Abstract

The performance and noise of a high speed SR-7A model propeller under takeoff/landing conditions are considered. The blade loading distributions are obtained by solving the three-dimensional Euler equations and the sound pressure levels are computed using a time domain approach. At the nominal takeoff operating point, the blade sections near the hub are lightly or negatively loaded. The chordwise loading distributions are distinctly different from those of cruise conditions. The noise of SR-7A model propeller at takeoff is dominated by the loading noise, similar to that at cruise conditions. The waveforms of the acoustic pressure signature are nearly sinusoidal, in the plane of the propeller. The computed directivity of the blade passing frequency tone agrees fairly well with the data at nominal takeoff blade angle.

Nomenclature

\( C_p \)  power coefficient, \( P/P_{on3D} \)
\( C_t \)  thrust coefficient, \( P/P_{on2D} \)
\( D \)  blade(tip) diameter
\( dC_p/dX \)  elemental power coefficient
\( dC_t/dX \)  elemental thrust coefficient
\( J \)  advance ratio, \( U_0/nD \)
\( M \)  Mach number
\( n \)  revolutions per second
\( P \)  power
\( P_s \)  static pressure
\( R \)  blade(tip) radius
\( r \)  radial coordinate
\( T \)  thrust
\( t \)  time
\( U \)  tunnel axial velocity
\( X \)  fractional radius, \( r/R \)
\( \beta \)  blade angle at 75 percent radius
\( \rho \)  density
\( \theta \)  traverse angle

Subscript:

\( o \)  free stream

Introduction

The advanced high speed turboprop is emerging as an efficient means of aircraft propulsion. The Propfan Test Assessment (PTA) flight program has validated the advanced propeller aircraft design features. Propfan aircraft, however, may produce considerable noise in the cabin as well as in the community. Installation effects can modify these noise levels. Propeller driven aircraft are known to produce more noise during takeoff than they would in level flight at the same operating point. The additional noise is attributed to the unsteady blade loading resulting from the angle of attack (of the propeller axis with the flow direction).

At takeoff conditions the main concern is the community noise. At zero angle of attack a noise level change is due to a change in blade setting angle or in the loading. The performance of the high speed (straight, SR-2 and swept, SR-3) propeller models at takeoff, climb and landing regimes was studied by Stefko and Jeracki.\(^1\) They tested the adjustable pitch models at Mach numbers \( M_0 \) = 0.1 to 0.34 in the NASA Lewis 10’x10’ supersonic wind tunnel. They generated detailed performance maps for takeoff, climb and landing conditions at zero angle of attack of the propeller axis with the flow direction. They found that the swept propeller had higher efficiencies than the straight one, in the regimes tested. This appears to be the only detailed performance data of advanced propellers available in these speed regimes.

Fujii et al.\(^2\) studied experimentally the aeroacoustics of advanced propellers at takeoff and landing conditions. They considered three configurations, backward swept blades, forward swept blades and alternately forward swept and backward swept blades. They evaluated both aspects of noise and performance. They found that, at small advance ratios (0.4 to 0.5) the mixed configuration, alternate forward-backward swept blade system gave the best results.
aerodynamically. The study of noise levels of the three configurations showed that the mixed configuration produced less noise than the only forward swept or only backward swept blades.

Recently, Woodward measured the sound pressure levels of a high speed propeller, SR-7A at simulated takeoff/landing conditions. The SR-7A has eight highly swept, highly loaded blades. He found that the total content of the SR-7A noise spectra was typically limited to the first three tone orders, with higher tone orders not present or masked by the broadband background noise probably associated with flow over the microphones. At zero angle of attack, he found that an increase in blade setting angle increased the peak noise level. He also investigated the effect of propeller angle of attack on noise level.

The present investigation is an attempt to predict the performance and noise characteristics of SR-7A model propeller at takeoff/landing conditions studied experimentally by Woodward. Here, only zero degree angle of attack is considered. The present calculations are done by solving the three-dimensional Euler equations. The computed blade pressures are used to compute the sound pressure level at any desired observer position, employing a time domain approach. For comparison with the measured acoustic data, the computed power level is scaled to the measured power level of each run.

Performance and Noise Computations

The blade loadings at takeoff conditions are obtained by solving the three-dimensional Euler equations employing the modified Denton computer program reported in Ref. 4. It was shown in Ref. 4 that the specification of nonreflecting far-field boundary conditions produced results which were in good agreement with experimental data at cruise conditions. Details of the flow field within the blade passage and the tip vortex were also found to be in qualitative agreement with probe/Laser Doppler Velocimetric (LDV) data.

Experimental data as well as the numerical predictions indicate a strong dependence of the total power coefficient of the propfan on the blade shape. It is difficult to determine the dynamic blade shape, An estimate of the twist of the blade with centrifugal loading was available for the design, cruise conditions. This twist was taken into account in the specification of blade angles in the numerical predictions reported in Ref. 4. Such an estimate of the twist of the blade for the takeoff conditions is not available. Setting angles used in the present numerical predictions are the "design" coordinates of the blade. The blade shape change with centrifugal loading is not accounted for in the present calculations.

The blade pressures are obtained from the three-dimensional Euler solutions. The predicted variations of the total power coefficient with the blade setting angle and advance ratio are compared with data. The elemental power and thrust coefficients are also computed.

The sound pressure levels are computed employing the blade pressures obtained from the aerodynamic code, using Farassat's computer program for advanced propeller noise predictions which employs a similar formulation. This formulation is valid for both near and far field noise calculations and handles observers fixed to the ground frame or fixed to the aircraft frame. It uses two forms of the solution of the Ffowcs-Williams and Hawking equation with thickness and loading source terms only. The subsonic or transonic solution is employed for the calculation depending on the radiation Mach number. Farassat's new formulation was shown to predict the higher harmonics accurately. Since we are interested here only in lower harmonics (up to 3xBPF) the formulation reported in Ref. 7 is used.

The program uses numerical integration techniques to compute the noise levels. The upper and lower surfaces of the blade are divided into panels. The pressure distribution on these panels obtained from the Euler solution are used to calculate the acoustic pressure signature at any observer position. The contributions of all panels are added together to obtain the acoustic pressure signature. The signature for only one blade is calculated. The signature for several blades is obtained by shifting the signature for one blade in time and summing the pressures for each observer time within a period. The acoustic pressure signature is then Fourier analyzed to obtain the noise spectrum. In the present computations, the sound pressure levels at eighteen axial locations are used to obtain a good definition of the directivity curve. The number of points computed for directivity is large enough to show the local maximum/minimum present, if any.

Discussion of Results

The configuration considered in the present study is the eight bladed SR-7A model propeller at takeoff condition, free stream Mach number = 0.2. The acoustic calculations are carried out for a 1.68 m sideline corresponding to the experimental study of Woodward. Figure 1 shows the SR-7A model propeller used in the anechoic wind tunnel for acoustic tests. The NASA Lewis 9'x15' anechoic wind tunnel is located in the low speed return loop of the supersonic 8'x6' wind tunnel. Acoustic instrumentation in the 9'x15' tunnel consisted of fixed array microphones on the tunnel floor, near wall and ceiling and two microphones on the remotely controlled translating microphone probe. The translating microphone probe traversed 6.5 m of the acoustically treated test section of the tunnel. The data used for comparison with the predictions in the present paper are those obtained with the traverse microphone.

Performance

The blade pressure distributions of the SR-7A model propeller at takeoff conditions are computed by solving the three-dimensional Euler equations employing the modified Denton computer program. The design characteristics of the SR-7A model propeller are shown in Table 1. The nominal takeoff conditions are the only available blade angles at 75 percent radius = 37.8°, free stream Mach number = 0.2, and advance ratio (Uo/nD), J = 0.89. The computations were done for three blade angles and three advance ratios. The computed total power coefficients are compared with data in Fig. 2.
The figure shows that the computed total power coefficient agrees fairly well with the wind tunnel data. The discrepancies observed may partly be due to the fact that the untwist of the blade under centrifugal loading is not considered in these computations.

The spanwise variations of the power coefficient are shown for three blade angles, namely, 32.0, 37.8, and 43.6° in Fig. 3. With increase in blade angle, the loading increases everywhere along the blade span. The peak in the elemental power coefficient occurs at about 85 percent blade radius for a blade angle of 43.6°. As the blade angle is decreased (total power decreased), the peak in the elemental power coefficient curve moves slightly inboard. For a blade angle of 32.0°, the peak in the elemental power coefficient occurs at about 82.5 percent radius. Such a movement of the peak is also illustrated in the elemental power coefficient with the blade angle was also found in the wind tunnel data of Stefko et al. 8

For the nominal takeoff blade angle of 37.8° and free stream Mach number of 0.2, the variations of the elemental power coefficient with advance ratio are shown in Fig. 4. The curves show a gradual increase in loading with decreasing advance ratio. The location of the peak in elemental power coefficient curve does not change for the range of advance ratios considered.

The variation of the elemental thrust coefficient with the blade angle are shown in Fig. 5. The curves show a significant increase in the peak thrust coefficient with blade angle as observed in the experiments. 8 The dependence of the thrust coefficient on the advance ratio is shown in Fig. 6. It is seen that the curves are smooth and show the expected variation along the span. At cruise conditions, a "transition region" in the elemental thrust coefficient curve moves inboard. For a blade angle of 32.0°, the peak in the elemental power coefficient occurs at about 82.5 percent radius. Such a movement of the peak is also illustrated in the elemental power coefficient with the blade angle was also found in the wind tunnel data of Stefko et al. 8

Because of the difference in loading distributions of takeoff and cruise conditions, it is instructive to examine the magnitudes of the noise components at takeoff. Figure 9 shows the directivity of the loading and thickness noise components and the total noise for nominal takeoff conditions. First, we note that the noise under takeoff conditions is dominated by the loading noise. Secondly, the loading noise directivity does not show a local minimum in the plane of rotation of the propeller as observed in the cruise conditions. 9 The peak in the total noise directivity occurs aft of the plane of rotation of the propeller as in the cruise conditions. 9, 10 The appearance of the total noise peak aft of the propeller in the computed sound pressure levels is associated with the nature of the blade sweep and thus the same trend is seen at takeoff and cruise conditions.

### Directivities and Waveforms

The predicted directivities of the blade passing frequency, second and third harmonics are shown in Figs. 10(a) to (c), for blade setting angles of 32.0, 37.8, and 43.6° respectively, at the nominal takeoff advance ratio of 0.8. The predicted sound pressure levels have been scaled to account for the overprediction of power by aerodynamic computations (Fig. 2). Also shown in these figures are the wind tunnel data 3 for comparison. For the blade angles considered, the peak in the BPF tone noise occurs aft of the plane of rotation of the propeller as shown in Fig. 9. The peak in the BPF directivity agrees well with the data for the blade angle of 32.0°. At higher blade angles discrepancies between the prediction and data are observed. The maximum discrepancy in the predicted peak noise occurs at 43.6° and is about 5 dB. The peak levels of the second harmonics are fairly well predicted.

The increasing discrepancy of the predicted noise levels with increasing blade angle is attributed to the leading edge vortex and the tip vortex effects, which are not taken into account in the present computations. The existence of the leading edge vortex was shown clearly in Refs. 11 and 12. As the blade angle increases, the strength of the leading edge vortex increases. Accounting for the leading edge vortex and in particular the variation of the vortex strength with the blade angle would improve the agreement of the predictions with data. Hanson 11 has found that accounting for the change in loading due to the leading edge tip vortex alone would not improve the predictions significantly. He found that the inclusion of the radial forces due to the leading edge tip vortex as additional noise sources would improve the predictions.

Figure 11 shows the predicted and measured waveforms of the acoustic pressure signal in the plane of the propeller at the three blade angles. The waveforms were measured by the fixed microphone located at 0.95 m from the axis of the propeller. The distance correction has been applied to the data for comparisons with the predictions at 1.68 m side line. Typical waveforms averaged 400 revolutions and over eight blades have been chosen for comparison. The waveforms are nearly sinusoidal. At high blade angles, the value at the negative peak is higher than that at
the positive peak. The measured trend of an increase in the difference in peak values with the blade angle is correctly predicted.

The peak noise level was observed to occur at the plane of rotation of the propeller (Fig. 10). The variation of the peak noise level with the blade setting angle is shown in Fig. 12. The discrepancy between the prediction and data may be significantly reduced if the radial forces produced by the leading edge vortex are considered as additional noise sources.\(^1\)

At the nominal takeoff blade angle of 37.8°, the effect of advance ratio on the noise level are shown in Figs. 10(b) and 13(a) and (b), which show the directivities of the BPF and harmonics. The predicted BPF tone levels agree fairly well with data in all the three cases. Figure 14 shows the waveforms in the plane of the propeller (BPF corresponding to each J) is indicated on the figure. The waveforms are nearly sinusoidal at a high advance ratio. As the advance ratio is increased, the difference between the values at the positive and negative peaks increase significantly. The large variations in the peak noise level with advance ratio are consistent with the computed BPF tone levels. The effect of advance ratio on the peak noise is summarized in Fig. 15. The figure shows that with increasing advance ratio (or decreasing rotational speed) the agreement of the predicted peak noise with data is improved.

It appears that the existence of the leading edge vortex and its interaction with the tip vortex are the major reasons for the discrepancy between the prediction and data.\(^1\),\(^2\) Fine grid solutions of the Euler equations of the flow through the SR-7A model propeller show the existence of a leading edge vortex. The details of the leading edge vortex and its interaction with the tip vortex are being investigated.

**Concluding Remarks**

The three-dimensional Euler solutions of the SR-7A model propeller flow at takeoff conditions predict the total power coefficients which are in agreement with wind tunnel data. Detailed blade loading distribution data are unavailable for comparison. The sound pressure levels have been computed using a time domain approach. The predicted peak noise level is 2.5 dB lower than the measured value at the nominal takeoff blade angle. At higher blade angles, however, the discrepancy between the prediction and data increases. The increased discrepancy is probably due to the increase of the strength of the leading edge vortex with blade angle. Although the existence of the leading edge vortex is evident from the Euler solutions of the flow field and the oil flow visualization studies, more detailed analysis is required to evaluate the variation of the leading edge vortex on the propeller performance and noise.
