| 16. Abstract<br>The objective of the Elevated Temperature Crack Growth Program is to evaluate proposed nonlinear fracture mechanics methods for application to hot section components of aircraft gas turbine engines. Progress during the past year included linear-elastic fracture mechanics data reduction on nonlinear crack growth rate data on Alloy 718. The bulk of the analytical work centered on thermal gradient problems and proposed fracture mechanics parameters. Good correlation of thermal gradient experimental displacement data and finite element predictions was obtained. |  |   |           |

## 1.0 INTRODUCTION

Critical gas turbine engine hot section components such as blades, vanes, and combustor liners tend to develop minute cracks during the early stages of operation. These cracks may then grow under conditions of fatigue and creep to critical size. Current methods of predicting growth rates or critical crack sizes are inadequate, which leaves only two extreme courses of action. The first is to take an optimistic view with the attendant risk of an excessive number of service failures. The second is to take a pessimistic view and accept an excessive number of "rejections for cause" at considerable expense in parts and downtime. Clearly it is very desirable to develop reliable methods of predicting crack growth rates and critical crack sizes.

To develop such methods, it is necessary to relate the processes that control crack growth in the immediate vicinity of the crack tip to parameters that can be calculated from remote quantities, such as forces, stresses, or displacements. The most likely parameters appear to be certain path-independent (PI) integrals, several of which have already been proposed for application to high temperature inelastic problems. A thorough analytical and experimental evaluation of these parameters needs to be made which would include elevated temperature isothermal and thermo-mechanical fatigue, both with and without thermal gradients.

Investigations of fatigue crack growth under elastic-plastic condition should consider the impact of crack closure on the appropriate crack growth model. Analytically, this requires the use of gap elements in a nonlinear finite element code to predict closure loads. Such predictions must be verified experimentally through detailed measurements; the best method for measuring crack closure has not been established in previous studies.

It is the purpose of this contract (NAS3-23940) to determine the ability of currently available PI-integrals to correlate fatigue crack propagation under conditions that simulate the engine combustor liner environment. The utility of advanced fracture mechanics measurements will also be evaluated and determined during the course of the program. These goals are to be accomplished through a nine task, combined experimental and analytical program. To date, an appropriate specimen design, a crack displacement measurement method, and boundary condition simulation in the computational model of the specimen has been achieved. Computational verification of the path-independence of the proposed integrals has been demonstrated for isothermal and thermal gradient cases. Also, the experimental testing and data acquisition is continuing. Tensile and cyclic tests were run at several strain-rates so that an appropriate constitutive model could be developed. The experimental data include cyclic crack growth tests under isothermal, thermo-mechanical, and thermal gradient conditions. This report summarizes the contractual efforts during 1986.

## 2.0 EXPERIMENTAL PROGRAM

Alloy 718, a  $\gamma$ - $\gamma'$  nickel-base superalloy, has been selected as the analog material for this program because over the temperature range from 800 to 1200°F, it shows very large changes in creep behavior. This permits the use of Alloy 718 to simulate the behavior of combustor liner materials while still performing experiments at a relatively low temperature. Tensile, creep and cyclic constitutive tests have been performed over the temperature range from 70 to 1200°F. Even though this material can experience large amounts of creep deformation at the upper end of this temperature range, the tensile and cyclic tests showed little evidence of strain rate sensitivity on constitutive response. Figure 1 shows the resultant tensile stress strain curves determined for 70, 800, and 1200°F. Tensile curves were also determined at 900, 1000 and 1100°F. These curves were used during the analysis of the temperature gradient tests which are described later in this report. In addition to the tensile data, the cyclic and creep data have been analyzed and are ready for use in future analytical efforts.

## 2.1 DATA ANALYSIS

The crack growth tests have been performed using a single edge notch (SEN) specimen with buttonhead grips. The width and thickness of the gage section is 0.4 and 0.1 inch, respectively. Detailed descriptions of the specimen, testing procedure and finite element analyses have been described previously [1]. The SEN tests were performed in a strain control mode with the experimental setup shown schematically in Figure 2. The controlling extensometer was mounted at the center of the 0.4 inch wide surface of the specimen. The other two displacement gages, one to monitor crack mouth opening displacement and one to monitor the back face deflection, were also used. The controlling and back face extensometers had a gage length of 0.5 inch and the crack mouth gage had a gage length of 0.03 inch. The crack length was monitored using a DC potential drop technique. The hysteresis loops from these tests [1] were open, indicative of large net section non-linear deformation (i.e., plasticity and creep).

Data analysis techniques were developed for analyzing the isothermal and TMF displacement control crack growth rate data. These data which are collected automatically in real time during the test include load, the three displacements, potential drop measurements, and temperature. One facet of the data analysis software is to detect closure as a function of crack length using the digital load displacement data. Using the developed software the 1000°F tests with a mean strain of zero ( $A\epsilon = \infty$ ) have been analyzed. These include a single tests with a strain range of 0.5 percent and duplicate tests with strain ranges of 1.15 and 1.7 percent. Figure 3 shows the crack lengths as measured with a DC potential drop

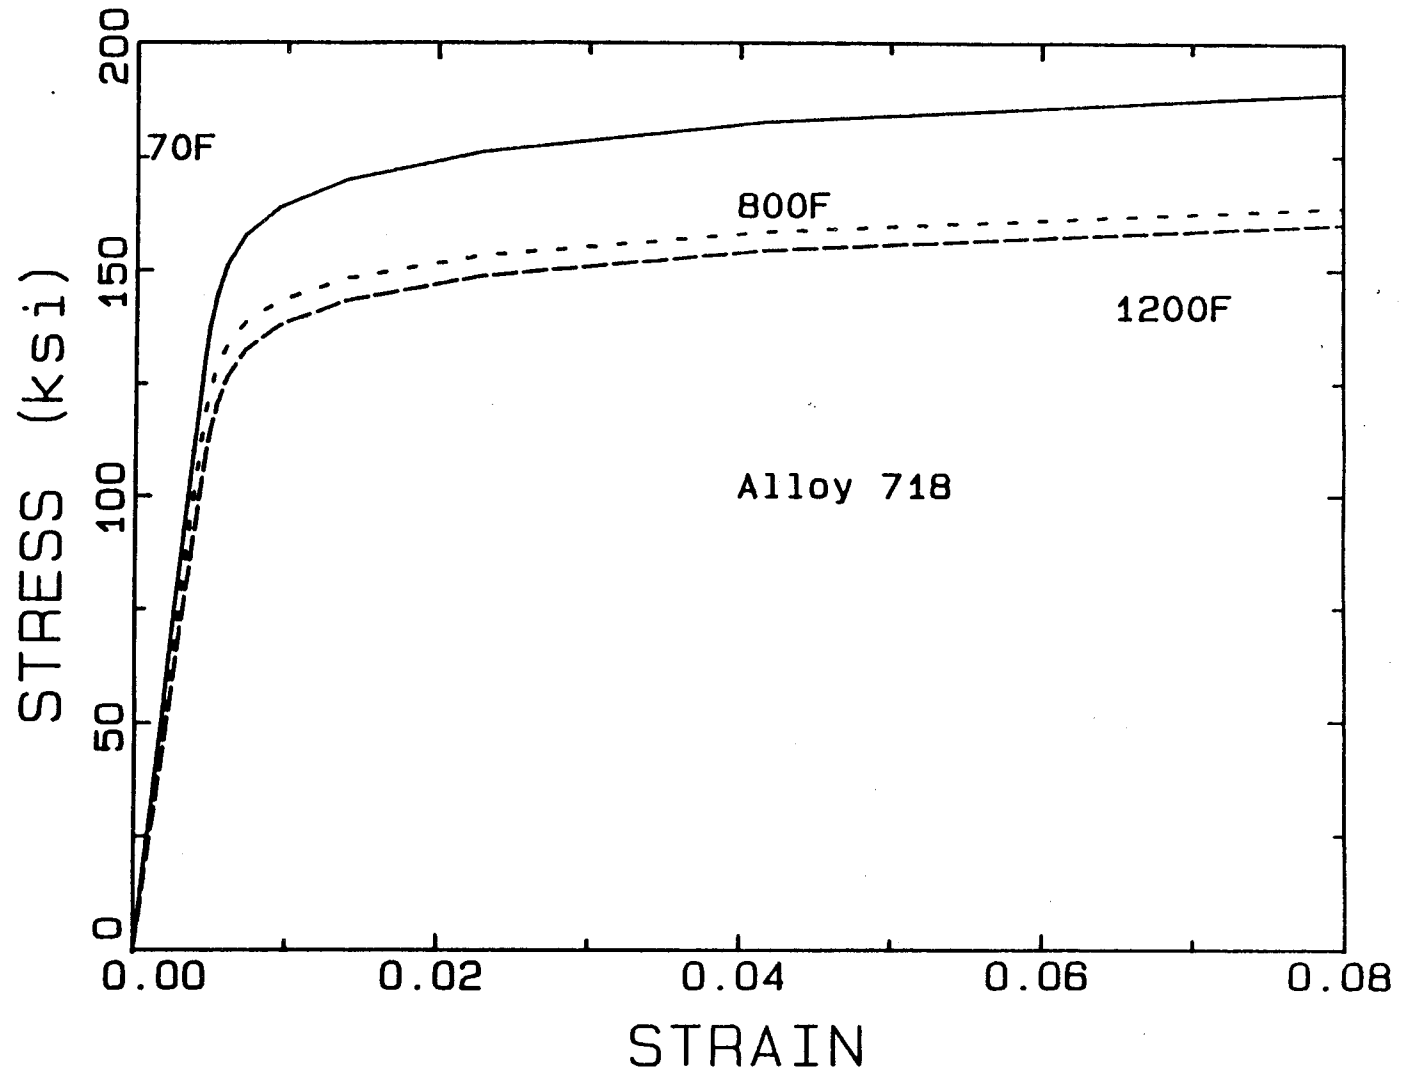

Figure 1. Temperature Dependence of the Monotonic Stress-Strain Curves of Alloy 718.

Figure 2. Schematic Drawing of SEN Test Method.

Figure 3. Variation of Crack Length with Cycles in Displacement Controlled SEN Tests.

technique plotted as a function of the number of cycles. These data show the excellent reproducibility of the test method. The cracks for the highest strain range grew extremely rapidly. The number of cycles used to propagate the cracks from a 0.01 inch deep EDM slot to over 0.3 inch in length required 95 and 100 cycles for the two 1.7 percent strain range tests. This extremely rapid crack growth rate makes measurement of current crack length and crack growth rate susceptible to large errors. Due to a malfunction in one of those tests during startup, its data is questionable. In subsequent figures, the data from that specimen will not be shown. Subsequent figures do not label the data from each strain range separately but use the same symbols used in Figure 3- "x" symbols, squares, and triangles represent data from 0.5, 1.15, and 1.7 percent strain range tests.

Figure 4 shows the variation in crack growth rate as calculated using a seven point sliding polynomial technique with crack length. The crack growth rates increase, pass through a maximum, and finally diminish with increasing crack length. These tests were run in remote displacement control and experienced changes in both load range and mean load as the crack grew. The degree of load drop can be observed in Figure 5 which plots the maximum value of  $K$  ( $K_{max}$ ) as calculated using linear elastic fracture mechanics principles as a function of crack length. Under a constant load control mode, the value of maximum  $K$  (Figure 5) and crack growth rate (Figure 4) would always increase with crack length. The decrease in load results from the displacement component from the crack. This becomes especially pronounced after the crack tip position extends past the controlling extensometer position ( $a = 0.2$  inch). Figure 4 also shows that there is a rather wide difference in crack growth rates between the three strain ranges. These large differences may preclude the determination of path-independent integrals for different strain ranges which also have identical crack growth rates.

The variation of crack growth rate with  $\Delta K$  and  $K_{max}$  is shown in Figures 6 and 7 respectively. The value of  $\Delta K$  was calculated using the total load range including that portion which was compressive.  $K_{max}$  considers only the positive portion of the loading which is the value of  $\Delta K$  as defined in ASTM standard test methods. Both of these figures show that the crack growth rates can not be uniquely defined in terms of LEFM parameters. This confirms that these tests will be good cases for evaluating path-independent integrals under elastic-plastic crack growth conditions. Comparison of the 0.5 percent strain range tests in Figures 6 and 7 show that the crack growth rates apparently can be well described by  $K_{max}$ . This test condition resulted in primarily elastic loading. For nominally elastic crack growth, the effective value of  $K$  should be calculated using only the positive load portion or  $K_{max}$ . This is the reason for the lack of agreement using  $\Delta K$ .

## 2.2 THERMAL GRADIENT EXPERIMENTS

Thermal gradient tests have been performed to evaluate the PI-integrals under non-isothermal conditions. The thermal gradient was established using a

Figure 4. Variation of Crack Growth Rate with Cycles in Displacement Controlled SEN Tests.

Figure 5. Variation of  $K_{max}$  with Cycles in Displacement Controlled SFN Tests.

Figure 7. Variation of Crack Growth Rate with  $K_{max}$  in Displacement Controlled SEN Tests.

combination of induction heating and forced air cooling. At the front or cracked surface, the crack mouth opening extensometer prevented the use of cooling air so the crack was grown from the high temperature to the low temperature. Cooling air was applied to the back face of the specimen above and below the extensometer with cooling tubes and to the gage section with air forced through the cooling passages in the extensometer probes. This gradient technique was originally developed on a specimen which was monitored with fifteen thermocouples. Three sets of five thermocouples were attached to the specimen along the crack plane and at planes 0.25 inch above and below the crack plane. The two latter locations correspond to the positions where the arms of the two large gage length extensometers contact the specimen. On all three planes, a thermocouple was located at each edge of the specimen and at four equally spaced intervals. The presence of the thermocouples prevented the attachment of the three extensometers, so the temperatures were monitored along the plane of the crack in another specimen using an optical pyrometer attached to a traveling microscope. The results of the temperature measurements are shown in the Figure 8. The line connecting the "X" symbols represent the optical pyrometry measurements. These results show a small amount of temperature difference from specimen-to-specimen and along the gage length. This variation is within an acceptable range.

### 3.0 ANALYTICAL EFFORTS

During 1986, the analytical efforts centered on thermal gradient aspects of the analysis problem. Initially, finite element analyses were performed to evaluate the path independent nature of the proposed  $J_x$ -integrals [2] using linear thermal gradients. Constant far-field boundary conditions were used in these cases. Once some thermal gradient experimental results were available, the experimental measurements were predicted by finite element analyses using the actual thermal gradient shown in Figure 8.

#### 3.1 THERMAL GRADIENT SIMULATIONS

Stress analyses of the SEN specimen with gap elements were performed under linear thermal gradient. Two verification cases were studied. In the first case the material properties were kept temperature-independent, and two uniform displacement magnitudes (0.0003 and 0.00036 inch) were applied which resulted in elastic and mildly elasto-plastic response, respectively. Temperature was kept 1200°F at the crack-mouth face ( $X=0$  inch) and 1000°F at the back face ( $X=0.4$  inch) and varied linearly through the width of the SEN specimen ( $L/W=1.25$ ,  $2L=1$ ",  $W=0.4$ ",  $t=0.1$ " ) as shown in Figure 9. The  $J_x$ -integral values were path-independent and they depended only on the traction (uniform displacement) loading; thermal contribution to  $J_x$  was negligible. For the two applied displacements (0.0003 and 0.00036 inch), all the  $J_x$ -integrals (Rice, Ainsworth, Blackburn, Kishimoto, and Atluri) converged to 3.2Lb/in ( $K_I = 8.78$  ksi  $\sqrt{\text{in}}$ ) and 4.6 Lb/in ( $K_I = 10.53$  ksi  $\sqrt{\text{in}}$ ), respectively. These values compared excellently with the pure traction loading results for  $(a/W)$  of 0.25 subjected to uniform applied displacements as found in previous contract work.

Figure 8. Measured Thermal Gradient Used in the Thermal Gradient Experiments.

ORIGINAL PAGE IS  
OF POOR QUALITY

Figure 9. Linear Temperature Gradient Applied to the SEN Specimen.

Thermo-mechanical  $J_x$ -Integral analyses of the SEN specimen with gap elements were also performed under linear thermal Gradient superimposed over mechanical loads. The material properties were temperature dependent (Figure 10) which resulted in material inhomogeneity along the direction of temperature gradient. Figure 11 shows the various contour integration paths used in computing the  $J_x$ -Integrals. The paths 1 and 2 are under the influence of the near-crack-tip region and the paths 3 and 4 are affected by far-field behavior. Figure 12 shows the  $J_x$ -Integral values along the various integration paths in the SEN specimen.

Two load cases are considered initially. In the first load case (L.C.1) the linear temperature gradient,  $T(x)$ , is applied along with a uniform far-field normal stress of magnitude 10 ksi. This resulted in a thermo-elastic stress state, slightly below incipient plastic yield, with a maximum effective stress of value 55 ksi near the crack-tip. For the L.C.1 it could be seen that the Kishimoto, Ainsworth and Blackburn Integrals are very close to each other for the various paths. The Rice Integral has significantly different values for each of the paths considered. In addition, the Rice Integral values are consistently numerically higher than the other  $J_x$  Integrals shown in Figure 12. For the sake of comparison the Tada, Paris & Irwin Handbook [3]  $K_I$ -solution due to the uniform normal stress at 1000°F is shown. The Tada solution is found to be in excellent agreement with all the  $J_x$ -Integrals except the Rice Integral. For the second load case (L.C.2) the uniform normal stress was increased to 20 ksi which resulted in a thermo-elastic-plastic response and a maximum effective stress magnitude of 100 ksi. The Rice Integral values for L.C.2 were in stronger disagreement with the other  $J_x$ -Integrals shown in Figure 12. The Tada solution for L.C.2 was found to be in agreement with all but the Rice Integral, as seen in Figure 12.

Figure 13 shows normal displacement ( $U_y$  at  $Y=L$ ) in the larger gage-length ( $L/W=1.25$ ) specimen subjected to various applied far-field uniform stresses superimposed over the linear temperature gradient. It could be seen that the  $U_y$  displacement has linear variation through the specimen width for all the load cases considered. The results for the load cases 2 and 3, with applied stresses of 10 and 20 ksi, respectively, were discussed in detail in the previous paragraph. Figure 14 shows the effective stress variation through the specimen width on crack plane ( $y=0$ ). The effective stress ahead of the crack-tip ( $x=0.1$ " ) are between 120 to 140 ksi for load cases 5, 6 and 7. Temperature dependent yield stresses are in the range of 63 to 70 ksi along the specimen width. Therefore a significant portion of the net-section is yielded for these load cases. Figure 15 shows the effective plastic strain variation along the crack plane ( $y=0$ ). The maximum plastic strains are 3.5, 1.5 and 0.5 percent for the applied stresses of 65, 50 and 35 ksi, respectively. Although the analysis treats the crack as stationary, the 1.5 to 3.5 percent plastic strains indicate potential for crack extension. Figures 16 and 17 show the effective stress contour plots and the plastic zones in the larger gage length ( $L/W=1.25$ ) specimen subjected to linear temperature gradient along with the applied stress of 35 and 65 ksi, respectively. In Figure 17 the plastic zone boundary is represented by the contour "G" which encompasses a major portion of the SEN specimen.

Figure 17. Effective Stress Contours in SEN Specimen Under Linear Temperature Gradient and Applied Stress of 65 ksi ( $L/W = 1.25$ ).

The computed thermo-mechanical  $J_x$ -Integrals for this gage-length ( $L/W=1.25$ ) are listed in Tables 1 through 5. Also listed in these Tables are the EPRI "EPFM Handbook" [4] isothermal (1100F) J-Integral values for comparison purposes. It could be seen that the path-independence is maintained for all thermo-mechanical  $J_x$ -integrals, except the Rice Integral, for all the load cases. A point to be noted is that the path-independent values of the Atluri  $T_p$ -Integral are larger than the thermo-mechanical  $T_p$ -Integral values. By definition the  $T_p$ -Integral is equal to the  $T_p$ -Integral plus a volume integral of strain energy like term over the whole volume of the specimen. For thermo-mechanical loadings this volume integral term is non-zero. This is one of the reasons the  $T_p$ -Integral does not represent the strength of crack-tip singularity for general loadings in elasti-plastic materials.

In addition to the analyses presented above, limited thermal stress analyses with a linear gradient were performed on the specimen geometry being tested on this program. The results were found to be consistent with the previous discussion; Table 6 summarizes one of these analyses.

### 3.2 THERMAL GRADIENT SPECIMEN ANALYSIS

The actual thermal gradient developed in the SEN specimen gage-section can be approximated as a trilinear relationship, as shown in Figure 18. It is approximately constant at 1200°F for the first 0.175 inch along the specimen width; it then linearly drops to 1050°F for the next 0.14 inch of the width; and, finally, it varies linearly to 900°F in the remaining 0.08 inch of the width. Stress analysis of the specimen with the measured temperature dependent material properties and the prescribed trilinear thermal gradient was performed. An interesting result was observed for the pure thermal gradient load case (zero applied load/deflection). For an  $a/W$  ratio of 0.25, a crack mouth opening displacement of 0.00015 inch was predicted. Figure 19 shows the normal stress variation ahead of the crack-tip for the pure thermal gradient load case. The normal stress has a value of 20 ksi near the crack-tip and it drops sharply to -8 ksi at  $x = 0.175$  inch and then gradually increases to 12 ksi by the end of the specimen width. This normal thermal stress is self-equilibrating in nature since there is no mechanical load applied. The whole specimen is in elastic state of stress with a maximum effective stress of 35 ksi. Since there exists a crack-tip stress field in the specimen for the measure thermal gradient load case, the various  $J_x$ -integrals were determined and found to be path-independent. The average value of these PI-integrals was 1.16 lbs/inch, which is equivalent to 5 ksi/in thermal- $K_I$  value.

The trilinear temperature gradient (Figure 18) and the temperature dependent stress-strain curves (Figure 1) were used to correlate the monotonic thermal gradient test measurements. Referring to Figure 2, the analysis used the control and back surface displacement measurements to construct the

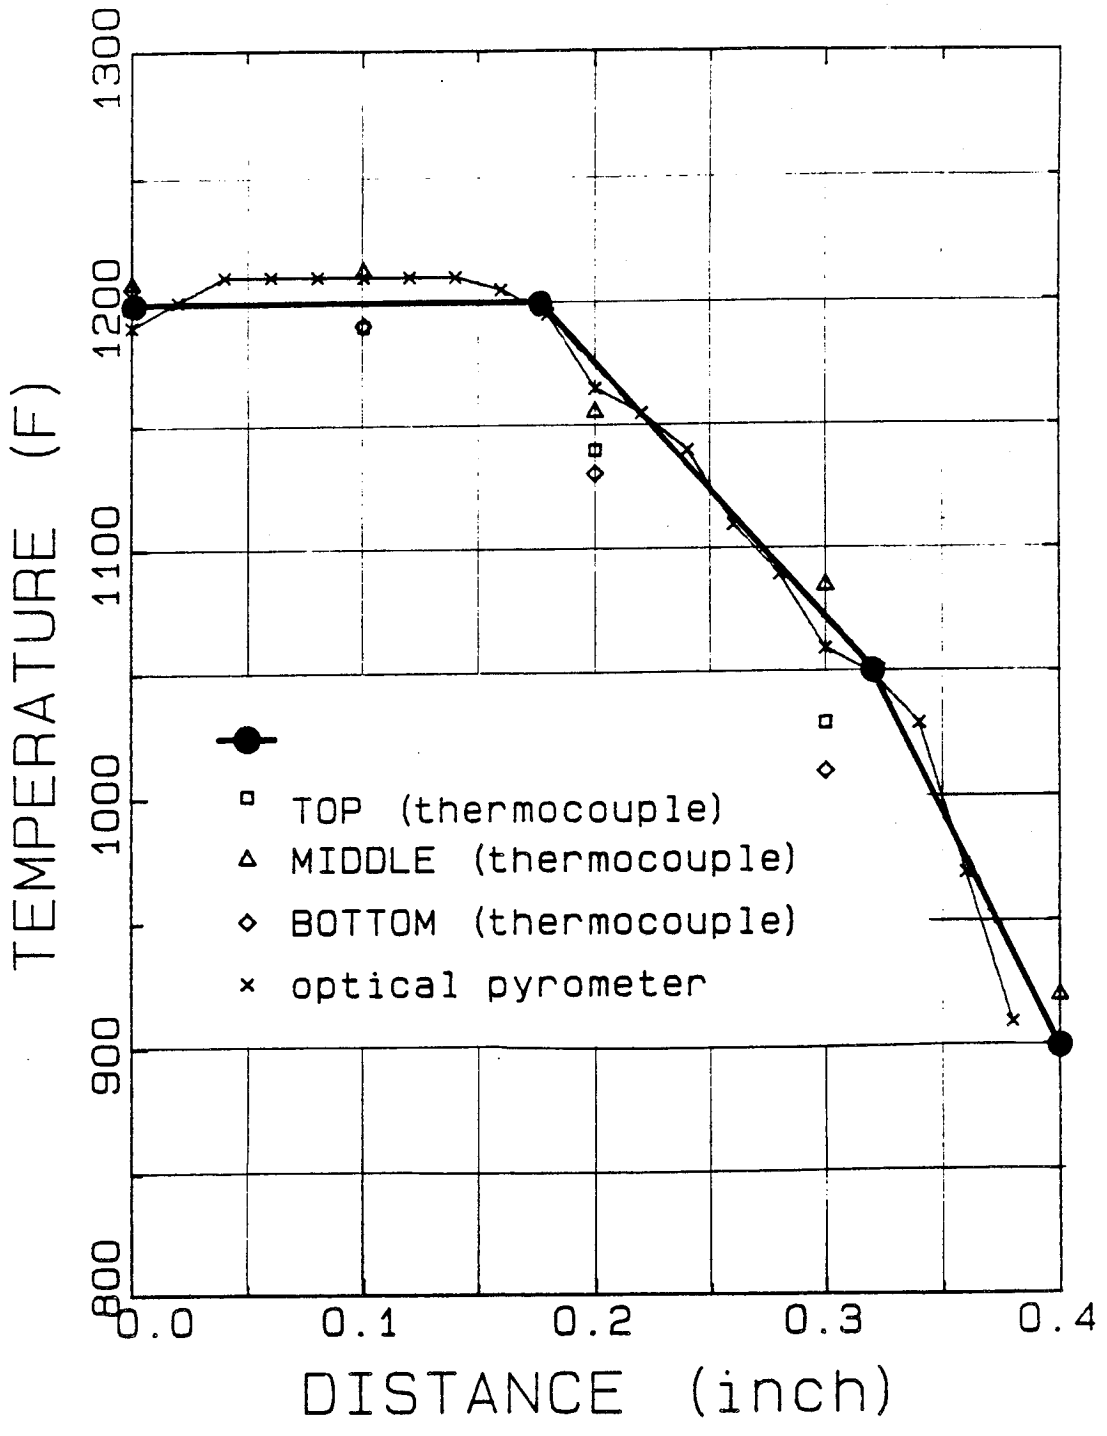

Figure 18. Analytical Representation of the Experimental Gradient.

Figure 19. Predicted Crack Plan Stress for the Experimental Temperature Gradient - No Applied Load.

displacement boundary conditions, see Figure 20. The displacement gradient along the specimen width was assumed to be linear (based on analysis results) such that these two measurements were sufficient to determine the displacement boundary conditions. Figure 21 shows the four analysis points compared to the two monotonic test results. Figure 22 shows that the average stress (measured load divided by cross-section area) is well predicted by the finite element analysis, as is the measured crack mouth opening displacement (CMOD) in Figure 23. These results demonstrate that the experimental and analytical portions of the program are in excellent agreement with each other.

#### 4.0 DISCUSSION

The work during 1986 has shown excellent progress toward understanding the results of the thermal gradient tests. The data analyses to date have demonstrated that the cyclic crack growth results are governed by nonlinear effects and that closure concepts may help to explain some of the results. These factors will be evaluated further by using finite element analyses of specimens including gap elements to simulate closure effects. This work which will include analyses of the TMF test data will attempt to correlate the data using available path independent nonlinear fracture mechanics parameters as described in [2].

CMOD ( $\frac{1}{2}$  Gage Length = 0.015 in.  
Control ( $\frac{1}{2}$  Gage Length) = 0.25 in.  
# of Element = 688, # of Nodes = 421  
# of Gop Elements = 35, W = 0.4 in.  
Smallest Element Size = 0.006 in.

Figure 20. FEM Mesh Used to Analyze the Thermal Gradient Experiments.

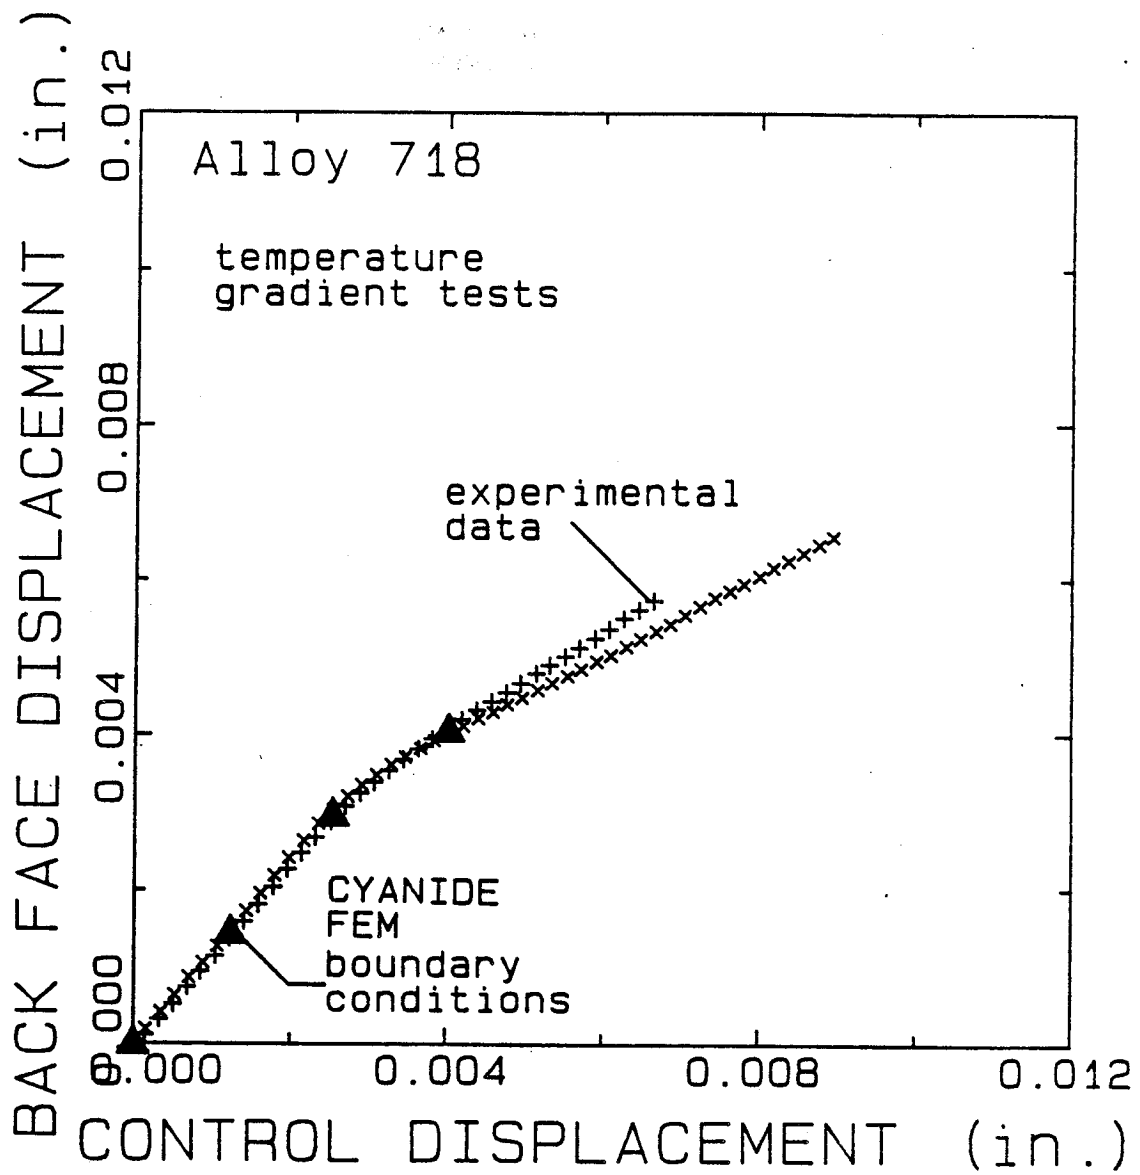

Figure 21. Measured Displacements Which Were Used to Drive the FEM Analysis.

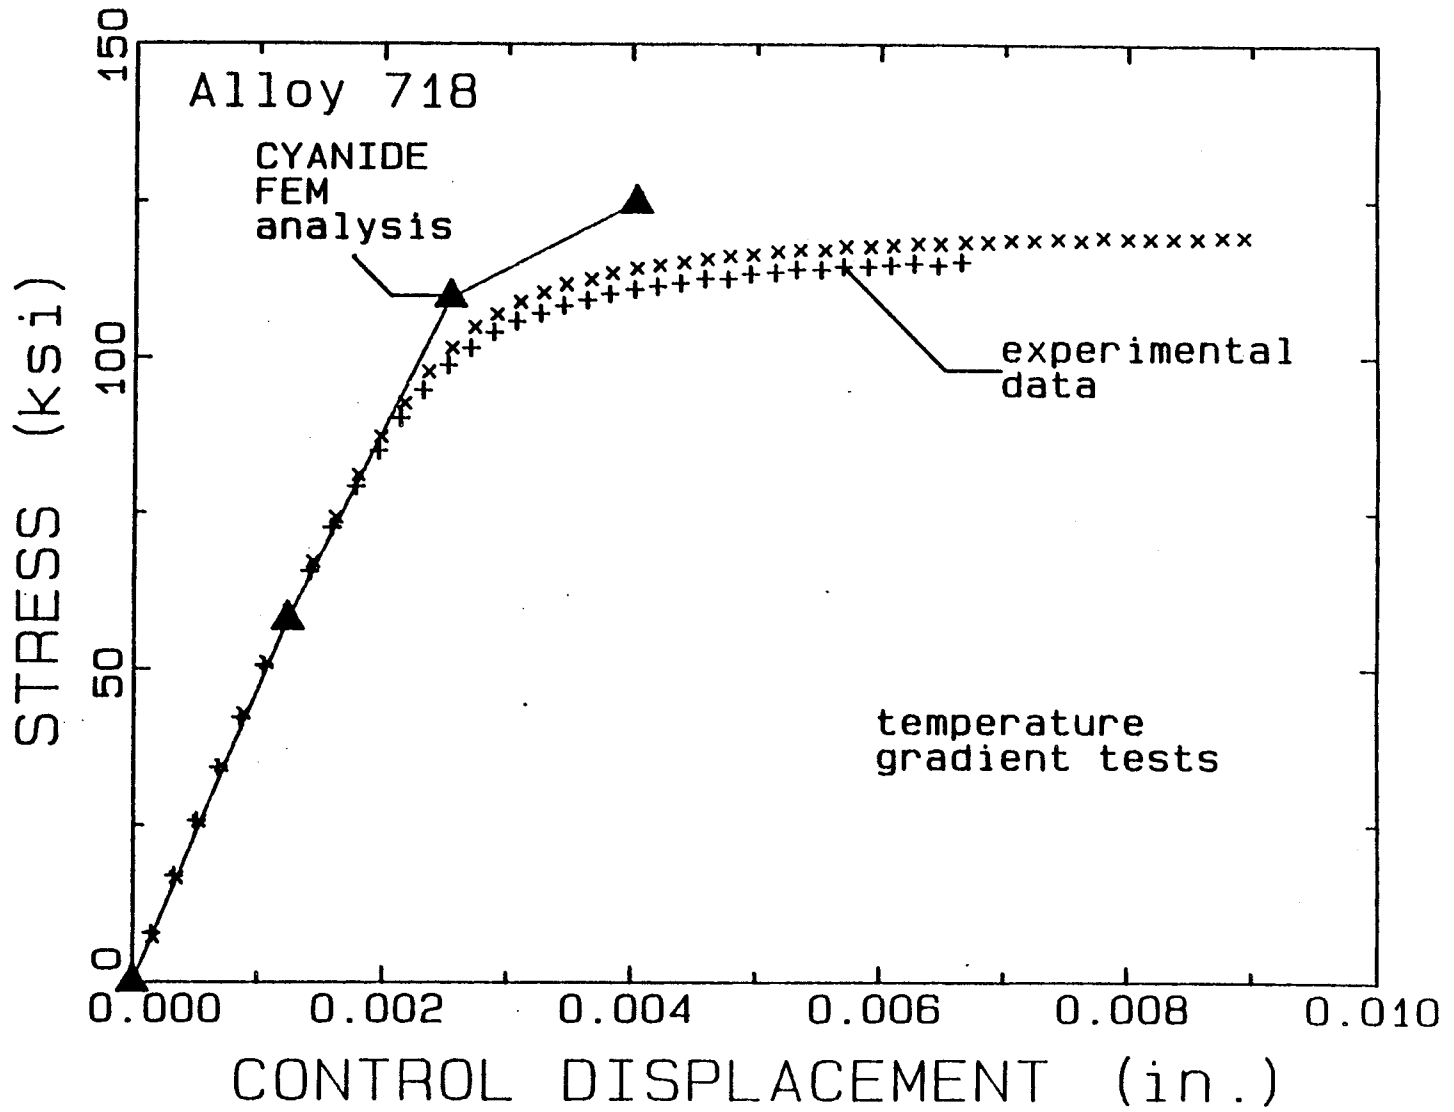

Figure 22. Comparison of Predicted and Measured Average Stress as a Function of Control Displacement.

Figure 23. Comparison of Predicted and Measured CMOD as a Function of Control Displacement.
