1. INTRODUCTION

The CLASSY algorithm attempts to decompose multivariate Landsat spectral data as a mixture of multivariate normal distributions. It is hoped that this information can be used to increase the accuracy of the estimates of area proportion of certain crops of interest. In order for this to be true, the mixture components of the CLASSY decomposition should each represent a spectral signature overwhelmingly of the crop class of interest. This note will study the purity of CLASSY components, and propose a Bayesian method for using that information to improve maximum likelihood area estimates. The method is then tested on ten LACIE Transition Year segments with the classifier trained by Analyst Interpreter labels.

2. PURITY OF CLASSY COMPONENTS

The CLASSY algorithm (Lennington and Rassbach [1979]) estimates a mixture decomposition of continuous multivariate data into multivariate normal components. When the data consists of spectral values from LACIE segments, possibly from several different acquisitions at widely spaced times, it is hoped that CLASSY decomposition may aid in the estimation of proportions of various crops present. If picture elements characteristic of a particular component represent only a random assortment of crop types, clearly nothing has been gained. The hope would be that in many cases a CLASSY component would represent the signature of a particular crop, or a special case of such a signature; therefore, picture elements characteristic of that component would overwhelmingly belong to the crop of interest.

This latter case is that of high component purity. We will measure purity by an index β , $\beta = 0$ means that none of the component is planted in the crop of interest, $\beta = .4$ means that 40% of the component is in the crop, and $\beta = 1.0$ means that all of the component corresponds to the crop. CLASSY is most useful to us when the β 's tend to be near zero and one.

The β 's may be estimated by the method of maximum likelihood (Lennington and Terrell [1980]). The purity for small grains of 113 CLASSY components of eleven Year Three LACIE segments were estimated using the MAXLABEL program; the estimator was trained using ground truth crop type for approximately 100 pixels per segment. Figure 1 shows a histogram of the β 's obtained. It is encouraging that a substantial majority are near zero or one.

In the sequel it will be useful to have a mathematical description of the statistical distribution of the component purities. In the case of two crop types, a Beta distribution with density

 $\frac{\Gamma(a + b)}{\Gamma(a)\Gamma(b)} x^{a-1} (1 - x)^{b-1}$ on (0,1)

Figure 1.- Estimated component purities.

and zero elsewhere would be convenient. Since the mean $\mu_{a,b} = \frac{a}{a+b}$ and variance $\sigma_{a,b}^2 = \frac{a^b}{(a+b)^2(a+b+1)}$, we may estimate a and b from the sample mean and standard deviation. In our data $X_{\beta} = .358$, $S_{\beta} = .389$. Now

$$a + b = \frac{u(1 - u)}{\sigma^2} - 1$$

so that $a = (a + b)\mu b = (a + b)(1 - \mu)$. Substituting population values we got

The continuous curve in figure 1 is sufficiently close to the observed distribution to reassure us of the plausibility of the assumption of a Beta distribution (It is simply the density $\beta_{.187,.335}$ rescaled for the histogram).

The fact that \hat{a} is smaller than \hat{b} is related both to the greater purity of non-small-grains components and the fact that small grains elements were in the minority in our sample segments. When a and b were estimated for another population of Transition Year segments, but the estimators were trained with Analyst Interpreter dots, $\hat{a} = .155$, $\hat{b} = .441$ were obtained. These are quite close in practice to the previous results; they seem to reflect in addition the tendency of Analyst Interpreters to make more errors of omission than of commission.

3. ESTIMATION OF POSTERIOR PURITY

We now proceed to utilize prior information to estimate small grains proportion. Two approaches to area estimation have been proposed: If α_j is the prior probability of component j, then a proportion estimate is $\sum_{j=1}^{\infty} \alpha_j$ where jcP if and only if $\beta_j > 1/2$. Alternatively, a proportion estimate is $\sum_{j=1}^{\infty} \alpha_j$ over all components (Lennington and Terrell (1980)). Notice that the two methods are equivalent if all components are pure.

The generalization of the Beta distribution to a number of simultaneously independently distributed purities is the Dirichlet distribution. In other words, the posterior density of the β_{ij} i = 1, ..., c, j = 1, ..., d where c is the number of crops and d is the number of components is

that

 $\sum_{\substack{j=1\\j=1}}^{C} \beta_{jj} = 1, \ 0 < \beta_{jj} < 1 \ \text{and} \ e_j > -1$

is a measure of typical prior purity of the ith crop, and K is a constant such that the distribution integrates to one.

Let \bar{X}_{ik_i} , where $K_i = 1, \dots, N_i$ be the spectral vectors of the set of training pixels labeled as crop i. Let f_j be the multinormal density of the jth component estimated by CLASSY. We will assume that the probability that a pixel belongs to a particular crop depends only on its component membership, and not on its spectral location within a component distribution. This simply means that each component is homogeneous; if this were not the case, it would cast doubt on the assumption of multinormality. The likelihood of the observations \bar{X}_{iK_i} is then

c "i d

$$\Pi$$
 Π Σ Prob { \vec{X}_{iK} , i, j}
i=1 K_i=1 j=1

$$= \frac{c}{\pi} \frac{N_{i}}{\pi} \frac{d}{\Sigma} \operatorname{Prob} \{\hat{X}_{iK_{i}}, i|j\} \operatorname{Prob} \{j\}$$

$$= \frac{c}{\pi} \frac{N_{i}}{\pi} \frac{d}{\Sigma} \operatorname{Prob} \{\hat{X}_{iK_{i}}, |i,j\} \operatorname{Prob} \{j\}$$

$$= \frac{c}{\pi} \frac{N_{i}}{\pi} \frac{d}{\Sigma} \operatorname{Prob} \{\hat{X}_{iK_{i}}, |i,j\} \operatorname{Prob} \{i|j\} \operatorname{Prob} \{j\}$$

$$= \frac{c}{\pi} \frac{N_{i}}{\pi} \frac{d}{\Sigma} \operatorname{Prob} \{\hat{X}_{iK_{i}}, |j\} \operatorname{Prob} \{i|j\} \operatorname{Prob} \{j\}$$

$$= \frac{c}{\pi} \frac{N_{i}}{\pi} \frac{d}{\Sigma} \operatorname{Prob} \{\hat{X}_{iK_{i}}, \beta_{ij}\} \beta_{ij}\alpha_{j}$$

Given the prior information represented by the e_i 's, we get a posterior likelihood

$$1 = K \prod_{j=1}^{c} \left\{ \begin{pmatrix} d & e_j \\ \Pi & \beta_{ij} \end{pmatrix} \begin{pmatrix} \Pi & \Sigma & f_j (\vec{X}_{iK_j}) \\ j=1 \end{pmatrix} \right\}$$

and taking logarithms

$$L = \log l = \log K + \sum_{i=1}^{c} e_i \sum_{j=1}^{d} \log \beta_{ij}$$

$$c \stackrel{N_i}{+} \sum_{\sum log \sum \alpha_j \beta_{ij} f_j} (\tilde{X}_{iK_i})]$$

$$i=1 K_i = 1 \qquad j=1$$

We will estimate cluster purities by taking the maximum posterior likelihood under the constraints $\sum_{j=1}^{C} \beta_{jj} = 1$, j = 1, ..., d, using the method of Lagrange multipliers. The recursive fixed-point solution was given by

$$B_{ij} = \frac{S_{ij}}{c}$$

$$\sum_{m=1}^{\Sigma} S_{mj}$$

$$S_{ij} = e_{i} + \sum_{K=1}^{N_{i}} \frac{a_{j}\beta_{ij}f_{j}(\vec{x}_{iK_{i}})}{\frac{d}{\sum_{k=1}^{Z} a_{j}\beta_{i1}f_{k}(\vec{x}_{iK_{i}})}}$$

Notice the parallel between this method and the classical maximum likelihood solution in Lennington and Terrell (1980). This solution becomes the classical solution by setting $e_i = 0$ for each i.

The ease with which the Dirichlet prior enters into this solution may be attributed to the fact that it is conjugate to the multinomial distribution, and the β 's have some of the character of multinomial probabilities.

TABLE 1 .- ESTIMATES OF SPRING SMALL GRAINS PROPORTION

4. APPLICATION TO SMALL GRAINS ESTIMATION

The procedure of the last section was incorporated into a FORTRAN program to run on the LARS system at Purdue University by modifying the MAXLABEL program (Horton and Lennington (1980)). Since the e_i 's may be negative, it was necessary to introduce the additional constraint that $0 \le \beta_{ij} \le 1$. This was accomplished by setting an S_{ij} equal to zero whenever it becomes negative during the process of iteration. No effect on the average rate of convergence was noted as a result of this change.

Ten Transition Year LACIE segments in which spring small grains were the major crop of interest were chosen because they had four good quality acquisitions spaced over the growing season, they had been handled by the P1 procedure so that approximately two hundred analyst-labeled pixels were available, and estimates of the true proportion of small grains were available from ground truth surveys. The four spectral values at each acquisition were projected onto the Kauth-Thomas (1976) greenness-brightness plane; thus, there were eight components of the spectral vector for each pixel.

The CLASSY program was run for each of the ten segments listed in column one giving a decomposition into mixtures of eight dimensional multinormal components for each segment. The program described above (called PRELABEL) was then run for the segments with several sets of values of the prior purities. The results are summarized in Table 1. For the third and fourth columns, all e_i 's were set to zero, giving the equivalent of a maximum likelihood solution. For columns five and six, $e_i = \hat{b} - 1 = -.665$ and $e_2 = \hat{a} - 1 = -.813$ were used as these are the empirical values found in section II. Column two is the ground truth proportion of spring small grains for each segment. At the foot of each column are the mean error in percent (called bias) and the mean squared error of each estimate. Columns two and four use the estimator

 Σ $\alpha_j \beta_{ij}$ and columns three and five use Σ α_j where $j \epsilon P_i$, if and only if $j \epsilon P_i$ $\beta_{ij} > 1/2$. It is clear that the introduction of prior purities made no difference to the second estimates and very little difference to the first. A further experiment in which the "diffuse" prior $e_i = -1$ for all i was used made even less difference. The results still reflect the analyst tendency to prefer errors of omission to errors of commission.

5. CONCLUSIONS

A notable result of this study was the success in fitting a Beta distribution to maximum likelihood estimates of component purity. The fact that \hat{a} and \hat{b} are substantially less than one indicates that CLASSY components show more than chance tendency to achieve high degrees of purity in crops of interest. This is the bulk of the evidence in existence that CLASSY actually extracts features of importance from Landsat data.

On the other hand, the methods studied for introducing the prior information into the process of estimation make little difference to the results when used with AI labeled samples, and are not recommended for incorporation into practical estimation procedures.
