Abstract

The 8-cm Hg ion thruster system was developed primarily to provide N-S station keeping of satellites with masses up to about 1800 kg. The on-orbit propulsion requirements of recently proposed Large Space Systems (LSS) are beyond the capabilities of the present 8-cm thruster system operated at baseline conditions. This paper presents a preliminary characterization of the performance capabilities of the 8-cm thruster in order to initiate an evaluation of its application to LSS propulsion requirements. With minor thruster modifications, the thrust was increased by about a factor of four while the discharge voltage was reduced from 39 to 22 volts. The thruster was operated over a range of specific impulse of 1950 to 3040 seconds and a maximum total efficiency of about 54 percent was attained. Preliminary analysis of component lifetimes, as determined by temperature and spectroscopic line intensity measurements, indicated acceptable thruster lifetimes are anticipated at the high power level operation. No attempts were made as yet to optimize thruster performance.

Introduction

The 8-cm, 5.0 mN Hg ion thruster system was primarily developed to provide N-S station keeping of geosynchronous satellites with masses up to about 1800 kg. The thruster is also capable of providing high precision attitude control, East-West station keeping, and station-change propulsion functions.[1,2] With the advent of the Shuttle, many missions have been recently proposed which employ Large Space Systems (LSS).[3-5] Such missions include space based radar, large communications platforms, and space laboratories. The masses, configurations, and orbits, of many of the proposed LSS imply on-orbit propulsion requirements beyond the capabilities of the present 8-cm thruster system operated at baseline conditions. This situation is illustrated in Fig. 1, which is based on data of Ref. 2. Figure 1 shows, for example, that for a configuration of two north and two south 8-cm thrusters, with two operating for 6 hours about each node, spacecraft masses of up to only about 1800 kg can be accommodated.

For LSS with large area to mass ratios, solar pressure effects also have to be considered. The solar pressure changes the eccentricity of a synchronous equatorial orbit, resulting in an apparent daily east-west oscillation[6]. For light weight structures such as Space Based Radar, the total impulse, and hence the propellant requirements, can increase by an order of magnitude when effects of solar pressure are included (Fig. 2). Such effects imply a need for increased capabilities of the on-orbit propulsion systems.

The objective of this study was to present an initial characterization of the performance capabilities and constraints of the 8-cm thruster and to allow a preliminary evaluation of its possible application to LSS propulsion requirements. In particular, the achievable levels of thruster performance were investigated at high power levels along with preliminary evaluation of thruster lifetime.

Apparatus and Procedure

Thruster

The 8-cm thruster with dished grids and a low open area accelerator grid used in this study has been described in Ref. 7. It was a SIT 8 thruster modified to conform to the 8-cm EMT design. The following modifications were made on the baseline 8-cm thruster: (1) copper strips were attached from the vaporizer-isolator interface to the ground screen to act as heat sinks so that vaporizer thermal control could be extended to higher discharge power levels, (2) the rolled foil insert in cathodes was replaced in all tests with a solid impregnated insert to improve the cathode performance and repeatability. Cathodes with both 0.25 mm (baseline design) and 0.73 mm orifices were tested.

Power Supplies and Facility

The power supplies consisted of laboratory types described in Ref. 7, with the discharge and screen grid supply capabilities increased to 4.5 and 1.0 amps, respectively. The tests were performed in a 1.5x6.1 meter vacuum facility operating at a no load pressure in the 4×10^{-5} to 1.3×10^{-4} Pa (3×10^{-7} to 1×10^{-6} Torr) range.

Optical Spectrometer Instrumentation

A Jarrel-Ash, 0.5 m Ebert scanning spectrometer with an electric drive was used with a strip chart recorder to measure the spectral radiation emanating from the 8-cm thruster. The spectrometer was located at the opposite end of the vacuum facility and viewed the thruster on axis through a quartz window. A slit size of 75 microns was used. The excited atomic molybdenum, MoI (3798 Å), atomic mercury, HgI (3802 Å), singly ionized mercury ion, HgII (3806 Å) and doubly ionized mercury ion, HgIII (4797 Å), spectral line intensities were measured as a function of thruster parameters.

Thruster Operation

The discharge chamber of the 8-cm thruster operates with only one propellant flow control loop (as compared to two for of the 30-cm thruster). The control loop adjusts the vaporizer power to provide the correct propellant flow rate for obtaining a desired discharge voltage. The beam current for the baseline thruster is controlled by varying the discharge current at a given discharge voltage. The 8-cm baseline discharge voltage of 39 volts, and discharge current of 0.5 A results in a beam current of ~72 mA. Higher beam current levels were achieved in this study by operating the thruster at higher discharge currents, higher propellant flow rates, and lower discharge voltages. As higher beam cur-

rents were obtained, increases of the screen and accelerator voltages were necessary to prevent excessive ion interception by the accelerator grid.

The operating ranges of the thruster parameters were limited by the vaporizer thermal control characteristics and the discharge current power supply.

Results and Discussion

Thruster Performance

Figure 3 shows the beam currents obtained with the 0.25 mm cathode configuration as a function of discharge current at various discharge voltages. It is evident that increasing the discharge current beyond the baseline value of 0.5 A (discharge voltage of 39 volts) did not result in corresponding increases in the beam current. However, the beam current did increase with increasing discharge current when the discharge voltage was reduced by increasing the propellant mass flow rate. At discharge voltages of 32 and 35 volts, the beam current began to decrease above discharge currents of 3.0 and 4.0, respectively. This occurred because as the discharge current was increased above these values, the flow rate started to decrease in order to keep the discharge voltage constant. The resulting lower flow rate led to a decrease in the beam current. At lower discharge voltages this decrease was not observed at the available discharge current values.

Increase in the propellant flow rate at a given discharge current resulted in reaching a minimum discharge voltage, at which point further increases in propellant flow rate resulted in increases in discharge voltage and decreases in beam current. The minimum discharge voltage for the 0.25 mm cathode orifice ranged from about 26 V at a discharge current of 1.5 A to 23 V at 4.5 A.

The range of thruster operation shown in Fig. 3 was limited at high discharge currents by the 4.5 A discharge current supply limit and at low discharge voltages and currents by the limit of the vaporizer heater power supply (or available propellant flow).

The characteristic increase of beam current with decreasing discharge voltage at various discharge currents can be observed in Fig. 4 for both cathode orifices. The beam current increased with decreasing discharge voltage in an approximately linear fashion for the 0.25 mm cathode orifice tests (Fig. 4(a)). The maximum beam current of 264 mA was 3.7 times that of the 8-cm thruster operated at the baseline condition and represents an average current density of about 5.3 mA/cm^2.

The discharge current-voltage characteristics of the large orifice cathode were somewhat different from that of the 0.25 mm cathode geometry. Two distinctive slopes were evident for discharge currents greater than 2 A, as compared to one slope in Fig. 4(a), but the maximum obtainable beam current of 270 mA was about the same as for the smaller cathode orifice.

The maximum beam current attainable at a given discharge current increased linearly with the discharge current, Fig. 5. The 0.73 mm cathode geometry data again displayed a somewhat different characteristic as compared to the smaller cathode orifice tests.

The operation of the thruster with the two orifice sizes differed in still another respect. For the small cathode orifice, the maximum beam current attainable for a given discharge current corresponded to the point of minimum discharge voltage. In the large orifice tests, the maximum beam current was reached at discharge voltages somewhat higher than the minimum attainable discharge voltage.

It appears that higher beam currents for the cathode geometries investigated could have been attained from the 8-cm thruster if higher discharge currents had been available because neither the breakdown voltage nor the perveance limit of the grids (see Fig. 6) had been reached. It is also probable that higher beam currents at a given discharge current (lower watts/beam ampere) could have been attained if the thruster geometry and magnetic fields had been optimized for operation at high discharge power.

The perveance limits of the dished grids with a gap of 0.50 mm is shown in Fig. 6 for the small cathode orifice geometry. The maximum attainable current density was about the same as that of the 30-cm thruster.[8]

The maximum mass utilization values (Fig. 7(a)) of 86-92 percent were obtained between discharge voltages of 26-35 volts with the 0.25 mm orifice cathode. These values compared well with the EMT baseline value of about 84 percent.

The propellant mass utilization curves in Fig. 7(a) had the same general characteristics at the various discharge current values. The utilization increased at low discharge voltage with increasing discharge voltage, reached a maximum, then decreased and again began to increase at high discharge voltages. The point of maximum utilization moved to lower discharge voltages with increasing discharge current. In the lower discharge voltage region, the propellant utilization at a given discharge voltage was found to increase with increasing discharge current.

The mass utilization of tests with the 0.73 mm orifice (Fig. 7(b)) were not as high as with the smaller cathode orifice and the shape of the curves for a given discharge current were different from those of Fig. 7(a). The maximum utilization was found to be at the highest operated discharge voltage, except at a discharge current of 1.0 amp. At this discharge current, the maximum utilization was found at a discharge voltage of 30 V.

The ion production costs at various discharge currents are shown in Fig. 8 for the small orifice cathode tests. For discharge currents greater than 1.0 A, the minimum ion production costs at a given discharge current ranged between 310 and 360 watts per beam ampere (W/A), as compared to about 250 W/A for the baseline 8-cm thruster. (The keeper costs of 3 to 6 W/A were not included in the calculations of Fig. 8.) The ion production cost at a given discharge current decreased significantly with decreasing discharge voltage or increasing beam current. In addition, the ion production costs decreased at a given discharge voltage with decreasing discharge current and beam current.

The production costs with the large cathode orifice had the same characteristics as with the

2

small cathode orifice, however, somewhat lower costs were achieved at large discharge currents and low discharge voltages.

Thrust, specific impulse and total thruster efficiency are shown in Fig. 9 as a function of thruster input power for the small orifice cathode operated at a discharge voltage of 26 volts. The characteristics of the performance parameters were generally insensitive to the discharge voltage and 26 volts was selected to display thruster performance at the upper range of input power (Fig. 3). The following assumptions were made in determining the data for Fig. 9: (a) a thrust loss factor of 0.95, to account for losses due to ion beam divergence and doubly charged ions, (b) constant power loss of 14 watts due to keeper and vaporizer operation of the main and neutralizer cathodes, (c) neutralizer mass flow rate (in equivalent amperes) of 10 percent of the ion beam current.

The input power was increased by increasing the beam current and the discharge power. As the beam current increased it was necessary to increase the total accelerating voltage to avoid ion defocusing in the grids (Fig. 6). For this reason the beam voltage increased with increasing input power which resulted, in conjunction with the utilization efficiency variation with beam current (Fig. 7(a)), in the specific impulse characteristics shown in Fig. 9. This figure shows that while the thrust increased almost linearly with increasing input power, the total efficiency reached a maximum and then remained almost constant. This leveling off is due to a decrease of the electrical efficiency at the high input power. Over the entire range of thruster operation (not shown in Fig. 9), the specific impulse ranged from 1950 to 3040 seconds, whereas the thrust varied from 5.3 to 20.4 mN, as compared to 4.8 mN thrust at the baseline conditions. The highest total efficiency of 55 percent was obtained at a discharge voltage of 24 volts and input power of 0.49 kW. It is believed, however, that optimization of thruster performance at high input power levels should result in improved performance.

Spectroscopic Intensity Measurements

The optical spectrometer has proven itself to be a useful tool in helping to evaluate thruster component lifetimes.[9,10] The spectral line intensity of molybdenum can be related to the sputtering rate of the molybdenum screen grid if the thruster operating conditions are kept constant.

A rough comparison may be made between the sputtering rates of the 8-cm and 30-cm thrusters, at the same operating conditions, by comparing the ratio of the excited atomic molybdenum (MoI 3798 Å) and the atomic mercury (HgI 3802 Å) intensities of the two thrusters (Fig. 10). The intensity ratios are shown as a function of average beam current density because this parameter is proportional to the average plasma density inside the discharge chamber. The data of the 30-cm thruster were taken at constant ion production cost, whereas because of the single control loop of the 8-cm thruster, this was not possible for the smaller thruster. The intensity ratios of the 8-cm thruster at a given beam current density was less than that of the 30-cm thruster at a discharge voltage of 35 volts but slightly higher at a discharge voltage of 32 volts.

Therefore, it is likely that the sputtering rates of the two screen grids at these operating conditions should be about the same. The lifetime of the 30-cm thruster at baseline conditions has shown to have an operating lifetime of about 15,000 hrs.[9] From known sputtering behavior, it may be reasoned that the sputtering rate of the 8-cm screen grid operating at low discharge voltages and high beam current may be about the same as the sputtering rate of the 30-cm thruster grid operating at the baseline conditions. A life test is necessary, however, to verify this comparison.

Test of the 30-cm thruster[9,10] have shown that the environment of the vacuum facility may have a significant effect on the sputtering rates of thruster components if the facility pressure is not sufficiently low enough. Preliminary tests (Fig. 11) indicated that operation of the 8-cm thruster at a high beam currents and low discharge voltages should not be affected by background pressure if operated at pressures of about 1×10^{-4} Pa (1×10^{-6} Torr) or less. Figure 10 is similar to curves obtained with the 30-cm thruster operating at higher discharges voltages and somewhat lower beam current densities. However, the knee at the top of the curve, which marks the beginning of the pressure effect on sputtering rates,[11] appears in Fig. 11 at higher than expected pressures when compared to the 30-cm data. The reason for this is not known.

Thruster Component Temperature Measurements

To ascertain the 8-cm thruster component integrity under high power operation, 9 thermocouples were installed on critical thruster components. Figure 12 shows typical temperatures of five of these components as a function of discharge power (neglecting keeper power). The data were obtained while a beam was extracted. The center of the cathode body exhibited the highest temperatures. (Cathode tip temperatures were not measured.) Its temperature increased with discharge current but showed minor changes with discharge voltage. The front of the anode was at the next highest temperature, approaching 500° C at 140 watts of discharge power. These measurements indicated that all components operated at temperatures which are believed to be as not excessive within the discharge power range tested.

Conclusions

The object of this study was to perform a preliminary characterization of the performance capabilities of the 8-cm mercury ion thruster. The thruster was operated with minor modifications with two cathode orifice geometries. Higher then baseline beam currents were attained by operating the thruster at higher discharge currents and propellant flow rates, and lower discharge voltages. The beam current was found to increase generally linearly with decreasing discharge voltage and increasing discharge current when operating with the small cathode orifice size of 0.25 mm. Operation with the large cathode orifice size of 0.73 mm resulted in a two slope discharge voltage-beam current characteristic. Beam currents (or thrusts) of up to 3.8 times the baseline condition of 72 mA were achieved at discharge voltages as low as 22 volts with both cathode configurations. Operation of the thruster at high power levels resulted in mass utilization of up to 92 percent, with the small size cathode ori-

fice. Tests with the larger cathode orifice re-
sulted in lower mass utilization. The ion produc-
tion costs were found to be somewhat higher than
baseline values for both cathode geometries tested.
The thrust and specific impulse increased with in-
creasing input power. Over the range of thruster
operation, a specific impulse of 1950 to 3040 sec-
onds was obtained, whereas a thrust of between 5.3
to 20.4 mN was achieved as compared to 4.8 mN thrust
at the baseline conditions. The highest total effi-
ciency of 55 percent was obtained at a discharge
voltage of 24 volts and thruster input power of
0.49 kW. No attempts were made to optimize thruster
performance.

Spectral line intensities of the atomic mer-
cury, singly and doubly charged mercury ions along
with atomic molybdenum were measured at various
thruster operating conditions. These measurements
and the knowledge of basic sputtering mechanisms
appear to indicate that the lifetime of the molyb-
denum screen grid (one of the major life limiting
components) operated at high discharge power levels
should not be a significant problem.

Also temperature measurements of critical
thruster components have indicated that all tempera-
tures were within safe operating limits.
