Lewis Research Center

SUMMARY

A program for a PDP-15 computer is presented which provides for control and analysis of trace element determinations by using X-ray fluorescence. The program simultaneously handles data accumulation for one sample and analysis of data from previous samples. Data accumulation consists of sample changing, timing, and data storage. Analysis requires the locating of peaks in X-ray spectra, determination of intensities of peaks, identification of origins of peaks, and determination of areal density of the element responsible for each peak. The program may be run in either a manual (supervised) mode or an automatic (unsupervised) mode.

INTRODUCTION

The recent development of high-resolution solid-state X-ray detectors has made possible the use of X-ray fluorescence as a tool for the detection of trace elements in a variety of applications. However, analysis of environmental samples by means of X-ray fluorescence generates energy spectra for which quantitative hand analysis is prohibitively tedious. In addition, the number of samples generated by any comprehensive monitoring program requires a speed of data acquisition and analysis which is possible only through the use of a computerized system. The present report describes the software designed for control and data analysis of such a system. This report should permit the reader to operate the system.

PRINCIPLES OF X-RAY FLUORESCENCE AND CHARACTER OF DATA

When properly stimulated, the atoms of any element emit X-rays whose energy (or wavelength) is strictly dependent upon the atomic number of the emitting atom. Since
these energies may be quickly and accurately measured, and since the X-ray energies of all elements are well known and tabulated, it is possible to identify, with little ambiguity, the element responsible for the emission. In addition, the number of X-rays emitted is proportional to the number of atoms stimulated, so that after a proper calibration, quantitative measurements of areal densities are possible.

The X-ray detectors commonly employed provide data in the form of analog electric pulses. Data acquisition consists of the digitizing and storing of these pulses, which arrive with random timing at the rate of several thousand per second. A schematic representation of the X-ray fluorescence facility is shown in figure 1. A typical X-ray spectrum is shown in figure 2. This particular spectrum resulted from excitation of a sample by using X-rays from a tungsten X-ray tube. It contains a peak (labelled Rh) which resulted from the presence in the primary X-ray beam of a small, known amount of rhodium, whose purpose was to provide a monitor of the number of photons incident on the sample.

Data analysis consists of determining from this spectrum the number of X-ray counts contained in each peak, identifying the origin of the peak, and converting the number to an areal density by using the expression

$$N(E) = N_i \left( \frac{d\sigma}{d\Omega} \right)_E \rho_x \Omega \epsilon(E)$$  \hspace{1cm} (1)

where

- $N(E)$: number of X-ray photons of energy $E$ detected
- $N_i$: number of X-ray photons incident on target
- $(d\sigma/d\Omega)_E$: cross section for production of X-rays of energy $E$ by exciting X-rays
- $\rho_x$: areal density of atoms producing X-rays of energy $E$
- $\Omega$: solid angle subtended by X-ray detector
- $\epsilon(E)$: efficiency of detector for detection of X-rays of energy $E$

In practice, only the quantity $N(E)$ is determined absolutely. The number $N_i$ is assumed to have the form

$$N_i = K_{Rh} N_{Rh}$$  \hspace{1cm} (2)

where $N_{Rh}$ is the number of rhodium (monitor) X-rays detected, so that the areal density may be written
The overall efficiency function

\[ \rho_X = \frac{N(E)}{K_{Rh} N_{Rh} \left( \frac{d\sigma}{d\Omega} \right)_E \Omega \varepsilon(E)} \]  

is then determined experimentally by using samples of known areal density of a number of elements. For elements other than those for which \( F(E) \) is measured directly, an interpolation is carried out with the assumption that the function varies smoothly with energy. The areal density then, in terms of directly measurable quantities, becomes

\[ \rho_X = N(E) \frac{F(E)}{N_{Rh}} \]  

Analysis then requires only the determination of the intensity and energy of each line in the X-ray spectrum and the intensity of the line used for normalization \( N_{Rh} \).

DATA ACQUISITION AND ANALYSIS

The entire X-ray fluorescence operation (sample changing, data acquisition, and data analysis) is carried out under the control of a PDP-15 computer. Communication between the computer and the X-ray fluorescence hardware is by means of a CAMAC system (ref. 1). The programmable interface between the computer and the CAMAC system has been described in detail elsewhere (ref. 2). The control panel of the PDP-15 computer, shown in figure 3, allows the input of a number of parameters as well as the selection of a number of different modes of operation, so that a sufficient degree of flexibility is provided to make the system useful for a variety of applications.

Data Acquisition

The two principal control tasks which the PDP-15 must perform are the changing of targets and the control (stop, start, and data transfer) of the 1024-channel analog-to-digital converter (ADC), through which all pulse-height data pass.
A typical data-taking cycle is initiated upon input of the last piece of sample identification data by means of the computer teletype unit. The ADC is turned on, and data transfers from the ADC to the computer memory take place autonomously by way of the CAMAC interface. During data acquisition the pulse-height spectrum is displayed on a video unit, which assures the user that all systems are functioning properly.

By means of push buttons on the computer control panel, data acquisition may be terminated at any time, either by pressing B4, which causes data to be recorded on magnetic tape, or by pushing B2, which ends the run without recording of the data. Data acquisition also terminates, with all accumulated data being recorded on tape, when the elapsed time reaches the preset value as entered (in tenths of seconds) on control panel thumb switch TH2.

Following termination and depending on the mode of operation selected, either another run is started automatically (T15 up) or a halt occurs (T15 down) until the operator chooses to continue by pressing B2. In either case sample changing may or may not be done, depending on the setting of rotary switch R1 on the control panel (sample is changed when R1=2).

The data recorded upon completion of a run include the run identification (a five-character file name and a three-digit file number), the time elapsed during data acquisition, and, of course, the pulse-height spectrum itself.

Because analog-to-digital conversion and data transfers take place at data-channel level, they proceed autonomously once initiated, so that the computer central processing unit is free at main-stream level to proceed with analysis of a previous data set if so instructed.

Data Analysis

Analysis of previous data sets may either be initiated by the operator (press B1) or take place automatically when the computer is operating in an automatic mode (T15 up). Analysis begins with the recalling of two previous runs from tape: one with the data of interest and one that is a background or blank run, which is subtracted to remove events resulting from scattering or impurities in the system or sample-supporting matrix.

When analysis is initiated by an operator, the program requests a file name and file number for each of these data sets. In the automatic mode the program searches for a data set with the same name as that previously analyzed, increases the file number to obtain the next data set, and uses the same background data set. Hence, it is always necessary that at least the first set be analyzed manually.

The first step in the analysis is the determination of the number of events $N_{Rh}$ contained in the monitor (rhodium) peak for both the sample data and background data.
This is accomplished by locating the rhodium peak and then fitting that portion of the spectrum within 20 channels of it with a Gaussian peak plus linear background. The number of events within the Gaussian peak is then the $N_{\text{Rh}}$ of equation (5). The amount of background in this region provides the normalization for subtraction of the blank spectrum.

It is assumed that since the blank spectrum results from an unloaded sample of the supporting matrix, it is identical in shape to that encountered in the loaded sample. Consequently, after normalization and smoothing over three channel segments, the two spectra are subtracted channel by channel to arrive at the spectrum to be analyzed.

The recalled spectrum (with background subtracted) then replaces the live display of data currently being accumulated on the video unit. Figure 4 shows the recalled spectrum derived from the data of figure 2. The number of events under each peak, that is, the number of detected X-ray photons of each energy, is determined by a least-squares fitting to each peak of a Gaussian distribution of adjustable height, width, and location. Initial estimates of peak locations may be supplied by the researcher by means of the light pen and video display (T11 down), or they may be located automatically by the program (T11 up). The automatic location procedure is described in appendix A.

Depending on the setting of toggle switches, an energy calibration may be supplied at this time (T16 down). The user may supply through the teletype console the energies of the first two peaks selected with the light pen. For operation in the automatic mode (T16 and T15 up) the program retains the energy calibration from the previous run. Hence, again at least one run must be done manually. The researcher is also asked to supply through the teletype console (unless the computer is operating in the automatic mode) an estimate of the full width at one-half of the maximum (FWHM) of a typical peak.

The fitting routine does each peak in turn from the lowest to the highest energy. When two peaks are found to lie within four times the estimated FWHM, they are fitted simultaneously. A more detailed description of the fitting procedure is given in appendix B.

Following analysis of each line for energy and intensity, an identification is made by comparing the measured energy with a table of energies and atomic symbols. The elements which are included in this table are listed in table I. If a peak is identified as a $K_{\alpha}$ line, a check is made to determine whether the $K_{\beta}$ line can also be observed. If a line of the proper energy is located, the expected intensity of the $K_{\beta}$ line (determined from the intensity of the $K_{\alpha}$ line) is subtracted from the $K_{\beta}$ candidate. The remainder of the peak is tested for other identification. No peak may be identified as an $L$ series X-ray unless both the $L_{\alpha}$ and $L_{\beta}$ lines are observed.

The experimental intensity is converted to an areal density by using the stored efficiency function $F(E)$. This function is assumed (for K series X-rays) to have the form
\log \frac{1}{F(E)} = \sum_{i=1}^{7} \frac{P(i)}{E^{i-1}} (6)

The parameters \( P(i) \) are determined by measuring the X-ray yield for a number of samples (approximately 10 to 15) of known areal density and performing a least-squares fit of the function given in equation (6) to that data. The parameters \( P(i) \) vary with any change in detector or source geometry and must be redetermined each time such a change occurs. A typical set of parameters \( P(i) \) is listed in table II. For heavier elements, which are measured by means of D series X-rays, tabulated efficiencies are used for those elements which the program can identify.

The estimates of errors in the computed areal density are based on the number of counts in each peak, given by

\[ N(E) = I(E)\sigma(E)\sqrt{\pi} \] 

where \( I \) and \( \sigma \) (as defined in appendix B) are the height and width, respectively, of the Gaussian distribution derived from the data. The areal density, given by equation (5), then becomes

\[ \rho_X = \frac{I(E)\sigma(E)\sqrt{\pi}F(E)}{N_{Rh}} \] 

Therefore, assuming the error in \( N_{Rh} \) to be small gives

\[ \frac{\delta\rho_X}{\rho_X} = \left| \frac{\delta I(E)}{I(E)} \right| + \left| \frac{\delta\sigma(E)}{\sigma(E)} \right| + \left| \frac{\delta F(E)}{F(E)} \right| \] 

or

\[ \frac{\delta\rho_X}{\rho_X} = \left| \frac{\delta I(E)}{I(E)} \right| + \left| \frac{\delta\sigma(E)}{\sigma(E)} \right| + \left| \frac{1}{F(E)} \frac{dF(E)}{dE} \right| \delta E \] 

The errors in each of the quantities \( I(E) \), \( \sigma(E) \), and \( E \) are derived in the usual way from the residuals of the least-squares fitting process.

Computed areal densities may be modified by an arbitrary multiplicative factor \( G \), which may be entered by means of thumb wheel TH1. The value of \( G \) may be between
0 and 9.9999, and its effect is included in all areal densities and errors listed as output. The principal purpose of this factor is to permit the user to convert to a convenient system of units if so desired. If \( G \) is set equal to 1, the results are in units of micrograms per square inch.

Output may consist of either one or two pages of teletype output as well as a record of the results on magnetic tape. These options are selected through the control panel toggle switches (p. 1, T14 up; p. 2, T12 up; and tape, T13 up). Samples of the two pages of teletype output are shown in figures 5 and 6. More detailed information on the results of the least-squares fitting process may be obtained by replying "T" (true) when the program inquires, through the teletype console, "Do you wish extra output? Output=". A sample of this augmented output is shown in figure 7. It includes the height, width, and location, as well as the standard deviation of each, for each line fitted by the program.

A flow chart for the entire program is shown in figure 8. A guide to the loading of the program into the PDP-15 is given in appendix C. Appendix D contains the details of the overlay structure necessary in order to fit the program into the available core. Appendix E contains a listing of the FORTRAN sections of the program.

CONCLUDING REMARKS

The program described in this report permits trace element analysis of environmental samples at a rate which would make meaningful monitoring surveys feasible. Specifically, data analysis requires between 3 and 12 minutes, depending on the complexity of the spectrum, while data acquisition requires 5 to 30 minutes, depending on the primary radiation source and associated hardware employed. The program works reliably in an automatic mode; it changes samples, takes data, locates peaks, measures intensities, and identifies elements. As a result samples may be processed without an operator in attendance, which makes around-the-clock analysis possible. In addition, when operated under the supervision of the user, the program is capable of treating a wide variety of nonroutine samples, such as those containing elements not automatically recognized and those containing a number of heavy elements and thus having extremely complex spectra. For these, the program permits the extraction of meaningful data with a minimum amount of effort on the part of the user.

APPENDIX A

AUTOMATIC PEAK LOCATING PROCEDURE

If the operator so desires, initial estimates of peak locations are determined by the program, using a method described by Mariscotti (ref. 3). The method is based on the construction of smoothed second differences of the experimentally measured energy spectrum. The smoothed second difference is defined by

$$S_i(z, m) = \sum_{j=1-m}^{i+m} \sum_{h=l-m}^{l+m} (N_{l+1} - 2N_l + N_{l-1})$$

or equivalently

$$S_i(z, m) = \sum_{\text{all } j} C_{ij}(z, m)N_j$$

where the $C_{ij}$ are weighting factors derived by Mariscotti, given by

$$C_{ij}(z, m) = \sum_{l=i-m}^{i+m} C_{lj}(z-1, m)$$

and

$$C_{ij}(0, m) = \begin{cases} 
0 & \text{if } |j - i| \geq 2 \\
1 & \text{if } |j - i| = 1 \\
2 & \text{if } j = i 
\end{cases}$$

The values of $z$ and $m$ used here are those found by Mariscotti to be most suitable, namely,

$$z = 5$$

$$m = \frac{(0.6\Gamma - 1)}{2}$$
The resulting function $S$ then vanishes for a linear spectrum and is similar to the second derivative of a Gaussian function if $N_j$ is a Gaussian function. The program assumes that a peak exists in channel $i$ if three conditions are present: First,

$$|S_i| > 1.6 |\delta S_i|$$

where $\delta S_i$ is the standard deviation in the function $S_i$, approximated by Mariscotti as

$$\delta S_i = \left( \sum C_{ij}^2 \right)^{1/2} \delta N_i$$

where $\delta N_i$ is the standard deviation in the data point $N_i$. The program assumes

$$\delta N_i = (N_i + B_i)^{1/2}$$

where $B_i$ is the amount of background previously subtracted from channel $i$ of the spectrum. Second,

$$S_i < 0$$

Third,

$$S_{i-1} < |S_i| > S_{i+1}$$

The code does not reject any peak on the basis of its width as suggested by Mariscotti.
APPENDIX B

LEAST-SQUARES FITTING

Once initial estimates of peak locations and widths have been obtained, a least-squares fitting is carried out by using the Gaussian function

\[ f(x) = I \exp \left[ \frac{(x - x_0)^2}{\sigma^2} \right] \]  \hspace{1cm} (B1)

to represent that portion of the spectrum being treated. In the event that several peaks fall within 4FWHM of each other, they are fitted simultaneously as the sum of as many as five Gaussian distributions, each of which has independently variable width.

For initial estimates, \( x_0 \) is taken to be the channel \( i \) either found by the automatic search routine described in appendix B or supplied through the light pen. The initial estimate of the intensity \( I \) is taken to be the number of counts in that \( i^{\text{th}} \) channel, and \( \sigma \) is calculated from the FWHM input (for a Gaussian distribution, \( \sigma = \text{FWHM}/1.665 \)).

Fitting is carried out by standard methods. In the event a satisfactory fit cannot be obtained within a specified number of iterations, the peak of highest energy is dropped from the multiplet, and the fitting process is restarted for the remainder of the peaks. In the event that a single peak cannot be satisfactorily fitted, a message to that effect is included on output page 1, and the peak is assigned intensity zero and a location equal to the starting channel number.
APPENDIX C

LOADING THE PROGRAM

As presented in this report the program (entitled SAVLOC) is too large to be loaded directly into a 16K PDP-15 computer. As a result it can only be used as a series of overlays, constructed by using the routine CHAIN (ref. 4). A listing of the execute file, titled SAVLOC, is given in appendix D; the listing includes the resident code as well as the structure of each of the links and a machine constructed map of the file.

At execution time the user must assign handlers to three slots in the device assignment table (dat): dat slot 1, for writing of raw data; dat slot 2, for reading of raw data; and dat slot 3, for writing of results of analysis (fig. 6). Dat slots 1 and 2 are normally assigned the same magnetic tape (dectape) unit, and dat slot 3 is assigned a second dectape unit.

An example of the entire loading sequence is as follows:

```
KMS15 V5C
$A DTE6 1,2/DTE7 3
$E SAVLOC

EXECUTE V4A
FNAME(A) =
```

where the underlined expressions are output from the computer.

chart for program.
"The aeronautical and space activities of the United States shall be conducted so as to contribute ... to the expansion of human knowledge of phenomena in the atmosphere and space. The Administration shall provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof."

—NATIONAL AERONAUTICS AND SPACE ACT OF 1958

NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

TECHNICAL REPORTS: Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

TECHNICAL NOTES: Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

TECHNICAL MEMORANDUMS: Information receiving limited distribution because of preliminary data, security classification, or other reasons. Also includes conference proceedings with either limited or unlimited distribution.

CONTRACTOR REPORTS: Scientific and technical information generated under a NASA contract or grant and considered an important contribution to existing knowledge.

TECHNICAL TRANSLATIONS: Information published in a foreign language considered to merit NASA distribution in English.

SPECIAL PUBLICATIONS: Information derived from or of value to NASA activities. Publications include final reports of major projects, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

TECHNOLOGY UTILIZATION PUBLICATIONS: Information on technology used by NASA that may be of particular interest in commercial and other non-aerospace applications. Publications include Tech Briefs, Technology Utilization Reports and Technology Surveys.

Details on the availability of these publications may be obtained from:
