### PHYTOPLANKTON ASSEMBLAGES WITHIN THE

## CHESAPEAKE BAY PLUME AND ADJACENT

#### WATERS OF THE CONTINENTAL SHELF

Harold G. Marshall Department of Biological Sciences Old Dominion University

#### SUMMARY

The Chesapeake Bay plume was identified and plotted in relation to the presence and high concentrations of phytoplankton assemblages. Seasonal differences occurred within the plume during the collection period, with *Skeletonema costatum* and an ultraplankton component the dominant forms. Patchiness was found along the transects, with variations in composition and concentrations common on consecutive day sampling within the plume in its movement along the shelf. The presence of 236 species is noted, with their presence indicated for plume and shelf stations during the March, June, and October 1980 collections.

#### INTRODUCTION

The Chesapeake Bay represents the largest estuary on the United States east coast. It extends along a north-south direction from the mouth of the Susquehanna River for approximately 275 km to the Virginia Capes. Typical of other estuaries, it receives outflow and substances from tributaries and other sources along its borders. These products come from agricultural and land run-off, an assortment of industries and municipalities, and shipping and boating activities within its waters. Throughout the year, the degree that these substances are present will often vary in combination with other ecological variables, resulting in a changing milieu more favorable at times to the growth of certain species than others within the phytoplankton community. These responses to changes in water quality and environmental conditions are enhanced by the short life cycle and the potential for rapid growth present in the phytoplankton populations. These population dynamics may then result in a phytoplankton complex that would be characteristic of Chesapeake Bay waters and the effluent that passes to the continental shelf. The initial purpose of this study was to characterize the phytoplankton within the Chesapeake Bay effluent plume in relation to phytoplankton populations over the continental shelf during three seasonal collection periods in March, June, and October 1980. Another goal was to use these assemblages as index species in identifying the passage and eventual breakdown of the plume over

the continental shelf. For definition, the Chesapeake Bay plume is considered as the water outflow from the lower Chesapeake Bay onto the continental shelf which is characterized by certain phytoplankton assemblages present in the lower Chesapeake Bay. In addition, it has subsequently become apparent that these data sets may have additional significance because the collection year (1980) coincided with a period of stream flow into the Chesapeake Bay that was approximately one-half of the water entry for a typical year (ref. 1). The influence of this reduced flow on the water quality and biota is unknown, but is a factor that should be further evaluated in subsequent studies.

Past phytoplankton studies in the lower Chesapeake Bay have identified the major phytoplankters as neritic north temperate species (ref. 2, 3, 4). Seasonal fluctuations in populations are common, with the flora generally dominated by diatoms through fall, winter, and spring, with a combination of diatoms, phytoflagellates, and nanoplankters common in the summer. The importance of Chesapeake Bay nanoplankton has been previously stressed in regard to high productivity values and its composition (ref. 4, 5, 6). Other forms seasonally common to the lower Bay are found over the continental shelf (ref. 4).

#### METHODS

Water samples were obtained from the participating vessels in the Superflux program. These included vessels from the National Marine Fisheries Service of NOAA, Old Dominion University, and the Virginia Institute of Marine Science. Additional launches were provided by the NASA Langley Research Center, the U.S. Coast Guard, and others. All collections were made during March, June and October 1980. These months were originally selected to coincide with periods of high, moderate, and low outflow from the Bay. However, as previously mentioned, this was an atypical year of very low stream inflow, so the quantity of outflow to the shelf was below seasonal averages. Samples for phytoplankton analysis were obtained at stations presented in Figures 1-4. These stations were located within the lower Bay, at the Bay entrance, and eastward to the shelf break and south to Oregon Inlet. Station coordinates, with salinity and temperature values, are also presented in Tables 1-3. In addition to the surface samples taken at each station, a series of vertical collections were also obtained at selected stations during each cruise. Several other side experiments were made, but will not be discussed at this time. Standard hydrographic water bottle casts were used to obtain the samples, of which 500 ml were placed directly in polyethylene bottles containing a buffered formalin solution. Using a settling and siphoning procedure, a 20 ml concentrate was obtained and subsequently examined with a Zeiss inverted plankton microscope. Random fields and minimal numbers were counted at 312X to provide a statistical accuracy of 85% (ref. 7). Species diversity was determined using the Shannon-Weaver diversity index. Identification was in accordance with the classification followed by Hendey (ref. 8) and Parke and Dixon (ref. 9). Salinity and temperature measurements were taken by personnel from the participating vessels. Special acknowledgement is given to Charles K. Rutledge, Stephen Cibik, and Laurie Kalenak for their assistance in this project.

#### RESULTS

During the three collection periods in March, June, and October 1980 a total of 223 water samples were analyzed for phytoplankton composition and concentration. A total of 236 phytoplankters were noted from these collections (Table 4). These consisted of Bacillariophyceae (126), Pyrrhophyceae (74), Haptophyceae (15), Cyanophyceae (9), Chlorophyceae (4), Cryptophyceae (3), Euglenophyceae (2), and Chrysophyceae (3). In addition, there was an unidentified ultraplankton component prominent in the plume and at the near shore stations. The ultraplankton are defined according to the classification given by Strickland (ref. 10), who placed cells within the size range of 0.5 to 10 µm as ultraplankton. These cells consisted of three size groups: less than 3  $\mu$ m, 3-5  $\mu$ m, and 5-10  $\mu$ m. Several samples of these cells exhibited fluorescence when stained with acridine orange and examined under a fluorescent microscope, whereas other cells did not fluoresce. This ultraplankton component is considered to be composed of several species, including coccoid cyanophyceans and chlorophyceans.

Concentrations of the phytoplankton were consistently higher in samples from the lower Bay and the Bay entrance area. Progressing eastward over the shelf there was a decrease in cell numbers and a change in the phytoplankton composition. Most typical was the transition in dominance from diatoms and ultraplankton cells (described above) in the Bay entrance area, to coccolithophores, with another diatom assemblage seaward. Evidence was also found of an increase in phytoplankton concentration near the shelf break. Moving southward from the Bay entrance to Oregon Inlet, the higher phytoplankton concentrations taper off, remaining larger near shore. Evidence for the breakdown of the plume and for mixed populations of shelf and plume phytoplankton increases toward Oregon Inlet. Throughout the collection period the phytoplankton composition within the Bay entrance and the Bay plume contained assemblages that could distinguish the plume from adjacent shelf waters.

## March 1980

The dominant phytoplankton found in Bay entrance waters and the Chesapeake Bay plume included the diatoms: Asterionella glacialis, Cyclotella sp., Skeletonema costatum, Leptocylindrus minimus, a pyrrhophycean Prorocentrum minimum, a cyanophycean Gomphosphaeria aponina, and the ultraplankton group of unidentified cells. In the Bay entrance, the concentration of Prorocentrum minimum was over 1.2 million cells per liter, with Cyclotella sp. at approximately 434,000 cells per liter. The different size categories of the ultraplankton group varied in their concentrations. Cells smaller than 3.0  $\mu$ m averaged approximately 200,000 cells/1 in the Bay entrance and 770,000 cells/1 in the near shelf stations. The cells in the 3-5  $\mu$ m range averaged approximately 100,000 cells/1 in the Bay entrance, with numbers markedly reduced beyond the entrance. The larger sized ultraplankton (5-10  $\mu$ m) did not reach

the concentrations of the other size classes near shore, but had highest concentrations (29,318 cells/1) at far shelf stations.

The phytoplankton composition and concentrations changed beyond the Bay entrance. The cell concentrations dropped significantly, only to increase dramatically at Station 22 where cell counts were over 1.1 million cells per liter. Dominant species at this station, located about 33 km beyond the Bay entrance, consisted of Prorocentrum minimum, several small-sized diatoms, dinoflagellates, cyanophyceans, and the ultraplankton green cells 5-10  $\mu$ m in In a clustering analysis of stations in this study, it was shown that size. Station 22 and Stations 7 and 8 (located in the lower Bay entrance area), which were sampled two days apart, have very close species relationships. This gives the impression that Station 22 waters may represent a pulse, or remnant, of an earlier plume outflow from the Bay. Continuing seaward the phytoplankton concentrations generally decreased. However, there was a population increase farther out over the shelf at Station 3. Here, the cell counts were over 394,000 cells per liter. At this station, small chainforming diatoms were dominant with the most abundant forms being Rhizosolenia delicatula and Thalassiosira nordenskioldii. The diatoms Nitzschia longissima and Thalassiosira rotula and the coccolithophore Emiliania huxleyi were also in high concentrations. A similar composition but in lower cell concentrations was found at the two most distant stations (1 and 2) along the transect.

## Vertical Distribution

Differences were noted in the vertical distribution of the phytoplankton. Similar species composition over the vertical series was found at several of the stations with other stations having a mixed assemblage (Table 5). Leptoculindrus danicus and Leptoculindrus minimus were common dominants or sub-dominants at several of these stations. At scattered surface locations there were also high cell concentrations for Emiliania huxleyi (Station 1), Prorocentrum minima (Station 5), green cells, 5-10  $\mu$ m (Station 22), and Guinardia flaccida (Station 33). When no dominant form was present, the composition was a mixed selection of predominantly diatoms. Species diversity was characteristically lower in plume waters, or where a few species were present in high concentrations. The higher diversity readings were noted in samples where concentrations were more uniform among a greater variety of species. Differences in station counts over the vertical range were mainly attributed to a higher concentration of one or two species that were typically dominant within the vertical sampling range. The unidentified green cells and Prorocentrum minimum were found in highest numbers at the surface, decreasing significantly with depth. With the exception of several samples where a single species dominated the counts, there was a similarity in composition over the vertical range of sampling. This was found in the Bay entrance and at stations located over the shelf.

### Plume Phytoplankton

The outflow from the Chesapeake Bay is directed southward, moving as a narrow band along the Virginia and North Carolina coast (ref. 11). This flow

would be altered seasonally in its extent eastward over the shelf and southward toward Cape Hatteras. The results of the March study associated highest cell concentrations with the plume at the entrance of the Bay, directly south of the entrance (Station 12), with an apparent isolated segment of the plume east of the Bay entrance at Station 22 (Figure 5). Beyond this area eastward increased concentrations of coccolithophores and other typical shelf species occurred. The plume phytoplankton assemblage was distinct for this sampling period in contrast to phytoplankton at the far shelf stations. Various degrees of mixing and phytoplankton patchiness were also identified in the shelf areas.

To summarize the results of the March collections, the dominant constituents of the Bay plume were the unidentified green cells, found in the three ultraplankton size groups. This component was significant in regard to its high concentrations and wide distribution. These were found to be more prevalent in the surface collections, with the majority of these cells believed to be either cyanophyceans or chlorophyceans. The vertical distribution patterns and concentrations of the phytoplankton were generally homogeneous, with the exception of several stations where there occurred high concentrations of single species (and green cells) at surface collections. The plume phytoplankton included Asterionella glacialis, Cyclotella sp., Skeletonema costatum, Leptocylindrus minimus, Prorocentrum minimum, Gomphosphaeria aponia, and unidentified ultraplankton-sized green cells. This assemblage was distinguished from the shelf populations.

## June 1980

Distinct differences were also apparent in the phytoplankton composition of the plume compared to other shelf stations in June 1980. The plume waters of the Chesapeake Bay were identified as extending from the Bay entrance southward and close to the Virginia coastline (Figure 6). The phytoplankton within the plume reached concentrations of over 7.9 million cells/liter. These waters were dominated by diatoms and the unidentified green cells in the 3-5 µm size range. Skeletonema costatum was the major constituent, with sub-dominants being Nitzschia pungens, Leptocylindrus danicus, Rhizosolenia delicatula, and Chaetoceros spp. `The pyrrhophyceans, coccolithophores and other representatives were in low concentrations within the plume. The diversity index for these stations ranged from 0.8351 to 2.1241. Because the sampling protocol placed specific restrictions on each vessel, collections were made over a six-day period, preventing short term synoptic coverage of the area. This was unfortunate because the location of the plume is known to fluctuate in its passage southward (ref. 11). Thus, the data used as a basis to identify the plume in Figure 3 were obtained over a six-day period and do not represent the plume outline for a specific date. Even with these limitations, the direction of plume flow is easily identified as moving south of the Virginia Capes and along the Virginia coastline. These waters apparently favor the growth of Skeletonema costatum and the green cell component. These are plankters of small cell size (ultraplankton) and high reproductive potential. Larger sized diatoms and the pyrrhophyceans were rare

at these stations. A more southern extension of the plume was noted off the North Carolina coast that was separated from the plume directly south of the Bay entrance by an area of lower cell count and mixed composition. The plume segment off the North Carolina coast was dominated by *Skeletonema costatum*, but contained a mixture of other forms, such as *Emiliania huxleyi* which is considered a common shelf species. This mixed composition is accompanied by increased species diversity values. During 23-27 June 1980 another leg of the cruise series was conducted that included stations near the Bay entrance and over the shelf (Figure 3). Even in this abbreviated collection series, large phytoplankton concentrations were noted in an identifiable plume south of the Bay entrance, with these larger concentrations directed southward (Figure 7). These stations have a similar assemblage of dominant species, as was found in the 17-22 June 1980 collections.

There was an increase in the species diversity at stations bordering the plume that ranged from 1.7258 to 2.8403. These waters also differed from the plume by having an increased number of co-dominant species. These included Emiliania huxleyi, Leptocylindrus danicus, the various sized green cells, Chaetoceros sp., Nitzschia pungens, Cryptomonas sp., Gumnodinium sp., and Rhizosolenia fragilaria. The stations nearest the Bay entrance had greater concentrations of Skeletonema costatum and Emiliania huxleyi. in contrast to what was found along the North Carolina coastline. Skeletonema costatum was noted at stations off the Carolina coast nearest to the shoreline. However, green cells that were less than 3  $\mu m$  and 3-5  $\mu m$  in size were the most abundant form in the near shore waters. These more southern plume waters indicate a degree of mixing between shelf waters and the Bay plume by the changing concentrations of Skeletonema costatum and Emiliania huxleyi. The concentrations of Skeletonema costatum in the plume decrease with movement of the plume southward and eastward over the shelf. The mixing and transformation of the plume phytoplankton increase both southward and eastward, with the concentrations of *Emiliania huxleyi* and other coccolithophores increasing.

Stations located near the shelf break and far east of the Bay plume contain a phytoplankton assemblage distinct from the plume waters and the near shelf mixing zone. These stations also show a trend of a decreasing species diversity in comparison to the near shore stations (ranging from 1.4187 to 2.3112). The dominant components at these stations were the coccolithophores with several dinoflagellates and green cells  $(3-5 \ \mu m)$  the sub-dominants. The major coccolithophores were *Emiliania huxleyi*, *Syracosphaera pulchra*, *Rhabdosphaera* sp. and *Pontosphaera* sp. Prominent diatoms included *Rhizosolenia alata*, *R. styliformis*, and *R. delicatula*, with an increased variety of the pyrrhophyceans. These included *Ceratium fusus*, *C. extensum*, *C. tripos*, *C. macroceros*, *Prorocentrum micans*, and *Protoperidinium* spp. The high concentration of coccolithophores in these waters supports the use of appropriate preservatives that would not destroy these populations prior to examination.

High concentrations of cells were commonly found in the sub-surface samples within the Bay plume (Table 6). *Skeletonema costatum* was the major

constituent with green cells  $(3-5 \ \mu\text{m})$  in high concentrations throughout the water column. Species diversity remained low below the surface, having lowest concentrations in the Bay entrance area, increasing slightly below Cape Henry. In the shelf areas on either side of the plume, numerous co-dominants provided a mixture of major species at the various depths that included green cells  $(3-5 \ \mu\text{m})$ , Leptocylindrus danicus, Emiliania huxleyi, and reduced numbers of Skeletonema costatum. The vertical sampling was limited to the surface and 3 meters at the far shelf stations, with the major constituents being the coccolithophores at both depths. The number of different species represented at these stations was much less (56) than at the near shore stations (155).

In summary, the June phytoplankton within the plume contained high concentrations of the diatom *Skeletonema costatum*, in association with unidentified green cells. Sub-dominants included *Chaetoceros* sp., *Cylindrotheca closterium*, *Leptocylindrus danicus*, *Nitzschia pungens*, and *Rhizosolenia delicatula*. The plume extended slightly eastward beyond the Bay entrance, with its flow to the south along the Virginia and North Carolina coastline. There was basically a homogeneous vertical distribution of dominants within the plume near the Bay entrance. This condition gradually broke down with the movement of the plume southward, with increasing numbers of coccolithophores and a decrease in *Skeletonema costatum*. A similar decrease in the various "green cells" within the plume did not occur. Numbers remained high for this group over the near shelf waters between the Virginia Capes and Oregon Inlet.

## October 1980

The highest phytoplankton concentrations for October were found at the Chesapeake Bay entrance (Station 801), off Cape Henry (Stations 69, 803), and to the south (Stations 808, 809, 811). Dominant phytoplankters were Skeletonema costatum and unidentified green cells (<3 microns in size). The concentrations at these stations were generally above a million cells per liter, with the highest counts found at Station 808 (October 15, 1980) where there were approximately 13.8 million cells/liter. South of the False Cape area to Oregon Inlet, the cell counts remained above one million cells/liter at the near shore stations, decreasing in numbers rapidly seaward. The Bay plume appears to extend over these stations, tapering from the area beyond the Bay entrance toward the North Carolina coastline (Figure 8). Beyond this plume area and extending over the shelf, the concentrations of Skeletonema costatum declined, but the ultraplankton component was present in reduced but significant concentrations. Diatoms also found in high concentrations at the plume stations were Asterionella glacialis, Nitzschia pungens, Chaetoceros sp., Lauderia borealis, Leptocylindrus danicus, Nitzschia delicatissima, Rhizosolenia stolterfothii, R. delicatula, R. fragilissima, Thalassiothrix mediterranea, and Cylindrotheca closterium. Other plume phytoplankters were Anacystis sp., Cryptomonas sp., and Emiliania The dinoflagellates were common throughout the sampling area, but huxleyi. were consistently found in low concentrations. An apparent patchiness in cell concentrations and composition was also noted at stations along transects,

with variations in concentrations at some of the same stations on subsequent sampling days.

An example of patchiness occurred on October 15, 1981 along transect Stations 69-805. At Station 802, the total cell count was approximately 121,000 with dominant species being Asterionella glacialis and Chaetoceros costatum. Skeletonema costatum was not found in the sample. At adjacent stations (69 and 803) located approximately 2 km to the east and west, cell counts for both stations were over 2 million cells per liter with Skeletonema costatum at concentrations of 1.9 and 1.7 million cells per liter. In contrast, the pattern along the 808-811 transect on October 15, 1981 indicated a decline in cell concentrations seaward along the first four stations in this series. However, there was a significant rise in population numbers (3.2 million) at Station 811, the station most distant from shore in this transect The presence of Emiliania huxleyi throughout the plume differs (Table 7). from the results of the June samples. This species was more common over the shelf and outside of the plume area in June, with its degree of entry along the peripheral areas of the plume more indicative of the extent of mixing and breakdown of the plume structure.

The shelf waters beyond the area of the plume contained a variety of phytoplankters, with many dominants similar to those in the plume waters. These included Skeletonema costatum, Leptocylindrus danicus, Nitzschia pungens, Anacystis sp., Emiliania huxleyi, and the unidentified ultraplankton components. The composition for the major phytoplankton groups along the transects is given in Table 7. The diatoms consistently have the highest concentrations of cells in the Bay entrance and in the plume directly south of Cape Henry. The green cell component is also significant, becoming more abundant than the diatoms southward. On October 22, samples were taken from an additional 4 stations along a transect from Cape Henry 125 km eastward and beyond the continental shelf. The general pattern in this series, as in the other transects seaward, was a marked reduction in the concentration of the phytoplankton. Cell concentrations dropped from 1.4 million cells per liter at Station 15 off Cape Henry to about 24,000 cells per liter at the far shelf station.

In summary, the dominant species for October at near shore stations and within the Bay plume was *Skeletonema costatum*. Also prominent in the majority of the samples were ultraplankton sized cells which were unidentified but appeared similar to coccoid cyanophyceans and chlorophycean species previously mentioned. The pyrrhophyceans were common but not abundant in the samples. Coccolithophores were common within the plume waters and were the dominant forms in the more distant stations over the shelf. *Cryptomonas* sp. was the dominant species at several stations with several cyanophyceans also abundant in the samples. In general, species diversity reflected the degree of dominance by *Skeletonema costatum* (or the other dominants), being lower where a large population concentration was the product of one or a few species, and usually found near shore. A higher diversity index value was more typical in assemblages of lower population numbers and lacking a significantly dominant form (Station 802).

### PHYTOPLANKTON ASSEMBLAGES

The Chesapeake Bay plume was characterized by its phytoplankton composition and high concentration of cells. Seasonal assemblages within the plume and in adjacent shelf waters for March, June, and October are given in The predominant species throughout the year in the plume waters was Table 8. Skeletonema costatum, in association with certain ultraplankton forms. These included several unidentified round, green cells of three different size groups (<3  $\mu$ m, 3-5  $\mu$ m, 5-10  $\mu$ m) that appear to be coccoid cyanophycean and chlorophycean species. The plume species were dominated by ultraplankton and nanoplankton components, generally characteristic of enriched areas, and capable of rapid growth. Beyond the plume, the shelf waters contained a variety of diatoms, the green cell component, and phytoflagellates, but were generally dominated by coccolithophores. Transects from near shore stations seaward were characterized by decreasing phytoplankton populations, from mainly a diatom floral assemblage to a mixed group with coccolithophores most The coccolithophores were useful indicators of the degree of prominent. plume mixing with the shelf waters for March and June, but to a lesser degree in October, when they were also common in the plume. The dominant species within the plume were similar to species previously noted for waters of this region (ref. 4, 12), with the high concentrations of Skeletonema costatum at near shore stations not unusual (ref. 4, 13). However, a high concentration of Skeletonema costatum was one of the characteristics that identified the The ultraplankton group is also associated with the plume and to a plume. lesser extent the shelf waters outside of the plume. Greater recognition has been given this group in recent years as a common and often major component of estuaries and marine waters (ref. 12, 13, 14, 15). There is need for many of these ultraplankton cells to be isolated, cultured, and identified to assure uniformity in the reporting of these species by various investigators.

The extent and permanence of the plume over the shelf varied during the sampling periods. Generally, there was a bulge area of high cell concentration just beyond the Bay entrance, with the southward extension of the plume close to the Virginia shoreline, tapering off toward Oregon Inlet. Although populations decreased in numbers seaward, there was also evidence along several transects of a moderate increase in cell concentration near the shelf break. Patchiness was also common along transects, indicating areas of both high and low concentrations, or dominant species development, along a series of stations. Significant variations in the composition and concentrations of the phytoplankton were also noted during consecutive-day sampling at the same station. Such changes occurred near shore, at the Bay entrance, and within the plume in its extent south toward Oregon Inlet. This implies a dynamic state for the area, in which water movement will be influenced by local wind patterns, tidal currents, and offshore upwelling and current action. Since the degree to which these activities are present will vary, fluctuations in the concentration and composition of the phytoplankton in these waters may be expected over short time periods, and may be included in the seasonal assemblages.

Table 3. Station coordinates, with surface salinity, temperature and date sampled for October 1980 collections.

•

•

Table 4. Phytoplankton observed during the March, June, and October 1980 Superflux cruises. The degree of numerical dominance for each period, within the plume at the Bay entrance and at shelf stations, is indicated by A, B, C (with A the most dominant) and X noting presence in the samples.
