exactly on the body surface. If a computer is to be used to solve for the potential flow over these bodies, someone must input the three coordinates of each point; this is a laborious and error-prone task. In addition, each point must be indexed in such a way that the four corner points of each panel are defined in a clockwise fashion. Checking the input for errors is also a tedious process since detecting errors by simply scanning a list of the input data points is extremely difficult. To minimize such errors one would like a simplified, orderly procedure for inputting the data, and an effective procedure of finding errors before lengthy potential flow calculations are made. Probably the simpliest procedure for inputting the data is to specify the shape of the body cross section at various stations along the longitudinal body axis. Among the most effective procedures for detecting input errors is to graph the points as viewed from various directions (See Figure 45).

While the above is true for any arbitrary body, in this report we are concerned only with aircraft fuselages which have a plane of symmetry along the longitudinal axis. In 1970 NASA, aware of the problems of specifying and checking numerical data, developed a computer program to generate the necessary instructions for automatic plotting of an airplane model in numerical form (Ref. 113). The plotting capability of this program along with its simplified data input procedure makes it ideal for producing a final, verified numerical data set describing an aircraft fuselage. The program also has the capability of displaying the complete aircraft configuration including wings, pods, fins, and canards. Using it one may draw three-view and oblique orthographic projections, as well as perspective projections of an airplane. The program even has the capability of plotting stereo frames of the aircraft suitable for viewing in a stereoscope. Because of its versitility the authors chose to use this NASA program to verify aircraft input data. A copy of the program, written for the CDC 6000 computer, was obtained from NASA Langley Research Center and then modified so that it would run on the IBM 370-165 computer at N. C. State University. User instructions, plotting software modification procedures, a program listing, and several sample output plots for the modified plot program are given in Appendix D.

234
Figure 45. Example of a correct and an incorrect data
set for the Cessna 182 fuselage.

It should be noted that most of the modifications made to the original program were those necessary to enable the program to run on the NCSU IBM computer. These modifications included:

(1) changing the DECODE form of program input to ordinary READ input

(2) removing the OVERLAY procedure used to reduce program size during execution at NASA

(3) adding subroutines which could call IBM software plotting instructions which were equivalent to the specified CDC software instructions[†]

(4) assigning variable names to the input and output file unit numbers as well as to data storage file unit numbers (the user must therefore only specify the appropriate file unit number required at his computing facility).

For more information concerning the basic program the reader is advised to consult Reference 113 which provides a detailed description of much of the program as well as flow charts of each important program section.

While the input to the PLOT program is as concise as possible, the input to the NCSU BODY program (as well as the XYZ potential flow program) is both lengthy and time consuming since three coordinates and two indexes are specified on each point input card. Accordingly, a program which converts a data set for the PLOT program into a properly indexed data set for the NCSU BODY program was developed; thus, once the plot data set is verified, a correct data set for the NCSU BODY program may be generated. As discussed in General Program Theory, one criteria for obtaining a reasonable potential flow solution is that adjacent body panels must generally have areas which differ by less than 50 percent. Therefore, the CONVERT program was also designed to compute the area of each body panel and display these areas in an orderly fashion. Also, the program displays the ratio of the area of each panel to the area of the panel below it and the panel to its right. These ratios simplify the procedure of checking panel areas to see if they meet the criteria described above. It should be noted that while the CONVERT program produces a data set for the fuselage, it will accept the input of a data set for a complete aircraft configuration and ignore the unnecessary information. The program input is obviously the same as the input for the PLOT program and its description is therefore not repeated in Appendix E; however, the program listing and a

---

[†]Since plotting software is different at almost every computing facility, the user _must_ either provide the original CalComp plotting software for which the program was designed or provide three _equivalent_ dummy subroutines as was necessary at the N. C. State faillity. See the Plotting Software Modifications section of Appendix D for detailed instructions.

236

sample output depicting the capabilities described above are given in the appendix.

By inspecting Figure D-1 and Figure F-1, the reader will discover that the body orientations, with respect to the input axis system, are different for the PLOT program and the NCSU BODY program. In order to overcome this difficulty the CONVERT program also contains the instructions required to invert the body with respect to the X-axis and approximately center the body about the origin. These instructions are necessary since the flow is in the direction of the negative X-axis for the NCSU BODY program.

In order to calculate the boundary layer over the body the NCSU BODY program must have the properties of the flow field as well as the body geometry. The CONVERT program was designed specifically for any plot data set as described in the original PLOT program, and these data sets describe only the body shape. It is therefore necessary to insert a flow field parameter card into the data set created by the CONVERT program before the data set is input into the NCSU BODY program. The card (described in Appendix F), which is inserted behind the first card (identification card), specifies the free stream velocity, density, and kinematic viscosity of the flow field as well as the reference area upon which the coefficients are based and an output control parameter. Failure to include this card in the NCSU BODY program input will result in an invalid program execution.

237

GENERAL PROGRAM THEORY FOR INVISCID BODY PROGRAM

The XYZ potential flow program, obtained from the Naval Ship Research and Development Center (Ref. 94) is a computer program for the computation of irrotational, incompressible potential flow about three-dimensional bodies of arbitrary shape. The solution method is essentially that developed by Douglas Aircraft Company in References 23 and 83. For a detailed description of the program theory the reader is advised to consult these references; however, an excellent brief description of the method is given in Reference 94, major portions of which are excerpted below.

The body surface is approximated by a set of plane quadrilaterals, and the solution is constructed in terms of a source density on the surface of the body. Based on the assumption that the source density is constant on each quadrilateral, a system of algebraic equations is used to approximate the integral equation for the source density over the body. The source density in each quadrilateral is chosen so that the normal component of the velocity is zero at one point in the quadrilateral. The matrix equation is solved by a simultaneous displacement iteration scheme with a two-eigenvalue extrapolation procedure to speed up convergence.

The XYZ program received at N. C. State is divided into five basic sections. Section 1 reads the input cards, computes the descriptive parameters for each quadrilateral, and checks for errors. Section 2 computes the matrix elements in the equations for the source density and the velocity for points on the body. Section 3 solves the matrix equation for the source density. Section 4 computes and edits the velocity and pressure coefficient on each quadrilateral. Section 5 computes the coordinates of the streamlines on the body surface.

The program actually solves a problem involving a stationary, three-dimensional body in a moving ideal fluid. The fluid is assumed to have a uniform velocity at infinity ($\vec{V}_\infty$) which is parallel with the x-axis of the body. The velocity potential ϕ satisfies the following equations:

$$\nabla^2 \phi = 0 \qquad \text{in the fluid} \qquad (1)$$

$$\frac{\partial \phi}{\partial n} = 0 \qquad \text{on the surface of the body} \qquad (2)$$

$$\phi = -x \cdot V_{\infty_x} - y \cdot V_{\infty_y} - z \cdot V_{\infty_z} \qquad \text{at infinity} \qquad (3)$$

238

where n indicates the direction normal to the surface. A solution to these equations is constructed in the form of a source density (S) on the surface of the body,

$$\phi(p) = \iint_{\text{Body Surface}} S(q) \frac{1}{r(p,q)} dA_q - x \cdot V_{\infty_x} - y \cdot V_{\infty_y} - z \cdot V_{\infty_z} \qquad (4)$$

where $r(p,q)$ is the distance between the point p at which we are interested in finding the potential and some other point q on the body, and A_q denotes the area of the quadrilateral containing the point q. Note that Equations (1) and (3) are satisfied by ϕ as defined by Equation (4). The boundary condition on the body, Equation (2), can be applied to obtain an equation for the source density (S).

$$0 = \frac{\partial \phi}{\partial n_p} = -2 S(p) + \iint_{\text{Body Surface}} S(q) \frac{\partial}{\partial n_p} \frac{1}{r(p,q)} dA_q$$

$$(5)$$

$$-n_{px} \cdot V_{\infty_x} - n_{py} \cdot V_{\infty_y} - n_{pz} \cdot V_{\infty_z}$$

Since the surface of the body is approximated by a set of plane quadrilaterals which are generated from input points (See Figure 46), in the limit the above equation requires that the body surface be represented by an infinite number of panels at each of which the flow normal to the surface is zero. It is important to obtain satisfactory results with a finite number of panels and to properly size and position these panels on the body surface. In Reference 23 Hess and Smith state that the proper distribution of elements over the body surface is largely a matter of intuition and experience. Panels should be concentrated in regions where the flow properties, particularly the source density, are expected to vary rapidly. The method gives correct results for convex corners, but concave corners cause difficulty that may or may not be serious. Accordingly, they recommend that panels should not be concentrated near unrounded concave corners; but if the corner is extreme enough to require rounding, a very great concentration of panels is necessary in that region. The panel sizes also play an important role in determining the validity of the solution. Hess and Smith note that if several small panels are in the vicinity of a large one, the accuracy is that associated with the large panel. Thus, the size of panels should change gradually when going from a region of highly concentrated small panels to a region of sparsely concentrated panels. They recommend that the characteristic dimensions of a panel should usually be no more than 50 percent greater than those of adjacent elements.   239
Figure 46. The approximate representation
of the body surface.

The source density is assumed to be constant in each of the body panels and is computed by satisfying Equation (5) at one point in each of the quadrilaterals. The point chosen is the panel centroid point. Thus, the integral Equation (5) is approximated by a matrix equation

$$S_i = \sum_j C_{ij} S_j + V_i \qquad (6)$$

where

$$C_{ij} = \frac{1}{2\pi} \iint_{\text{Quad. } j} \frac{\partial}{\partial n_i} \left(\frac{1}{r_{ij}}\right) dA$$

$$C_{ii} = 0, \text{ and}$$

$$V_i = -\frac{1}{2\pi} (n_x \cdot V_{\infty_x} + n_y \cdot V_{\infty_y} + n_z \cdot V_{\infty_z}).$$

240

Equation *(8)* is solved for S_j by the iterative procedure mentioned above (see Reference 83 for more detail). The velocity components at each centroid point are then computed from the following equations:

$$VX_i = \sum_j V1_{ij}S_j + V_{\infty_x} \tag{7}$$

$$VY_i = \sum_j V2_{ij}S_j + V_{\infty_y} \tag{8}$$

$$VZ_i = \sum_j V3_{ij}S_j + V_{\infty_z} \tag{9}$$

where

$$V1_{ij} = -\iint_{Quad.\ j} \frac{\partial}{\partial x}(\frac{1}{r_{ij}})dA$$

$$V2_{ij} = -\iint_{Quad.\ j} \frac{\partial}{\partial y}(\frac{1}{r_{ij}})dA,\ and$$

$$V3_{ij} = -\iint_{Quad.\ j} \frac{\partial}{\partial z}(\frac{1}{r_{ij}})dA$$

The pressure coefficient is then computed from these velocity components.

An integral over a quadrilateral is evaluated by one of three methods, depending upon the ratio of the distance of the ith point from the quadrilateral to the maximum dimension of the quadrilateral. If the ratio is greater than 4.0, the quadrilateral is approximated by a monopole (as if it were concentrated at one point). If the ratio is greater than 2.0 and less than or equal to 4.0, the quadrilateral is approximated by a quadrupole. If the ratio is less than or equal to 2.0, the integrals are evaluated exactly. The approximate methods are used because they require much less time than the exact method. The evaluation of the integrals is extensively discussed in References 23 and 83.

The on-body streamlines are computed once the velocities are known at each quadrilateral centroid. The streamline computation procedure used in the XYZ program is discussed in some detail in a report to be published by Charles W. Dawson and Janet S. Dean of the Naval Ship Research and Development Center in late 1975. This procedure may be outlined in the following manner:

(1) The coordinates of a starting point within a particular quadrilateral are specified.

(2) The two points at which the streamline, passing through the starting point, intersects the sides of the starting quadrilateral are found.

(3) The intersection point which is in the upstream flow direction is retained.

(4) A search is made of the adjacent quadrilaterals to determine which quadrilateral the streamline is entering in the upstream direction.

(5) Using this quadrilateral as a starting quadrilateral the point at which the streamline leaves this new quadrilateral in the upstream direction is determined.

(6) The above procedure, steps (4) and (5), is continued until the streamline reaches the nose of the body.

(7) The upstream portion of the streamline so traced is now defined by the coordinates of its intersection points on the sides of the quadrilaterals through which it passes.

(8) It should be noted that as each point on the streamline is found, the velocity at that point and the distance from that point to the previous streamline point are calculated.

(9) After returning to the original starting quadrilateral the same procedure is used to trace the streamline in the downstream direction to the body tail.

(10) The arc lengths computed from point to point in (8) are then all referenced to the nose of the body so that the distance of any point on a streamline from the nose of the body is known.

242

GENERAL PROGRAM MODIFICATIONS

Many of the changes made in the XYZ potential flow program as obtained from the Naval Ship Research and Development Center may be classified as general program modifications applicable to the entire program rather than a particular subroutine; these general modifications are discussed below. Throughout the remainder of the text the program as received at N. C. State will be referred to as the XYZ program while the modified viscous flow program will be referred to as the NCSU BODY program.

The XYZ program required only minor modifications in order to execute on the IBM 370-165 computer at N. C. State. Four of the five separate sections of the program were changed to subroutines all of which were called by the first section which was designated as the mainline. It was also necessary to modify the input and output file numbers as well as some of the data storage files.

In the interest of saving scratch file space, several of the files in the XYZ program were eliminated or reduced in size. In some cases the information stored on these files was put into a COMMON statement and thus made available to all five sections of the program. Table 3 gives a list of both the original file numbers used in the XYZ program and, if the information on these files was not commoned or deleted, the new file numbers used in the NCSU BODY program. Variable names were assigned to the input and output file unit numbers (JREAD-input, JWRITE-output) and to each scratch file unit number used in the NCSU BODY program. The values of the unit numbers are assigned by specification statements at the beginning of the mainline of the NCSU BODY program (JREAD=1, JWRITE=3, KFILE1=7, KFILE2=8, KFILE3=9, KFILE4=10, and KFILE5=11). For installations having different input/output unit numbers and file numbers these specifications may be easily changed. The addition of a wake body to the original body required more body panels and therefore more panel geometry storage space on file KFILE1. To prevent recalculating original panel geometry, the appropriate information for the new quadrilaterals was calculated and then added to the original information by using a second file (KFILE2) for panel geometry information. The original panel geometry which was unchanged was copied from file KFILE1 to KFILE2, and the new information was then added to file KFILE2. This two-file procedure is used to prevent file READ-WRITE incompatibilities at other computing facilities.

In an effort to reduce the size of the XYZ program by specializing it to the problem of interest, several modifications were made. Since the program was to be used for bodies at zero angles of attack and sideslip, those portions of the XYZ program which calculate the contributions to the flow and pressure over the body resulting from the Y-flow and Z-flow components were removed when the NCSU BODY program was created. Thus, the free stream velocity in the NCSU BODY program was specified as -1.0 in the X-direction, 0.0 in the Y-direction and 0.0 in the Z-direction. While the potential flow calculations are correctly made using just this unit velocity, the viscous part of the program

243

requires the specification of the magnitude of the free stream velocity or the Reynolds Number in order to make the boundary layer calculations. The magnitude of the free stream velocity must therefore be specified (see last paragraph in this section).

XYZ Program	NCSU BODY Program	
File Number	File Name	File Number
1	KFILE3	9
2	KFILE4	10
3	Information Commoned	
4	KFILE KFILE1 KFILE2	7 8
5 (Input)	JREAD	1 (input)
6 (output)	JWRITE	3 (output)
7	File Deleted	
8	File Deleted	
9	File Deleted	
11	KFILE5	11
12	File Deleted	
16	File Deleted	

Table 3. Data file comparison for the XYZ and NCSU BODY Programs.

The maximum array size for the quadrilateral input arrays and geometry storage arrays was set at 650. This maximum input array size coupled with the addition of the wake body, which uses part of the geometry storage arrays, means that the user should specify the original body using less that 600 panels. The coefficients of local quadratic representation of the body surface, which were stored on a scratch file as quadrilateral geometry information in the XYZ program,

244

were deleted from file storage in the NCSU BODY program, thereby reducing the file storage space and the size of the file input array B. The WS array contained in the XYZ program was also deleted from the NCSU BODY program, and the required control variables originally held in this array were commoned or placed in subroutine argument lists.

The addition of the wake body to the original body and the assumption of a plane of symmetry necessitated two important restrictions on specifying data for the NCSU BODY program. First, the line of reference with respect to which the Y-coordinates of the body are specified must be the Y=0 line. Second, the line of reference with respect to which the X-coordinates of the body are specified must be a line parallel to a line from the nose of the body to the tail of the body (see Figure 47). This last restriction was incorporated in order to determine the direction in which the wake body should be added onto the original body.
Figure 47. Orientation of body with respect to reference line.

In addition to those mentioned above, there were also other input and output modifications made to the XYZ program. Many of the input integers in the XYZ program were just specified as constant values in the NCSU BODY program: NSE=1, MIX=150, ISM=1, EPS=0.0001, and ISP=0. The other input integers MIY, MIZ, IUCT, IPS, AND IPF were deleted. While the above input variables were deleted, it was also necessary to add the variables VINF (free stream velocity), VO (kinematic viscosity), ROE (density), REFA (reference area), and IWRITE to the NCSU BODY program input. The first three were added to supply the boundary layer routines with the necessary information

245

to compute the Reynolds Number of the body. REFA was added to provide a reference area for normalizing the lift and drag coefficients. IWRITE was added as an output control parameter which has the value 0, 1, or 2. IWRITE= 0 gives maximum output while IWRITE=2 gives minimum output. For an exact description of the input required for the NCSU BODY program the reader is referred to the User Instructions in Appendix F.

246

STREAMLINE MODIFICATION AND BOUNDARY LAYER CALCULATION

The only practical method for predicting the viscous flow field about an arbitrary three-dimensional body involves the same procedure as that used for the viscous flow about two-dimensional airfoils. The basic steps for this procedure are: (1) obtain an inviscid flow solution for the basic arbitrary body, (2) obtain a boundary layer solution based on the inviscid flow solution, (3) construct a modified body by adding a wake body to the original body, and (4) obtain an inviscid flow solution for the body plus wake body to obtain the final pressures and force coefficients on the physical body. These steps represent an outline of the procedure used in the NCSU BODY program.

The basic method for obtaining the inviscid flow solution has already been discussed in the section General Program Theory For Inviscid Body Program. Present methods available for obtaining a three-dimensional boundary layer solution over arbitrary bodies are very time consuming, require a large amount of computer storage, and are therefore beyond the scope of this report. As an alternative, the authors chose to use two-dimensional boundary layer calculations along streamlines to approximate the actual three-dimensional case. Justification for this procedure has already been discussed in detail beginning on page 113 of the theory section. This method is ideally suited for use with XYZ since the program already provides the capability for computing on-body streamlines. Further, the streamline procedure calculates the absolute velocity and surface length from the nose for each streamline point. Considering the approximate nature of two-dimensional boundary layer solutions along streamlines as applied to this problem, it is appropriate to employ relatively simple laminar and turbulent boundary layer calculation procedures. The boundary layer displacement thickness δ^* and wall shear τ_w are calculated at each of the panel centroid points. Assuming τ_w in each panel is constant over that panel area, and given (1) the axial (X-direction) component of velocity from the potential flow solution, (2) the absolute velocity for each panel, and (3) the area of each panel, the skin friction drag coefficient is found by integrating the axial component of τ_w over the body surface. The values of δ^* at the panel centroids are used to construct a wake body which is added to the original body. As in the case of the airfoil, the purpose of the wake body is to model the relief of the stagnation condition at the body tail accompanying the presence of the boundary layer (see page 128). The construction of the wake body is discussed in the next section of this report. Once the wake body is generated, a new inviscid solution for the body plus wake body is found; this solution represents the viscous flow solution over the original body. There is no iterative procedure as was the case with the airfoil because of the large amount of computer time required for each solution.

Thus far this section has presented a brief summary of how the viscous flow solution over an arbitrary body can be obtained by modifying the inviscid flow solution. Attention will now be directed to (1) the actual modifications made in the streamline section of the XYZ program and (2) the addition of the two-dimensional boundary layer calculation procedures.

Since the inviscid solution calculates the velocities at the panel centroid points, the appropriate boundary layer parameters are also estimated at these centroids. This is accomplished by the following procedure:

(1) For a given panel a streamline is traced, using the centroid point as the starting point, from the body nose to three points downstream of the panel centroid. The reader should note that this represents two modifications of the original streamline procedure provided in the XYZ program. First, in the XYZ program, the coordinates for a streamline starting point were read in by the user, while in the NCSU BODY program the streamline starting points are automatically specified as the panel centroid points; thus, the user no longer has the option of inputting the starting coordinates for streamlines. Second, the XYZ program traced a streamline from the nose of the body to the body tail; however, since the boundary layer information is needed only at the panel centroid, computation time is simply wasted by continuing to trace a streamline far downstream of a panel centroid. In the NCSU BODY program at most only three points are traced downstream of the panel centroid point.

(2) A cubic spline curve of streamline velocity versus arc length is fitted to the streamline points. This curve is used to generate a more finely spaced set of velocity versus arc length points as well as the derivative of the velocity with respect to arc length. This information is required by the boundary layer computation procedure. The cubic spline curve was used because it may be differentiated to give smooth first derivatives from tabulated data.

(3) A boundary layer is computed along each streamline with transition fixed at the point on the streamline where the arc length is 5 percent of the total length of the body. If laminar separation arises before this point is reached, the program assumes that turbulent reattachment occurs at the point of laminar separation. The laminar boundary layer is computed using the Holstein-Bohlen formulation of the Kármán-Pohlhausen momentum integral method (Ref. 65). If the velocity for the first point on the streamline is zero then the laminar routine assumes stagnation point starting conditions; however, if a nonzero velocity is found then flat plate starting conditions are used. These two types of starting conditions are necessary since the potential flow program does not always achieve a stagnation point (zero velocity) at the nose of the body. The turbulent boundary layer method, derived by Goradia in Reference 31, is a shortened version of the one used in the airfoil program (Appendix A). Goradia's method is designed to remain stable under the influence of extreme gradients, both favorable and adverse, and provide reasonable momentum and displacement thicknesses downstream of the turbulent separation point. Consequently, turbulent separation is never predicted with this method.

(4) The streamline values of δ^* and τ_w at the point corresponding to the streamline starting point (panel centroid point) are retained. These quantities are later used for the construction of the wake body and the calculation of the skin friction drag coefficient.

The above procedure, steps (1) through (4) are repeated for each panel centroid point except for the triangular panels at the nose and tail of the body. Initiating streamlines from the centroids of triangular panels is omitted because it was found that the streamline tracing procedure experiences great difficulty in the region where apexes of several triangular panels come together (i.e. in the region of the nose or tail). Thus, it is necessary to approximate the values of δ^* and τ_w at the centroids of the panels using the following procedure:

(1) For the triangular panels at the nose of the body, the values of δ^* and τ_w are taken to be one-third of their respective values in the quadrilateral immediately aft of each triangle.

(2) For triangular panels at the tail of the body the values of δ^* and τ_w are taken to be equal to their respective values in the quadrilateral immediately preceeding each triangle.

The streamline procedure was modified in one final way which has not been referred to as of yet. In the XYZ program a search is made of all quadri- laterals to determine the next quadrilateral into which a streamline is traced. In actuality, a streamline traced in either the upstream or downstream direction must enter one of five quadrilaterals adjacent to the quadrilateral it is leaving. Consequently, only these five quadrilaterals need to be checked to see which quadrilateral the streamline will enter. To reduce program execution time this modified search procedure is incorporated in the NCSU BODY program. Figure 48 illustrates the order in which each of the five quadri- laterals are searched when tracing in either the upstream or downstream direction.

It should also be mentioned that in the original XYZ program the stream- line variables were dimensioned large enough to provide for tracing 650 stream- line points. This is well in excess of the number needed for the NCSU BODY program. The array sizes of the appropriate streamline variables were there- fore reduced in the NCSU BODY program in order to reduce overall program size.

ADDITION OF WAKE BODY

In order to predict the drag of an arbitrary three-dimensional body both the skin friction drag and pressure drag must be calculated. As seen in the previous section, the skin friction drag coefficient is calculated by integrating the wall shear over the body surface. Unfortunately, estimating the pressure drag using an inviscid flow solution technique is not quite as simple. Actually, the pressure or form drag is a relief of the rear stagnation condition caused by the presence of the boundary layer. Thus, in order to estimate the pressure drag this viscous phenomenon must be correctly modeled in the inviscid flow solution. The authors chose to model this effect with the addition of a wake body. A detailed discussion of the effect of the wake on the pressure drag, the modeling of the wake with a wake body, and the procedure chosen to construct the wake body is given beginning on page 128 in the theory section and is therefore not repeated here. Accordingly, in this section, attention will be directed toward the programming aspect of adding the wake body to the inviscid solution.

(1) The authors chose to define the wake body as the last two sets of panels (modified to some extent) on the original body plus two additional sets of panels downstream of the original body (See Figure 49).
Figure 49. Definition of wake body.

(2) For simplicity's sake, the wake body is chosen as a body of revolution with its axis on the line joining the nose and tail of the original body as shown in Figure 47. The reader should note that the original body must therefore be input using a reference line parallel to the line between the nose and tail of the original body.

(3) The radius of the wake body is chosen to decrease exponentially from the beginning of the wake body to the end. The particular exponential shape is calculated using the average radius and initial slope at the beginning of the wake body as well as the total length of the wake body.
Figure 50.   Panel boundaries on the original body and the wake body.

(4) Noting Figure 50, the average radius of the original body is computed for the X-coordinate of the panel centroids at station 2 and is denoted by AVXCG. The average value is computed for the boundary layer displacement thickness of the panels at station 2 and is denoted by AVDELS.

(5) The actual radius is computed for each body input point at station 1 and is denoted by R1. The radius corresponding to each body input point is computed for each panel at station 2 and is denoted by R2. Twice the average boundary layer displacement thickness is then added to each of the R2 values computed.

(6) A value for the slope (denoted as SLOPE) at each panel around the circumference of the body is then computed from the equation below:

$$SLOPE = (R2 - R1) / (XHOLD1 - AVXCG)$$

where XHOLD1 is the X-coordinate of station 1.

252

(7)   The average slope (denoted by AVSLOP) is computed by summing each slope previously calculated and dividing this sum by the number of points at station 1.   This slope is taken to be the initial slope of the exponential.

(8)   The location of the end of the wake body, XINF, is then computed from the following equation:

$$XINF = XHOLD1 - AREAT / (3.14159*RAV)$$

where AREAT = 4.0*AREAAV*2.0*MMAXQD and MMAXQD is the total number of points around the half body.

(9)   Since all the parameters needed to determine the exponential curve have been found, the X-stations at 3, 4, and 5 are chosen to give panel areas on the surface of the wake body which are approximately equal to AREAAV.   The radii corresponding to these X-stations are then calculated using the exponential curve.

(10)   It should be noted that if a non-negative average slope is calculated for the initial slope of the exponential, the average slope is calculated from the following equation:

$$AVSLOP = - Absolute Value (RAV / (XINF - XHOLD1)).$$

(11)   Using the radii values at stations 3 through 6, the X, Y, and Z-coordinate values are generated for surface points on the wake body.

(12)   Since the geometric information for the panels on the original body ahead of station 1 need not be changed, this information is copied from KFILE1 to KFILE2 (see page 243) in General Program Modifications). The geometric information for the wake body panels is then calculated and this information is added to KFILE2 in such a manner that body plus wake body appears as one large pseudo-body.

(13)   The pressure coefficients for the panels on the pseudo-body are calculated by finding a new inviscid solution over this body.   These pressure coefficients are then applied to the corresponding panels on the original physical body along the normals of the original panels (see pages 127 - 132).   The appropriate components of these pressure coefficients are then integrated over the body surface to yield a pressure drag coefficient and a pressure lift coefficient.

As an illustration of the shape and location of the wake body with respect to the original body Figures 51 and 52 are included.   Figure 51 depicts a 3-1 ellipsoid before and after a wake body is added, while Figure 52 shows the Cessna 182 which has an arbitrary cross-section.

DISCUSSION OF PROGRAM RESULTS

To the time of the present writing it has not been possible to investigate the applicability of the NCSU BODY program to as many test cases as the authors would have liked. The greater geometric variability and intricacy characteristic of fuselages (in contrast to relatively simple geometry of airfoil families at least), the paucity of reliable experimental data, the extended development time required for the program, and finally, the cost of running the program (more than 10 times as much as the airfoil program) all served to limit the number of runs made using the final version of the program. Three bodies, however, were studied.

The first was a sphere. For a Reynolds Number of 2 million (based on sphere diameter) a drag coefficient of 0.041 was computed. This is about 1/5 the commonly accepted value for the sphere at such Reynolds Numbers. The reason for the low drag value, however, is easy to explain. It may be recalled that the computer program adds the wake body only behind the last two sets of surface panels in the X-direction. For a sphere the wake obviously emanates from a much larger area than the last two sets of panels if one uses a reasonably large number of quadrilaterals to represent the body. During the course of program development it was readily demonstrated that beginning the wake body at the point where separation is observed experimentally does in fact yield the correct value of drag. However, most streamlined bodies produce proportionately smaller separated flow regions; since the program is intended for use primarily with streamlined bodies, it was felt that the wake body formation procedure should attempt to model closely only the wakes of such bodies. One might also point out that if one better understood the relationships among the direction of and location of the flow separation from the body and the body geometry and flow Reynolds Number, then one could include analytical versions of these relationships in the system of equations used to calculate the flow; the appropriate wake body would then come out as part of the solution. In the absence of such knowledge, we can do little more than choose a model representative of one class of bodies.

The second body against which the program predictions were tested was a 3:1 prolate spheroid. In this case a Reynolds Number of 6 million was used in the computations. With 560 panels the calculated drag coefficient was 0.094 With only 100 panels the drag coefficient was 0.109 indicating the effect which a poorer representation of the body has on the computed drag value. No direct experimental data was found for this case but a 2:1 ellipsoid was found (Ref. 117) to give C_D = .07. There is also some evidence that the 3:1 ellipsoid should have a slightly higher drag because the surface area (skin friction) increases faster than the wake size, and hence, the form drag, diminishes. At any rate, the drag coefficient computed by the program for prolate spheroids with fineness ratios of 3 to 10 appears to be approximately correct.

The final test case was the Cessna 182 fuselage. It was found quite difficult to represent such a body with 560 or fewer panels of nearly equal area. As a result, while the rule of keeping adjacent panel areas within a ratio of 1:1.5 was honored, there is substantial variation in panel areas between the nose region (where many panels are needed to represent the geometry satisfactorily) and the aft cabin region (where large panels are adequate). This variation, it is felt, could be responsible for some error in the computation. The computed drag coefficient value, based on wing area and a length Reynolds Number of 30 million, was .01245. The body lift coefficient at the same condition was 0.00444. The computation, it may be noted, also assumes a turbulent boundary layer for most of the fuselage. It is therefore applicable primarily to the higher speed portions of the flight envelope.

Of course no test data were available against which to compare these figures, but a computation using the $C_{D\pi}$ method (Ref. 2) gives a drag coefficient .00876, about 30% less than the value given by the NCSU BODY program. The $C_{D\pi}$ method is probably the method most often used for preliminary design in the light aircraft industry. It does not differentiate between laminar and turbulent boundary layers but nevertheless it seems to yield drag values which match measured performance reasonably well. Thus it is to be expected that the drag value given by the NCSU BODY program is approximately correct. A more detailed test of the ability of the NCSU BODY program and the other programs discussed in the present work to predict the aerodynamic characteristics of actual aircraft is planned for early 1975. A light twin with an advanced wing design is being carefully instrumented for a series of performance and stability tests. It will be among the objectives of these tests to develop lift and drag flight test data against which to compare the prediction of the programs given in the present work. Until the results of this and other comparisons are available, the authors suggest that potential users of the NCSU BODY program employ its predictions cautiously until its range of validity is better defined.

APPENDICES

APPENDIX A- Two-Dimensional Wing Aerodynamic Characteristics Program

User Instructions

The program is written in FORTRAN IV and is designed to run in single precision on an IBM 370-165 computer with an average execution time of 20 to 25 seconds for each angle of attack. The program calculates the two-dimensional viscous flow solution of an arbitrary airfoil and evaluates its aerodynamic force and moment coefficients. The program requires the specification of the following input data:

(1) The 80 characters of the array TITLE which are used as a header for identifying output. Since the program allows more than one airfoil to be analyzed in a given run, TITLE is used as a control variable to end execution. Termination of execution is achieved by following the last set of airfoil data to be analyzed by a title card having only the word END in the first three spaces (see last card of the sample data set in Figure A-2).

(2) The number NXU of specified upper surface airfoil coordinates, the number NXL of specified lower surface airfoil coordinates, the control parameter IWRITE, the control parameter IALPHA, and the control parameter IPUNCH. The largest allowed value of either NXU or NXL is 65 and no more than 100 total airfoil points may be specified (NXU + NXL ≤ 100). The control parameter IWRITE (either 0, 1, 2, or 3) determines the amount of output desired for each set of airfoil data. IWRITE = 0 yields the maximum amount of output while IWRITE = 3 yields the minimum (examples of all the IWRITE options are given in Figure A-3 through Figure A-6). The control parameter IALPHA specifies the line of reference for the angle of attack. The line of reference is the x-axis of the reference system of the input data points. For IALPHA = 1 the line of reference is the longest chord line of the airfoil. Thus, if the user knows the location of the chord line of the airfoil and specifies the airfoil data points so that the chord line is parallel to the x-axis of the reference system of the input data points, he should use IALPHA = 0. If the user is unsure of the position of the airfoil chord line with respect to the x-axis of the input data system, he may choose IALPHA = 1, in which case, the program calculates the longest chord line and references the angle of attack to this line. The user will find that for most cases he will want to use the IALPHA = 0 option. For further explanation of this option see page 112. The control parameter IPUNCH gives the user the option of obtaining punched data (lift, drag, and quarter-chord moment coefficients for each angle of attack) which may be used in the program designed to estimate three dimensional aerodynamic characteristics of wings (see Appendix C). IPUNCH = 1 gives punched output while the default IPUNCH = 0 gives none.

(3) The NXU values of the abscissa XU for the upper surface input points. The XU array should be monotonic increasing from airfoil leading to trailing edge with 8 points per data card.

(4) The NXU values of the upper surface ordinate ZU which correspond to the XU values. The ZU array is specified with 8 data points per card.

(5) The NXL values of the abscissa XL for the lower surface input points. The XL array should be monotonic increasing from airfoil leading to trailing edge with 8 points per data card.

(6) The NXL values of the lower surface ordinate ZL which correspond to the XL values. The ZL array is specified with 8 data points per card.

(7) The number NA of angles of attack to be read for which a solution is desired. NA must be less than or equal to 10.

(8) The NA values of angle of attack, ALPHA, given in degrees, 8 values per data card.

(9) The number NM of free stream Mach numbers to be read for which a solution is given at each of the NA angles of attack. NM must be less than or equal to 5.

(10) The NM values of free stream Mach number, FSMACH, 5 values per data card.

(11) The reference chord CREF in feet and the scale factor SF. The reference chord is used to non-dimensionalize all of the output. The scale factor is a multiplicative constant used to convert the values of XU, ZU, XL, ZL, XTRAN, and ZTRAN to feet. It would be advantageous for the user to input the airfoil coordinates as percentages of the reference chord so that CREF and SF will have the same numerical values.

(12) The stagnation temperature TO in degrees Rankine, the Reynolds number RN in millions, the Prandtl number PR, and the heat transfer factor KF. Reynolds number should be calculated based on CREF, and since it is read in millions, RN = 3.0 corresponds to a Reynolds number of 3,000,000. (It should be noted that this Reynolds number specification differs from that used in the NASA program which used millions per foot.) It is recommended that a value of 1.0 be used for the heat transfer factor. For cases where heat transfer effects may be important, the user should consult Reference 32 to determine an appropriate value for KF.

(13) The control variable LTRAN which determines whether boundary layer transition is free (LTRAN = 0) or fixed (LTRAN = 1), the x location for transition XTRAN, and the z location for

transition ZTRAN. If free transition (LTRAN = 0) is used both XTRAN and ZTRAN should be specified as 0.0, and the program will predict the location of the transition points. It should be noted that if the fixed transition option is used the program will still use its own predicted point of transition if it occurs before the specified transition point. Since transition must be specified on both surfaces, _two_ transition cards must be read (upper surface card first).

Statements (1) through (13) represent a complete set of data for a particular airfoil. The format specification for this data is given in Figure A-1. A sample data set of the 23012 airfoil with IWRITE = 3 option is shown in Figure A-2. The output of this particular data set is shown in Figure A-3, and in addition, examples of the other IWRITE options are given in Figures A-4, A-5, and A-6.

      SUBROUTINE MAIN2(IERR,K)
C000  SOLUTION FOR AIRFOIL GAMMAS IS CONSIDERED TO BE THE SUM OF A
C000  CAMBER SOLUTION AND A THICKNESS SOLUTION. THE CAMBER SOLUTION IS
C000  OBTAINED FROM THE BASIC AIRFOIL AT AN ANGLE OF ATTACK WITH ITS
C000  MEAN CAMBER LINE MODIFIED BY THE DIFFERENCE IN THE UPPER AND LOWER
C000  SURFACE BOUNDARY LAYER DISPLACEMENT THICKNESSES. THE THICKNESS
C000  SOLUTION IS OBTAINED FROM A SYMMETRIC AIRFOIL AT ZERO ANGLE OF
C000  ATTACK WHICH HAS THE SAME THICKNESS DISTRIBUTION AS THE BASIC
C000  AIRFOIL PLUS UPPER AND LOWER BOUNDARY LAYER DISPLACEMENT THICK-
C000  NESSES. SINCE THE CAMBER SOLUTION NECESSARILY INCLUDES A THICKNESS
C000  EFFECT ALSO, IT IS MODIFIED BY SUBTRACTING THE SOLUTION OF A
C000  SYMMETRIC AIRFOIL AT ZERO ANGLE OF ATTACK WITH THE SAME THICKNESS
C000  DISTRIBUTION AS THE BASIC AIRFOIL.

APPENDIX B - Polynomial Fit of Two Dimensional Data

User Instructions

This program is written in Fortran IV and is designed to run in single precision on an IBM 370-165 computer. Execution requires 54,000 bytes of core storage and approximately six seconds to fit one set of two-dimensional airfoil data giving four polynomial curve fits of degree four. For each airfoil the program requires the following input data:

(1) The 80 characters of the array TITLE which are used as a header for identifying output. Since the program allows more than one airfoil to be analyzed in a given run, TITLE is used as a control variable to end execution. Termination of execution is achieved by following the last set of airfoil data to be analyzed by a title card having only the word END in the first three spaces (see the last card of the sample data set in Figure B-2).

(2) The number NUM. The largest allowable value of NUM is 20. This variable specifies the number of angles of attack which follow.

(3) The first element values of the arrays AL, CL, CD, CM. These are the angle of attack and the two-dimensional coefficients of lift, drag, and pitching moment for that angle of attack. Similar cards with successive array elements follow until the number of points specified by NUM are read in.

In addition to the previous input data specification an internal switch is provided to suppress the plot of the input points and the curve fit function. When SWITCH is set to zero, plots are produced; however, when SWITCH is set to one, the plots are suppressed. Another internal switch PUNCH which operates similarly allows for the fitted coefficients to be punched into card form for use with other programs.

Statements (1) through (3) represent a complete data set for a particular airfoil. The format specification for this data is given in Figure B-1. A sample data set of the 23012 airfoil is shown in Figure B-2. The output of this particular data set is shown in Figure B-3.

APPENDIX C - Airfoil-to-Complete-Wing Program

User Instructions

This program is written in Fortran IV and is designed to run in single precision on an IBM 370-165 computer. Execution requires 60,000 bytes of core storage and approximately eight seconds to produce the three-dimensional lift, drag, and pitching moment for a given wing-body configuration. For each configuration the program requires the following input data:

(1) The aspect ratio ASPEC, the thickness ratio of the tip TAUT, the thickness ratio of the root TAUR, the taper ratio TAPER, the geometric twist TWIST in degrees (If geometric twist is specified, the aerodynamic twist TWISA must be set to a value of 100.), the number of spanwise stations R (R must be less than or equal to 20.), Reynolds number in millions based on wing mean aerodynamic chord REYND, and a criterion for convergence of the lift distribution DISCR.

(2) Fuselage height to wing span ratio A, fuselage width to wing span ratio B, the height of the wing above the fuselage centerline H, again as a ratio to wing span, wing-body incidence angle ALPHR in degrees, x-coordinate of the moment reference point X, z-coordinate of the moment reference point Z, the aerodynamic twist TWISA in degrees (If aerodynamic twist is specified, the geometric twist TWIST must be set to a value of 100.).

(3) The number of airfoil families (two tables per family) to be read in with this configuration IFAM, a control parameter for reading in wing geometric parameters ISWIT(1), a control parameter for printing out intermediate calculations as they are performed ISWIT(2), a control parameter for printing out matrices ISWIT(3), and an indicator that the tip airfoil is or is not of the same family as the root IRT. A yes action is implied when the control parameter or indicator is set to one; otherwise, the appropriate space is filled with a zero.

4) The 80 characters of the array NAME which are used as a header for identifying output.

(5) The 80 characters of the array TITLEI which serve as identification for the first airfoil table.

(6) The thickness ratio of the airfoil in the first table RTI.

(7) The five coefficients of the lift polynomial CCLRT1 for the airfoil in the first table.

(8) The domain for which the coefficients of CCLRT1 are valid XLO(1) and XHI(1).

310

(9) The five coefficients of the drag polynomial CCDRT1 for the airfoil in the first table.

(10) The domain for which coefficients of CCDRT1 are valid XLO(2) and XHI(2).

(11) The five coefficients of the moment polynomial CCMRT1 for the airfoil in the first table.

(12) The domain for which the coefficients of CCMRT1 are valid XLO(3) and XHI(3).

(13) The five coefficients of the alpha polynomial CALRT1 for the airfoil in the first table.

(14) The domain for which the coefficients of CALRT1 are valid XLO(4) and XHI(4).

(15) A duplication of (4) through (14) for each additional airfoil until the correct number of airfoil coefficient tables are stored.

(16) The 20 elements of the array ALPHB representing the angles of attack for which three-dimensional lift, drag, and moment coefficients are to be calculated. One element of this array must contain the value 99.0 to insure a later return to the main portion of the program.

The program allows for additional configurations to be calculated during the same run. This may be accomplished simply by repeating the previous input. The program will continue execution until it encounters an ASPEC value of 99.0 followed by a blank card.

Statements (1) through (16) represent a complete data set for a particular configuration. The format specification for this data is given in Figure C-1. A sample data set using a 23020 root-23012 tip wing is shown in Figure C-2. The output of this particular data set is given in Figure C-3.

Figure C-3. Sample output of the airfoil-to-complete-wing program.

APPENDIX D - PLOT Program

User Instructions

This program was originally written for a CDC 6000 computer (Ref. 113) and was then modified to run in single precision on an IBM 370-165. Given a set of input data the program generates the necessary instructions for automatic plotting of an airplane numerical model and can be used to draw three-view and oblique orthographic projections, as well as perspective projections. These plots are very useful in checking the validity of numerical model data. The program has an average execution time of 3 minutes and 20 seconds for a job yielding 8 different views of the same aircraft.

In order to be compatable with the potential flow program used in this report (see Appendix F), the body coordinates are specified with the body nose at, or near the origin of the coordinate system, and the body's longitudinal axis is extended along the X-axis (see Figure D-1). The origin of the Y-axis must lie in the XZ-plane of symmetry, and the Z-axis must be the vertical axis of the body.

Reference 113 does an excellent job of describing the input data cards; therefore, the data specification given below is taken directly from that description. Additional information on this program is available in the cited reference.

Configuration Cards

Since the airplane has to be symmetrical about the XZ-plane, only half of the airplane need be described to the computer. The convention used in presenting the input data is that the half of the airplane on the positive Y-side of the XZ-plane is presented. The program then uses this information to construct the complete airplane. The number of input cards depends on the number of components used to describe the configuration, whether a component has been described previously, and the amount of detail used to describe each component. The method of input is by FORTRAN "READ" statements.

Columns	FORTRAN Name	Description
01 to 03	JO	If JO=0, no reference area If JO=1, reference area to be read If JO=2, reference area same as previously read

Columns	FORTRAN Name	Description
04 to 06	J1	If J1=0, no wing data If J1=1, cambered wing data to be read If J1=-1, uncambered wing data to be read If J1=2, wing data same as previously read
07 to 09	J2	If J2=0, no fuselage data If J2=1, data for arbitrarily shaped fuselage to be read If J2=-1, data for circular fuselage to be read (with J6=0, fuselage will be cambered; with J6=-1, fuselage will be symmetrical with XY-plane; with J6=1, entire configuration will be symmetrical with XY-plane) If J2=2, fuselage data same as previously read
10 to 12	J3	If J3=0, no pod data If J3=1, pod data to be read If J3=2, pod data same as previously read
13 to 15	J4	If J4=0, no fin data If J4=1, fin data to be read If J4=2, fin data same as previously read
16 to 18	J5	If J5=0, no canard data If J5=1, canard data to be read If J5=2, canard data same as previously read
19 to 21	J6	Simplification code: If J6=0, indicates a cambered circular or arbitrary fuselage if J2 ≠ 0 If J6=1, complete configuration is symmetrical with respect to XY-plane, which implies uncambered circular fuselage if there is a fuselage If J6=-1, indicates uncambered circular fuselage with J2 ≠ 0
22 to 24	NWAF	Number of airfoil sections used to describe the wing; $2 \leq$ NWAF ≤ 20
25 to 27	NWAFOR	Number of ordinates used to define each wing airfoil section; $3 \leq$ NWAFOR ≤ 30

324

Columns	FORTRAN Name	Description
28 to 30	NFUS	Number of fuselage segments; $1 \leq$ NFUS ≤ 4
31 to 33	NRADX(1)	Number of points used to represent half-section of first fuselage segment; if fuselage is circular, the program computes indicated number of y- and z-ordinates; $3 \leq$ NRADX(1) ≤ 30
34 to 36	NFORX(1)	Number of stations for first fuselage segment; $4 \leq$ NFORX(1) ≤ 30
37 to 39 40 to 42	NRADX(2) NFORX(2)	Same as NRADX(1) and NFORX(1), but for second fuselage segment
43 to 45 46 to 48	NRADX(3) NFORX(3)	Same as NRADX(1) and NFORX(1), but for third fuselage segment
49 to 51 52 to 54	NRADX(4) NFORX(4)	Same as NRADX(1) and NFORX(1), but for fourth fuselage segment
55 to 57	NP	Number of pods described; NP ≤ 9
58 to 60	NPODOR	Number of stations at which pod radii are to be specified; $4 \leq$ NPODOR ≤ 30
61 to 63	NF	Number of fins (vertical tails) described; NF ≤ 6
64 to 66	NFINOR	Number of ordinates used to define each fin airfoil section; $3 \leq$ NFINOR ≤ 10
67 to 69	NCAN	Number of canards (horizontal tails) described; NCAN ≤ 2
70 to 72	NCANOR	Number of ordinates used to define each canard airfoil section; $3 \leq$ NCANOR ≤ 10; if NCANOR is given a negative sign, the program will expect to read lower ordinates also; otherwise, airfoil is assumed to be symmetrical

Cards 3, 4, . . . - remaining data input cards. - The remaining data input contain a detailed description of each component of the airplane. Each card contains up to 10 values, each value punched in a 7-column field with a decimal and may be identified in columns 73 to 80. The cards are arranged in the following order: reference area, wing data cards, fuselage data cards, pod (or nacelle) data cards, fin (vertical tail) data cards, and canard (or horizontal tail) data cards.

325

Reference area card: The reference area value is punched in columns 1 to 7 and may be identified as REFA in columns 73 to 80.

Wing data cards: The first wing data card (or cards) contains the locations in percent chord at which the ordinates of all the wing airfoils are to be specified. There will be exactly NWAFOR locations in percent chord given. Each card may be identified in columns 73 to 80 by the symbol XAFj where j denotes the number of the last location in percent chord given on that card. For example, if NWAFOR=16, there are 16 ordinates to be specified for every airfoil, and two data cards will be required. The first XAF card is identified as XAF 10 and the second as XAF 16.

The next wing data cards (there will be NWAF cards) each contain four numbers which give the origin and chord length of each of the wing airfoils that is to be specified. The cards representing the most inboard airfoil are given first, followed by the cards for successive airfoils. The information is arranged on each card as follows:

Columns	Description
1 to 7	x-ordinate of airfoil leading edge
8 to 14	y-ordinate of airfoil leading edge
15 to 21	z-ordinate of airfoil leading edge
22 to 28	airfoil streamwise chord length
73 to 80	card identification, WAFORGj where j denotes the particular airfoil; for example, WAFORG1 denotes first (most inboard) airfoil

If a cambered wing has been specified, the next set of wing data cards is the mean camber line (TZORD) cards. The first card contains up to 10 Δz values, referenced to the z-ordinate of the airfoil leading edge, at each of the specified percents of chord for the first airfoil. If more than 10 values are to be specified for each airfoil (there will be NWAFOR values), the remaining values are continued on successive cards. The remaining airfoils are described in the same manner, data for each airfoil starting on a new card, and the cards arranged in the order which begins with the most inboard airfoil and proceeds to the outboard. Each card may be identified in columns 73 to 80 as TZORDj, where j denotes the particular airfoil.

Next are the wing airfoil ordinate (WAFORD) cards. The first card contains up to 10 half-thickness ordinates of the first airfoil expressed as percent chord. If more than 10 ordinates are to be specified for each airfoil (there will be NWAFOR values), the remaining ordinates are continued on successive cards. The remaining airfoils are each described in the same

326

manner, and the cards are arranged in the order which begins with the most inboard airfoil and proceeds to the outboard. Each card may be identified in columns 73 to 80 as WAFORDj, where j denotes the particular airfoil.

Fuselage data cards: The first card (or cards) specifies the x values of the fuselage stations of the first segment. There will be NFORX(1) values and the cards may be identified in columns 73 to 80 by the symbol XFUSj where j denotes the number of the last fuselage station given on that card.

If the fuselage is circular and cambered, the next set of cards specifies the z locations of the center of the circular sections. There will be NFORX(1) values and the cards may be identified in columns 73 to 80 by the symbol ZFUSj where j denotes the number of the last fuselage station given on that card.

If the fuselage is circular, the next card (or cards) gives the fuselage cross-sectional areas, and may be identified in columns 73 to 80 by the symbol FUSARDj where j denotes the number of the last fuselage station given on that card. If the fuselage is of arbitrary shape, the y-ordinates for a half-section are given (NRADX(1) values) and identified in columns 73 to 80 as Yi where i is the station number. Following these are the corresponding z-ordinates (NRADX(1) values) for the half-section identified in columns 73 to 80 as Zi where i is the station number. Each station will have a set of Y and Z cards and the convention of ordering the ordinates from bottom to top is observed.

For each fuselage segment a new set of cards as described must be provided. The segment descriptions should be given in order of increasing values of x.

Pod data cards: The first pod or nacelle data card specifies the location of the origin of the first pod. The information is arranged on the card as follows:

Columns	Description
1 to 7	x-ordinate of origin of first pod
8 to 14	y-ordinate of origin of first pod
15 to 21	z-ordinate of origin of first pod
73 to 80	card identification, PODORGj where j denotes pod number

The next pod input data card (or cards) contains the x-ordinates, referenced to the pod origin, at which the pod radii (there will be NPODOR of them)

327

are to be specified. The first x-value must be zero, and the last x-value is the length of the pod. These cards may be identified in columns 73 to 80 by the symbol XPODj where j denotes the pod number. For example, XPOD1 represents the first pod.

The next pod input data cards give the pod radii corresponding to the pod stations that have been specified. These cards may be identified in columns 73 to 80 as PODRj where j denotes the pod number.

For each additional pod, new PODORG, XPOD, and PODR cards must be provided. Only single pods are described but the program assumes that if the y-ordinate is not zero an exact duplicate is located symmetrically with respect to the XZ-plane; a y-ordinate of zero implies a single pod.

Fin data cards: Exactly three data input cards are used to describe a fin. The information presented on the first fin data input card is as follows:

Columns	Description
1 to 7	x-ordinate of lower airfoil leading edge
8 to 14	y-ordinate of lower airfoil leading edge
15 to 21	z-ordinate of lower airfoil leading edge
22 to 28	chord length of lower airfoil
29 to 35	x-ordinate of upper airfoil leading edge
36 to 42	y-ordinate of upper airfoil leading edge
43 to 49	z-ordinate of upper airfoil leading edge
50 to 56	chord length of upper airfoil
73 to 80	card identification, FINORGj where j denotes fin number

The second fin data input card contains up to 10 locations in percent chord (exactly NFINOR of them) at which the fin airfoil ordinates are to be specified. The card may be identified in columns 73 to 80 as XFINj where j denotes the fin number.

The third fin data input card contains the fin airfoil half-thickness ordinates expressed in percent chord. Since the fin airfoil must be symmetrical,

328

only the ordinates on the positive y side of the fin chord plane are specified. The card identification, FINORDJ, may be given in columns 73 to 80, where J denotes the fin number.

For each fin, new FINORG, XFIN, and FINORD cards must be provided.

Only single fins are described but the program assumes that if the y-ordinate is not zero an exact duplicate is located symmetrically with respect to the XZ-plane; a y-ordinate of zero implies a single fin.

Canard data cards: If the canard (or horizontal tail) airfoil is symmetrical, exactly three cards are used to describe a canard, and the input is given in the same manner as for the fin. If, however, the canard airfoil is not symmetrical (indicated by a negative value of NCANOR), a fourth canard data input card will be required to give the lower ordinates. The information presented on the first canard data input card is as follows:

Columns	Description
1 to 7	x-ordinate of inboard airfoil leading edge
8 to 14	y-ordinate of inboard airfoil leading edge
15 to 21	z-ordinate of inboard airfoil leading edge
22 to 28	chord length of inboard airfoil
29 to 35	x-ordinate of outboard airfoil leading edge
36 to 42	y-ordinate of outboard airfoil leading edge
43 to 49	z-ordinate of outboard airfoil leading edge
50 to 56	chord length of outboard airfoil
73 to 80	card identification, CANORGJ where J denotes the canard number

The second canard data input card contains up to 10 locations in percent chord (exactly NCANOR of them) at which the canard airfoil ordinates are to be specified. The card may be identified in columns 73 to 80 as XCANJ where J denotes the canard number.

The third canard data input card contains the upper half-thickness ordinates, expressed in percent chord, of the canard airfoil. This card may be identified in columns 73 to 80 as CANORDJ where J denotes the canard number. If the canard

329

airfoil is not symmetrical, the lower ordinates are presented on a second CANORD card. The program expects both upper and lower ordinates to be punched as positive values in percent chord.

For another canard, new CANORG, XCAN, and CANORD cards must be provided.

Plot Cards

A single card contains all the necessary information for one plot. The available options and the necessary input for each are described in the succeeding sections.

Orthographic projections. - For orthographic projections, the card should be set up as follows (See Figure D-5):

Columns	FORTRAN Name	Description
1	HORZ	"X", "Y", or "Z" for horizontal axis
3	VERT	"X", "Y", or "Z" for vertical axis
5 to 7	TEST1	Word "OUT" for deletion of hidden lines; otherwise, leave blank
8 to 12	PHI	Roll angle, degrees (See Figure D-1)
13 to 17	THETA	Pitch angle, degrees (See Figure D-1)
18 to 22	PSI	Yaw angle, degrees (See Figure D-1)
48 to 52	PLOTSZ	PLOTSZ determines the size of plot (scale factor is computed using PLOTSZ and maximum dimension of configuration)
53 to 55	TYPE	Word "ORT"
72	KODE	If KODE=0, continue reading plot cards If KODE=1, after processing this plot, read new configuration description

An attempt is made to center the given configuration within the specified field. If the desired plot size is greater than 28 inches, centering is attempted within 28 inches so care must be taken in choosing the view. Minimum values are adjusted so that body axis lines with no rotation angles coincide with grid lines on the plotter paper. Therefore, the plotter pen should always be positioned exactly 1 inch from the side of the plotting space and on the intersection of heavy grid lines at the start of plotting.

330

Plan, front, and side views (stacked). - For plan, front, and side views, the card should be set up as follows (See Figure D-4):

Columns	FORTRAN Name	Description
8 to 12	PHI	y-origin on paper of plan view, inches
13 to 17	THETA	y-origin on paper of side view, inches
18 to 11	PSI	y-origin on paper of front view, inches
48 to 52	PLOTSZ	PLOTSZ determines size of plot (a scale factor is computed using PLOTSZ and maximum dimension of configuration)
53 to 55	TYPE	Word "VU3"
72	KODE	If KODE=0, continue reading plot cards If KODE=1, after processing this plot, read new configuration description

Perspective views. - For perspective views, the card should be set up as follows (See Figure D-10):

Columns	FORTRAN Name	Description
8 to 12	PHI	x of view point (location of viewer) in data coordinate system
13 to 17	THETA	y of view point in data coordinate system
18 to 22	PSI	z of view point in data coordinate system
23 to 27	XF	x of focal point (determines direction and focus) in data coordinate system
28 to 32	YF	y of focal point in data coordinate system
33 to 37	ZF	z of focal point in data coordinate system
38 to 42	DIST	Distance from eye to viewing plane, inches
43 to 47	FMAG	Viewing-plane magnification factor; it controls size of projected image

331

Columns	FORTRAN Name	Description
48 to 52	PLOTSZ	Diameter of viewing plane, inches; DIST and PLOTSZ together determine a cone which is field of vision; PLOTSZ value is also relative to type of viewer which is to be used.
53 to 55	TYPE	Word "PER"
72	KODE	If KODE=0, continue reading plot cards If KODE=1, after processing this plot, read new configuration description.

Stereo frames suitable for viewing in a stereoscope. - For stereo frames suitable for viewing in a stereoscope, the input is identical to that for the perspective views except that the word "STE" is used in columns 53 to 55.

Specification of the cards above represent a complete set of data for a particular body. The format specification for this data is given in the above text. A sample data set of a Cessna 182 light aircraft is shown in Figure D-2. The output of this particular data set, with different plot cards, is shown in Figures D-3 through D-14.

Since plotting software is different at almost every computing facility, this section of the appendix is included to help the user specify the appropriate software plotting instructions expected by the plot program. To institute a plotting procedure at any computing facility the user's program must first be linked with the plotter. In the original plot program linkage was established by the statement: CALL CALCOMP. The user must provide the necessary instructions to produce the same result at his facility. This instruction is given on card COO 35 in the Program Listing presented in the next section of this appendix. In addition, at most installations an instruction must also be given to close the plotter data set (i.e. turn the plotter off) after plotting has been completed. In the original plot program this was accomplished by the statement: CALL CALPLT(0.,0.,999). The user must provide an equivalent instruction for his installation as seen on card COO 67 in the Program Listing.

The actual plotting in the program is accomplished using three basic subroutines (CALPLT, NOTATE, and LINE) from the CalComp software package. For the program to operate properly, the user must either provide the original CalComp routines or provide three equivalent dummy subroutines as was necessary at the N. C. State computing facility. Given below is a description of the arguments to, and the results produced by these subroutines. Also included are listings of the equivalent dummy subroutines used at N. C. State to produce the same results as the original CalComp subroutines.

Subroutine CALPLT

Purpose:
To move the plotter pen to a new location with the pen either up or down, and to turn off the plotter.

Use:
CALL CALPLT(X,Y,IPEN)

where

X,Y   are the floating point values for pen movement.

IPEN=2   pen is moved in a lowered position.
=3   pen is moved in a raised position.

Negative IPEN (-2 or -3) will assign $X = 0$, $Y = 0$ as the location of the pen after moving the pen to X,Y (create a new reference point or origin).

333

IPEN=999   Turns the plotter off, the X and Y
values are ignored.

Restrictions: All X and Y coordinates must be expressed as
floating point inches (actual page dimensions)
in deflection from the origin.

(Equivalent N. C. State Routine)

```
SUBROUTINE CALPLT(A,B,I)
DIMENSION A(1),B(1)
IF (I.LT.0) GO TO 5
J=I-2
CALL PLOT(A,B,J)
RETURN
5 J=IABS(I)
J=J-2
CALL PLOT(A,B,J)
CALL ORIGIN(A,B,1.0)
RETURN
END
```

Subroutine NOTATE

Purpose: To draw alphanumeric information for annotation
and labeling.

Use: CALL NOTATE(X,Y,HEIGHT,BCD,THETA,N)

where

X,Y   are the floating point page co-
ordinates of the first character.

For alphanumeric characters, the
coordinates of the lower left-hand
corner of the characters are
specified.

HEIGHT   specifies the height in floating point
inches for a full-size character.

BCD   is the string of characters to be
drawn and is usually written in the
form: nHXXXX--- (the same way an alpha
message is written using FORTRAN for-

334

BCD con't

mat statements). Instead of specifying
alpha information as above, one may give
the beginning storage location of an
array containing alphanumeric infor-
mation.

THETA   is the angle in floating point degrees
             at which the information is to be
             drawn. Zero degrees will print hori-
             zontally reading from left to right, 90°
             will print the line vertically reading
             from bottom to top, 180° will print the
             line horizontally reading from right to
             left (i.e., upside down), and 270°
             will print vertically reading from top
             to bottom.

N   is the number of characters, including
             blanks, in the label.

(Equivalent N. C. State Routine)

```
    SUBROUTINE NOTATE(A,B,C,D,E,I)
    DIMENSION D(1),DD(21)
    DATA STOP/4H   _/
    J=I/4
    XI=I
    XR=XI/4
    IF ((XR-J).GT.0.1)J=J+1
    DO 5 K=1,J
  5 DD(K)=D(K)
    DD(J+1)=STOP
    CALL SYMBOL(A,B,C,DD,E)
    RETURN
    END
```

Subroutine LINE

Purpose: To draw a continuous line through a set of suc-
              cessive data points where the minimum values and
              scale factors are stored at the end of the data
              arrays.

Use: CALL LINE(XARRAY,YARRAY,N,K,J,L,S)

335

where

XARRAY and YARRAY are the names of arrays containing the X values and Y values, respectively, to be plotted. Values must be in floating point.

N	is the number of points to be plotted.
K = 1	this value of K is constant in the plot program.
J = 0	for line plot. Only line plots are used in the plot program.
L	is an integer describing symbol to be used. This variable is not used but a space for it in the calling sequence must be provided.
S	is the desired symbol height. This variable is not used but a space for it in the calling sequence must be provided.

Restrictions: LINE expects the adjusted minimums and scale factors. These two parameters (two for the XARRAY and two for the YARRAY) are automatically calculated and provided by the plotting program at the ends of the XARRAY and YARRAY respectively. The points actually plotted by LINE are

(XARRAY(J) - XARRAY(N+1))/XARRAY(N+2)   for J=1,N

and

(YARRAY(J) - YARRAY(N+1))/YARRAY(N+2)   for J=1,N.

(Equivalent N. C. State Routine)

```
SUBROUTINE LINE(A,B,I,J,K,L,S)
DIMENSION A(1),B(1),X(31),Y(31)
XMIN=A(I+1)
XSCALE=A(I+2)
YMIN=B(I+1)
YSCALE=B(I+2)
DO 5 II=1,I
X(II)=(A(II)-XMIN)/XSCALE
```

336

```
5 Y(II)=(B(II)-YMIN)/YSCALE
  CALL PLOT(X,Y,I)
  RETURN
  END
```

-30° with respect to the Y-Z plane.

APPENDIX E - CONVERT Program

User Instructions

This program is written in FORTRAN IV and is designed to run in single precision on an IBM 370-165 computer. Given a set of plot input data as described in Appendix D, this program (1) produces a properly indexed data set for the NCSU BODY program, (2) computes the area of each body panel described by the input points and displays each area in an orderly fashion, and (3) displays the ratio of the area of each panel to the area of the panel below it and the panel to its right. It should be noted that while the CONVERT program produces a data set for the aircraft body, it will accept the input of a data set for a complete aircraft configuration and ignore the un- necessary information (wing, tail, nacelles, etc.). Execution requires 92,000 bytes of core storage and approximately 15 seconds to run a case with 560 panels specified. A description of the input data cards is not included here since it is the same as that for the PLOT program in Appendix D. The format specification is also the same. The program listing is given in the next section of this appendix and is followed by the sample output (Figure E-1) corresponding to the Cessna 182 data set given in Figure D-3.

APPENDIX F- NCSU BODY Program

User Instructions

The program is written in FORTRAN IV and is designed to run in single precision on an IBM 370-165 computer with an execution time of 10-12 minutes for a half-body with 560 panels (1 minute for a half-body with 100 panels). The 560 panel case required 250,000 bytes of core storage. The program calculates an approximate solution of the three-dimensional viscous flow over an arbitrary body and estimates the body lift and drag coefficients. The program was obtained by making major modifications to the XYZ potential flow program (Ref. 94) supplied by the Naval Ship Research and Development Center, Bethesda, Maryland. The data input and program logic modifications were employed to specialize the program for light aircraft fuselages; therefore, this modified program no longer has the design capability of the original XYZ program. Figure F-1 illustrates how the body ordinates should be input to provide the correct body orientation with respect to the flow direction.

The program input data specification is based on the description given in Reference 94 except where changes were made. The input consists of an identification card, two parameter cards, and several body point cards.[†] A description of the program input is given below.

    Card 1 - Identification - Card 1 contains any information to identify the problem in columns 1 through 80.

    Card 2 - Flow Control Variables - Card 2 contains 3 variables which determine the flow Reynolds Number, the reference area upon which the co-efficients are based, and an output control parameter. This is the only card which must be inserted into a data set produced by the CONVERT program in Appendix E.

Parameter	Column	Description
VINF	1-10	Reference free stream velocity in ft./sec. if the body input points are specified in feet (in general it will be units/second where units are the units in which the body input points are specified).
VO	11-20	Kinematic viscosity of the fluid in which the body is moving in $ft.^2/sec.$ if the velocity is specified in ft./sec.

[†]All of these cards except one (card 2) is supplied by the CONVERT program given in Appendix E.

376

Parameter	Column	Description
ROE	21-30	The density of the fluid in which the body is moving in slugs/ft.^{3}
REFA	31-40	The reference area upon which the aerodynamic coefficients will be based in ft.^{2}
IWRITE	45	Control variable which denotes the amount of output the user desires. IWRITE=0 yields maximum output. IWRITE=1 deletes information given for each input point. IWRITE=2 deletes streamline and boundary layer information as well as input point information. (See Sample Output).

Card 3 - Control Integer - Card 3 contains a control integer which must be right justified.

Parameter	Column	Description
NQE	1-4	Number of quadrilateral panels to be specified by the point cards. The value of NQE should generally be less than 600 (see page 244).

Cards 4, 5, . . . - Point Cards - Each point card contains the following information for one point on the body surface. If one section is used for the fuselage there should be P points specified where P is equal to the maximum MI times the maximum NI.

Parameter	Column	Description
XI	1-12	X-coordinate of the input point.
YI	13-24	Y-coordinate of the input point.
ZI	25-36	Z-coordinate of the input point.
NI	39-40	N body station index (see Figure F-2). For plotting purposes NI≤30.
MI	43-44	M body station index (see Figure F-2). For plotting purposes MI≤30.
NS	45-48	Section identification number. The CONVERT program (Appendix E) supplies a one-section data set with a section number of 1.

<u>Last Card - End of Data Set</u> - The last card is a blank card to signify the last card of a particular data set.

It should be noted that the program can be run for more than one data set; the user must simply put the complete data sets he desires to analyze in consecutive order. For more information about this program the user should see pages 243 - 255 which describe the modifications made to the original program as well as Reference 94 which describes the original program.

Specification of the cards above represent a complete set of data for a particular body. The format specification for this data is given in Figure F-3. A sample data set of a prolate spheroid is shown in Figure F-4. Portions of the sample output for the light aircraft data set shown in Figure D-3 and plotted in Appendix D are given in Figure F-5. The light aircraft data set was not used in Figure F-4 as the sample data set because of the excessive length of the light aircraft data set (in excess of 600 cards).

APPENDIX G- Theoretical Basis of Oeller's Method

If an inviscid two-dimensional flow is everywhere parallel to the surface of a closed body, then the surface of the body can be represented by a streamline on which the stream function, ψ, is constant. Oeller (Ref. 26) used this fact to develop a method for obtaining the potential flow about an airfoil. He replaced the airfoil surface by a vortex sheet and required that the sum of the stream function for a uniform stream and the stream function for the vortex sheet be a constant on the airfoil surface. This requirement is represented by the integral equation

$$\psi = z(s)\, V_\infty \cos\alpha - x(s)\, V_\infty \sin\alpha - \frac{1}{2\pi}\oint \gamma(s')\, \ell n\left[r(s,s')\right]ds' \qquad \text{(G1)}$$

where ψ is the unknown constant stream function value on the airfoil surface, V_∞ is the free stream velocity, α is the angle between the free stream and the x-axis of the reference system, $\gamma(s')$ is the vorticity strength at any point s' on the surface, $r(s,s')$ is the distance between points s and s', and $x(s)$ and $z(s)$ are the coordinates of the point of interest s. s and s' are arc lengths measured along the airfoil surface starting from the trailing edge. s is any fixed point on the airfoil surface while s' is the integration variable point which moves from the trailing edge over the airfoil surface back to the trailing edge. (See Figure G-1.)
Figure G-1. Geometry for potential flow calculation.

Note that the reference system is chosen with its x-axis parallel to the airfoil chord line so that α will be the angle of attack of the airfoil.

To solve Equation (G1) for ψ and $\gamma(s')$, the integral is approximated by a summation. The airfoil is divided into N segments, $\gamma(s')$ is assumed constant on each segment, and Equation (G1) is applied at the mid-point of

each segment to yield the following system of simultaneous linear equations (see Figure G-2).

$$\psi = z_{c_i} \, V_\infty \cos \alpha - x_{c_i} \, V_\infty \sin \alpha - \sum_{j=1}^{N} K_{ij} \, \gamma_j \qquad \text{(G2)}$$

for $i = 1, 2, \ldots N$

where

$$K_{ij} = \frac{1}{2\pi} \int_{s_j}^{s_{j+1}} \ln \left[r(s_{c_i}, s') \right] ds'$$

and

$$x_{c_i} = (x_{i+1} + x_i)/2$$

$$z_{c_i} = (z_{i+1} + z_i)/2$$

are the coordinates of the midpoint of the ith segment. This point is called control point s_{c_i}, and it is the point where the requirement that ψ have a constant value is enforced.
Figure G-2. Airfoil approximation by polygon.

K_{ij} represents the influence coefficient for the effect of the vorticity of line segment j at the control point i. The influence of all of the line segments at control point i is obtained by summing over j as is done in Equation (G2). To obtain the required expressions for the K_{ij} we must evaluate the integrals

$$\int_{s_j}^{s_{j+1}} \ln \left[r(s_{c_i}, s') \right] ds' \quad .$$

First consider the case where $i \neq j$, $i.e.$ the ith control point (x_{c_i}, z_{c_i}) does not lie on the jth segment of the airfoil as shown in the figure on the following page.

406
Figure G-3. Geometry for calculation of K_{ij}, $i \neq j$.

Now with a change in variables from s' to s ($s = s' - s_j$),

$$\int_{s_j}^{s_{j+1}} \ln \left[r(s_{c_i}, s') \right] ds' = \int_0^{s_{j+1} - s_j} \ln \left[r(s_{c_i}, s) \right] ds. \qquad (G3)$$

In the above figure, x and z are the coordinates of the moving integration variable point s which moves from point (x_j, z_j) to point (x_{j+1}, z_{j+1}) as s changes from 0 to $s_{j+1} - s_j$. Since we are considering a straight line segment

$$x = x_j + \frac{(x_{j+1} - x_j)}{(s_{j+1} - s_j)} s$$

$$z = z_j + \frac{(z_{j+1} - z_j)}{(s_{j+1} - s_j)} s$$

$$(G4)$$

$$r^2 = (x - x_{c_i})^2 + (z - z_{c_i})^2$$

$$= s^2 + \frac{2}{(s_{j+1} - s_j)} \left[(x_j - x_{c_i})(x_{j+1} - x_j) + (z_j - z_{c_i})(z_{j+1} - z_j) \right] s$$

$$+ (x_j - x_{c_i})^2 + (z_j - z_{c_i})^2$$

$$= s^2 + bs + a$$

for $0 \leq s \leq s_{j+1} - s_j$.

407

Now

$$\int \ln\left[r(s_{c_i},s)\right]ds = \int \ln\left\{\left[r^2(s_{c_i},s)\right]^{1/2}\right\}ds$$

$$= \tfrac{1}{2}\int \ln\left[r^2(s_{c_i},s)\right]ds \; ; \qquad\qquad (G5)$$

therefore

$$\int_{s_j}^{s_{j+1}} \ln\left[r(s_{c_i},s')\right]ds' = \tfrac{1}{2}\int_0^{s_{j+1}-s_j} \ln\left[r^2(s_{c_i},s)\right]ds$$

$$= \tfrac{1}{2}\int_0^{s_{j+1}-s_j} \ln\left[s^2 + bs + a\right]ds$$

$$= \tfrac{1}{2}\left[\left(s + \frac{b}{2}\right)\ln(s^2 + bs + a) - 2s \right.$$

$$\left. + \sqrt{4a - b^2}\,\tan^{-1}\left(\frac{2s + b}{\sqrt{4a - b^2}}\right)\right]_0^{s_{j+1}-s_j} .$$

$$(G6)$$

The integral has this value provided $4a - b^2 > 0$. That this is always true for this representation of airfoils can be shown by substituting the expressions for a and for b from Equation (G3) into $4a - b^2$ to obtain

$$4a - b^2 = 4\left[\frac{(x_j - x_{c_i})(z_{j+1} - z_j) - (z_j - z_{c_i})(x_{j+1} - x_j)}{(s_{j+1} - s_j)}\right]^2$$

$$> 0 .$$

Also

$$\sqrt{4a - b^2} = 2\left|\frac{(x_j - x_{c_i})(z_{j+1} - z_j) - (z_j - z_{c_i})(x_{j+1} - x_j)}{(s_{j+1} - s_j)}\right| \qquad (G7)$$

$$= 2C$$

where the absolute value signs are used to insure that the <u>positive</u> square root is obtained.

To obtain a final expression for Equation (G6) we must evaluate the terms $s + b/2$ and $s^2 + bs + a$ for $s = 0$ and for $s = s_{j+1} - s_j$, corresponding to the two ends of the jth line segment. For $s = s_{j+1} - s_j = \Delta s$,

$$s^2 + bs + a = (x_{j+1} - x_{c_i})^2 + (z_{j+1} - z_{c_i})^2$$

$$= R2 \qquad\qquad (G8)$$

$$s + b/2 = \left[(x_{j+1} - x_{c_i})(x_{j+1} - x_j) + (z_{j+1} - z_{c_i})(z_{j+1} - z_j)\right]/\Delta s$$

$$= T2 .$$

408

For s = 0

$$s^2 + bs + a = (x_j - x_{c_i})^2 + (z_j - z_{c_i})^2$$

$$= R1$$

$$s + b/2 = \left[(x_j - x_{c_i})(x_{j+1} - x_j) + (z_j - z_{c_i})(z_{j+1} - z_j)\right]/\Delta s \qquad (G9)$$

$$= T1 \quad .$$

Substituting the above expressions into Equation (G6) and Equation (G2) we obtain

$$K_{ij} = \frac{1}{4\pi}\left[T2 \ln (R2) - T1 \ln (R1)\right] - \frac{\Delta s}{2\pi} + \frac{C}{2\pi}\left[\tan^{-1}\left(\frac{T2}{C}\right) - \tan^{-1}\left(\frac{T1}{C}\right)\right] (G10)$$

for $i \neq j$.

Now consider the case where $i = j$, *i.e.* the ith control point lies on the jth segment as shown in the figure below.
Figure G-4. Geometry for calculation of K_{jj}.

Here we have (letting $\Delta s = s_{j+1} - s_j$)

$$r(s_{c_j},s) = \frac{\Delta s}{2} - s \qquad \text{for} \qquad 0 \leq s \leq \frac{\Delta s}{2}$$

and

$$r(s_{c_j},s) = s - \frac{\Delta s}{2} \qquad \text{for} \qquad \frac{\Delta s}{2} \leq s \leq \Delta s \quad .$$

Thus for Equation (G3) we have

$$\int_0^{s_{j+1}-s_j} \ln\left[r(s_{c_j},s)\right]ds = \int_0^{\Delta s/2} \ln\left[\frac{\Delta s}{2} - s\right]ds + \int_{\Delta s/2}^{\Delta s} \ln\left[s - \frac{\Delta s}{2}\right]ds$$

$$= \Delta s\left[\ln\left(\frac{\Delta s}{2}\right) - 1\right] \qquad (G11)$$

and therefore

$$K_{jj} = \frac{\Delta s}{2\pi}\left[\ln\left(\frac{\Delta s}{2}\right) - 1\right] . \qquad (G12)$$

409

Equation (G2) represents a system of N equations in N + 1 unknowns, *i.e.* γ_1, γ_2,...γ_N and ψ. The additional equation needed to close the system is obtained from the Kutta condition which is represented by

$$\gamma_N \, (s_{N+1} - s_N) = - \gamma_1 \, (s_2 - s_1) \, . \tag{G13}$$

Although Equation (G13) appears to be a rather odd way to express the Kutta condition, the discussion below will show that it is indeed correct.

The solution of the system of Equations (G2) plus Equation (G13) gives a set of γ_j's for the N segments of the airfoil. These vorticity strengths, γ_j's, are the same as the actual local tangential velocities at the mid-chord control points. Because only the body points are stored in the program and all calculations are referred to these body points, one observes (refer to Figure G-2) that what is actually desired are the local tangential velocities at the <u>body</u> points which are the <u>end</u> points of the line segments. Therefore, some form of an averaging procedure is needed to obtain the vorticity at a body point from the vorticities on the two line segments that join at the body point. .Letting $\overline{\gamma}_j$ denote the vorticity (and thus the local tangential velocity) at body point s_j, the correct averaging procedure is

$$
\begin{aligned}
\overline{\gamma}_j &= \left[\gamma_j \, (s_{c_j} - s_j) + \gamma_{j-1} \, (s_j - s_{c_{j-1}}) \right] / (s_{c_j} - s_{c_{j-1}}) \\
&= \left[\gamma_j \, (s_{j+1} - s_j) + \gamma_{j-1} \, (s_j - s_{j-1}) \right] / (s_{j+1} - s_{j-1}) .
\end{aligned}
\tag{G14}
$$

Since γ times a line segment length is the circulation due to a vortex sheet of that length, Equation (G14) is equivalent to requiring the circulation due to $\overline{\gamma}_j$ on the line segment $s_{c_j} - s_{c_{j-1}}$ be the same as the circulation due to γ_{j-1} on line segment $s_j - s_{c_{j-1}}$ plus the circulation due to γ_j on line segment $s_{c_j} - s_j$.

Now consider the Kutta condition represented in Equation (G13). Substituting Equation (G13) into Equation (G14) gives

$$\overline{\gamma}_1 = \overline{\gamma}_{N+1} = 0$$

and thus there is a stagnation point at the trailing edge which is the Kutta condition.

As discussed on page 122 , the program actually uses a modified Kutta condition which states that the upper and lower surface velocities at the trailing edge are equal but not necessarily zero. For this case, the trailing edge velocities $\overline{\gamma}_1$ and $\overline{\gamma}_{N+1}$ are calculated from

$$\overline{\gamma}_1 = \overline{\gamma}_{N+1} = \frac{|\gamma_1|(s_2 - s_1) + |\gamma_N|(s_{N+1} - s_N)}{(s_2 - s_1 + s_{N+1} - s_N)} \, . \tag{G16}$$

All other body point velocities are calculated using Equation (G14).

410

APPENDIX H-Rapid, Inviscid Computation of the Pressure Distribution of

Symmetrical Airfoils for Mach Numbers Less Than or Equal To I.O

Prior to undertaking the present study, the senior author had the occasion to estimate the characteristics of some unusual symmetrical airfoils at Mach numbers from zero to unity. These airfoils were reportedly capable of relatively low drag at transonic speeds. It was the intention of the research to test models of these airfoils and to develop fairly simple, yet reasonably accurate, methods for predicting their behavior. The reader will recognize that the development of such methods usually follows one of two paths: either some new bit of physical or mathematical insight is uncovered which permits one to legitimately simplify the formulation of the problem or its method of solution; or one seeks to find or assemble correlations among empirical results. To pursue the first path—certainly the more elegant and distinctive of the two—requires that the researcher be struck by unusual inspiration, an occurrence that is not always within his power to command, at least during a fixed time interval. For this reason many simple, but reasonably accurate, prediction methods are at least semi-empirical.

In reviewing some of the semi-empirical methods given in the literature for predicting the pressure distribution on airfoils at free stream Mach numbers near unity it was found that they require as a starting condition the pressure distribution at $M_{CRITICAL}$. Thus in order for one to investigate the utility of these methods or modifications thereof it would be necessary to have some fairly reliable means of predicting the M_{CR} pressure distribution. The task of mounting the computer program discussed in NASA CR-1843 (Ref. 34) seemed to be more involved than was warranted by the uncertainties of the final result. For this reason it was decided to obtain the pressure distribution by using the 16-point Weber method (Ref. 20) to which had been added a Kármán-Tsien Mach number correction. This method is easily programmed for computer solution because Weber, by fixing the chordwise location of the 16 points (see Table H-1) at which the pressure is computed, was able to determine, once and for all, coefficients by which the airfoil ordinates at these 16 points could be multiplied and the results summed to find the surface pressures and velocities. One merely supplies these coefficients (which are given in Weber's paper and here in Tables H-2 through H-7) as a permanent data set and the ordinates of the airfoil for which the pressures are desired as a changeable data set. It must be understood, however, that this form of Weber's method is restricted to inviscid flow about symmetrical airfoils. Thus it can be expected to give reasonable lift and moment values only for relatively thin airfoils at moderate-to-small angles of attack. No drag values can be obtained.

Because of its simplicity the method permits the calculations to be carried out very rapidly by even the smallest computer. It therefore seems well suited for use by those who would be satisfied to investigate the characteristics of new symmetrical airfoils in a more qualitative fashion, those whose access to larger machines or computing funds is restricted, or those with limited skill or time to mount foreign programs. The accuracy of the method is quite good except in the immediate vicinity of the leading edge as can be seen in Figure H-1.

The computer program for performing the calculations required by the 16-point Weber method was given the name TRINSON. This program provides the pressure data upon which a second program, COMPR, operates to modify the pressure distribution for Mach numbers other than zero. As noted above, below M_{CR}, a Kármán-Tsien correction is used. For $M > M_{CR}$ a series of semi-empirical correlations are used to obtain the pressure distribution over the complete airfoil surface. These are described in more detail in Ref. 103. Essentially, the procedure uses an approximate analytical method (by Truitt, Ref. 104) to locate the shock on the airfoil at $M = 1$. The pressure distribution between the shock and the sonic point at $M = 1.0$ is found from the correlation of Thompson and Wilby (Ref. 106). Sinnotts' (Ref. 105) semi-empirical correlation, which gives the pressure distribution aft of the airfoil peak in terms of the pressure distributions at $M = 1$ and $M = M_{CR}$, is used for intermediate Mach numbers. A spline fit of pressure data at the airfoil peak and that near the sonic point plus the idea that the pressure distribution on blunt bodies in supersonic flow "freezes" (does not change with changes in M_∞) are used to represent the airfoil surface pressures between the leading edge and the airfoil peak. The pressure rise through the shockwave is then "smeared out" following the empirical result presented in Schlichting (Ref. 65) that the pressure rise occurs over a streamwise distance of about 50 boundary layer thicknesses for laminar boundary layers and over about 12 boundary layer thicknesses for turbulent boundary layers.

Comparisons between the predictions obtained through the use of TRINSON and COMPR and experimental data for one airfoil obtained in the NCSU transonic wind tunnel are shown in Figure H-2. Note that qualitatively the agreement is quite good; quantitatively, however, the predictions do not match the experimental results as closely as one might expect for Mach numbers just above the critical. In particular, it is evident that for Mach numbers between M_{CR} (~ 0.77) and $M_\infty = 0.85$ the pressure rise through the shock is even more "smeared out" than that suggested by the 50δ criterion. On the other hand, for $M > 0.85$ this concept seems to give very good results.

On the basis of these results an effort was made to develop a somewhat more accurate prediction by using the 32-point Weber method, given here as TRANSON, and a more accurate representation of the pressure rise through a shock. Experimental data showing pressures during the interaction of very weak normal shocks with laminar boundary layers seem to be quite scarce as are correlations identifying the governing parameters in a useable fashion.

412

As a result, it was not possible to find a model analogous to the 50δ concept which was capable of accurately representing the pressure rise through the shock at all Mach numbers from M_{CR} to M = 1.0. Also, the 32-point Weber method does not appear to give results markedly different from those obtained by the 16-point method except for the first 10 percent of the airfoil chord. Apparently, off-body viscous effects, which are of course inadequately described by any potential flow treatment or, for that matter, even by simple boundary layers added to potential flows, are sufficiently prominent in the experimental data to prevent one from achieving a better prediction using this approach.

Since these computer programs have not been previously made available in any form and since they provide comparatively rapid, at least qualitatively accurate, predictions of the pressure distribution on a limited, but highly useable class of airfoils for all Mach numbers less than or equal to unity, it was felt that inclusion of these programs here may prove helpful to many readers: Those who, on occasion, may not wish to incur the expense of running the 65-point airfoil program and who are thereby willing to accept the inherent limitations of the shorter programs; and those who wish at least a qualitative prediction of airfoil lift and moment characteristics at Mach numbers above the applicable range of the 65-point program. The following discussion provides listings of three programs, instructions for entering data, and typical output.

413
Figure H-1. Comparison of 16 point Weber, 32 point Weber, and 65 point Lockheed methods for predicting airfoil pressure distributions on the NCSU 0010 at α = 2.5°.

Table H-7. Continued.

424
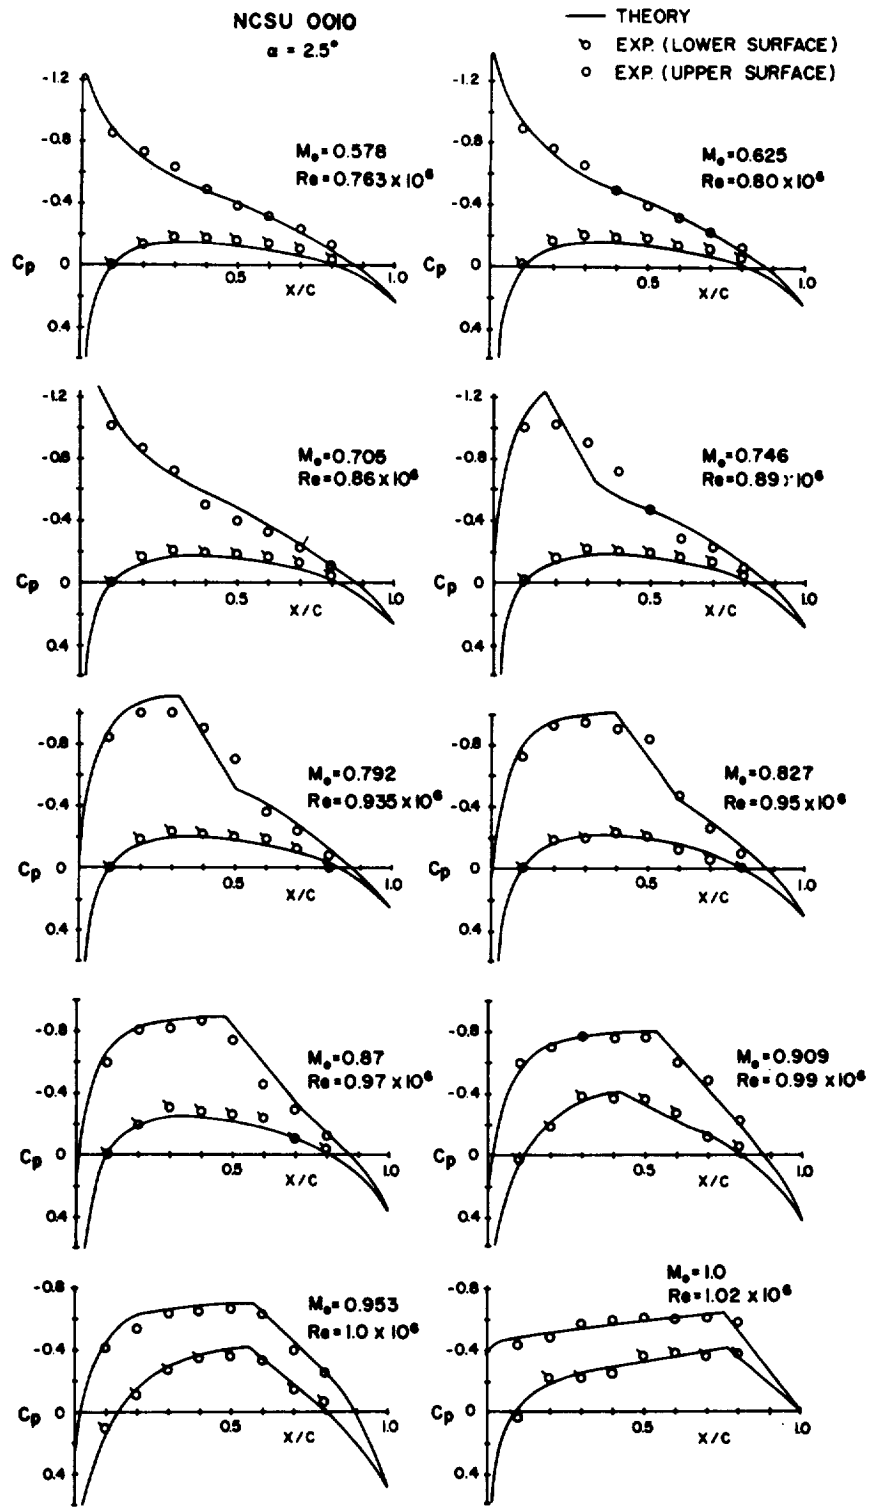

Figure H-2. Comparison of theory and experiment
for one airfoil.

This program is written in FORTRAN IV and is designed to run in single precision on an IBM 370-165 computer. Execution requires 32,000 bytes of core storage and approximately 3 seconds to produce the two-dimensional zero Mach number pressure distribution for an airfoil at six angles of attack by the 16-point Weber method. For a given run, the program requires the following input data:

(1) The 240 elements of the Matrix S1 given in A.R.C. R&M 2918 and listed herein as Table H-2.

(2) The 240 elements of the Matrix S2 also given in A.R.C. R&M 2918 and listed herein as Table H-3.

(3) The 256 elements of Matrix S3 also given in A.R.C. R&M 2918 and listed herein as Table H-4.

(4) The 72 characters of the array TITLE which are used as a header for identifying output. It is an alphameric array and usually contains information about the type of airfoil, run number, and any other such information desired by the programmer as a header.

(5) The values of X, the x-coordinates (given as X/C of the airfoil to be considered) from Table H-1.

(6) The values of Y (the normalized y-coordinate of the airfoil to be considered) corresponding to the values of X.

(7) The values of angle of attack, A, and airfoil leading edge radius, RHO, for a given airfoil, followed by a last card indicator giving A a value of greater than 15.

(8) Additional data sets containing information from item (4) through item (7), for another airfoil, if needed. Only two airfoils may be considered per run.

Format specifications for these variables may be found in Figure H-3. A sample data set of the NCSU 0010 may be found in Figure H-4 and the output for that data set is given in Figure H-5.

Figure H-5. Sample output for TRINSON.

This program is written in FORTRAN IV and designed to run in single precision on an IBM 370-165 computer. Execution requires 23 seconds and 68,000 bytes of core to produce complete pressure distributions about a two-dimensional airfoil with a round leading edge for ten Mach numbers from zero to one at one angle of attack. The calculations are carried out first for the upper surface and then the lower. For each airfoil the program requires the following input:

(1) The 72 characters of the array TITLE. This array, which should contain an accurate description of the airfoil, is printed at the first of the output for identification.

(2) The variable NNN and the value of JPRINT, an integer from 2 to 10 which specifies the print information. NNN should first take on the value 1, which implies that the data to follow is that of the upper surface and later, the value 2, which implies that the data to follow is that of the lower surface. The number of points printed may be calculated by (10 + 90/JPRINT).

(3) The 28 values of the array X, the x-coordinate (given in fraction of chord) as measured from the leading edge. These values must be specified at every one percent chord starting from x/c = 0.01 to x/c = 0.10. From x/c = 0.10 to x/c = 1.00 values at each five percent chord are sufficient.

(4) The 28 corresponding values of the array Y, the absolute value of a y-coordinate of either the upper or lower surface according to the value of NNN previously specified.

(5) The 28 values of the array CPI. These are the incompressible pressure coefficients (for the angle of attack of interest) corresponding to X and Y above. Note from (2) and (3) above that these values of CPI are not given at the same points as specified by TRINSON or TRANSON (the 16-point or 32-point incompressible pressure distribution programs respectively, from which this information is supplied). The data from these programs must be plotted, smoothed, and the correct values of CPI read off at the specific coordinate locations of (2) and (3).

(6) The angle of attack A in degrees, the airfoil maximum thickness in fraction of chord, the airfoil slope, E, given at x/c = 0.01, the airfoil slope, G, given at x/c = 1.0, the maximum y-coordinate above the chord line ZMAX in fraction of chord, and CREST, the x-position of the maximum y-coordinate given in percent chord.

(7) The value of N1N, the number of free stream Mach numbers for which the calculations are to be made.

(8) The values of a free stream Mach number XM, a Reynolds Number, RE, corresponding to that Mach number, and KTPE which takes on the value one to specify the type of boundary layer as laminar and the value zero to indicate a turbulent boundary layer. Item (8) is repeated until N1N Mach numbers have been entered.

(9) Items (2) through (8) should be entered now for the lower surface. Only one airfoil may be considered for each run.

Format specification for these variables may be found in Figure H-6. A sample data set of the NCSU 0010 may be found in Figure H-7 and the output of that data set is given in Figure H-8.

Program Listing – COMPR

```
C     PROGRAM TO CALCULATE PRESSURE DISTRIBUTIONS ABOUT TWO-DIMENSIONAL
C     AIRFOILS WITH ROUND LEADING EDGES AT ONE GIVEN ANGLE OF ATTACK AND
C     AT MACH NUMBERS FROM M=0 TO M=1.0 . THE CALCULATIONS ARE
C     CARRIED OUT FOR FIRST THE UPPER SURFACE AND THEN FOR THE LOWER
C     SURFACE.
C
C     THE INPUT DATA NEEDED ARE DESCRIBED BELOW.
C
C     TITLE= PERTINENT DESCRIPTION OF AIRFOIL THAT IS TO BE PRINTED
C            AT THE FIRST OF THE OUTPUT.
C
C     NNN=1, TO SPECIFY UPPER SURFACE
C     JPRINT= AN INTEGER FROM 2 TO 10 WHICH SPECIFIES THE PRINT
C             INFORMATION.  THE NUMBER OF POINTS PRINTED MAY BE
C             CALCULATED BY (10*90/JPRINT).
C     X(I)= X/C, AIRFOIL ABSCISSA MEASURED FROM LEADING EDGE IN FRACTION
C           OF CHORD.  THESE MUST BE GIVEN EVERY ONE PERCENT CHORD
C           STARTING FROM X/C=0.01 TO X/C=0.1 . FROM X/C=0.1 TO X/C=1.0
C           COORDINATES EACH 5% CHORD ARE SUFFICIENT.  THIS GIVES
C           28 POINTS ON THE UPPER SURFACE.
C     Y(I)= Y/C, AIRFOIL ORDINATES CORRESPONDING TO THE SAME
C     CPI(I)= INCOMPRESSIBLE PRESSURE COEFFICIENTS (FOR THE ANGLE OF
C             INTEREST) CORRESPONDING TO X(I) AND Y(I) ABOVE.
C     A= ANGLE OF ATTACK IN DEGREES.
C     THIC= AIRFOIL MAXIMUM THICKNESS IN FRACTION OF CHORD, THIC=T/C
C     E= AIRFOIL SLOPE AT X/C=0.01 .
C     G= AIRFOIL SLOPE AT X/C=1.0 .
C     ZMAX= THE MAXIMUM Y(I) ORDINATE ABOVE THE CHORD LINE.
C     CREST= THE (X/C)*100. POSITION OF MAX Y/C.
C     NIN= NUMBER OF MACH NUMBERS FOR WHICH CALCULATIONS ARE TO BE MADE.
C     XM= FREE-STREAM MACH NUMBERS FOR WHICH CALCULATIONS ARE TO BE
C         MADE.  THERE MUST BE NIN VALUES OF XM.
C     RE= REYNOLDS NUMBER CORRESPONDING TO XM
C     KTPE= TYPE OF BOUNDARY LAYER CORRESPONDING TO XM AND RE
C     KTPE= 1, FOR LAMINAR BOUNDARY LAYER
C     KTPE= 0, FOR TURBULENT BOUNDARY LAYER
C
C     NNN= 2 TO SPECIFY LOWER SURFACE.
C     REPEAT ABOVE INPUTS FOR THE LOWER SURFACE.
C     READ IN THE LOWER SURFACE ORDINATES Y(I) AS POSITIVE EVEN THOUGH
C     THEY ARE BELOW THE CHORD LINE.
C
C     REFER TO FORMAT STATEMENTS IN PROGRAM FOR PRECISE FORMAT SPECS.
C
C     XMC = CRITICAL MACH NUMBER
C     DIV(J) = SLOPE OF AIRFOIL SURFACE (RADIANS)
C     P = STATIC PRESSURE
C     XX = X/C COORDINATE OF AIRFOIL
C     YY = Y/C COORDINATE OF AIRFOIL
C     THETA(J) = ARCTANGENT OF DIV(J)
C     LAMBDA = PROPORTIONALITY FACTOR FOR CALCULATION OF THE SONIC
C              PRESSURE DISTRIBUTION
C     TO = STAGNATION TEMPERATURE (DEGREES RANKINE)
C     PO = STAGNATION PRESSURE (POUNDS/FT.**2)
C     RO = STAGNATION DENSITY (SLUGS/FT.**3)
C     TI = FREE-STREAM STATIC TEMPERATURE (DEGREES RANKINE)
C     CI = FREE-STREAM SPEED OF SOUND (FT./SEC.)
C     UNI = FREE-STREAM VELOCITY (FT./SEC.)

Figure H-8. Continued.

This program is written in FORTRAN IV and is designed to run in single precision on a IBM 370-165 computer. Execution requires 42,000 bytes of core storage and approximately 6 seconds to produce the two-dimensional zero Mach number pressure distribution for an airfoil at six angles of attack by the 32-point Weber method. For a given run the program requires the following input data:

(1) The 992 elements of the Matrix S1 given in A.R.C. R&M 2918 and listed herein as Table H-5.

(2) The 992 elements of the Matrix S2 also given in A.R.C. R&M 2918 and listed herein as Table H-6.

(3) The 1024 elements of Matrix S3 also given in A.R.C. R&M 2918 and listed herein as Table H-7.

(4) The 72 characters of the array TITLE which are used as a header for identifying output. It is an alphameric array and usually contains information about the type of airfoil, run numbers, and any other such information desired by the programmer as a header..

(5) The values of X, from Table H-1.

(6) The values of Y, the y-coordinates (given in fraction of chord) of the airfoil to be considered at the previously specified values of X.

(7) The values of angle of attack, A, and airfoil leading edge radius, RHO, for a given airfoil, followed by a last card indicator giving A a value of greater than 15.

(8) Additional data sets containing information from item (4) through item (7), if needed. Only two airfoils may be considered per run.

Format specifications for these variables may be found in Figure H-9. A sample data set of the NCSU 0010 may be found in Figure H-10 and the output for that data set is given in Figure H-11.

APPENDIX I - A Computer Program Providing Rapid Evaluation

of Closed-Form Solution for the Flow About a

Prolate Spheroid Moving Along Its X-Axis

In order to evaluate the accuracy of the method described in the body of this work for predicting potential flow about an arbitrary three-dimensional body, a search was undertaken for a suitable body with a closed-form velocity distribution. The most obvious was the sphere. While the sphere does provide a means for such comparison, it is a very crude approximation of an aircraft fuselage or similar type three-dimensional body. A body which had a higher length-to-width ratio would be more representative; therefore, an analytical method for generating the potential flow about an ellipsoid was examined.

The solution for potential flow about an ellipsoid is well known and can be found in Lamb (Ref. 6) and Munk (Ref. 66). The solution and formulae for generating the velocity distributions are also given in Timman (Ref. 49). The equations in the latter work, originally developed for a yawed ellipsoid, were degenerated to apply to the case of a spheroid (ellipsoid with y and z axes equal) in a uniform flow field of velocity U_o at zero incidence to the x-axis of the spheroid.

The velocity distribution of the spheroid was calculated by a computer program in the following manner:

Knowing the x-axis (a), the y and z-axes (b) of the spheroid, and the x, y, and z coordinates of the point for which the potential flow is to be evaluated, a series of coefficients is then determined:

$$S = \sqrt{1 - b^2/a^2}$$

$$\alpha_o = \frac{2\ ab^2}{(a^2 - b^2)^{3/2}} \left[\ \tanh^{-1}(S) - S\right]$$

$$P = \frac{2\ U_o}{(2 - \alpha_o)}$$

$$G = \frac{x^2}{a^4} + \frac{1}{b^4}(y^2 + z^2)$$

447

Following Timman, one may manipulate the degenerate form of the equations to obtain the velocity components in terms of these coefficients:

$$u = \frac{-P}{Gb^4} (y^2 + z^2)$$

$$v = \frac{P}{G} (\frac{xy}{a^2 b^2})$$

$$w = \frac{P}{G} (\frac{xz}{a^2 b^2})$$

Given the dimensions of the spheroid and the free stream velocity, the program then computes u, v, and w at a specified x, y, and z on the surface of the spheroid by means of the relations above.

From the equations it can be seen that the potential flow about a sphere may also be generated by letting a be equal to b. Because of the indeterminant form of the solution for this case, it is necessary to obtain a solution for a sphere by letting a = 1.01b.

Because of its speed and accuracy this program was most helpful in establishing when the general three-dimensional body potential flow program was running correctly and how many panels were required and in what distribution to represent a body adequately. It is presented here so that the reader may use it for that purpose or as a direct solution for a special class of fuselages. The latter case may be of special interest to those with limited computing facilities or those who wish to demonstrate the design concepts related herein without incurring the large computing expenses of the general three-dimensional body program. The following discussion provides a listing, instructions for entering data, and typical output.

Figure I-2. Sample data set for SPHEROID.

This program is written in Fortran IV and is designed to run on an IBM 370-165 computer. Execution requires 30,000 bytes of core storage and approximately 10 seconds to predict the velocity distribution and pressure coefficient for 1600 points. For a given run, the program requires the following input data:

(1) The 80 characters of the alphameric array TITLE which are used as a header for identifying output. It is used to terminate execution by setting the first four characters to "ENDﬗ".

(2) The x-axis (a), the y and z-axes (b), the free stream x-velocity, U_o , the mode indicator, IX, and the number of points for this run, N. The mode indicator, IX, may take on two values. If IX is zero a meridian solution of N points is generated by the program. By indicating IX as one, the programmer implies that a meridian solution is not desired and that N specifically selected points will follow.

(3) The points x, y, and z (if IX equals one) at which the solution is to be calculated.

Format specifications for these variables may be found in Figure I-1. A sample data set of a three-to-one prolate spheroid is given in Figure I-2 and the output for that data set is given in Figure I-3.

Figure I-1. Format specification for SPHEROID.

APPENDIX J - Supplementary Bibliography

Listed below is bibliographic information on some post-1970 documents in the NASA information collection dealing, at least in a general way, with the estimation of aerodynamic characteristics of subsonic aircraft. The methods described are, for the most part, intended for computer solution. A listing of the appropriate program is given in quite a number of these documents along with user instructions. The documents are available (except where noted) from the National Technical Information Service by requesting the first number (document accession number) shown in each citation.

The list was assembled from a computer search of the NASA information collection for documents indexed under both aerodynamic characteristics and computer methods or numerical methods. Results from a second search employing the terms Prediction Analysis Techniques, Flow characteristics, Aerodynamic Drag, Aerodynamic Coefficient, and Performance Prediction are also included. Titles and mini-abstracts were then examined to select those citations given below. The present authors have not seen the complete document in most cases. The list is intended to provide some contemporary references for the worker just entering the field as well as an indication of the direction in which contemporary research is moving for the benefit of the more casual reader. Because the task of assembling this work as a whole necessarily limited the period of preparing the literature review to late 1972 it was not possible to include the documents listed here in the review.

In German
The Effect of Wing Planform Modifications on the Aerodynamic Performances
of Fighter Aircraft
Staudacher, W.
Oesterreichische Gesellschaft Fuer Weltraumforschung Und Flugkoerpertechnik
and Deutsche Gesellschaft Fuer Luft-Und Raumfahrt, Gemeinsame Jahrestagung,
6th, Innsbruck, Austria, Sept. 24-28, 1973.

161. 74A11606   SAE Paper 730876   9 pages
New Airfoil Sections for General Aviation Aircraft --- Cruising and Flap
Development Tests
Wentz, W. H., Jr.
Society of Automotive Engineers, National Aerospace Engineering and
Manufacturing Meeting, Los Angeles, Calif., Oct. 16-18, 1973.

162. 73A43028   11 pages
In German
The Panel Method for the Calculation of the Pressure Distribution on
Missiles in the Subsonic Range
Kraus, W.; Sacher, P.
Zeitschrift Fuer Flugwissenschaften, Vol. 21, Sept. 1973, p.301-311.

163. 73A41192   13 pages
The Aerodynamic Development of the Wing of the A 300B
Mcrae, D.M.
Aeronautical Journal, Vol. 77, July 1973, p. 367-379.

164. 73A38007   4 pages
Prediction of the Lift and Moment on a Slender Cylinder-Segment Wing-Body
Combination
Crowell, K.R.; Crowe, C.T.
Aeronautical Journal, Vol. 77, June 1973, p. 295-298.

165. 73A34676   SAE Paper 730318   25 pages
Applications of Advanced Aerodynamic Technology to Light Aircraft
Crane, H.L.; McGhee, R.J.; Kohlman, D.L.
Society of Automotive Engineers, Business Aircraft Meeting Wichita,
Kan., Apr. 3-6, 1973.

166. 73A32819   49 pages
In French
Calculation of the Characteristics of Tail Fins in the Vortical Field of
a Wing
Yermia, M.
Association Aeronautique et Astronautique de France, Colloque D'Aero-
dynamique Appliquee, 9th, Saint-Cyr-L'Ecole, Yvelines and Paris, France,
Nov. 8-10, 1972.

167. 73A25490   AIAA Paper 73-353   10 pages
Application of Computer-Aided Aircraft Design in a Multidisciplinary
Environment
Fulton, R.E.; Sobieszczanski, J.; Storaasli, O.; Landrum, E.J.;
Loendorf, D.
AIAA, ASME, and SAE, Structures, Structural Dynamics, and Materials
Conference, 14th, Williamsburg, Va., Mar. 20-22, 1973.

168. 73A23856   32 pages
Transonic Airfoils - Recent Developments in Theory, Experiment, and
Design
Nieuwland, G.Y.; Spee, B.M.
In Annual Review of Fluid Mechanics. Volume 5. (A73-23851 10-12)
Palo Alto, Calif., Annual Reviews, Inc., 1973, p. 119-150.

169. 73A1419   2 pages
Lift of Wing-Body Combination
Yang, H. T.
AIAA Journal, Vol. 10, Nov. 1972, p. 1535, 1536.

170. 74N21645   AD-775538 MDC-J5831   277 pages
Analytical Studies of Two-Element Airfoil Systems
James, R.M.
Interim Report, Feb. 1971 - Dec. 1973.

171. 74N21635   NASA-TN-D-7579   15 pages
On the Use of Thick-Airfoil Theory to Design Airfoil Families In Which
Thickness and Lift are Varied Independently
Barger, R.L.

172. 74N20694   AD-774430   91 pages
Addition of an Arbitrary Body Analysis Capability to the Boeing TEA
236 Finite Element Computer Program
Westphal, J. L.
M.S. Thesis
Air Force Inst. of Tech., Wright-Patterson AFB, Ohio. (School of
Engineering)

173. 74N18654   AGARD-R-614   20 pages
Interfering Lifting Surfaces In Unsteady Subsonic Flow Comparison
Between Theory and Experiment
Becker, J.
Presented at 37th AGARD Structures and Mater. Panel Meeting, The Hague,
7-12 Apr. 1973.

174. 74N17707   41 pages
In German; English Summary
Reciprocal Influence of a Body of Finite Length and a Wing at Mid-Wing
Position at Subsonic Speed
Gregoriou, G.
Avail. Ntis HC $5.25; Bundeswehramt, Bonn 30 DM

175. 74N13674   24 pages
Reynolds Number Effects at Low Speeds on the Maximum Lift of
Two-Dimensional Aerofoil Sections Equipped with Mechanical High Lift
Devices
Thain, J.A.
In Natl. Res. Council of Can. Quart. Bull. of the Div. of Mech. Eng.
and the Natl. Aeron. Estab. p. 1-24 (see N74-13673 04-34)

476

176. 74N11821   NASA-TN-D-7428   71 pages
Low Speed Aerodynamic Characteristics of a 17 Percent Thick Airfoil
Section Designed for General Aviation Applications
McGhee, R.J.; Beasley, W.D.

177. 74N11815   NASA-TT-F-15183   25 pages
Calculation of Flows Around Zero Thickness Wings with Evolutive Vortex
Sheets
Rehbach, C.
Transl. into English from Rech. Aerosp. (France), No. 2,
Mar. - Apr. 1972, p. 53-61.

178. 74N10019   NASA-CR-2344   97 pages
The Effects of Leading-Edge Serrations on Reducing Flow Unsteadiness
About Airfoils, an Experimental and Analytical Investigation Final
Report
Schwind, R.G.; Allen, H.J.

179. 73N26000   NASA-TT-F-14959   42 pages
Airfoil Profiles in a Critical Reynolds Number Region
(Force Measurements and Pressure Distributions on Three Gottinger
Airfoil Profiles Druing Transition From Laminar To Turbulent Boundary
Layer Flow)
Kraemer, K.
Transl. into English from Soderdruck Aus der Z. Forsch. Auf Dem Gebiete
des Ingenieurwesens' ' (West Germany), V. 27, No. 2, 1961, p. 33-46.

180. 73N25002   ARC-R/M-3180   19 pages
Observations of the Flow Over a Two Dimensional 4 Percent Thick Aerofoil
At Transonic Speeds
(Wind Tunnel Tests to Determine Pressure Distributions for Four Percent
Thick, Circular ARC, Biconvex Airfoil at Transonic Speeds)
Henshall, R.D.; Cash, R. F.
In ARC Aerodyn. Res., Including Heating, Airfoils, and Boundary Layer
Studies, Vol. I, p. 63-81 (see N73-24999 16-01).

181. 73N24040   AD-757813   81 pages
An Exact Method of Designing Airfoils with Given Velocity Distribution in
Incompressible Flow An Extension of the Lighthill and Arlinger Methods
(Application of Conformal Mapping Procedures for Designing Airfoil
Shapes with High Design Lift Coefficients)   Final Report
Strand, T.
15 Jun. - 15 Dec. 1972.

182. 73N24000   ARC-R/M-3238   40 pages
      The Pressure Distribution on Two-Dimensional Wings Near the Ground
      (Numerical Analysis of Pressure Distribution in Incompressible Flow
      on Two-Dimensional Airfoils Near Ground)
      Bagley, J.A.
      In ARC Res. Progr. on Aerodyn. Heating, Airfoils, Wings, and Aircraft
      During 1960, Vol. 1, p. 79-118 (see N73-23995 15-01).

183. 73N22977   NASA-CR-112297   233 pages
      An Analytical Study for the Design of Advanced Rotor Airfoils
      (Design and Evaluation of Two Airfoils for Helicopter Rotors for
      Reduction of Rotor Power Requirements)
      Kemp, L.D.

184. 73N21914   AD-755480 MDC-J5679-01   166 pages
      Calculation of Potential Flow About Arbitrary Three-Dimensional
      Lifting Bodies
      (Development of Method for Calculating Potential Flow about Arbitrary
      Lifting Three-Dimensional Bodies with Emphasis on Bound Vorticity and
      Application of Kutta Condition)   Final Technical Report
      Hess, J.L.

185. 73N21907   NASA-TN-D-7183   41 pages
      Low-Speed Wind Tunnel Investigation of A Semispan Stol Jet Transport
      Wing Body with an Upper Surface Blown Jet Flap
      (Wind Tunnel Tests to Determine Static Longitudinal Aerodynamic
      Characteristics of Jet Transport Wing-Body with Upper Surface Blown Jet
      Flap for Lift Augmentation)
      Phelps, A.E., III; Letko, W.; Henderson, R.L.

186. 73N21054   7 pages
      Wake Characteristics of a Two-Dimensional Symmetric Aerofoil
      (Generation of Aerodynamic Noise by Turbulent Wake Behind Rotary
      Wing Airfoil and Relationship to Drag and Lift Coefficients)
      Kavrak, I.
      In AGARD Aerodyn. Rotary Wings (see N73-21031 12-02)

187. 73N20995   198 pages
      An Analysis of the Design of Airfoil Sections for Low Reynolds Numbers
      (Design of Airfoil Sections for Low Reynolds Numbers Based on Requirement
      to Achieve Transition Upstream of Major Adverse Pressure Gradient)
      Miley, S.J.
      Ph.D. Thesis
      Mississippi State Univ., State College. Avail Univ. Microfilms
      Order No. 72-20272.

188. 73N16283   AD-751075 MDC-J5713   63 pages
A New Family of Airfoils Based on the Jet-Flap Principle
(Air Foils Based On Utilization of Jet-Flap Principle)
Bauer, A.B.
Technical Report, Apr. 1971-Apr. 1972.

189. 73N15992   AD-751045   116 pages
Circulation Control By Steady and Pulsed Blowing for a Cambered
Elliptical Airfoil
(Short Takeoff Aircraft Lift Augmentation and Prevention of Airflow
Separation on Cambered Ellipitical Airfoil Section Using Circulation
Control)
Walters, R.E.; Myer, D.P.; Holt, D.J.

190. 73N15050   DLR-FB-72-63   42 pages
In German; English Summary
Theoretical Parameter Studies of Wing-Fuselage Combinations
(Prediction Analysis Method to Determine Influence of Geometry
Parameters on Aerodynamic Characteristics of Body-Wing Configuration)
Koerner, H.
Deutsche Forschungs- und Versuchsanstalt Fuer Luft- und Raumfahrt,
Brunswick (West Germany). (Abteilung Fuer Theoretische Aerodynamik.)
Avail. Ntis HC $4.25; Dfvlr. Porz, West Ger. 11 DM.

191. 73N15010   16 pages
The Effect of Leading Edge Geometry on High Speed Stalling
(Aerodynamic Configurations of Swept Wings to Improve Lift Performance
at Stall in Higher Range of Subsonic Speeds)
Moss, G.F.; Haines, A.B.; Jordon, R.
In AGARD Fluid Dyn. of Aircraft Stalling (see N73-14998 06-02).

192. 73N15009   12 pages
A Simplified Mathematical Model for the Analysis of Multielement Airfoils
Near Stall
(Development of Procedure for Determining Characteristics of High Lift
Systems Where Viscous Effects Dominate)
Bhateley, I.C.; Bradley, R.G.
In AGARD Fluid Dyn. of Aircraft Stalling (see N73-14998 06-02).

193. 73N15008   12 pages
The Low Speed Stalling of Wings With High Lift Devices
(Analysis of Aerodynamic Stall Characteristics of Wing Sections With
High Lift Devices in Two-Dimensional Flow)
Foster, D.N.
In AGARD Fluid Dyn. of Aircraft Stalling (see N73-14998 06-02).

194. 73N15007   27 pages
Aerodynamics in High Lift Airfoil Systems
(Analysis of Aerodynamic Processes Occurring in Flow Past Unpowered
Multi-Element Airfoils in High Lift Attitude)
Smith, A.M.O.
In AGARD Fluid Dyn. of Aircraft Stalling (see N73-14998 06-02).

195. 73N14998   AGARD-CP-102   342 pages
Partly in English and Partly in French
Fluid Dynamics of Aircraft Stalling
(Proceedings of Conference on Fluid Dynamics of Aircraft Stalling to
Include Stall and Post-Stall Aerodynamic Characteristics of Various
Military Aircraft)
Advisory Group for Aerospace Research and Development, Paris (France)
Avail. Ntis HC $19.25
Presented at Fluid Dyn. Panel Specialists Meeting, Lisbon, 25-28 Apr. 1972.

196. 73N14051   AD-749726   FTD-HT-23-181-72   36 pages
Application of the Wing Impulse Theory to the Determination of Propeller
Slip Stream Influence on Wing Aerodynamic Characteristics
(Wing Impulse Theory Applied to Determination of Propeller Slipstream
Influence on Wing Aerodynamic Characteristics, Using Airfoil of Finite
Span)
Kopylov, G.N.
Transl. into English from Tr. Vysshee Aviationnoe Uchilishche
Grazhdanskii Aviatsii (USSR), No. 24, 1965, p. 24-43.

197. 73N14043   AD-749485   AFFDL-TR-72-96-PT-2   86 pages
Development of Theoretical Method for Two-Dimensional Multi-Element
Airfoil Analysis and Design. Part 2 Leading-Edge Slat Design Method
(Computer Program for Designing Leading Edge Slats for Producing
Specified Pressure Distribution on Main Airfoil)
McGregor, O.W.; McWhirter, J.W.
Final Report, 24 May 1971 - 12 Jun. 1972.

198. 73N10242   AD-740124 MCD-J5264-VOL-2   310 pages
Investigation of Aerodynamic Analysis Problems in Transonic Maneuvering.
Volume 2 Airfoil Analysis Computer Program
(Development of Computer Program for Analyzing Mono-Element and Multi-
Element Airfoils at Subsonic Speed with Attached Air Flow - Vol. 2)
Gentry, A.E.
Final Report, Jun. 1970 - Aug. 1971.

"The aeronautical and space activities of the United States shall be conducted so as to contribute . . . to the expansion of human knowledge of phenomena in the atmosphere and space. The Administration shall provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof."
—NATIONAL AERONAUTICS AND SPACE ACT OF 1958

NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

TECHNICAL REPORTS: Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

TECHNICAL NOTES: Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

TECHNICAL MEMORANDUMS: Information receiving limited distribution because of preliminary data, security classification, or other reasons. Also includes conference proceedings with either limited or unlimited distribution.

CONTRACTOR REPORTS: Scientific and technical information generated under a NASA contract or grant and considered an important contribution to existing knowledge.

TECHNICAL TRANSLATIONS: Information published in a foreign language considered to merit NASA distribution in English.

SPECIAL PUBLICATIONS: Information derived from or of value to NASA activities. Publications include final reports of major projects, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

TECHNOLOGY UTILIZATION PUBLICATIONS: Information on technology used by NASA that may be of particular interest in commercial and other non-aerospace applications. Publications include Tech Briefs, Technology Utilization Reports and Technology Surveys.

Details on the availability of these publications may be obtained from:
