ACCELERATED LIFE TESTING EFFECTS ON  
CMOS MICROCIRCUIT CHARACTERISTICS

PHASE IV REPORT

CONTRACT NAS8-31905

I. INTRODUCTION

The results of Phase I and Phase II of this contract (250°C and 200°C accelerated tests) as well as work done by RCA's various activities in the field of reliability improvement suggest that reduced longevity of the CMOS microcircuits under high-temperature accelerated testing is primarily due to contaminants external to the chip. The presence of small amounts of moisture enhances the mobility of the contaminant ions, thereby contributing to increased leakage currents and changes in other device characteristics, such as threshold and output voltage, under the high-temperature accelerated testing. Phase IV introduces modifications and additions to the present process of making CMOS microcircuits which are designed to provide protective layers on the chip to guard against moisture and contaminants.

II. OBJECTIVES

Phase IV of this contract has the following objectives:

1. The improvement of the Class A CMOS microcircuit high-temperature accelerated-test characteristics through deposition of silicon nitride protect layers.
2. The selection of the optimum process for further evaluation under high-temperature accelerated-test conditions.

### III. THE PROCESS

The standard wafer-manufacturing process was modified by the introduction of two distinctly different silicon nitride ( $\text{Si}_3\text{N}_4$ ) protect layers. These two kinds of  $\text{Si}_3\text{N}_4$  layers are distinguished by the method of deposition and, therefore, resultant characteristics.

The high-temperature  $\text{Si}_3\text{N}_4$  layer is deposited in a furnace at  $800^\circ\text{C}$ . This method of deposition results in a dense layer which is impervious to contaminants, has a slow etch rate, and which provides a good barrier to sodium. The deposition of the layer over the field oxide presents few problems. When the layer is deposited over the channel oxide, its thickness must be minimized ( $175 - 200\text{\AA}$ ) to prevent the formation of a metal-to-channel oxide interface and the possibility of accumulation of undesirable charges. Fig. 1(c) shows the location of this layer.

The low temperature  $\text{Si}_3\text{N}_4$  layer is plasma deposited after the metalization, at  $310^\circ\text{C}$ , a temperature low enough to prevent alloying of aluminum metal into the silicon. This type of deposition results in a less dense layer with a higher etch rate. The layer is deposited over the entire chip and is made relatively thick ( $3\text{k}\text{\AA}$  to  $10\text{k}\text{\AA}$ ) in an attempt to make it impervious to contaminants, Figs. 1(b) and (c). The PSG (phosphorous silica glass) layer standard in current RCA processing is retained with the idea that it may still serve the useful function of gettering for those contaminants that might be trapped under the protect layer.

### VI. DEVICE SELECTION

The simplicity of the CD4007A device type was the compelling reason for choosing it as the vehicle for this experiment. A wealth of life-test information is also available for this device type. The schematic diagram of Fig. 2 shows the internal connections of the CD4007A; the easy accessibility to individual transistors should greatly facilitate the analysis of failures resulting from subsequent testing and evaluation.

Fig. 2 - CMOS dual complementary pair plus inverter, CD4007A.

## V. DEVICE FABRICATION

The experimental cell matrix was developed as shown in Fig. 3. Twenty-four wafers were processed by means of the standard RCA process for fabricating commercial CMOS IC's through channel-oxide deposition. At this point, the lot was split as shown on the matrix of Fig. 3, into one control cell (No. 1) and seven (Nos. 2 through 8) test cells. The seven test cells represent the low-temperature deposition of  $\text{Si}_3\text{N}_4$  to various thicknesses in combination with (Group I) the high-temperature  $\text{Si}_3\text{N}_4$  layer or without (Group II) the high-temperature  $\text{Si}_3\text{N}_4$  layer.

The wafers were circuit probed with high resultant yields, which is a good indicator of the manufacturability of the process. For comparison, the circuit probe yields for the CD4007A were:

For the 1977 year, 80 to 85%

For the  $\text{Si}_3\text{N}_4$  experiment, 82%

The control cell (No. 1) and the test cells (Nos. 2 through 8) were assembled in standard plastic dual-in-line packages. The pellets were mounted with epoxy used in the RCA CD4000 commercial series. The Novolac plastic package is thought to accentuate problems that might be encountered in subsequent testing, thereby reducing the duration of tests. The assembled devices were screened to commercial specifications to net 60 good devices per cell for further evaluation.

The devices in test cells Nos. 9, 10 and 11 were to be eutectically mounted in ceramic (DIC) packages so that they could be tested under high-temperature accelerated-test conditions. These three cells represent those test cells appearing as the last line in the experiment matrix of Fig. 3.

## VI. TEST AND EVALUATION

The evaluation of the effectiveness of the  $\text{Si}_3\text{N}_4$  protect layers as the barriers to contaminants required the type of testing that provides sufficient

Fig. 3 - Experimental cell matrix.

stressing, particularly in two areas: the high-temperature and high-humidity environment. Three tests were used to achieve this type of stress:

1. 200°C bias/temperature test
2. 150°C bias/temperature test
3. 85°C/85% relative-humidity, bias/humidity test.

All tests were conducted at 12.5 V dc. The circuit bias arrangement used was the standard burn-in bias configuration shown in Fig. 4. Each test cell from No. 1 to No. 8 was tested in accordance with the schedule of Fig. 5. The electrical measurements were taken initially and at each down-time as indicated for tests 1, 2, and 3. The anticipated end-of-test time for each test is also shown in Fig. 5 as the last down-time.

It was thought, from experience, that all test cells would have generated a sufficient number of out-of-specification devices at each end-of-test time to provide the basis for comparison among the test cells. However, it was found during the actual testing that the longevity of the test devices was underestimated. Neither 240 hours at 200°C nor 1152 hours at 150°C were producing enough out-of-specification devices for conclusive evaluation. Because of time and equipment limitations it was then decided to continue beyond the anticipated end-of-test time with the 200°C bias-temperature test only. The 200°C test in actuality had to be extended to 500 hours and eventually to 768 hours before a conclusive evaluation could be done.

The test parameters and the limits used were those of the standard commercial device specifications. The use of specifications more relaxed than those of the MIL-M-38510 commercial specifications was dictated by the need to detect gross differences among the test cells rather than differences resulting from subtle process variations.

One group of devices was evaluated in an entirely different way. These devices were assembled in ceramic packages with eutectic mounts and tested with a 200°C bias/temperature test. These devices were represented by the

Fig. 4 - Burn-in connections.

ALL DEVICES AT EACH DOWN TIME ARE CRITICIZED TO COMMERCIAL LIMITS

Fig. 5 - Testing and evaluation of each cell.

three test cells Nos. 9, 10, and 11. Test-cell No. 10 had the low temperature  $\text{Si}_3\text{N}_4$  layer only while test-cell No. 11 had both the low-temperature and the high-temperature  $\text{Si}_3\text{N}_4$  layers. Test cell No. 9 was accidentally lost during handling.

The electrical measurements on this group of devices were performed by using the test programs based on the MIL-M-38510 detail specifications. This method of testing provided test results directly comparable to earlier accelerated-test evaluations of CMOS microcircuits to the MIL-M-38510 specifications. It also provided a preview of the capability of the eutectic-mount and  $\text{Si}_3\text{N}_4$  protect-layer combination under high-temperature accelerated-test conditions.

## VII TEST RESULTS

The test matrix in this experiment was designed so that the analysis of the test results could be conducted in steps. At first a determination must be made as to whether there is an improvement in either of the two test groups over the control cell. If there is an improvement in more than one cell, a comparative evaluation among the test cells must be made to determine which of the test cells possesses the best characteristics. The improvement must be demonstrated in both the high-temperature and high-humidity environments. The test results are summarized in Table I.

The 150°C bias/temperature test can be eliminated from consideration immediately because the control cell has not produced a single out-of-specification device in this test. The results of the other two tests, the 200°C bias/temperature and the 85°C/85% relative-humidity tests, can be analysed by the application of the three regions in the life of a device: The "infant-mortality" region, the "constant-failure-rate" region, and the "wear-out" region.

None of the test devices has been burned-in; consequently, the devices which exceeded the specification limits during the first 16 hours in the 200°C test as well as the out-of-specification devices occurring within the first 168 hours in the 85°C/85% relative-humidity test could be attributed to the infant mortality. The constant-failure-rate region appears to fall between the 16-hour point and the 500-hour point in the 200°C test. At the 500-hour point, devices begin exceeding the specification limits in numerous cells,

an indication of the onset of the wear-out region. The test data at 768 hours clearly indicates that the wear-out region for all the cells has been reached before that time. Because of the absence of out-of-specification devices in the control cell within the constant-failure-rate region, the wear-out region must be used as the criterion for comparative evaluation of cells. By using that criterion, cells 2, 4, and 6 appear as having demonstrated characteristics equal to or better than those of the control cell. None of these cells has had an out-of-specification device in the constant-failure-rate region, up to and including the 500-hour point. The two out-of-specification devices in cell No. 4 are attributed to infant mortality. The control cell had an out-of-specification device at the 768-hour point. The wear-out region for these test cells lies somewhere between 500 hours and 768 hours. The rate of deterioration for the devices in this region is probably similar for all cells, as can be judged by the recorded number of out-of-specification devices at the 768-hour point.

Similarly, the onset of the wear-out region in the 85°C/85% relative-humidity test, at least for some cells, is evidenced at the 4000-hour point. From among the test cells identified earlier, only cell No. 4 remains in the contest with the control cell because of the condition that a cell must demonstrate improvement in both the 200°C and the 85°C/85% relative-humidity test to be in contention. At the 4000-hour point cell No. 4 has had one out-of-specification device versus five such devices (exclusive of one early out-of-specification device) in the control cell. This result tends to indicate the possibility that the heavy coat (9kÅ) of low-temperature  $\text{Si}_3\text{N}_4$  is presenting a barrier to moisture. The group with two  $\text{Si}_3\text{N}_4$  layers did not do as well, in general, suggesting that perhaps the technique of depositing the thin high-temperature  $\text{Si}_3\text{N}_4$  layer may need further perfecting.

Test cells No. 10 and 11 were tested at 200°C and evaluated to the MIL-M-38510 detail specifications. At the 16-hour down time, both test cells had produced devices out of specification in leakage ( $I_{SS}$ ); test cell No. 11 has had decreasing threshold voltage ( $V_{TH}$ ) in addition to out-of-specification leakage ( $I_{SS}$ ).

Table II summarizes the number and kind of out-of-specification devices which occurred in test cells No. 10 and 11. The threshold problems have occurred in the same devices that failed leakage tests. The early problems of the kind that were observed indicated the possible presence of mobile ions. This possibility was checked in both test cells by baking devices at 150°C for 24 hours. A complete recovery in some cases and partial recovery in many others was observed. The bias/temperature test was repeated for another 16 hours, and a recurrence of excessive  $I_{SS}$  and  $V_{TH}$  problems was observed. The threshold deterioration in test cell No. 11, which has both  $Si_3N_4$  layers, is further evidence that there may have been a problem in the deposition of the high-temperature  $Si_3N_4$  layer. The results of this testing do not compare favorably with the results of tests conducted in Phase II of this contract on CD4011A, CD4013A, and CD4024A devices.

#### CONCLUSION

The results of the evaluation of the high-temperature and low-temperature  $Si_3N_4$  protect layers conducted within the scope of this effort lead to the following conclusions:

1. The application of the  $Si_3N_4$  layers in all of the tested combinations failed to lead to a demonstrably conclusive improvement in device reliability characteristics.
2. There is some evidence that a heavy ( $9k\text{\AA}$ ) layer of low-temperature  $Si_3N_4$  presents a barrier to moisture. A further, more detailed study is required for a more conclusive statement.
3. The testing of eutectically mounted devices has not produced a desirable degree of improvement in reliability characteristics.

Table II - Test Results, Cells No. 10 and 11

| Cell No. | Sample<br>Size | No. & Type of Failure |          |
|----------|----------------|-----------------------|----------|
|          |                | $I_{SS}$              | $V_{TH}$ |
| 10       | 20             | 8                     | -        |
| 11       | 20             | 15                    | 9        |
