PYROXENES AND OLIVINES:
STRUCTURAL IMPLICATIONS OF SHOCK-WAVE DATA FOR HIGH PRESSURE PHASES*

Raymond Jeanloz and Thomas J. Ahrens

*Contribution No. 2812, Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, California 91125
ABSTRACT

A reexamination of Hugoniot equation of state data and three new release adiabat points indicates that results for enstatite-bronzite composition pyroxene are compatible with its transforming to a perovskite phase at high pressure (for En₉₀: ρ₀ = 4.20 g/cm³, K₀ = 260 ± 35 GPa, K₀' = 3.5 ± 0.65). The release adiabat data as well as results from porous samples imply that the shock-wave data do not define an equilibrium, high pressure phase Hugoniot below about 100 GPa. These also suggest a further transformation to a phase (or assemblage) with density about 5% (or more) greater than that of orthorhombic perovskite. The data would allow such a transformation to occur at pressures as low as about 60 GPa under shock, representing an upper bound for the equilibrium transition pressure.

Hugoniot data on magnesian olivines also appear to represent states of thermodynamic disequilibrium or a mixed phase region below about 80-100 GPa. However, Hugoniot points for Mg-pyroxene and Mg-olivine coincide at pressures above 70 GPa suggesting that these minerals transform to high pressure phases or phase assemblages of comparable density. Since MgO (presumably as periclase or in a closely related structure) attains relatively low densities at these pressures, the shock-wave data are in strong disagreement with the disproportionation of Mg₂SiO₄ to a MgSiO₃ (perovskite) + MgO assemblage above 80-100 GPa. Conversely, the shock-wave data do not preclude a transformation of the type, Mg₂Si₂O₆ → Mg₂S'̅tO₄ ("post-perovskite" phase) + SiO₂ (rutile or fluorite structure). Again, these results would imply polymorphism to very dense, "post-perovskite" phases. Based on the arguments made for pyroxene, this could occur at pressures as low as 60 GPa under equilibrium conditions.

We note that the combined results of high-pressure experiments allow Mg-pyroxene compositions to be as likely candidates for the lower mantle as olivine.
INTRODUCTION

Upon recognition that the features associated with plate tectonic processes on the earth (subduction zones, ridges and plumes) are either minor surficial expressions, or alternatively reflect an integral sampling of the mantle convective flow field, and with the perspectives attained from the last decade of terrestrial planetary exploration, experimental high-pressure geophysics has focussed increasingly on studying candidate materials of the earth's lower mantle and core.

Current ideas [e.g., Schubert and Anderson, 1975] suggest that active convection in the earth takes place to depths of at least \(\sim 750\) km. However, it is important to discern whether the upper mantle above \(\sim 350\) km depth, and possibly the phase transition region extending to depths of at least \(\sim 670\) km, represents a differentiate of the lower mantle and is thus atypical of the silicate zone of the earth as proposed by D. L. Anderson et al. [1972] and D. L. Anderson [1976], in contradistinction to the views of Ringwood [1975] which have emphasized the essential homogeneity of the mantle.

Clear-cut data specifying the composition of the upper mantle stems largely from inclusions in kimberlites [e.g., Boyd, 1973] and nodules from volcanic rocks of deep-seated origin [MacGregor, 1975 and Basu, 1975, for example] which demonstrate the upper mantle to be largely garnet lherzolite with minor amounts of eclogite. This composition is not unlike the "pyrolite" model originally proposed by Clark and Ringwood [1964] which, by means of variations in temperature, pressure, and degree of partial melting, accounts for the genesis of a large class of effusive and plutonic rocks which penetrate the crust [Green, 1972].

The lower mantle, extending from depths of 670 to 2900 km, represents 49% of the mass of the earth. What can be learned of its mineralogy and thermal state must, at present, be inferred from comparison of shock-wave
and seismological data [Al'tschuler and Sharpidzhanov, 1971a, b; Anderson et al., 1972; and Anderson 1976], and by extrapolation of results based on quench products from static high pressure, petrological experimentation [e.g. Ringwood, 1975; Akimoto et al., 1976; Liu, 1975a, b, 1976] using largely ultrasonic and static compression equations of state.

Not unrelated to the questions of the properties of pyroxenes and olivines at high pressures and hence, of mantle compositions, has been an increasing awareness among earth scientists, that the composition, structure, and thermal history of the earth must ultimately be related to the composition of the sun, the moon, meteorites and other terrestrial planets, and the processes of planetary accretion [e.g. Lewis, 1972; Ringwood, 1975; Hanks and Anderson, 1969].

In the present study the nature of the shock-induced, high-pressure phases of olivine and pyroxene rocks is examined in the light of data for the densities of a new class of perovskite-related silicate structures synthesized by Liu [1975a, b, and 1976], and some new Hugoniot and release adiabat data for bronzite. Previous data for olivine-rich samples in the range Fo100 to Fo85 and for enstatitic samples (over a similar range of Fe contents) are reported by Trunin et al. [1965] and McQueen et al. [1967]. Trunin et al. [1965] and recently Simakov and Trunin [1973] have reported single datum points for four different compositions, extending our knowledge of Hugoniot states for ferromagnesian silicates to pressures in excess of 240 GPa.
EXPERIMENTAL METHODS

Discs (1 cm-diameter) of Bamle bronzite (Mg$_{.56}$, Fe$_{.14}$)SiO$_3$ were cored from the same aliquot previously studied to shock pressures of 48 GPa [Ahrens and Gaffney, 1971] and machined to thickness tolerances of $\pm0.05$ mm. The density of each disc was determined at least twice by weighing in air and in reagent grade toluene (temperature corrections from Berman, 1939). The samples were mounted on 0.5 mm thick Cu or Ta driver plates and impacted by flyer-plate bearing projectiles at speeds ranging from 5.4 to 6.1 km/sec with a light-gas apparatus qualitatively similar to that described by Jones et al. [1966]. Pure (commercial-grade) Cu and Ta flyer plates, 2.5 mm thick, with a minimum diameter of 17 mm (Fig. 1) are hot-press welded into lexan projectile blanks using techniques developed by A. Mitchell (private communication, Lawrence Livermore Laboratory). After molding and stress relieving, a polyethylene, gas sealing rear portion of the projectile was press fit onto the 6 mm long lexan flyer plate (front) portion of the projectile. The final projectile diameter was machined so as to provide a $\pm0.03$ mm interference fit with the light-gas gun launch tube. The resulting projectiles had masses of 14 and 20 gm for Cu and Ta flyer plates, respectively. The light-gas gun used to accelerate these projectiles employs a 20 m-long, 16 cm diameter pump tube in which a $\sim20$ Kg high-density polyethylene piston is used to compress the propelling gas, H$_2$, initially at a pressure of 0.1 MPa. The polyethylene piston achieves speeds of $\sim0.4$ km/sec using approximately 3 Kg of double-based propellant. The projectile is launched upon bursting of a diaphragm (at a gas pressure of $\sim0.07$ GPa) at the breech of the 25 mm diameter - 7 mm long launch tube. The total flight of the projectile from the muzzle of the launch tube to the target is $\sim500$ mm and occurs in a vacuum of 10 to 30 mtorr. Projectile velocities are measured using the flash X-ray method.
of Jones et al. [1966], except that interruption of a continuous X-ray beam [Long and Mitchell, 1972] is used to trigger the first flash X-ray unit (≈15 ns exposure), and the breakage of a 0.05 mm diameter copper wire intercepting the outer edge of the projectile is used to trigger the second flash X-ray unit. The center lines of the two flash X-ray units are ≈350 mm apart and the time interval between X-ray flashes is measured to within an uncertainty of ±0.01 μsec. Since triggering in our initial experiments was not reliable, we have had to rely on the redundancy provided by measuring the electronic delays of both flash X-ray units, and the time interval between the second X-ray flash and the closure of the redundant pin switch(es) mounted on the sample assembly (Fig. 1) to infer impact velocity. The ≈3° projectile tilt observed in Fig. 1, is highly reproducible and the sample assembly was thus pre-oriented to achieve nearly normal impact.

As in the experiments of Ahrens et al. [1971] an electronically triggered, image-converter streak camera was used to record shock transit-time through the sample. However, in the present experiments the onset of illumination on shock arrival at the mirrors (presumably arising from the high temperatures behind the shock in the glass) was used to record shock arrivals with the streak camera, and the arrival of the shock at the mirror free-surface was observed to result in the immediate loss of illumination (Fig. 2). We infer this effect is caused by the disintegration of the specular mirror surface, probably upon incongruent vaporization of the glass, and the accompanying sudden adiabatic expansion of the vaporized species. In the present experiments the streak camera was writing at a speed of 25 mm/μsec for a duration of ≈2 μsec on 20 X 22.5 cm (4 X 5 inch) Tri-X film. Developing procedures were used to force the film to a sensitivity of ASA 3000. Time calibration was obtained using a Pockel-cell modulated Ar-ion laser beam modulated at 20
Mhz, thus providing time marks at 50 μsec intervals. The writing rate at any point on the streak camera trace was measurable to within ±0.25%, and a practical time resolution of ~2 nsec was achieved.

Hugoniot states are determined using the impedance match method Rice et al. [1958] and release adiabat data employ the buffer technique described by Ahrens et al. [1969]. The equations of state for Ta and Cu employed in the impedance match solutions are those given by McQueen et al. [1970].
EXPERIMENTAL RESULTS FOR GLASS AND BAMLLE BRONZITE

The unexpected self-illumination and prompt light decay upon passage of strong shocks through the soda-lime glass mirrors (microscope slide quality, plate glass) provided consistent, and we believe reliable measurements of shock-wave velocities in this material. The resulting data are given in Table 1 and plotted in Figures 3 and 4. The shock wave velocity \( U_s \) - particle velocity \( U_p \) relation in Fig. 3 is concordant with data reported by Dremin and Adadurov [1964] to pressures of 41 GPa for a glass of similar zero-pressure density (2.48 gm/cm\(^3\)) but of slightly different composition. The linear \( U_s - U_p \) relation indicated in Fig. 3 fits the present four data points, and Dremin and Adadurov's data points at 33 and 41 GPa with a coefficient of correlation \( r^2 = 0.997 \). This fit was used to obtain the release adiabat points for the Bamlle bronzite (Figure 5, Table 2).

Qualitatively, the behavior of Na-Ca glass is observed to be similar to that first reported by Wackerle [1962] for fused quartz. It appears that above \( \approx 15 \) GPa, the Si\(^{+4} \) ion begins to transform from tetrahedral to octahedral coordinations with the O\(^{2-} \) ion, as in the case of the quartz to stishovite transition [McQueen et al., 1963]. This, and possible coordination increases of the Na\(^+ \) an and Ca\(^{++} \) ions, account for the imcompressible behavior indicated above 50 GPa. The zero-pressure \( (P_0) \) density shown in Fig. 4 is calculated using our microprobe analyses, standard oxide molar volumes [Robie and Waldbaum, 1962], and assuming a stishovite molar volume of 14.014 cm\(^3\) for SiO\(_2\).

Although the uncertainties in the measurement of projectile and shock velocity can be obtained from scatter of redundant projectile time-interval measurements and uncertainties in discerning shock arrival-times on the streak records, the calculation of uncertainties in the pressure-density plane shown in Figures 4 and 5 are less straightforward. The non-orthogonality
of the uncertainty brackets shown in both figures for the Hugoniot data arise from the fact that the particle velocity, and hence pressure and density, are not independently related to uncertainties in projectile and shock velocity via the impedance match solution. The uncertainty arising from both the density and pressure are calculated from the uncertainty in projectile velocity holding the shock velocity fixed (at its average value) and vice versa. The uncertainty in the three release points take into account only the uncertainty in shock velocity through the buffer (1 mm-thick glass).
DISCUSSION

Shock-wave data for magnesian pyroxenes are summarized in Figure 5, including results for porous (synthetic aggregate) samples, non-porous samples, and our new data on Bamle bronzite (cf. Table 2). At pressures below about 70-100 GPa it is clear that the porous Hugoniot data bear an anomalous relation with respect to the non-porous data since the former should lie on "hot compression" curves, systematically displaced to lower densities (at a given pressure) from the principal Hugoniot presumably defined by non-porous data. The energy associated with irreversible compaction of porosity represents a thermal pressure as a function of initial density, via Grüneisen's $\gamma (V,T)$, which defines this displacement. For this reason, the porous data have, in general, been very scantily discussed, considered uninterpretable, or outright dismissed as wrong [McQueen, Marsh, and Fritz, 1967; McQueen, 1968; Ahrens, Anderson, and Ringwood, 1969; Davies and Gaffney, 1973; Simakov and Trunin, 1973].

The relatively high density attained by the porous materials on shocking can, nevertheless, be explained as a kinetic effect [c.f. McQueen et al., 1967, and 1970]. Assuming that pyroxene transforms to a dense phase or assemblage above a given pressure, this transformation, even once initiated under shock, may not have time to go to completion without substantial overdriving. Because porous samples become much hotter on shocking, their rate of transformation is expected to be significantly enhanced, thus yielding a larger proportion of high pressure phase material for a given pressure compared with non-porous samples. Assuming this model applies, it is easy to explain the distribution of Hugoniot data in the figure.

The pressure-release points shown in Figure 5 provide independent support for such a model. Since the release path is adiabatic (isentropic to within
The approximation of reversibility) while entropy increases monotonically up a material’s Hugoniot, the P-V slope of the release path should be no steeper than the Hugoniot slope at a given pressure [see Duvall and Fowles, 1966, for example]. Because the measured release adiabat points lie below the Hugoniot data, this indicates that a mixed phase region extends to pressures around 70-100 GPa with transformation to a high density assemblage complete at pressures no lower than these. This high pressure assemblage must have a metastable Hugoniot with a P-V slope at least as great as the release paths, and thus supports the hypothesis of an extended mixed phase (or disequilibrium) region probably associated with the rate of phase transformations under shock.

At pressures above about 100 GPa, the non-porous samples achieve densities that are generally (and consistently) higher than the porous points. So we believe that the shock-wave data begin to define an equilibrium, high-pressure assemblage Hugoniot at these pressures, below which one or more phase transformations result in a wide mixed-phase region.

Similarly, Hugoniot data for magnesian olivines are summarized in Figure 6. These show the same anomalous relations between porous and non-porous samples, implying transformation to a high density phase or assemblage subject to kinetic effects (though release adiabat data for such compositions are not yet available). This conclusion fits in with the discussion of Ahrens and Petersen [1969].

Aside from these results with porous data and steep measured release paths [c.f. Ahrens et al., 1969; Grady, 1975 and this volume, as well], a comparison of shock-recovery and static high-pressure experiments [Ahrens and Graham, 1972; Liu, 1974, 1975c; Schneider and Hornemann, 1976] also indicate that overdriving beyond equilibrium transition pressures is commonly needed in silicates to achieve a given phase transformation under shock, clearly implying control by kinetics of nucleation and growth of high pressure phases [but note Podurets and Trumin, 1974]. Thus, porous samples may well
indicate the presence and nature of high pressure phases (or assemblages) more readily than non-porous samples under shock. Also, high pressure phase Hugoniots will tend to be significantly steeper (and therefore centered at higher $P_0$ densities) than would be apparent from the distribution of the data.

Zero-pressure densities for high-pressure phases interpreted from pyroxene and olivine shock-wave data by several workers are summarized in Figure 7. The tendency has been to assign higher densities (for a given composition) to olivine ($A_2BO_4$) than to pyroxene ($ABO_3$) stoichiometries. One problem is apparent near the magnesian end, however, in that interpreted densities seem to actually decrease with increasing Fe-content. Barring very complex phase relations, this is highly unlikely due to the enormous difference in the atomic masses of Fe and Mg. Rather, it appears that the density estimates for the magnesian endmembers have been biased upwards relative to the Fe-bearing compositions by the high densities implied by the porous data (which only exist for the endmembers, forsterite and enstatite). Based on the arguments developed above, it is not appropriate to directly compare the porous data with the data for (non-porous) Fe-bearing compositions.

Liu's recent [1975a, b, 1976; Liu and Ringwood, 1975] static high pressure experiments have confirmed the previously suspected occurrence and significance of perovskite-related structures in silicates [Reid and Ringwood, 1975, 1974, 1969; Ringwood and Major, 1971; Shimizu et al., 1970]. Distorted (non-cubic), perovskite-like structures have been quenched from diamond-anvil experiments on both magnesian olivines and pyroxenes. These structures, apparently of the orthorhombic rare-earth orthoferrite type [Marezio et al., 1970] will be loosely termed perovskites. Densities versus composition for the perovskite phases and assemblages of pyroxene ($ABO_3$) and olivine ($ABO_3 + AO$) derived from Liu's [1975a, b] X-ray parameters are also shown in Figure 7. It is interesting to note that an olivine stoichiometry actually results in a lower
density perovskite assemblage than a pyroxene stoichiometry. This is a direct consequence of the low density of (Mg, Fe)O in the ABO₃ + AO assemblage. The densities of such (Mg, Fe)O recovered from high pressure lie directly between the densities of MgO (periclase) and FeO (stoichiometric wüstite) as can be seen in Figure 7. This is compatible with the shock-wave data on MgO which shows no evidence for phase transformations to pressures over 100 GPa [Carter et al., 1971; McQueen and Marsh, in Birch, 1966; McQueen, 1968].

In order to compare the static results with the shock wave data, theoretical metastable Hugoniots were constructed for perovskite of appropriate composition (Mg₀.₉Fe₁.₁SiO₃) based on Birch-Murnaghan principal adiabats. This approach is philosophically and computationally similar to that of Davies & Caffney [1973]. Necessary parameters are shown in Table 3 along with the values used here. Density and the energy of the pyroxene-perovskite transformation (at P₀) were derived from Liu's work via Figure 7 and by using ΔEₜrut ≡ (-PdV + TdS)ₜrut. Since the last term is not known it is assumed to be negligibly small (i.e., \( \frac{dT}{dT} = 0 \) for the phase boundary). Because the experimental data upper bound the equilibrium pressure of transition, and most likely TdS ≤ 0, the resulting estimate for ΔEₜrut is probably a strict upper bound (and rather high). Incidentally, though we discuss the direct transformation from pyroxene to perovskite structures under shock, this obviously represents a metastable phase boundary (based on our current knowledge from Liu's work). Intermediate structures may well be involved.

Estimates of the bulk modulus \( K₀ \) and \( K₀' = \left( \frac{dK}{dP} \right)_{P=0} \) were based on their empirical correlation with density, with particular emphasis given to data for perovskite-structured compounds [Davies, 1976; Beattie and Samara, 1971]. The wide range in values given easily overlap estimates based on the various K-\( \varphi \) relations that have been proposed [O. L. Anderson, 1972; D. L. Anderson, 1969, 1967; D. L. Anderson and O. L. Anderson, 1970; O. L. Anderson et al., 1968].
Similarly, Grüneisen's (bulk or thermodynamic) $\gamma$ was estimated from typical values for various compounds, with a volume dependence that has been found to be not unreasonable for those cases where it has been studied. Temperature dependence was assumed to have a negligible effect and, again, rather wide bounds were given for reasonable values. Finally, a family of theoretical perovskite Hugoniots was constructed for the best estimate values given in Table 3 and by varying each of the parameters within the stated bounds. An envelope containing this family of curves along with the Hugoniot based on the best values are shown in Figure 5.

It is immediately clear that the shock-wave data is compatible with Mg-pyroxene transforming to a perovskite structure at pressures above approximately 80 GPa. This is contrary to the conclusions of Simakov and Trunin [1973]. In fact, by considering the most porous data (which achieve high densities at relatively low pressures) and the arguments presented above, it seems that perovskite-like densities can be achieved by about 50 GPa. If anything, the left half of the envelope in Figure 5 agrees with the data as well as the best estimate, which could be consistent with an even lower pressure, for transformation to the perovskite structure. This, then, is an upper bound for the pressure of transformation based solely on Hugoniot data, yet still represents a significant overdriving compared to the static experiments [Liu, 1975b, 1976].

Compared with the theoretical Hugoniots, the release paths still appear to have very steep slopes, and the most porous data cross over to yet higher densities. These latter data may be erroneous [Simakov and Trunin, 1973], but assuming that they are not they suggest, along with the release adiabats, the possibility of a phase (or assemblage) with a zero-pressure density even higher than perovskite. Transformation to such a "post-perovskite" phase could occur at pressures as low as about 60 GPa, according to the shock data;
this would therefore be an upper limit for the equilibrium transition pressure.
An initial density of 5% or so greater than for orthorhombic perovskite could be consistent with the data.

In similar fashion, a theoretical Hugoniot (Figure 6) was constructed for a perovskite assemblage corresponding to olivine stoichiometry (MgSiO₃ (perovskite) + MgO (periclase)) based on the best-estimate Hugoniot in Figure 5 and the rather well determined Hugoniot of MgO [Carter et al., 1971; McQueen, 1968; McQueen and Marsh, in Birch, 1966] shown in Figure 8. Because the left half of the envelope in Figure 5 appeared most consistent with the pyroxene points a corresponding band is shown in Figure 6.

In this case, perovskite-like densities are achieved in the 60-80 GPa range. Once more, the shock wave data are consistent with the static results which demonstrate olivine transferring to perovskite at high pressures (but again at pressures significantly lower than under shock). On the other hand, the olivine points are clearly shifted to higher densities than the perovskite-assemblage Hugoniot at pressures above about 70 GPa. Because the theoretical curve for the perovskite assemblage cannot be shifted without causing a significant deviation from the pyroxene points, the olivine data are in strong disagreement with a perovskite assemblage at high pressure.

If the olivine points did not deviate so systematically from the theoretical Hugoniot which is consistent with the pyroxene shock data, this divergence might well be ascribed to be within experimental error. However, the same discrepancy emerges from Figure 8, quite apart from any theoretical curves. The point here is that above about 70 GPa, the olivine and pyroxene data overlap, whereas a perovskite model would predict olivine densities to be lower than pyroxene densities (i.e., shifted towards the MgO Hugoniot) as was mentioned above and can be inferred from Figure 7. Granted that we have discussed kinetic effects and a mixed phase region to the 100 GPa range, but
the overlap continues to much higher pressures. Furthermore, the nature of
the perovskite-forming transformations would suggest that pyroxene (which
involves no disproportionation) would form perovskite at least as readily as
olivine, whereas in the high-pressure data of Figure 8 one must either con-
sider the olivine too dense or the pyroxene not dense enough to agree with
a self-consistent perovskite model.
CONCLUSIONS

After reviewing experimental techniques, we presented new Hugoniot data for Bamle bronzite including simultaneously measured release paths, based on the mirror-buffer technique. Calculation of Hugoniot states for the mirror glass provides a satisfactory internal check, with the soda-lime glass behaving in a fashion similar to fused quartz under shock.

Reexamining available shock data for magnesian pyroxenes and olivines leads to the conclusion that they define a mixed phase (or disequilibrium) region to about the 100 GPa range, related to the kinetics of phase transformation in these silicates. By recognizing this point, certain discrepancies in previous interpretations of shock data can be explained. A set of theoretical Hugoniot states for pyroxene and olivine stoichiometry, perovskite-bearing assemblages was constructed based on their properties deduced from high-pressure work, showing that the shock data is compatible with transformations to perovskites in the 45-70 GPa region (decidedly above the equilibrium pressure of transformation).

A perovskite model implies different densities for pyroxene and olivine stoichiometries, however. We note that considering an extremely simplistic assemblage for the lower mantle, consisting of high-pressure phases of only olivine and pyroxene, varying the proportions of these components results in a significant variation in the overall density of the assemblage. In other words, any compelling evidence for density variations within the lower mantle (based, say, on seismological data) can be readily explained without resorting, for example, to variations in Mg:Fe ratios. This degree of freedom is likely to exist whatever the pertinent, multi-phase assemblage may be for the lower mantle. In fact, we consider our two-phase model simplistic if for no other reason than that we have ignored (for lack of data) the effects on phase relations of other likely components such as Al or Ca.
In addition, the high-pressure shock data suggest the presence of a yet higher density phase (or assemblage) than perovskite. In particular, the results on olivine diverge from predicted estimates and from densities consistent with pyroxene Hugoniot points. Taken together, the data do not preclude transformations involving a "post-perovskite" phase of Mg₂SiO₄ at pressures above 80-100 GPa, and including a reaction of the type: Mg₂Si₂O₆ + Mg₂SiO₄ ("post-perovskite" phase) + SiO₂ (rutile, α-PhO₂, or fluorite structure: c.f., German et al., 1974; Jamieson, this volume).

We reiterate that the static high-pressure results (and thus our analysis) involve an orthorhombic (i.e., non-ideal) modification of perovskite. Since this class of structures includes a wide variety of related modifications [succinctly summarized by Salje, 1976], it is quite possible that the higher-pressure phase suggested by the shock data in fact is a perovskite such as the ideal cubic form. Indeed, it is quite possible that the phase quenched from high pressure is a modification of the actual structure attained under pressure. Bearing in mind the well known difficulties of recovering these high-pressure polymorphs on quenching [e.g., Liu and Ringwood, 1975] and the important effects of environmental conditions on the perovskite modifications [see Sis et al., 1973, for example] it is not unlikely that they are involved in higher density assemblages than have yet been described. Recently discussed hexagonal forms, may be an example of this [compare Burbank and Evans, 1948]. However, there are other structure-types which could also be likely, some of which have only begun to be discussed as possible high-pressure polymorphs [e.g., Moore, 1976; also, Reid and Ringwood, 1970, and as reviewed by Ringwood, 1975].

Finally, the shock data indicate very similar properties for olivine and pyroxene at high pressures making them both equally likely candidates for the lower mantle.
ACKNOWLEDGEMENTS

This is the first scientific report of results obtained with the light-gas gun apparatus housed in the Helen and Roland W. Lindhurst Laboratory of Experimental Geophysics. The physical facilities of this laboratory owe their existence to the generosity of Mrs. Helen W. Lindhurst. This research was supported under NSF Grant DES75-15006 and NASA Grant NGL05-002-105. We appreciate the skilled operation and maintenance of our apparatus by H. Richeson, D. Johnson, and V. Nenow. We thank M. Manghnani for organizing an extremely productive meeting and for the opportunity to present this work to a critical audience. We also thank Ian Jackson for helpful comments.

(1) From data of Liu [1975a, b].

(2) See Davies [1976], for example.
FIGURE CAPTIONS

Figure 1. Flash radiographs of projectile taken at stations 390 mm (upper) and 33 mm (lower) from target. Nominal exposure times are ~15 nsec. Projectile speed is 5.5 km/sec. Shot LGG14.

Figure 2. Static (a) and dynamic (b) streak camera photograph of bronzite Hugoniot and release adiabat experiment. Shot LGG14.

Figure 3. Shock velocity versus particle velocity data for soda-lime glass.

Figure 4. Shock pressure versus density for soda-lime glass.

Figure 5. Compilation of shock data of Mg-rich pyroxenes. Hugoniot points for samples of varying porosities (synthetic, polycrystalline aggregates) and pyroxene-rich (>90%) rocks are included, as are newly determined release paths (arrows). Theoretical Hugoniot (solid curve) and envelope (dashed) are discussed in the text and Table 3. McQueen and Marsh [1966] are quoted in Birch [1966].

Figure 6. Compilation of shock data for Mg-rich olivines including results on porous samples (synthetic, polycrystalline aggregates) and olivine-rich (>90%) rocks. Theoretical Hugoniot (solid curve) for a Mg-endmember, high-pressure assemblage are discussed in the text. Dashed curve corresponds to the left side of the envelope in Figure 5. McQueen and Marsh [1966] are quoted in Birch [1966].

Figure 7. Summary of zero-pressure densities for high-pressure phases of olivines and pyroxenes as a function of composition based on interpretation of shock-wave data (symbols), and calculated from X-ray parameters for AB0₃ (perovskite) and AO quenched from high-pressure diamond-anvil experiments (lines through points). MgO (periclase) and FeO (stoichiometric wüstite) values are from: Bénard [1954], Katsura et al. [1967], Robie et al. [1966], and Robie and Waldbäum [1968], with error bars showing variations in measurement and estimate, while error bars on the remaining points are based on Liu's [1975a, b] estimates of error in the X-ray parameters.
Figure 7. The dashed line \((\text{ABO}_3 + \text{AO})\) corresponds to the density of a perovskite assemblage with olivine stoichiometry (assuming \(K_{\text{Mg-Fe}}^{\text{D ol-perov}}=1\)). Symbols are keyed as follows:

- A  Ahrens [1971]
- AAR Ahrens, Anderson, and Ringwood [1969]
- AG Ahrens and Gaffney [1971]
- AS Al'tschuler and Sharpidzhanov [1971a]
- DA Davies and Anderson [1971]
- DG Davies and Gaffney [1973]
- KP Kalinin and Pan'kov [1974]
- NHF McQueen, Marsh, and Fritz [1967]
- PK Pan'kov and Kalinin [1975]

Figure 8. Representative Hugoniot data from Figures 5 and 6 compared with the Hugoniot for MgO [Carter et al., 1970; McQueen, 1968; McQueen and Marsh, quoted in Birch, 1966].
