# PARTICULATE CONTAMINANT RELOCATION DURING SHUTTLE ASCENT 

by

John J. Scialdone*<br>Goodard Space flight Center Greenbelt, Maryland 20771

## Aistract

The dislodgement, venting, and redeposition of particles on a surface in the shuttie bay by the vibrcacoustic, gravitational, and aerodynamic forces present during shuttle ascent have been investigatea. The particles of different sizes which are displaced, vented, and redistributed have been calculated; and an estimate of the increased number of particles on certain surfaces and the decrease on others has been indicated. The average sizes, velocities, and length of time for certain particles to leave the bay following initial shuttle doors opening and thermal tests have been calculated based on indirect data obtained during several shuttle flights. Suggestions for future measurements and soservations to characterize the particulate ervironment and the techniques to imit the in-orbit rarticulate contamination of surfaces and environment have been offered.

## Introduction

The redistribution of contaminant particles in the shuttle bay during ascent and the release to space of some of these particles following the bay doors opening in orbit have been investigated. The pa.ticles are left in the bay volume and on surfaces before launch. They escape cleaning efforts to remove them from the cargo bay and payloads at several stages of the flight preparation. The understanding of these partic?es; redistribution on surfaces and their release in the field of view of an instrument is important in view of the changes they may cause to the thermophysical properties of surfaces on which they deposit and to the optical degradation of the environment in which they may escape. Some of the effects of particles on surfaces and in the environment are: physical obscuration of a surface; scattering of radiation which changes the transmission properties of a surface aid/or a volume; increased diffuse reflection of a surface; emission by the particles of certain radiations which may be detrimental to certain instruments' observations.

Figure 1 shows pictorially the particulate redistribution events which may occur during orbiter ascent. This paper is concerned with the particuiate redistribution during

[^0]launch/ascent and the particles released from the orbiter bay immediately following bay door opening and after certain orbiter operational tests. The particles residing in the bay at launch are dislodged, scattered, and redeposited by vibroacoustic, gravitational, and aerodynamic forces present during orbiter ascent. Some of the released particles are removed by the gaseous venting of the bay through the shuttle vents; others will redeposit on surfaces of the bay according to the surface orientation with respect to the orbiter acceleration vector. In the following, the fraction of particles of different size ranges dislodged, redistributed, and vented are calculated per unit surface area, irrespective of the original particulate distribution coverage. The interchange of particles from a particle-covered surface to another surface has been calculated. The resulting cleaning of one surface and the increased contamination of another surface have been estimated. An estimate of the particles residing on a surface in the shuttle bay when in orbit has been made based on the original particulate conditions before launch. Calculations of the diameters and velocities of the particles released from the orbiter into space immediately following the bay opening and the characteristics of those emitted during shuttile thermal tests and attitude changes have been carried out based on experimental data. Suggestions for future measurements of bay particulate conditions during and inmediately after orbiter ascent have been offered with the intenticn of clarifying the generation and the mechanics of the particles during that phase of flight and of reducing the particulate contamination on future spacecraft.

Figure 1. Particulate contaminant redistribution events.

Particles Adhesion and Displacement Forces during Shuttle Ascent

Particles may be held on surfaces by the following adhesion forces (Ref. l):

1. Van der Waals or molecular forces which are proportional to the particle dimensions; 2. Contact potential differences due to surface effects of dissimilar materials producing electrostatic forces proportional to the two-thirds power of the particle dimensions; 3. Coulomb forces arising from charges produced on the particle by external electric fields; 4. Capillary forces produced by water surface tensions also proportional to the size of the particles.

As concluded in Ref. 1, the adhesion force approaches the Van der Waals force during ascent when the adhesion force may change in a complicated manner. This force from experiments and analyses (Ref. 1, 2, 3 and 4) is expressed as $F=K d$ where $K=130-212$ dynes $/ \mathrm{cm}$. These $K$ values apply to quartz particles of about $50 \mu$ diameter and for a $50-60 \%$ removal fraction of these particles from a glass surface. In this paper, the adhesion force will be assumed, for simplicity and for exploratory purpose, to be

$$
\begin{equation*}
F=200 d \quad \text { (dynes) } \tag{1}
\end{equation*}
$$

where $d(c m)$ is .he particle equivalent spherical diameter.

During shuttle ascent, che particles held on the surfaces will be ac:ed upor by gravity, launch acceleration, vioroacoustic random accelerationi, resonart frequencies accelerations.. :elative motion of surfaces, and gaseous flow momenta. The ranye of particle diameters, which could be relfased from the surfaces by forces equal or greater than the above adhesion force, cari be escimated as follows:
a) Launch Ascelerations

An estimate of the diameters of spherical partisies which can be displaced can be obtained fiom the balance of forces acting on a part:cle of mass $m(g)$ subjected to a force $F=k d(d y n e s)$
and to an acceleration $a\left(\mathrm{~cm} / \mathrm{s}^{2}\right)$; i.e.,

$$
\begin{align*}
& F=m g=m a \text {, so that } m=\frac{F}{a+g} \text { and with the } \\
& \text { substitution of } m=\rho_{p} V=\frac{\pi d^{3}}{6} \rho_{p} \text {, one obtains } \\
& d=\left[\frac{6 K}{\pi \rho_{p}(a+g)}\right]^{1 / 2} \quad(\mathrm{~cm}) \tag{2}
\end{align*}
$$

The particles dislodged by this mechanism would have diameters larger than $d=0.22 \mathrm{~cm}(2200 \mu)$ for $K=200 \mathrm{dy} ., \mathrm{e} / \mathrm{cm}$, acceleration $(\mathrm{a}+\mathrm{g})=39_{\mathrm{c}}$
where $g_{0}=981 \mathrm{~cm} / \mathrm{s}^{2}$, and an average particle density of $\rho_{\mathrm{p}}=2 \mathrm{~g} / \mathrm{cm}^{3}$.

## b) Random Accelerations

For payload systems and components, Goddard Space Flight Center suggests qualifications test levels of 12.9 grms for random vibrations in the range of frequencies of 20 to 2000 Hz (Ref. 5). This level refiects the power spectral density of accelerations for the entire frequency range of excitations. It is a generalized estimate of the response of components of moderate weight attached to a typical structure exposed to vibroacoustic levels in the empty STS cargo bay. The use of this acceleration in equation (2) indicates that the released particles would have diameters greater than 0.122 cm (1220 $)$.

## c) Acceleration of Surfaces at Resonant

 FrequenciesThe maximum acceleration of a harmonic oscillator at resonant frequency $f_{n}$ is $a=4 \pi^{2} f_{n}{ }^{2} x_{0}$ where $x_{0}$ is the amplitude of vibration. The diameter of the particles which could be released by this mechanism is

$$
\begin{equation*}
d=\left(\frac{6 K}{4 \pi^{2} f_{n}^{2} x_{0} \rho_{p} \pi}\right)^{1 / 2} \tag{3}
\end{equation*}
$$

Accordingly, again using $K=200$ dyne $/ \mathrm{cm}$, and $\rho_{p}={ }^{-} . g / \mathrm{cm}^{3}$ ), the particle diameter which could be released is $d=2.2 / f_{n} \sqrt{x}(\mathrm{~cm})$. A $100 \mu$
particle could be released by a following combination of frequencies and amplitudes: $f_{n}=$ 10 Hz and $x_{0}=4.4 \mathrm{~cm} ; f_{n}=10^{3} \mathrm{~Hz}$ and $x_{0}=.048$ $\mathrm{cm} ;$ and $f_{n}=2 \times 10^{3} \mathrm{~Hz}$ and $x_{0}=.012 \mathrm{~cm}$.
A $1 \mu$ particle would require a $f_{n} \sqrt{x}=2.2 \times 10^{4}$ combination of frequency and displacement. As expected, the removal of smaller particies requires higher frequencies and amplitudes.
d) Air Stream Particles Displacement An estimate of the gas venting flow and its velocity is needed to estimate the aerodynamic forces acting on a particle attached to a surface of the shuttle hay. The bay is vented via eight, vents, each having an approximate area of $0.062 \mathrm{~m}^{2}$. The maximum pressure differential $\Delta P$ between the internal bay pressure and the external pressure during launch is approximately 0.7 psi. This differential, which exists for a few seconds, occurs $50-60$ sec into launch, when the external pressure $P_{0}$ is about 9 psi. The
flow at the vents is, therefore, subsciic and can be estimated using Torricelli's equation as

$$
\begin{align*}
Q & =A \psi \sqrt{2 g R T_{0} \frac{\Delta P}{P_{0}}}=24 A \psi \sqrt{\frac{T_{0} \Delta P}{P_{0}}} \\
& =72.3 A \quad\left(\mathrm{~m}^{2} / \mathrm{s}\right) \tag{4}
\end{align*}
$$

where $\psi=0.63$ is ine discharge coefficient, $T_{0}=$ $293^{\circ} \mathrm{K}$ is the gas temperature, and $R=29.26 \mathrm{~m} /{ }^{\circ} \mathrm{K}$ is the gas constant for air.
The flow at each vent is about $4.3 \mathrm{~m}^{3} / \mathrm{s}$; and
the total vent flow is about $34.65 \mathrm{~m}^{3} / \mathrm{s}$. The air velocity at the vent is

$$
\begin{equation*}
V=\alpha\left(\frac{2 g R T_{0} \Delta P}{P_{0}}\right)^{1 / 2}=112.27(\mathrm{~m} / \mathrm{s}) \tag{5}
\end{equation*}
$$

where $\alpha=0.9^{`}$ is the velocity discharge coefficient. Assuming a bay sectional area of about $18 \mathrm{~m}^{2}$, the gas velocity in the bay may be about $3 \mathrm{~m} / \mathrm{s}$. The velocity will be higher within restrictions provided by payloads and systems. For these conditions, the Reynolds number for a particle of diameter $d=10^{-2} \mathrm{~cm}$, gas velocity $V=3 \times 10^{2} \mathrm{~cm} / \mathrm{s}$, air density $\rho=7.83 \times 10^{-4}\left(\mathrm{~g} / \mathrm{cm}^{3}\right)$, and viscosity $\mu=1.84 \times 10^{-4}$ dyne $/ \mathrm{cm}^{2} \cdot \mathrm{~s}$ is $R_{e}=\frac{\rho V d}{\mu}=12.76$. The drag coefficient $C_{D}$ for spherical particle at this Reynoid's number is $C_{D}=24 / \operatorname{Re} \sim 2$
(Ref. 6) so that the drag on a particle having a diameter $\mathrm{d}(\mathrm{cm})$ not too different from
$d=10^{-2} \mathrm{~cm}$, will be approximately

$$
\begin{equation*}
F=C_{D} A \rho \frac{v^{2}}{2}=\frac{\pi d^{2}}{4} \rho v^{2}=84.5 d^{2} \text { (dynes) } \tag{6}
\end{equation*}
$$

The ratio of this force to the Van der Waals adhesion force is about 0.42d. A high gas velocit, ir needed to remove a particle of mocron size from a surface even if only a component of the adhesion force needs to be overcome. Furthermore, the small particles on the surface are submerged, for the most part, in a boundary layer of air where the velocity is slower than in the rest of the gas. Some particles may move some distances along the surfaces in the direction of the air flow, and a very few could leave the surface due to fluctuations of the air velocity in the vicinity of the particle (Ref. 7). In any event, the gas flow provides an additional force to remove from the surfaces and accelerate the particles.

## Particles Displaced During Ascent

These calculations show that very large accelerations are needed for removal of micron size particles. However, test data show that accelerations in the range of those expected during orbiter ascent can release some fractions of the small size particles. Figure 2, taken from Ref. 8, presents test results obtained by several authors showing the fraction of resident particles for each size range that may be released from the surface and put in temporary suspension by certain acceleration forces. As pointed out by the authors, the data are subject to considerable uncertainty and provide order of magnitude indications on real conditions. The data obtained from Ref. 1, 2, 4, and 9 were correlated by Ref. 8 using a statistical method developed by Ref. 1. There are two periods during launch when particles on surfaces have a good probability of being displaced, resettled, and carried into the filter vents. The first period covers about 2 minutes of the iaunch acceleration profile, during which the orbiter accelerates to about $3 g$ and the bay volume is vented to the atmosphere as shown in figure 3. Maximum venting occurs during the transonic region of the flight, when vibration and the pressure differential between bay and the external pressure are it their maximum. The velocity of the exhausting air in the bay as indicated is at about $3 \mathrm{~m} / \mathrm{s}$. The particles originally in the bay volume and those released from the surfaces by vibroacoustic accelerations and by other forces will be engulfed in the exhausting gas flow. As shown later, some of these particles will be carried into the vents; others, the larger ones, will strike and settle on the lower rear of the orbiter on surfaces perpendicular to the direccion of the orbiter acceleration. Those settled on the surfaces will not be dispaced again Decause the direction of the acceleration is in a direction restraining them. The second period, as shown on the acceleration profile, occurs after about 2 minutes into flight when the orbiter resumes its acceleration. The acceleration reaches about $3 g$ at 7 minutes into the flight. It remains constant at that value for about 1 minute, and then it drops to a negligible value.

The vibroacoustic forces during this last propulsive period may be more effective in displacing particles attached to surfaces. The surface tension forces that help in retaining particles on the surfaces may become negligible because of the evaporation of the medium between the particles and the surfaces. In any case, those particles released during this last period will have an acceleration of 3 g and may acquire velocities of about $32 \mathrm{~m} / \mathrm{s}$ at the bay aft-bulkhead, which is about 18 m below the bulkhead.

## ORIGNAL PAGE IS <br> OF POOR QUALTTY

Figure 2. Particle resuspended fraction vs acceleration test data - glass particles on s. steel (Ref. 8).

Figure 3. Acceleration versus time history for ascent phase.

They will remain in the bay in the absence of an effective gas flow and, on striking a surface, may bounce in a zern g environment. The bouncing will continue until their kinetic energies are dissipated by collisions among themselves and by their anelastic collisions with surfaces. An estimate of the particle speeds required for bouncing and or settling is discussed later.

Particles Vented During the
First Two Minutes of Flight
For an estimate of the particles released from bay surfaces that will remain in the bay or will be transported to the vents by the vent gas, an analogy with the cascade impactor design has been used. According to Ref. 10, the separation of particles in a cascade impactor can be characterized by the ratio of the forces of inertia and drag of the particles entrained in the gas jet. The cascade impactor consists of a nozzle through which air laden with particles of diameter $D$ exits at velocity $V$ and of a particle callector plate located perpendicular to the nozzle at a distance $L$. The inertia to drag force is referred as Stokes number, St and is defined as

$$
\begin{equation*}
S t=\rho_{\mathrm{p}} V D^{2} / 18 \mu L \tag{7}
\end{equation*}
$$

where $\rho_{\mathrm{p}}$ is the particle density, $\mu$ is the gas viscosity. It has been found empiricaily that for St~0.2, the probability that a particle of diameter D will strike the collector plate rather than follow the deflected air stream is $50 \%$ and the particle diameter is $D_{50} \sim\left[\frac{\mu L}{\rho_{\mathrm{P}} V}\right]^{1 / 2}$.
The reference indicates that to account for pressure lower than standard, a coefficient $C$ which increases $w$ th decreasing gas density should be included in the denominator of the equation.for $\mathrm{D}_{50}$. Fr.r the shuttle conditions, the Stokes
number--i.e., the ratio of the particle inertia to the drag force--is

$$
\begin{align*}
S t & =2 m g / \rho_{a} V^{2} A C_{D}=\frac{4}{3} \cdot \frac{\rho_{\mathrm{p}} g d}{\rho_{\mathrm{a}} V^{2} C_{D}} \\
& =\frac{\rho_{\mathrm{p}} \mathrm{~d}^{2} g}{18 \mu V} \tag{8}
\end{align*}
$$

where $d(c m)$ is the particle diameter, $A$ its cross sectional area, $\mu$ is the gas viscosity, $V$ is the gas velocity, $\rho_{p}$ the particle density and the drag coefficient $C_{D}=24 / R_{e}=\frac{24}{V d} \frac{\mu}{\rho_{a}}$ consistent with the gas velocity, gas density $\rho_{\mathrm{a}}\left(\mathrm{gr} / \mathrm{cm}^{3}\right)$ and for a spherical particle. The
diameters of the particles having a 50\% probability to follow the gas are then

$$
\begin{equation*}
\nu_{50}=\left[\frac{18}{g} \frac{\mu V}{\rho_{\mathrm{p}}}(\mathrm{St})\right]^{k} \quad(\mathrm{~cm}) \tag{9}
\end{equation*}
$$

The same relation can also be obtained taking the ratio of the particle "relaxation time"
$\tau=d^{2} \rho_{\mathrm{p}} / 18 \mu$ (Ref. 11) to the gas acceleration time, $t=V / g$. The gas acceleration time used for the cascade impactor is $t=L / V$. The substitution of $\mathrm{g}=3 \mathrm{~g}_{0}=2943 \mathrm{~cm} / \mathrm{s}^{2}, \rho_{\mathrm{p}}=2$ $\mathrm{gr} / \mathrm{cm}^{3}$, $\mathrm{St}=0.2$, and $\mu=1.84 \times 10^{-4}$ dynes/ $\mathrm{cm}^{2}$. s indicates that the $50 \%$ diameter is $\mathrm{D}_{50}=$ $3.35 \times 10^{-4}(\mathrm{~V})^{\frac{1}{2}}(\mathrm{~cm})$. The diameter is less than
$58 \mu$ when a max gas venting velocity of
$3 \times 10^{2} \mathrm{~cm} / \mathrm{s}$, which lasts about 5 sec , is used. The definition of $\mathrm{D}_{50}=58 \mu$ may be stated in a
different form: $50 \%$ of particles with diameter less than $58 \mu$ will be transported to the filters and $50 \%$ of those of diameter larger than $58 \mu$ will remain in the bay. However, a general conclusion may be that most of the particles with diameters larger than $58 \mu$ will remain in the bay after this initial period of launch. These could include particles which had become sufficiently large as a result of water supersaturation on them, but that would return to their original small diameters after a subsequent sublimation of the condensate. Supersaturation occurs on critical particle diameters as a result of a rapid, adiabatic gas expansion.

## Particles Released and Retained by a Surface Ouring Orbiter Ascent

The percentage of particles ( $\psi$ ) in each diameter range released from a surface exposed to a 12.9 grms vibroacoustic acceleration, the same as the value employed far testing, is obtained from the figure 2 and is plotted in figure 4. These particles under the orbiter acceleration may fall on lower surfaces, where they will be held by the same acceleration. For the first 2 min of ascent, some of the released particles ( $<58 \mu$ dia.) will be dragged to the vents where those of less than $35 \mu$ dia. will vent out of the bay and those of diameters between $35 \mu$ and $58 \mu$ dia. will remain on the filters (the bay filters have a $35 \mu$ GBR glass bead rating

A tabulation of the percentages of particles released and remaining on the surface for each size range was prepared. The actual number of particles released and retained depends on the
original particle distribution per unit area of the surface. The MIL-STD-1246A defines the product cleanliness on the basis of the number of particles on a component. The number of particles per square foot of surface for all particles of specified size or larger plot as a straight line on $\log$ versus $\log ^{2}$ scales. The particulate cleanliness level is defined by the line crossing the abscissa. For example, Level 750 crosses the abscissa at one $750 \mu$ part. per square foot. Figure 5 shows the number of particles in each range remaining on an upper bay surface, $R_{1}=N_{0}(1-\psi)$, after the initial 2 min acceleration,
based on an assumed initial particulate density $N_{0}$ (particle/ft ${ }^{2}$ ) corresponding to the surface
cleanliness level 750 of the MIL-STD-1246A.
After the initial removal, the second period of acceleration, also having a value of about 13 grms vibroacous+ic acceleration, will release an additional fraction of the particles. The particles remaining on the surface after these accelerations,
$R_{t}=(1-\psi)^{2} N_{c}$, are shown by the lower curve in
figure 5. This shows that a surface will retain a large number of small particles while releasing all particles larger than about 85-90 .

Figure 4. Fraction of particles removed by surface vibration.

> Additional Particles Acnuired by a Surface During Orbiter Ascent

From the same tabulations of the released particles, the particles which may accumulate on a lower bay surface can be evaluated. Figure 6 shows the resulting distribution
$A_{1}=N_{0}(1+\psi)$ on a surface assumed to be at the $\mathrm{P}_{0}$, corresponding to the 750 initial level, which has received particles released from an upper surface also originally at 750 cleanliness level. As a result of the first acceleration, which includes venting, the surface receives only a small fraction of particles less than $58 \mu$, since those were directed by gas flow to the vent filters. The filters stop particles greater than $35 \mu$ (filter sizes) and allows smaller particles to go out of the bay. During the second accelerating period, all the released particles can drop on another surface, since the air flow will no longer remove particles from the bay. As shown by the plot, there is a small additional degradation of the surface receiving and holding those particles; and the total accumulation is
$A_{T}=N_{N}[(1+\psi)+\psi(1-\psi)]$. The degradation is more pron8unced in the distribution for particle greater than $58 \mu$. In fact, in that region, the surface level may change from the assumed 750 Lv to about 800 Lv. However, the new surface cleanliness level acquired by a clean surface (less than Lv 500 ) exposed to the falling particulate during ascent is shown in figure 7. The initial acceleration produces a level of about 700 for the particle range between 58 and $100 \mu \mathrm{dia}$. and 750 for those ranges beyond $100 \mu$. The subsequent second period of acceleration adds the particle of diameters less than $58 \mu$. The distribution for dia. less than $58 \mu$ corresponds to about 500 550 Lv showing the discontinuity in distribution at $58 \mu$.

Figure 5. Particles depletion during shuttle ascent from a surface not facing the acceleration vector, contaminated to a 750 ! v of MIL-STD-1246A.

Figure 6. Particles accumulation during shuttle ascent on a surface facing the acceleration vector at a prelaunch Lv 750, from a depleting surface aiso at 750 Lv with a one-to-one field of view.

Figure 7. Particles accumulation during shuttle ascent on a clean surface (pre-launch Lv 500 ) facing acceleration from a depleting surface at $\mathbf{L v} 750$ - one-to-one field of view.

## Rebounding of Particles and Brownian Motion

The particle; displaced during the early 2 min of the flight and not transported to the filters will settle on surfaces restrained by the orbiter acceleration. During the second phase of the acceleration, additional particies will be shaken from surfaces. Those particles
may acquire relocities given by $v=(2 g h)^{2}$ where $h$ is the fali distance. For a fall of about 18 m and a 3 g acceleration, the velocity is $32.54 \mathrm{~m} / \mathrm{s}$. Those particles with sufficient kinetic energies to overcome the adhesion force potentials and the collision anelastic energy losses will rebound at impact. The rebound may continue for a period of time since, by that time, the orbiter is no longer accelerating. The particles will rebound if their kinetic
energies ( $\frac{1}{2} m v^{2}$ ) exceed the adhesion force potential of the particle on the surface, $P=$ $F Z$ where $F=200 \mathrm{~d}$ is the adhesion force and
$Z=5 \times 10^{-8} \mathrm{~cm}$ is the range of the adhesion force. For conservation of energy and momentum, both linear and angular, the particle will rebound when the vertical velocity component of impact meets the following criteria (Ref. 4).

$$
\begin{equation*}
v^{2}=\frac{2 p}{m} \frac{1-e^{2}}{e^{2}} \tag{10}
\end{equation*}
$$

where $m$ is the particle mass and $e$ is the coefficient of restitution. For a particle of density, $o_{p}=2 \mathrm{gr} / \mathrm{cm}^{3}$ and a conservative $\mathrm{e}=0.8$ for the inpact of a quartz particle on a quartz surface, the particle of diameter $d(\mu)$, will rebound if its velocity is $\mathrm{V}>\frac{32.7}{\mathrm{~d}}(\mathrm{~cm} / \mathrm{s})$. According to these criteria, a $1 \mu$ dia. particle will rebound when its velocity is $V>32.7 \mathrm{~cm} / \mathrm{s}$ while a 100 u dia. rebounds when $V>0.327 \mathrm{~cm} / \mathrm{s}$. Eventually, the particles on colliding with the surfaces will stop when the above criteria have been met. However, the particles in the bay will be engulfed in a gaseous density produced by the outgassing whir.i may be equivalent to about $10^{-2}$ torr pressure, 1 hour after launch. At this pressure, the mean free path of the molecules is $\lambda \sim 2 \times 10^{-1} \mathrm{~cm}$ and the mean velocity of the molecules is $4.5-5.0 \times 10^{4} \mathrm{~cm} / \mathrm{s}$. The mean time between collisions is about $4.2 \times 10^{-6} \mathrm{sec}$. Therefore, many collisions will occur between molecules and particles during the 1-2 hours of closed bay door conditions. The particles will be losing energies and will randomly move following a Brownian motion with mean velocities according to statistical mechanics and thermal energies of $v=\left[\frac{3 K T}{m}\right]^{t}$. This mean velocity amounts to $0.11 \mathrm{~cm} / \mathrm{s}$ for a $1 \mu$ dia particle and $3.5 \times 10^{-3} \mathrm{~cm} / \mathrm{s}$ for a $10 \mu$ dia particle at $\mathrm{T}=293^{\circ} \mathrm{K}$.

The diffusion coefficient of these particles is

$$
D=\frac{k T}{3 \pi \eta d}=\frac{2.4 \times 10^{-7}}{d} \quad\left(\mathrm{~cm}^{2} / \mathrm{s}\right)
$$

Wiに~s $d(\mu)$, and they may travel a mean distance of $X=(D t)^{1} \mathrm{~cm}$. Then, a $1 \mu$ particle during an hour could travel a distance of 0.3 cm and a $100 \mu$ dia of 0.03 cm . Therefore, some of the particles in the range of $1-100 \mu$ diameter, having lost most of their initial kinetic energies on bouncing, may be randomly moving among the outgassing molecules, traveling at very low speeds for short distances without contacting a surface. Small accelerations provided by the orbiter attituae changes should have negligible effect on the floating narticles in the bay. A measure of their response to disturbances is provided by the particle relaxation time, $\tau=d^{2} \rho_{p} / 18 \mu$ already mentioned.
As expected, small particies respond immediately to changes, while larger ones have very long
response times $\left(1 \mu \mathrm{dia}, \tau=10^{-5} \mathrm{sec} ; 10 \mu\right.$,
$\tau=10^{-3} \mathrm{sec}$ ).

## Particles Leaving the Orbiter Bay - Experimental Data

When the orbiter bay doors are opened, the particles moving randomly in the bay will diffuse out of the bay. The particle depletion can be represented by the following differential equation

$$
\begin{equation*}
v \frac{d n}{d t}=-n v A \tag{11}
\end{equation*}
$$

where $V \sim 1 \times 10^{4} \mathrm{ft}^{3}\left(2.83 \times 10^{8} \mathrm{~cm}^{3}\right)$ is the bay volune, $A \sim 86 \times 10^{6} \mathrm{~cm}^{2}$ is the bay doors' aperture area, $n\left(\mathrm{~cm}^{-3}\right)$ is the particles' concentration, and $v(\mathrm{~cm} / \mathrm{s})$ is their velocities. The solution of the equation for an initial density,

$$
\begin{align*}
n_{0} \text { at } t & =0 \text { is } \\
n & =n_{0} \exp \left(-\frac{A v t}{V}\right) \\
& =n_{0} \exp (-t / \tau)\left(c m^{-3}\right) \tag{12}
\end{align*}
$$

where $\tau=\frac{V}{A v}$ (hr) is the e-folding time. Also, the rate of particles leaving the bay is

$$
\begin{equation*}
\frac{d n}{d t}=-\frac{n_{0}}{\tau} \exp (-t / \tau) \quad\left(\mathrm{cm}^{-3} h r^{-1}\right) \tag{13}
\end{equation*}
$$

The on-orbit particle environment has been probed with the camera-photometer during the STS-2,3,4 and STS-9 missions. The cameraphotometer, which is one of the measuring instruments of the Induced Environmental Contamination Measurements (IECM) package, takes on film $32^{\circ}$ FOV stereo pictures of particles as small as $25 \mu$ at a distance of 20 m when the particles are illuminated by the Sun against the dark sky or Earth background. Figures 8 and 9 (Ref. 12, 13, and 14) show the time history of the particles seen by the camera during those missions. Figure 8 indicates the percent number of frames showing particles versus time for the first 48 hours of flight. The percentage of frames showing more than 10 particles/frame appears to drop with an e-folding time of about 9.5 hrs . The bay doors in these flights have been opened at about 2-2.5 hr mission elapsed time (Met), and the frame takings have been initiated at about 4.5 hrs Met. Particles from water dumps and other operations are not recorded in these frames. The same plot for the STS -9 mission, figure 9 , shows an e-folding time, which has been estimated to be about 15 hrs . Figure 9 shows also a second burst of particles with a corresponding decay. This second event, which started at 55 hrs MF. F , will be discussed latar. Using the time conrtant of $\tau=9.5 \mathrm{hrs}$ for missions STS 2-3-1, and the time constant definition, one calculates that the average velocity
of the escaping particles was

$$
V=\frac{V}{A \tau}=3.45 \times 10^{-1} \mathrm{~m} / \mathrm{h}\left(9.61 \times 10^{-3} \mathrm{~cm} / \mathrm{s}\right)
$$

Figure 8. Summary of particulates observed during the first 48 hours of STS-2,--3, and -4. (Ref. 12).

Figure 9. Percentage of STS-9 camera-photometer frames showing particles (ref. 14).

The average mass of the particle can be estimated by equating its kinetic energy to its theriflal energy. The average mass of the above particles at a temperature of $T=298^{\circ} \mathrm{K}$ is $\mathrm{m}=$
$\frac{3 K T}{V^{2}}=1.33 \times 10^{-9}$
where $K=1.38 \times 10^{-16} \mathrm{ergs} / \mathrm{K} / \mathrm{g}$
is the Boltzmarin constant.
The corresponding average diameter of the
particle of density $\rho_{\mathrm{p}}=2 \mathrm{gr} / \mathrm{cm}^{3}$
is $d=\sqrt[3]{\frac{6 m}{\pi \rho_{p}}}=1.09 \times 10^{-3} \mathrm{~cm}(10.9 \mu)$
For the STS-9 time constant of $\tau=15 \mathrm{hrs}$, the corresponding calculated particle parameters
are: velocity $v=6.08 \times 10^{-3} \mathrm{~cm} / \mathrm{s}$; mass
$m=3.32 \times 10^{-9} \mathrm{~g}$ and diameter $\mathrm{d}=2.48 \times 10^{-3} \mathrm{~cm}$ ( $14.8 \mu$ ). From the above equations, one can calculate that the concentration of particles remaining in the bay will be $1 \%$ of the initial after $4.6 \tau$; i.e., after 43.7 hrs for the STS 2-3-4 missions and 69 hrs for the STS-9. After those elapsed times, the likelihood of not seeing particles is $99.48 \%$. These calculations appear to confirm the data points and likelihood plots shown in the tivo figures. One should note that the calcuiated average diameters of the particles leaving the bay, 10 and $15 \mu$, are small and must have been released during the second period of acceleration; otherwise they could have been vented out by gas flow. Furthermore, figures 10 and 11 of Ref. 12, 13, and 15 show the distribution of particles collected on the IECM passive sample array, which was positiuned perpendicular to the $Z$ axis (parallel to the bay doors). The plots indicate three principal peaks near 4, 12, and $22 \mu$ diameters which are within the statistical distribution of the
diameters calculated here. The justification for those particles having deposited on the array may be that they had lost their energies by collisions and settled on the array surface on which they had impinged. The drift velocities of the particles leaving the bay have not been measuren. The velocities of the particles, as estimated from the camera photometer observations, are mucn higher than these calculated drift velocities.

Figure 10. Passive sample array particle distributions (Rets. 12, 13, 15).

Figure 11. Passive sample array: particle-size distributions for STS-4, combined mission operations (Refs. $12,13,15$ ).

The rate of particles leaving the bay is

$$
\begin{equation*}
\dot{n}=-\frac{n_{0} V}{\tau} \exp (-t / \tau)\left(h r^{-1}\right) \tag{14}
\end{equation*}
$$

where $\dot{n}\left(h r^{-1}\right)$ is the rate at time $t(h r)$, $n_{0} V$ (particle) is the total number of particle
at time zero and $\tau$ (hr) is the time constant. The ime requitred for the rate to drop to a value $n$ is $t=-T \ln n_{0}(h r)$, which requires a knowledge of $\tau$ and of $\hat{\Pi}_{0}$, which is the density of drifting particles in the bay when doors are opened.

From the above calculations indicating wricies of mean diameters of $10-15 \mu$ drifting out of the
bay at velocities of $9-6 \times 10^{-3} \mathrm{~cm} / \mathrm{s}$, one may also conclude that particles greater than thret to four times the above diameters released during the last stage of the orbiter acceleration lose sufficient energy and settle on surfaces.

## Other Particles Ejected from Bay

The camera photometer data in figure 9 indicate a recurrence of particles in the field of view at about 55 hr Met of the STS -9 mission when the inftial particle emission appeared to have subsided. That emission cook longer than the first to decay and appeared to have a time constant of the order of 75 hrs . The reason for this second emission not experienced on other flights may be found by comparing the frames with particles plot versus time of figure 9 with the plot of figure 12 . Figure 12 shows the tempersture of the Quartz Crystal Microbalance (QCM), which measured in bay molecular contamination and indicates shuttle attitudes and other operations versus time experienced during that flight mission (Ref. 16). A shuttle cold test was carried starting at about 34 hr Met and terminating at about 57 hrs. The QCM temperature had dropped to $-83^{\circ} \mathrm{C}$ at that time. The cold test was followed immediately by multiple attitude changes lasting till about 85 hours Met. The attitude changes were resumed at 95 hrs MET, but these were not preceded by the cold test followed by the sudden increase in temperature as had occurred at 57 hrs Met. A close examination of the frame plot in figure 9 shows a corresponding behavior for particle emission. At about 55-57 hours, there was a sudden increase af frames with particles, which lasted up to 55 hr Met. During that period, a drop of frames with particles is not apparent. A decay does appear after 95 hrs Met, which may be estimated to have a time decay of $50-75 \mathrm{hrs}$. Using the same procedure as before, the velocity of these particles at a temperature of 273 K and for a $T=60 \mathrm{hrs}$ is $1.52 \times 10^{-3} \mathrm{~cm} / \mathrm{s}$. The corresponding mass is $4.89 \times 10^{-8} 9$, and the mean diameter is $36.2 \mu$. These particles, larger than those calculated for the initially released
particles ( $10-15 \mu$ ), must have been generated by the sudden temperature excursions and the attitude changes. Motions experienced by the shuttle immediately before and during particle release, differential thermal displacements of materials, contractions and expansions of surface occiusions, and friction between surfaces could have generated these larger particles. Speculation that the particles seen in the camera field of view during this period could have been produced by frozen water particles exhausted from the attitude control engines and from water dumps should be excluded. Those frozen ice particles would have considerable exhaust velocities and would have dispersed rapidly, not remaining in the field of view for hours. In fact, water dumps particles were observed to have e-folding times of about 5 min as shown in figure 13, Ref. 12.

Other particle release mechani,ims should be investigated, such as: the diminished attraction force of particles on surfaces, thermal shock desorption of particles, meteoritics impact release and generation of surface particles, radiometric force, and electric fields changes reducing the coulombic forces between particle; and surfaces.
:fcles Velocities as Seen oy the Camera/Photometer

The particles leave the shuttle bay along randort directions and at velocities of $6-9 \times 10^{-3} \mathrm{~cm} / \mathrm{s}$. When outside of the bay, they are acceleroted by drag forces caused by the rarefied atmosphere at density $\rho_{a}$. The acceleration of a particle of
diameter $d$, density $\rho_{p}$, moving at the velocity $v$ of the orbiter, ignoring the particle small exit velocity, is

$$
\begin{equation*}
a=\frac{F}{m}=\frac{3}{4} C_{D} \frac{\rho_{p}}{\rho_{p}} \quad \frac{v^{2}}{d} \quad\left(\mathrm{~cm} / \mathrm{s}^{2}\right) \tag{15}
\end{equation*}
$$

The drag coefficient $C_{0}$ depends on the ratio of the speed of the particle and those of the natural particle and on the specular or diffuse refiectivity of the particles (Ref. 17). Its vaiue varies between 2 and 4 and the acceleration is $a=\frac{\rho_{a}}{\rho_{p}} \frac{y^{2}}{d}$ if one assumes, for simplicity, $C_{D}=2.66$. The particle should acquire a

Figure 12. IECM CQCM surface contamination measurements and sensor temperature (Ref.16).
velocity $v=(2 a L)^{1}$ with respect to the orbiter in the direction of the acieleration, where $L$ is the distance the particle travels parallel to the orbiter. The distance depends on the distance $r$ of the particle from the observation point (bay) and on the FOV angle $\alpha$ of the obse'ver. It is approximately, $L=2 \operatorname{rtn} \alpha / 2$ and the observed velocity is then

$$
\begin{equation*}
v=\left[4 \frac{\rho_{a}}{\rho_{p}} \frac{y^{2}}{d} \text { rtn } \alpha / 2\right] t \quad \mathrm{~cm} / \mathrm{s} \tag{16}
\end{equation*}
$$

indicating that the velocity is proportiorial to the square root of the ratio of the observation distance to the particle diameter. The camera photometer with a FOV angle of $\alpha=32^{\circ}$, taking abcut 24 frames/hour would have indicated, for a 25 u particle, a velocity of $1.49 \mathrm{~m} / \mathrm{s}$ if photographed at 20 m distance and $0.33 \mathrm{~m} / \mathrm{s}$ if at 1 m distance. The numerical values for the other parameters for the calculations are $\rho_{p}=2$
$\mathrm{gr} / \mathrm{cm}^{3} \rho_{\mathrm{a}}=7.65 \times 10^{-14} \mathrm{gr} / \mathrm{cm}^{3}$ at 241 km orbit
(Ref. 18), and $V=8.5 \times 10^{5} \mathrm{~cm} / \mathrm{s}$. These calculated velocities seem to be confirmed by the recent evaluation of the camera photometer measurements (Ref. 19) and are in good agreement with those reported for the Skylab (Ref. 20). When out of the bay, the particles will be accelerated and will be losing energy with respect to the orbiter. The particles move away from the orbiter and enter eccentric orbits. As seen from the orbiter, the particles will move down behind and then in front of and up the orbiter. The continuous loss of energy by rag will lower the particles orbit continuousiy changing their distances from the orbiter. Figure 14, taken from Ref. 21, shows the orbits as a function of time and distance for a 100 dia particle released from a spacecraft with a velocity of $3 \mathrm{~m} / \mathrm{s}$ at various angles from the orbit zenith. Other orbit plots in terms of directions, velocities, drag coefficients, and time are shown in Ref. 22, 23, and 24.

## Summary and Conclusions

Particulate contaminants on shuttle bay surfaces and on surfaces of payloads carried by the shuttle will be resuspended during shuttle ascent ty vibroacoustic, gravitational, and aerodynamic loadings.

Random mechanical accelerations of about 13 g ms in the frequency ringe of 20 to 2000 Hz experienced during ascent by surfaces and systems are expected to release from surfaces all the particles in excess of $80-90 \mu$ dia. and only $1-2 \%$ of particles less than $10 \%$. These particles--depending on the direction of the releasing surface with respect to the acceleration vector--will fall back on the surface, fail on another surface properly
positioned with respect to the velocity vector, or be transported to the vent filters. Also, if they have sufficient falling kinetic energy, they may bounce from surface to surface until efther they deposit on a surface or are entrained by the outgassing molecules in the bay acquiring the energy of the outgassing molecules which will be colliding with them. The particles not deposited will be moving randomly in this relatively tcnous gas oniy rarely hitting surface.

Two periods of releasing and resetting of particles are envisicned. During these two ? •Iods, the random acceieration forces have limeynitudes of about 13 g rms including some peak magnitudes of about 39 g .

An initial number of particles will be released during the initial 2 min of ascent while venting of the bay volume is occurring. During the transonic region of flight with max mechanical disturbance at the surfaces and max vent velocity in the b:y, released particles less than abjut $58 \mu$, will be entrained by the gas flow. Most of them may be directed to the vents where they are trapped if greater than about $35 \mu$. Others $c$ apped in a turbulent flow will remain in random motion in the bay.

Figure 13. Particle count decay after water dump termination (Ref. 12).

Figure 14. Trajectories as viewed from the spacecraft are given for a dust particle with $r_{d}=100 \mu \mathrm{~m}$ and $\mathrm{V}_{o}=3 \mathrm{~m} / \mathrm{sec}$ at a $350-\mathrm{km}$ altitude and average atmospheric density. The tick marks represent times of $100 \mathrm{sec}, 500 \mathrm{sec}, 1000 \mathrm{sec}, 1500 \mathrm{sec}$, 2000 sec, etc. $\theta$ is the angle from the zenith of the initiai particle velocity vectcr $\mathrm{V}_{o}$. (Ref. 21).

Released particles greater than $58 \mu$ will resettle on the surface of origin if the surface is normal and facing the velucity vector. Those released from surfaces parallel and/or not facing the velocity vector will drop on surfaces facing the vector by virtue of the shuttle acceleration.

During the second stage of the ascent, which terminates about 9 min after iaunch, additional particles are released and resettled. Aerodynamic drag in the bay is no longer effective in moving particles; and those released either will be accommodated on the surface by the shuttle acceleration or will be floating about in the bay in a zerc $g$ environment.

The followiny particle redistributions may be expected during launch in the shuttle or in an instrument:

- A surface facing opposite the acceleration vector will lose particles as it cleans up. In orbit, that surface will have slightly less particles in the size range up to $36 \mu$ and considerably less particles of larger size than it had at launch. No particle greater than about $90 \mu \mathrm{will}$ be left on that surface.
- A surface looking into the velocity vector and located toward the rear recovers its own acceleration released particles and collects particles released from other surfaces which
are accelerated toward the rear of the shuttle or of the instrument. The increased number of particles on these surfaces are mainly those of diameter greater than $58 \mu$. The number of particles per unit area may double for this range if there is a one-to-rne view factor between the rejecting and accepting surfaces. If the area of the surfaces releasing particles is $k$ times the area of those surfaces receiving particles, then the accommodation is approximately K times the or for the one-to-one view factor. For the shuttle bay, the distribution per unit area on the aft surface of the bay may be approximately 18 times that for the double distribution obtained for the one-to-one view factor.
- A relatively clean surface (less than Level 500) will be contaminated with particles from other surfaces greater than $58 \mu$, and with few particles with diameters between 58 and $5 \mu$.
- The redistribution of particles on surfaces assumed to have ar initial distribuition of particles corresponding to Level 750, with a surface correspondence of a one-tc-one, has been indicated. These assumptions can be changed since the losses and gains of particles are provided in terms of the percentage of the density/unit area in the specific particle size range. The gain on à unit surface can be estimated by modifying the results for a one-to-one relation by the area ratio of the surface losing to the one gaining particulates.
- Some small particles $<58 \mu$, which did not enter the vents or were released during the second phase of acceleratior, are entrained in the outgassing molecules and move randomly in the bay where the outgassing mean free pach is a few tens of cm . After about 2 hours in orbit when the bay doors are opened, those particles which have mean diameters of $10-15 \mu$ 'eave the bay with
average velocities if about $1 \times 10^{-2} \mathrm{~cm} / \mathrm{s}$. Outside of the bay, these particles are decelerated with respect to the orbiter by drag forces and will be moving away from the velocity vector. The camera-photometer observing these particles at various distances from the bay will see the particle moving at about $1.5 \mathrm{~m} / \mathrm{s}$ if the particle is $20 . \pi$ away and abcut $0.33 \mathrm{~m} / \mathrm{s}$ if at 1 m away. These bay released particles lose energy with respect to the shuttle and enter a different orbit.
- Particles of mean diameter of about $36 \mu$ which had deposited on surfaces and/0r did not leave the bay will be made to leave the bay at velocities of $1.5 \times 10^{-3} \mathrm{~cm} / \mathrm{s}$ by
thermally induced effects. Thermal shock, differential thermal expansions, friction between surfaces, photodesorption, thermophoresis, desorption from surfaces, and other mechanisms can be the cause of these additional emissions, which have been observed by the camera photometer in one of the shuttle flights.

## Recommendations

1. Clean the bay surfaces and payloads to optimum level of cleanliness before launch. Protect the clean surfaces whenever possible.
2. Surfaces normal to the acceleration vector should be as clean as possible, since they will receive additiona? particles from otner surfaces above them not facing the acceleration vector.
3. The bay doors shnuld be opened as soon as possible to allow particles fioating in the bay to exit. This will limit the settling of those particles on surfaces.
4. Provide particulate shielás, cceers, and doors on surfaces normal to acceleration. The covers should firmly enclose the protected surface preventing particles carried by turbulent venting flow from entering the spacing between cover and surface.
5. Optical observations out of the bay should be carried out after the source of particles leaving the bay is depleted. The time constant ( $1 / \mathrm{e}$ drop in number) is about 10-15 hours. The time to wait for the number of particles leaving the bay to be a few percent of the initials is therefore 40-50 hours after bay opening. This delay in observation may also be necessary after an initial thermo-shock of the shuttle bay.
6. Suggested measurements and data collections which may provide additional understanding of the release and redistribution of particles in the bay are:
a. Photomicrograph control surfaces located on bulkhead and aft of the bay, before launch, after rocket boosters' separacion ( 2 min ), after tank separation. Analyze these photos for particles redistributions as a function of ascent stages.
b. Analyze the particulates on a filter vent before launch and in orbit. The sample filter could be replaced in orbit and returned to ground in a protected enclosure.
c. Inspect and check visually for particulate deposits in the aft bay and bulkhead after shuttle flights to note gross differences in deposits.
d. Use particle deposition instruments located at strategic locations in the bay and
timed to operate at specific periods of the ascent to provide particulate density data in the bay at various times.
e. Use QCMs with sticky surfaces to collect particulates at various bay locations during ascent.
f. Use optical systems to get data on particulate density in the bay as a function of time while bay doors are closed and when opened.

| 16. Abstract <br> The dislodgement, venting and redeposition of particles on a surface in the shuttle bay by the vioroacoustic, gravitational, and aerodynamic forces present during shuttle ascent have been investigated. The particles of different sizes which are displaced, vented, and redistributed have been calculated; and an estimate of the increased number of particles on certain surfaces and the decrease on others has been indicated. The average sizes, velocities, and length of time for certain particles to leave the bay following initial shuttle doors opening and thermal tests have been calculated based on indirect data obtained during several shuttle flights. Suggestions for future measurements and observations to characterize the particulate environment and the techniques to limit the in-orbit particulate contamination of surfaces and environment have been offered. |  |  |
