(ABSTRACT)

A method is presented for calculating the shape sensitivity of a wing aeroelastic response with respect to changes in geometric shape. Yates' modified strip method is used in conjunction with Giles' equivalent plate analysis to predict the flutter speed, frequency, and reduced frequency of the wing. Three methods are used to calculate the sensitivity of the eigenvalue. The first method is purely a finite difference calculation of the eigenvalue derivative directly from the solution of the flutter problem corresponding to the two different values of the shape parameters. The second method uses an analytic expression for the eigenvalue sensitivities of a general complex matrix, where the derivatives of the aerodynamic, mass, and stiffness matrices are computed using a finite difference approximation. The third method also uses an analytic expression for the eigenvalue sensitivities but the aerodynamic matrix is computed analytically. All three methods are found to be in good agreement with each other. The sensitivities of the eigenvalues were used to predict flutter speed, frequency, and reduced frequency. These approximations were found to be in good agreement with those obtained using a complete reanalysis. However, it is recommended that higher order terms be used in the calculations in order to assure greater accuracy.
Acknowledgements

The authors would like to express their sincere thanks to Drs. Jean-Francois Barthelemy and Gary L. Giles at NASA, Langley Research Center for their helpful suggestions and contributions to this research. They would also like to thank Dr. R. T. Haftka and Dr. E. R. Johnson for their suggestions and comments.

1.0 Introduction.

1.1 Introduction and Background

Flutter, an aeroelastic instability, is a self-sustaining oscillation that involves the coupling of inertial, elastic, and aerodynamic forces. Tail flutter was the earliest documented case of dynamic aeroelastic instability. It was discovered on the twin-engined Handley Page 0/400 Bomber at the beginning of World War I that the fuselage and tail had two principal modes of vibration. In the first mode, the elevators oscillated about their hinges 180 degrees out of phase, because the elevators were not attached by a torque tube. In the second mode, the fuselage oscillated in torsion. The coupling between these two modes resulted in a self-sustained oscillation [1].

Modern aircrafts are subjected to numerous types of flutter phenomena. Classical flutter is associated with potential flow and involves coupling of two or more degrees of freedom. Nonclassical flutter is concerned with oscillations due to boundary layer effects, such as separated flow and reattaching flows. Nonclassical flutter is more difficult to
analyze from a theoretical standpoint. Only classical flutter will be analyzed in this presentation.

Flutter analysis capabilities have been available for well over four decades. Loring [2] developed a general approach to the flutter problem in 1941. Yates [3] developed a modified strip analysis to analyze flutter characteristics for finite-span swept and unswept wings at subsonic and supersonic speeds in 1958. This method is still used today to calculate the lift and moment forces. For example, Landsberger and Dugundji [4] used these expressions, with a modification for camber effects given by Spielberg [5], to study the flutter and divergence of a composite plate. The present day computers allow still more complex aerodynamic programs to be developed and used. To name a few, the unsteady vortex-lattice method developed by Strganac and Mook [6], the double lattice method developed by Waldman [7], and the MCAERO code developed by Hawk and Bristow [8].

The dynamics of any physical system is important from a designer’s view point. The onset of flutter in a modern aircraft will involve large oscillatory distortions of the structural components. Therefore, it would be advantageous to the designer to have a tool which can be used to predict the changes in flutter with the changes in basic shape parameters.

Sensitivity analysis was first recognized as a useful tool for assessing the effects of changing parameters in mathematical models of control systems. The gradient based mathematical programming method used in optimal control and structural optimization furthered the development of sensitivity derivatives, because sensitivity derivatives are used in search directions to find optimum solution [9,10,11,12]. Inefficient optimization programs lead to further interest in efficient calculation of sensitivity derivatives. As a
result, sensitivity analysis has become a versatile design tool, rather than just an instrument of optimization programs [13].

Shape sensitivity analysis of any physical system under aeroelastic loads can be important from different points of view: 1) to understand and predict the system's response and 2) to optimize the response of the system for a set of physical constraints. In order to predict or optimize the response the sensitivity derivatives must be calculated. This can be done by a finite difference calculation or analytical calculation of the sensitivity derivatives. Analytical sensitivity analysis has found increased interest in engineering design. The analytical derivatives eliminate the uncertainty in the choice of step size, which if too large can lead to truncation errors and if too small can lead to ill-conditioning.

Adelman and Haftka [13] have shown that structural sensitivity analysis has been available for over two decades. Structural sensitivity analysis has been sufficient in the past because sizing variables such as plate thickness and cross-sectional areas effect the mass and stiffness properties of the airframe but, not its basic geometry. Therefore, aero-dynamic sensitivity analysis capability has been limited in development until recently.

For example, Rudisill and Bhatia [14] developed expressions for the analytical derivatives of the eigenvalues, reduced frequency and flutter speed with respect to structural parameters for use in minimizing the total mass. However, this method is limited because the structural parameters are sizing variables such as cross-sectional areas, plate thickness and diameters of spars.

Pedersen and Seyranian [15], examined the change in flutter load as a function of change in stiffness, mass, boundary conditions or load distribution. They showed how sensitivity
analysis can be performed without any new eigenvalue analysis. The solution to the main and an adjoint problem provide all the necessary information for evaluating sensitivities. Their paper mainly focuses on column and beam critical load distributions.

Hawk and Bristow [8] developed aerodynamic sensitivity analysis capabilities in subcritical compressible flow. They first analyzed a baseline configuration, and then calculated a matrix containing the partial derivatives of the potential at each control point with respect to each known geometric parameter by applying a first-order expansion to the baseline configuration. The matrix of partial derivatives is used in each iteration cycle to analyze the perturbed geometry. However, this analysis only handles chordwise perturbation distributions, such as changes in camber, thickness and twist. A new approach, which is still under development, has been proposed by Yates [16] that considers general geometric variations, including planform, for subsonic, sonic and supersonic unsteady, nonplanar lifting-surface theory.

Barthelemy and Bergen [17] explored the analytical shape sensitivity derivatives of a wing static aeroelastic response. They found that the second derivatives of the wing's aeroelastic characteristics, such as section lift, angle of attack, rolling moment, induced drag, and divergence dynamic pressure, for subsonic subcritical flow, with respect to geometric parameters are small enough to be well approximated by sensitivity based linear approximations. These approximations are valid within a range that are useful to the designer in the initial design phase.

This work is an extension of previous work performed by Barthelemy and Bergen [17], and details the theoretical and computational derivation of a method to obtain the sensitivity of a wing flutter response to changes in its geometry. Specifically, the objective is to determine the derivatives of flutter speed and frequency with respect to wing area.
aspect ratio, taper ratio, and sweep angle. Chapter 2 gives a brief description of the structural formulation which was originally formulated at the NASA Langley Research Center by Giles [18]. The program is based upon a Raleigh-Ritz formulation in which the displacement functions are made up of polynomial expressions. The aerodynamic formulation is presented in Chapter 3. The expression for lift and moment are derived from potential flow theory and have been modified to account for finite span. In Chapter 4, the formulation is validated using examples found in other works. Once there is sufficient confidence in the flutter speed prediction capabilities, it is shown that the sensitivity analysis will predict the flutter speed for changes in the structural parameters. Three different approaches are used to obtain the sensitivity of the flutter speed, frequency, and reduced frequency to various shape parameters. These include:

(i) a purely numerical approach using the finite difference method;
(ii) a semi-analytical method that uses an analytic expression given by Murthy and Haftka [19], for calculating the sensitivity of the eigenvalues of a generalized eigenvalue problem and a finite difference approximation of the derivatives of the aerodynamic, mass and stiffness matrices with respect to the geometric parameters; and
(iii) an analytic approach that uses the analytic expression for calculating the sensitivity of the eigenvalues and an analytically derived expression for the sensitivity of the aerodynamic matrix with respect to geometric parameters.

Chapter 6 gives conclusions and suggestions for future work.
2.0 Structural Model

2.1 Introduction

This chapter presents the structural formulation which was originally programmed by Giles [18]. The program is based upon a Ritz solution technique using the the energy functionals for a laminated plate which includes the bending and stretching of the reference surface. This program is capable of analyzing unsymmetric wing box sections arising from airfoil camber, laminate sequences, or different thicknesses in upper and lower cover skins. Thermal loadings can be represented as temperature distributions over the planform of the cover skins.

The aerodynamic formulation restricts the chordwise length to remain straight during oscillations, therefore only high aspect ratio wings will be analyzed in this presentation. Only bending and torsional deformations are considered in this analysis procedure. In the theory of plates, the Kirchhoff assumption is made that lines normal to the reference plane remain straight and normal after deformations.
The planform geometry of the wing is represented by a trapezoidal segment. To represent cranked wing boxes, multiple trapezoidal segments can be defined. Each segment has a separate local coordinate system. The local coordinates are nondimensional such that \( \xi \) refers to a fraction of the chord and \( \eta \) a fraction of the span as shown in Figure 1.

Figure 2 illustrates a possible geometry of the wing box and coordinate system. The mid-camber surface is measured from a reference plane. The distance, \( Z_c \), is represented as a polynomial in the global coordinates \( x \) and \( y \).

\[
Z_c(x,y) = z_{00} + z_{10}x + z_{20}x^2 + z_{01}y + \ldots + z_{mn}x^my^n \tag{2.1.1}
\]

The depth of the wing box, \( H(x,y) \) is measured from the midchord surface and the thickness \( t(x,y) \) of each laminate is also defined by polynomial expressions \( x \) and \( y \). The expressions for the depth and thickness are:

\[
H(x,y) = H_{00} + H_{10}x + H_{20}x^2 + H_{01}y + \ldots + H_{mn}x^my^n \tag{2.1.2}
\]

\[
t(x,y) = t_{00} + t_{10}x + t_{20}x^2 + t_{01}y + \ldots + t_{mn}x^my^n \tag{2.1.3}
\]

In the present formulation, the depth of the wing box and thickness of the skins is assumed to be constant throughout. The coefficients of equations (2.1.2) and (2.1.3) are:

\[
H_{00} = .100 \text{ meters} \quad t_{00} = .002 \text{ meters}
\]

\[
H_{mn} = 0.0 \quad t_{mn} = 0.0 \quad m = 1,...,5 \quad n = 1,...,5
\]

The wing box used for this presentation is shown in Figure 3. The box section chordline is straight, therefore \( Z_c(x,y) \) is zero for this presentation.
Figure 1  Local Coordinate System
Figure 2  Possible Wing Box Geometry
Figure 3  Wing Box Section Used
2.2 Displacement Function

The Rayleigh-Ritz formulation assumes a deflection shape for the wing structure. This deflection shape is a linear combination of \( n \) assumed displacement functions. The assumed displacement functions are specified as products of polynomial \( x \)-direction and \( y \)-direction global coordinates. The deflection equation can be written as:

\[
W(x, y) = \sum_{n=0}^{N} \sum_{m=2}^{M} C_{nm} \left( \frac{x}{x_{\text{max}}} \right)^n \left( \frac{y}{y_{\text{max}}} \right)^m
\]

[2.2.1]

where \( N \) is restricted to five terms and \( M \) is restricted to six terms in order to prevent numerical difficulties in the manipulation of the matrices. \( W(x, y) \) is the transverse deflection of the reference line, and \( C_{nm} \) the set of unknown coefficients.

The deflection equation can also be written as:

\[
W(x, y) = \sum_{i=1}^{np} y_i(x, y) C_i
\]

[2.2.2]

where \( y_i(x, y) \) is the nondimensional displacement function and \( np \) is \( N \) times \( M \). All the assumed displacement functions satisfy the geometric boundary conditions for a cantilever plate. The constants \( x_{\text{max}} \) and \( y_{\text{max}} \) are defined in magnitude as the root chord and span respectively. The displacement functions are nondimensional quantities in order to prevent numerical difficulties in manipulation of the matrices.
2.3 Energy Expressions

The strain energy $U$ for a symmetric anisotropic laminate is given as:

$$ U = \frac{1}{2} \int \int_A \left( D_{11} W_{xx}^2 + 2D_{12} W_{xx} W_{yy} + D_{22} W_{yy}^2 ight) dA $$

$$ + 4D_{16} W_{xy} W_{xx} + 4D_{26} W_{xy} W_{yy} + 4D_{66} W_{xy}^2 ) dA $$  \[2.3.1\]

where a comma denotes partial differentiation and $D_{ij}$ are the bending stiffness terms.

The kinetic energy $T$ for the plate is:

$$ T = \frac{1}{2} \int \int_A m W^2 dA $$  \[2.3.2\]

where $m$ is the distributed mass per unit area, $W$ is the transverse velocity at $x$ and $y$, and $A$ is the area of the plate.

The Ritz solution procedure is used to determine the numerical values of the set of unknown coefficients, $C_i$'s. To use the Ritz solution procedure, and to integrate these equations the global $x$ and $y$ were transformed into a local system. This was achieved by the following transformation.

$$ x = e + a' \xi + (f - e) \eta + (c - a') \eta \xi $$  \[2.3.3\]

$$ y = g' + B \eta $$  \[2.3.4\]
The coefficients \( a', B, c, e, f, g' \) are dimensions of the local coordinate system as shown in Figure 1.

The Ritz solution procedure is based upon the second variational principle. The second variational principle states that the total energy of the structure can be written in terms of any kinematically admissible function. If the total energy, \( E(\bar{y}) \), in terms of the kinematically admissible function \( \bar{y} \), is stationary at \( \bar{y} = y \) with \( E(y) = 0 \), then the function represents the real modes of the structure. If the function represents the real modes of the structure then it can be used as a valid approximation to the exact solution. The total energy of the structure can be written as:

\[
E = U - T
\]  

[2.3.5]

The extremum principle states that the energy is stationary with respect to \( C \), i.e.

\[
\frac{\partial E}{\partial C} = 0.
\]

This produces a system of \( n \) simultaneous equations. In matrix form then the equations are expressed as:

\[
[[K] - \omega^2[M]](C) = 0
\]  

[2.3.6]

where \([K]\) and \([M]\) are the stiffness and mass matrices resulting from the partial differentiation of the potential and kinetic energies, respectively, with respect to the generalized coordinates.
3.0 Aerodynamic Model

3.1 Aerodynamic Forces

This chapter presents the formulation of the aerodynamic coefficient matrix. An incompressible, 2-dimensional, unsteady strip theory was used to calculate the aerodynamic coefficients. This method was first developed by Barron, et. al., [20] and was modified by Yates [16] to include the effects of finite span. Lift and moment forces are defined along the midchord and acting upon sections perpendicular to this midchord line (called the reference line hereafter).

The flow field is represented by a uniform stream (non-circulatory component) superposed by the disturbance-velocity distribution (circulatory component) which will model the effect of the position and motion of the wing. It is modeled such that the condition of tangential flow at the wing surface is met.

The position of each point of the segment taken perpendicular to the reference line is:
\[ Z = h + x'\theta \]  

Where \( h \) is the deflection of the midchord, positive up, \( \theta \) is the rotation of a section measured perpendicular to the midchord positive leading edge down, and \( x' \) is the perpendicular distance from the reference line, measured positive back.

The lift and moment forces are written in terms of a circulatory and non-circulatory components. As taken from Yates' modified strip analysis [3], the lift force (positive up) per unit length of the wing, is given as:

\[
L = -\pi \rho b^2 [h + V_n\dot{\theta} + V_n\tau \tan \Lambda - bai(\dot{\theta} + V_n\tau \tan \Lambda)]_{nc} \]

\[
- \left[ C_{ta,n} \rho V_n b C(k_n) \right]_{c} \]  

[3.1.2]

where subscript nc indicates the noncirculatory component and c indicates the circulatory component. The air density is \( \rho \), \( b \) is the halfchord, \( V_n \) is the air speed measured perpendicular to the midchord. \( C_{ta,n} \) is the section lift coefficient which is constant along the span, \( \Lambda \) is the midchord sweep angle, and \( a \) is the off-set of the reference line from the midchord line, assumed to be zero in this presentation. The local bending slope of the reference axis is represented by \( \sigma \) and the local rate of change of twist is represented by \( \tau \). \( C(k_n) \) is Theoderson's circulation function. The reduced frequency, \( k_n \) is a measure of the amount of circulation in the flow field and is used in the circulation function and is given as [10]:

\[
C(k_n) = 1 - \frac{0.165}{1 - 0.455 k_n} - \frac{0.335}{0.3 k_n} \]  

[3.1.3]
Similarly, the expression for the moment $M$, per unit length about the midchord (positive leading edge down) is:

$$M = -\pi \rho b^4 \left[ \left( \frac{1}{8} + a^2 \right)(\hat{\theta} + V_n \sigma + V_n \tan \Lambda) + \pi \rho b^2 V_n (\hat{\theta} + V_n \sigma \tan \Lambda) + \pi \rho b^3 a(\hat{\theta} + V_n \sigma \tan \Lambda) \right]$$

$$+ \pi \rho V_n^2 b^2 (\theta - ab \tan \Lambda) \right]_{nc}$$

$$\left[ -2\pi \rho V_n^2 b^2 \left[ \frac{1}{2} - (a - a_{cn}) C(k) \frac{C_{ls_1}}{2\pi} \right] Q_d \right]_c$$

[3.1.4]

where $a_{cn}$ is the distance to the aerodynamic center from the reference line, and $Q_d$ is the downwash distribution defined by:

$$Q_d = \hat{\theta} + V_n \sigma + V_n \sigma \tan \Lambda + b \left( \frac{C_{ls_1}}{2\pi} + a_{cn} \right) (\hat{\theta} + V_n \sigma \tan \Lambda)$$

[3.1.5]

The airfoil geometry with typical dimensions is shown in Figure 4.
Figure 4  Airfoil Geometry of a Typical Section
The lift and moment forces can be reduced to the following expressions assuming the wing is undergoing infinitesimal harmonic oscillations about its steady-state position [20].

\[ L = -\pi pb^3 \omega^2 (B_{ch} h + B_{c\theta} \theta) \] \[ M = -\pi pb^4 \omega^2 (B_{ah} h + B_{a\theta} \theta) \]

The coefficients \( B_{ch}, B_{c\theta}, B_{ah}, \) and \( B_{a\theta} \) are defined as:

\[ B_{ch} = \frac{1}{b} A_{ch} - \frac{i \sigma}{k_n h} A_{ch} \tan \Lambda \] \[ B_{c\theta} = A_{cs} + \frac{i}{\theta} b A_{ct} \tan \Lambda \]

\[ B_{ah} = \frac{1}{b} A_{ah} - \frac{i \sigma}{k_n h} A_{ah} \tan \Lambda \] \[ B_{a\theta} = A_{as} + \frac{i}{\theta} b A_{at} \tan \Lambda \]

and:

\[ A_{ch} = 1 + \frac{2i C(k_n) C_{ia,n}}{k_n 2\pi} \]

\[ A_{cs} = a + \frac{i}{k_n} + \frac{2i C(k_n) C_{ia,n}}{k_n 2\pi} (1 - 2a) + \frac{2 C(k_n) C_{ia,n}}{k_n^2 2\pi} \]

\[ A_{ct} = \frac{ia}{k_n} + \frac{2 C(k_n) C_{ia,n}}{k_n 2\pi} (-a_{cn} - a) \]
\[ A_{ah} = a - \frac{2iC(k_n)C_{la,n}}{k_n2\pi} (-a_{cn} + a) \]  \[ A_{ax} = -\frac{1}{8} - a^2 + \frac{i}{k_n} \left( \frac{1}{2} - a \right) \]

\[-\frac{2C(k_n)C_{la,n}}{k_n^22\pi} (a_{cn} - a) - \frac{2iC(k_n)C_{la,sub,n}}{k_n2\pi} (a_{cn}^2 - a^2) \]  \[ A_{at} = -\frac{i}{k_n} \left[ -\frac{3}{8} + \frac{i}{2k_n} - (a_{cn}^2 - a^2)A_{ch} \right] \]

The bending deflection, h, and the torsional deflection, \( \theta \), are defined along the reference line -- the midchord.

Special attention must be made when expressing the quantities which relate the aerodynamic and structural models. The aerodynamic forces and displacements are derived in terms of sections perpendicular to the reference line. The displacement functions (see Chapter 2) and their derivatives define rotations parallel to the free stream flow. In order to be consistent in the formulation, \( \gamma_{ix} \), \( \gamma_{iy} \), \( \gamma_{ixx} \), \( \gamma_{iyy} \), \( \gamma_{ixy} \) must be transformed to define \( \theta, \tau, \) and \( \sigma \) in the plane perpendicular to the reference line. These transformations are as follows:

\[ \theta (\tilde{x}, \tilde{y}) = \sum_{i=1}^{np} C_i(\gamma_{ix}(\tilde{x}, \tilde{y}) \cos \Lambda - \gamma_{iy}(\tilde{x}, \tilde{y}) \sin \Lambda) \]  \[ \tau (\tilde{x}, \tilde{y}) = \sum_{i=1}^{np} C_i(\gamma_{ix}(\tilde{x}, \tilde{y}) \sin \Lambda + \gamma_{iy}(\tilde{x}, \tilde{y}) \cos \Lambda) \]
\[ \sigma(\tilde{x}, \tilde{y}) = \sum_{i=1}^{n_p} C_i(\gamma_{i,xx}(\tilde{x}, \tilde{y}) \cos \Lambda \sin \Lambda + \gamma_{i,xy}(\tilde{x}, \tilde{y}) (\cos^2 \Lambda - \sin^2 \Lambda) - \gamma_{i,yy}(\tilde{x}, \tilde{y}) \cos \Lambda \sin \Lambda) \] 

Here the superscripts represent the fact that \( x, y \) are not any arbitrary values of \( x \) and \( y \), but \( \tilde{x}, \tilde{y} \) are the coordinates of the reference line in \( x \) and \( y \). Furthermore:

\[ \tilde{x} = \tilde{y} \tan \Lambda \]  

Therefore \( h, \theta, \tau, \) and \( \sigma \) are functions of \( \tilde{y} \) only, where \( \tilde{y}(= \frac{\tilde{y}}{\cos \Lambda}) \) is the distance of the point \( \tilde{x}, \tilde{y} \) from the origin along the reference line. For simplicity, \( h, \theta, \tau, \) and \( \sigma \) can be written as:

\[ h(\tilde{y}) = \sum_{i=1}^{n_p} C_i \tilde{y}(\tilde{y}) \]  

\[ \theta(\tilde{y}) = \sum_{i=1}^{n_p} C_i \tilde{y}_{i,\tilde{x}}(\tilde{y}) \]  

\[ \sigma(\tilde{y}) = \sum_{i=1}^{n_p} C_i \tilde{y}_{i,\tilde{y}}(\tilde{y}) \]  

\[ \tau(\tilde{y}) = \sum_{i=1}^{n_p} C_i \tilde{y}_{i,\tilde{y}\tilde{y}}(\tilde{y}) \]
The lift and moment forces can then be written in terms of the displacement functions \( \overline{y}_i(\overline{y}) \) and the unknown coefficients, \( C_i \). Based upon equations 3.1.5, 3.1.6, and 3.1.17-3.1.24, the lift and moment can be written as:

\[
L = -\pi \rho b^3 \omega^2 \left( \frac{1}{b} \sum_{m=1}^{np} \overline{y}_m(\overline{y}) C_m - \frac{i}{k_n} \tan \Lambda \sum_{m=1}^{np} \overline{y}_m, \overline{y}(\overline{y}) C_m \right) A_{ch} \\
+ A_{cs} \sum_{m=1}^{np} \overline{y}_m, \overline{z}(\overline{y}) C_m + b A_{ct} \tan \Lambda \sum_{m=1}^{np} \overline{y}_m, \overline{y}(\overline{y}) C_m \quad [3.1.25]
\]

\[
M = -\pi \rho b^4 \omega^2 \left( \frac{1}{b} \sum_{m=1}^{np} \overline{y}_m(\overline{y}) C_m - \frac{i}{k_n} \tan \Lambda \sum_{m=1}^{np} \overline{y}_m, \overline{y}(\overline{y}) C_m \right) A_{ah} \\
+ A_{as} \sum_{m=1}^{np} \overline{y}_m, \overline{z}(\overline{y}) C_m + b A_{at} \tan \Lambda \sum_{m=1}^{np} \overline{y}_m, \overline{y}(\overline{y}) C_m \quad [3.1.26]
\]

Having obtained the lift and moment forces, in terms of the displacement function and unknown coefficients, attention must be focused on the principle of virtual work since these forces are non-conservative. At this point forward, \( \overline{y}(\overline{y}) \) will be represented as \( \overline{y} \) for ease in derivations.
3.2 Virtual Work

The lift and moment forces are non-conservative forces, therefore the principle of virtual work must be employed. The definition of virtual work gives:

\[
\delta W_{nc} = \int_0^L L \delta h \, dx + \int_0^L M \delta \theta \, dx = \sum_{j=1}^{n} Q_j \delta C_j \tag{3.2.1}
\]

where \( \delta h \) and \( \delta \theta \) are the virtual displacements and \( Q_j \) are the generalized forces. The virtual displacements are defined as:

\[
\delta h = \sum_{j=1}^{n} \tilde{j}_j \delta C_j \tag{3.2.2}
\]

\[
\delta \theta = \sum_{j=1}^{n} \tilde{\eta}_j \delta C_j \tag{3.2.3}
\]

The virtual work can be expressed in terms of generalized forces and displacements as:

\[
\delta W_{nc} = \sum_{i=1}^{n_p} Q_i \delta C_i \tag{3.2.4}
\]

This can be written as:
\[ \delta W_{nc} = - \sum_{j=1}^{np} \left[ \int_0^t \rho b^3 \omega^2 \sum_{i=1}^{np} \left[ \frac{1}{b} (\overline{v}_i \overline{v}_j) C_i - \frac{i}{k_n} \tan \Lambda(\overline{v}_i, \overline{v}_j) C_i \right] A_{ch} \right. \\
+ (\overline{v}_i, \overline{v}_j) C_i A_{ca} + b \tan \Lambda(\overline{v}_i, \overline{v}_j) C_i A_{ct} \left. \right] d\theta \delta C_j \\
- \int_0^t \rho b^4 \omega^2 \sum_{i=1}^{np} \left[ \frac{1}{b} (\overline{v}_i, \overline{v}_j, \overline{x}) C_i - \frac{i}{k_n} \tan \Lambda(\overline{v}_i, \overline{v}_j, \overline{x}) C_i \right] A_{ah} \right. \\
+ \overline{v}_i, \overline{v}_j, \overline{x} C_i A_{aa} + b \tan \Lambda(\overline{v}_i, \overline{v}_j, \overline{x}) C_i A_{at} \left. \right] d\eta \delta C_j \]  

[3.2.5]

The generalized forces are defined as:

\[ Q_j = \omega^2 \sum_{i=1}^{np} A_{ji} C_i \]  

[3.2.6]

The aerodynamic matrix then becomes:

\[ A_{ji} = - \int_0^t \rho b^3 \left[ \frac{1}{b} (\overline{v}_i, \overline{v}_j) - \frac{i}{k_n} \tan \Lambda(\overline{v}_i, \overline{v}_j) \right] A_{ch} \]

\[ + \overline{v}_i, \overline{v}_j A_{ca} + b \tan \Lambda(\overline{v}_i, \overline{v}_j) A_{ct} \right] d\eta \]

\[- \int_0^t \rho b^4 \left[ \frac{1}{b} (\overline{v}_i, \overline{v}_j, \overline{x}) - \frac{i}{k_n} \tan \Lambda(\overline{v}_i, \overline{v}_j, \overline{x}) \right] A_{ah} \]

Aerodynamic Model
The integral equations for the aerodynamic matrix are obtained by substituting the expressions for the aerodynamic coefficients, and the displacement functions $\tilde{y}$'s into the expression for the virtual work of the non-conservative forces. The integration is performed numerically by a 15 point gaussian quadrature numerical integration scheme [23]. The roots of the Legendre Polynomial and the weight factors used in the numerical integration are given in Table 1.

3.3 Flutter Analysis

The V-g method [24] was used in computing the flutter speeds. This method introduces a structural damping coefficient $g$ into the equations of motion. Neutral stability (flutter) is attained for a given velocity, when the damping of the structure goes to zero. Assuming harmonic motion the equations of motion become:

$$[[K](1 + ig) - \omega^2[M]](C) = \omega^2[A](C)$$  \[3.3.1\]

In the absence of non-aerodynamic forces, the resulting generalized eigenvalue problem can be written as:

$$[[I]\lambda - [B]](C) = (0)$$  \[3.3.2\]

$B$ is a generalized complex matrix, $\lambda$ is the eigenvalue and $(C)$ is the eigenvector. The eigenvalue $\lambda$ is defined as:

$$\lambda = \frac{1 + ig}{\omega^2}$$  \[3.3.3\]

The generalized complex bar matrix bar $[B]$ is defined as:

$$[B] = [K]^{-1}[M + A]$$  \[3.3.4\]

The flutter speed perpendicular to the chord is defined as:

$$V_n = \frac{\omega b}{k_n} \cos \Lambda$$  \[3.3.5\]
Where $b$ is defined as the halfchord perpendicular to the midchord reference line. The flutter frequency bar is $\omega$, and $k_a$ is the reduced frequency.
4.0 Validation of Analysis Program

4.1 Introduction

This chapter gives comparisons between results found in literature and the present code. The validation process is broken down into four sections. To validate the stiffness matrix, the static deflections are checked. The mass matrix is verified by comparing the natural frequencies of vibration with isotropic as well as composite materials. Once sufficient verification of the structural model is complete, the static aerodynamic loads are checked for divergence of swept and unswept wings. The dynamic aerodynamic matrix is verified by comparing the flutter frequencies and speeds with results found by Castel and Kapania [21] who developed a simple element for the aeroelastic analysis of laminated wings. Their formulation allows for unsymmetric laminations, arbitrary geometry including chord and thickness taper, and multiple sweep angles.
The comparisons made in this presentation are for a wing consisting of top and bottom flat laminated skins rigidly connected as shown in Figure 3. For all isotropic comparisons, the material properties of the rectangular box beam were taken to be Aluminium:

\[ E_{11} = E_{22} = 6.8948 \times 10^{10} \frac{N}{m^2} \quad v_{12} = 0.30 \]

The material properties of the material used in the laminated wing are:

\[ E_{11} = 6.9 \times 10^{10} \frac{N}{m^2}, \quad E_{22} = 5.0 \times 10^{10} \frac{N}{m^2}, \quad v_{12} = 0.28 \]

\[ G_{12} = 1.5 \times 10^{10} \frac{N}{m^2}, \quad \rho_{mat} = 2.71 \times 10^3 \frac{kg}{m^3} \]

It should be noted that the material properties were arbitrarily chosen.

### 4.2 Static Deflections

The static deflections are compared with Beer and Johnston [22], and Castel and Kapania [21]. For tip loading of a uniform cantilever beam, Beer and Johnston [22] give the tip deflection to be:

\[ Z = -\frac{P l^3}{3EI} \quad (positive \ up) \quad [4.2.1] \]

Comparisons with the results obtained using the EPFAC (Equivalent Plate Flutter Analysis Code) are given in Table 2, for different aspect ratios, AR.
Next, the tip deflection under the same loading condition was tested against results of Castel and Kapania [22] for the wing in Figure 3. In this formulation, Castel and Kapania used four finite elements to model the structure. Each beam element has twenty-four degrees of freedom, twelve at each end. Results for zero sweep and variation in fiber angle are given in Figure 5. Excellent agreement between the finite element code and EPFAC exists for the entire range of values of the fiber angle.

Figure 6 gives a clear comparison between the two different models. EPFAC is termed a skewed wing while the model of reference 21 is a rotated wing. The differences in deflections obtained using the different modeling of the wing structure can be accounted for as follows. The rotated wing's boundary conditions are such that the analysis procedure assumes an effective root and tip perpendicular to the reference line, regardless of sweep angle. As a result, the static deflections are independent of the sweep. The skewed wing assumes the root and tip parallel to the flow. As the wing is swept forward or backward, the torsional and bending stiffnesses become coupled. Static deflection comparisons for different sweep angles of the composite material are given in Figure 7.

4.3 Free Vibration Analysis

For the wing under consideration, the natural frequencies obtained from the present code EPFAC was compared with those obtained using the expressions for a uniform Bernoulli-Euler Cantilever Beam [25]. The comparisons of these values are shown in Table 3. The results show excellent agreement for different aspect ratios.
EPFAC was compared with Ref. [21], for an unswept wing having different ply angles. The results are plotted in Figure 8. The natural frequencies of forward and aft swept wings were also tested. The results are shown in Figure 9. The differences between the two sets of results at larger sweep angles are due to the differences in modeling of the boundary conditions, in the two studies as discussed previously in section 4.2.

4.4 Divergence and Flutter

Having gained confidence in the structural model, the results for aeroelastic response of swept and unswept wings were compared with the results from two different codes: (i) a code written by Barthelemy and Bergen [17], and (ii) a code written by Castel and Kapania [21]. Barthelemy and Bergen used Weissinger’s L-Method to obtain the static aerodynamic loading matrix.

In Weissinger’s L-method, the flow around the wing is modeled by a lifting line of vortices bound at the wing quarter-chord line. A no-penetration boundary condition is specified at na control stations along the wing. The placement of the control points determines the spanwise distribution of . An modification to the position of the downwash distribution was employed to account for the slope of the \( C_l \) vs \( \alpha \) curve less than 2\( \pi \).

The wing dimensions used for comparison with the present method are:

\[ S = 20.0 \, m^2 \quad AR = 10.0 \quad tp = 1.0 \]

where \( tp \) is the taper ratio of the half wing. The results are shown in Figure 10. An excellent agreement is observed between the two sets of results.

Castel and Kapania [21] used Yates’ modified strip method [3] to obtain both the static and dynamic aerodynamic loadings for swept and unswept composite wings. For different values of sweep the fiber orientation was varied and the results for the divergence and flutter speeds were obtained with EPFAC. Figures 11-15, show the comparison...
between the results obtained using the EPFAC code and that of Castel and Kapania for divergence and flutter speeds for different values of sweep and fiber orientation. The differences at large sweep angles are due to the different models used in the two studies. As discussed previously in the section on deflection in this chapter, the model used in Reference [21] is a rotated model, compared to a skewed model used in EPFAC.

5.0 Sensitivity Analysis

5.1 Introduction

This chapter presents the calculation for the sensitivity of the flutter speed, flutter frequency, and reduced frequency to geometric shape parameters namely: (i) aspect ratio, (ii) surface area, (iii) taper ratio, and (iv) sweep angle. The sensitivity calculations require the sensitivity of the aerodynamic, mass and stiffness matrices with respect to various shape parameters. A key objective of this study is to check the viability of calculating the desired derivatives using an analytical approach. It was decided to analytically obtain the sensitivities of the aerodynamic matrix. The analytical derivatives eliminate the uncertainty in the choice of step size which if too large can lead to truncation errors and if too small can lead to ill-conditioning.

The derivation of the analytic derivative of the aerodynamic matrix, is given in this chapter. To validate the expressions for the eigenvalue derivatives, these derivatives are calculated using three different methods. The first method is purely a numerical ap-
proach that uses a finite difference approximation to find the eigenvalue derivatives. The second method is a semi-analytic approach, because the derivatives of the aerodynamic matrix are found using finite difference approximations, and then using the expression for the derivative of the eigenvalue as given by Murthy and Haftka [19]. The third "analytic" method uses an analytically derived derivative of the aerodynamic matrix, along with the eigenvalue derivative expression given by Murthy and Haftka [19].

5.2 Eigenvalue Derivatives and Solution Procedures

In the first method of calculating the derivatives, the flutter problem is solved twice and the derivatives of the eigenvalues are approximated using a forward finite difference scheme.

The second and third methods use the expression for the eigenvalue derivative as given by Murthy and Haftka [19]. The expression is derived using the main and the adjoint problem. The main eigenvalue problem is:

\[
([\lambda] - [B])e_s = 0
\]

[5.2.1]

where \(e_s\) is the right hand eigenvector, and \([B]\) is defined in equation 3.3.4. Similarly the adjoint problem is:

\[
(e_i)'([\lambda] - [B]) = 0
\]

[5.2.2]
where $e_i$ is the left hand eigenvector. The eigenvalues in both cases are the same. Taking the derivative of equation 5.2.1 with respect to a shape parameter $p_s$ yields:

$$
[[I] \frac{\partial \lambda}{\partial p_s} - \frac{\partial [B]}{\partial p_s}] (e_r) + [[I] \lambda - [B]] (\frac{\partial e_r}{\partial p_s}) = 0
$$

[5.2.3]

Multiplying the above equation by left eigenvector gives:

$$(e_i)^{T} [[I] \frac{\partial \lambda}{\partial p_s} - \frac{\partial [B]}{\partial p_s}] (e_r) + (e_i)^{T} [[I] \lambda - [B]] (\frac{\partial e_r}{\partial p_s}) = 0
$$

[5.2.4]

Equation 5.2.2 reduces this to:

$$(e_i)^{T} [[I] \frac{\partial \lambda}{\partial p_s} - \frac{\partial [B]}{\partial p_s}] (e_r) = 0
$$

[5.2.5]

For the $i^{th}$ eigenvalue, the eigenvalue derivative is expressed as:

$$
\frac{\partial \lambda^i}{\partial p_s} = \frac{(e_i)^{T} \frac{\partial [B]}{\partial p_s} (e_i)}{(e_i)^{T} (e_i)}
$$

[5.2.6]

Recalling equation 3.3.3, the eigenvalue derivative in terms of flutter frequency, damping, and there derivatives is written as:

$$
\frac{\partial \lambda}{\partial p_s} = -\frac{2 \frac{\partial \omega}{\partial p_s}}{\omega^3} + \frac{\frac{\partial g}{\partial p_s} \omega^2 - 2 \omega \frac{\partial \omega}{\partial p_s} g}{\omega^4} i
$$

[5.2.7]

Sensitivity Analysis
To obtain the derivative of the generalized complex matrix \([B]\), the derivatives of the aerodynamic matrix \([A]\); of the inverse of the stiffness matrix \([K]^{-1}\), and of the mass matrix \([M]\) are needed.

\[
\frac{d[B]}{dp_s} = \frac{\delta[K]}{\delta p_s} \left[ \left[ K^{-1} \right] + \left[ A \right] + \left[ K^{-1} \left[ \frac{\delta[M]}{\delta p_s} + \frac{d[A]}{dp_s} \right] \right] \right] \tag{5.2.8}
\]

The derivatives of the mass matrix, and the inverse of the stiffness matrix are obtained using the forward finite difference method. A study was first conducted to obtain an appropriate step size for the finite difference calculations. The results of this study are shown in Table 4. These step sizes indicate that the calculated derivatives are stable as indicated in Table 4.

The derivatives of the aerodynamic matrix \([A]\) with respect to a geometric shape parameter are obtained using two different methods: (i) finite difference method; and (ii) analytic method. The calculation of the sensitivity of the aerodynamic matrix \([A]\) is made difficult by the fact that this matrix depends upon shape parameters \(p\), and also on the reduced frequency \(k_n\). The reduced frequency is not really an independent variable, as its value for a new value of \(p ( = p_s^{\text{old}} + \Delta p_s)\) should be such that the imaginary part of the eigenvalue corresponding to the perturbed configuration should be zero.

In the finite difference method, the sensitivity of the aerodynamic matrix \([A]\) is obtained as follows:

\[
\frac{d[A]}{dp_s} = \frac{\left[ A(p_s + \Delta p_s, k_n + \Delta k_n) - [A(p_s, k_n)] \right]}{\Delta p_s} \tag{5.2.9}
\]
To obtain the value of $\Delta k_\alpha$, an iterative procedure, as described in Figure 16, is used. As a first step, $\Delta k_\alpha$ is put equal to zero, and the sensitivity of the eigenvalue is obtained. Obviously, the imaginary part of the new eigenvalue thus obtained will not be zero. This fact is used to obtain the value of $\Delta k_\alpha$ as explained in the following.

The change in the damping coefficient $g$, a function of both the shape parameters and reduced frequency, can be written as:

$$dg = \frac{\partial g}{\partial \rho_s} d\rho_s + \frac{\partial g}{\partial k_n} dk_n \quad [5.2.10]$$

At flutter speed:

$$g = 0 \quad , \quad dg = 0$$

Therefore

$$\frac{dk_n}{d\rho_s} = -\frac{\frac{\partial g}{\partial \rho_s}}{\frac{\partial g}{\partial k_n}} \quad [5.2.11]$$

Note that $\frac{\partial g}{\partial k_n}$ was already obtained during the calculations of the flutter speed. The values of reduced frequency are varied in the initial problem to compute the value at the point the damping coefficient goes to zero. Therefore, $\frac{\partial g}{\partial k_n}$ is easily computed by a forward finite difference scheme. The value of $\frac{\partial g}{\partial \rho_s}$ is obtained from the imaginary part of the sensitivity of the eigenvalue obtained in the first step. This is computed directly from the eigenvalue derivative. Recalling equation 5.2.7:

Sensitivity Analysis
\[
\frac{\partial g}{\partial p_s} = \text{imag}(\frac{\partial \lambda}{\partial p_s}) \omega^2 + \frac{2 \frac{\partial \omega}{\partial p_s} g}{\omega}
\]  [5.2.12]

where \(\omega\) is obtained from the original flutter problem and;

\[
\frac{\partial \omega}{\partial p_s} = -\frac{\text{real}(\frac{\partial \lambda}{\partial p_s}) \omega^3}{2}
\]  [5.2.13]

If \(\frac{\partial g}{\partial p_s}\) is not within a tolerance of \(10^{-6}\), the aerodynamic matrix \([A]\) is recalculated at a new value of the reduced frequency while also keeping the same perturbation in the shape parameter. Once \(\frac{dk}{dp_s}\) is known, an approximation to the value of \(k_n\), corresponding to flutter speed for a new value of \(p_s\), is obtained using a Taylor's series expansion:

\[
k_n^{\text{new}} = k_n^{\text{old}} + \frac{dk}{dp_s} \Delta p_s
\]  [5.2.14]

This process is repeated until the tolerance is met.

In the "analytical" method, the sensitivity of the generalized complex matrix \([B]\) is obtained in a similar fashion except the sensitivity of the aerodynamic matrix \([A]\) is computed analytically. This is expressed as follows:

\[
\frac{\partial [A]}{\partial p_s} = \frac{\partial [A]}{\partial p_s} + \frac{\partial [A]}{\partial k_n} \frac{dk}{dp_s}
\]  [5.2.15]

Both \(\frac{\partial [A]}{\partial p_s}\) and \(\frac{\partial [A]}{\partial k_n}\) are derived in section 5.4. The value of \(\frac{dk}{dp_s}\) is computed from the eigenvalue derivative, as explained above. In the first iteration, \(\frac{dk}{dp_s}\) is assumed to be zero. The aerodynamic matrix derivative is computed and combined with the deriva-
tives of the mass [M], inverse stiffness matrices [K]^{-1} to form \( \frac{\partial [B]}{\partial p} \). The eigenvalue derivative is then computed. The value of \( \frac{dk_n}{dp} \) is calculated as described above. Figure 17 shows a detailed flow chart of the analytic method.

The derivative of the flutter speed is:

\[
\frac{\partial V_f}{\partial p} = \frac{k_n \left[ \frac{\partial \omega_\beta}{\partial p} b + \omega \frac{\partial b}{\partial p} \right] - \omega b \frac{\partial k_n}{\partial p}}{k_n^2} \tag{5.2.16}
\]

The flutter speed at the new configuration is then computed using a truncated taylor series. As before:

\[
V_{fnew} = V_{fold} + \frac{\partial V_f}{\partial p} \Delta p
\tag{5.2.17}
\]

To calculate the analytic derivative of the aerodynamic matrix, the geometric parameters must first be defined.

### 5.3 Geometric Parameters

The Aerodynamic matrix is composed of geometric parameters which are a function of surface area, aspect ratio, taper ratio and sweep angle. These parameters are the span, root chord, tip chord, halfchord, the global x and y coordinates, the displacement functions, and their derivatives with respect to global x and y coordinates. These are expressed as:
\[ B = \sqrt{ARS} \]  
\[ C_r = \frac{2S}{(1 + tp)\sqrt{ARS}} \]  
\[ C_t = \frac{2Stp}{(1 + tp)\sqrt{ARS}} \]  
\[ \text{crd}(i) = C_r + (C_t - C_r) \frac{(n(i) + 1)}{2} \quad i = 1, \ldots, 15 \]  
\[ x(i) = \frac{C_r}{2} + y(i) \tan \Lambda \quad i = 1, \ldots, 15 \]  
\[ y(i) = \frac{Bn(i) + B}{2} \quad i = 1, \ldots, 15 \]  
\[ b(i) = \frac{\text{crd}(i)}{2} \cos \Lambda \quad i = 1, \ldots, 15 \]

Where \( b \) is the halfchord measured perpendicular to the reference line, \( AR \) is the aspect ratio, \( S \) is the surface area, \( C_r \) is the root chord, \( C_t \) is the tip chord, \( \text{crd}(i) \) is the chord length at station \( i \), and \( tp \) is the taper ratio.

### 5.4 Analytic Derivatives

For general purposes, \( p \), will represent the shape parameters, where \( s = 1 \) is the surface area, \( s = 2 \) is the aspect ratio, \( s = 3 \) is the taper ratio, and \( s = 4 \) is the sweep angle. The Sensitivity Analysis
Aerodynamic matrix, given in equation 3.2.7, must be differentiated with respect to the shape parameters and the reduced frequency. In order to avoid the use of Leibnitz's Rule, and facilitating numerical integration using Gauss integration, the integrals must be changed over to local coordinates. Equation 3.2.7 is written as:

\[ A_{ji} = -\int_{-1}^{1} \pi \rho b^2 \omega^2 \left[ \left[ \frac{1}{b} (\bar{y}_i, \bar{y}_j) - \frac{i}{k_n} \tan \Lambda(\bar{y}_i, \bar{y}_j) \right] A_{ch} \right. \]

\[ + \bar{y}_i, \bar{y}_j A_{ca} + b \tan \Lambda(\bar{y}_i, \bar{y}_j) A_{cA} \right] \frac{B}{2 \cos \Lambda} \ d\eta \]

\[ - \int_{-1}^{1} \pi \rho b^4 \omega^2 \left[ \left[ \frac{1}{b} (\bar{y}_i, \bar{y}_j) - \frac{i}{k_n} \tan \Lambda(\bar{y}_i, \bar{y}_j) \right] A_{ah} \right. \]

\[ + \bar{y}_i, \bar{y}_j, \bar{y}_A A_{aa} + b \tan \Lambda(\bar{y}_i, \bar{y}_j, \bar{y}_A) A_{Aa} \right] \frac{B}{2 \cos \Lambda} \ d\eta \]

where \( d\bar{y} \) is replaced by \( \frac{B}{2 \cos \Lambda} \ d\eta \).

The derivative of the aerodynamic matrix with respect to a general shape parameter, representing \( B' = \frac{B}{\cos \Lambda} \), is:

\[ \frac{dA_{ji}}{dp_j} = -\pi \rho \omega^2 \left[ \int_{-1}^{1} \left\{ \left( \frac{eb}{k_n} \frac{\partial \bar{y}_i}{\partial p_j} \bar{y}_j \tan \Lambda + \frac{ib^3}{k_n} \frac{\partial \bar{y}_i}{\partial p_j} \bar{y}_j \tan \Lambda + \frac{ib^3}{k_n} \bar{y}_i \frac{\partial \bar{y}_j}{\partial p_j} \tan \Lambda \right) A_{ch} \right. \]

\[ - \left[ \frac{3eb^2}{k_n^2} \frac{\partial \bar{y}_i}{\partial p_j} \bar{y}_j \tan \Lambda + \frac{ib^3}{k_n} \frac{\partial \bar{y}_i}{\partial p_j} \bar{y}_j \tan \Lambda + \frac{ib^3}{k_n} \bar{y}_i \frac{\partial \bar{y}_j}{\partial p_j} \right] \tan \Lambda \]

\[ + \frac{ib^3}{k_n^2 \cos^2 \Lambda} \bar{y}_i \bar{y}_j \frac{\partial \Lambda}{\partial p_j} - \frac{ib^3}{k_n} \bar{y}_i \bar{y}_j \tan \Lambda \frac{\partial k_n}{\partial p_j} \right] A_{ch} \]
+ (3b^2 \frac{\partial b}{\partial \gamma_i, \bar{x}} \bar{y}_j + b \frac{\partial \gamma_i, \bar{x}}{\partial p_s} \bar{y}_j + b^2 \gamma_i, \bar{x} \frac{\partial \bar{y}_j}{\partial p_s}) A_{cx} \nonumber \\
+ (4b^3 \frac{\partial b}{\partial p_s} \bar{y}_i, \bar{x} \bar{y}_j \tan \Lambda + b^4 \frac{\partial \gamma_i, \bar{x}}{\partial p_s} \bar{y}_j \tan \Lambda + b^4 \gamma_i, \bar{x} \frac{\partial \bar{y}_j}{\partial p_s} \tan \Lambda + \frac{b^4}{\cos^2 \Lambda} \bar{y}_i, \bar{x} \bar{y}_j \frac{\partial \Lambda}{\partial p_s}) A_{ct} \nonumber \\
+ (3b^2 \frac{\partial b}{\partial p_s} \bar{y}_i, \bar{x} \bar{y}_j \tan \Lambda + \frac{\partial \gamma_i, \bar{x}}{\partial p_s} \bar{y}_j \tan \Lambda + b \gamma_i, \bar{x} \frac{\partial \bar{y}_j}{\partial p_s}) A_{ah} \nonumber \\
- \left[ \frac{4ib^3}{k_n} \frac{\partial b}{\partial p_s} \bar{y}_i, \bar{x} \bar{y}_j \tan \Lambda + \frac{ib^4}{k_n} \frac{\partial \gamma_i, \bar{x}}{\partial p_s} \bar{y}_j \tan \Lambda + \frac{ib^4}{k_n} \frac{\partial \bar{y}_j}{\partial p_s} \tan \Lambda \right] A_{an} \nonumber \\
+ (4b^3 \frac{\partial b}{\partial p_s} \bar{y}_i, \bar{x} \bar{y}_j \tan \Lambda + b^4 \frac{\partial \gamma_i, \bar{x}}{\partial p_s} \bar{y}_j \tan \Lambda + b^4 \gamma_i, \bar{x} \frac{\partial \bar{y}_j}{\partial p_s}) A_{ax} \nonumber \\
+ (5b^4 \frac{\partial b}{\partial p_s} \bar{y}_i, \bar{x} \bar{y}_j \tan \Lambda + b^5 \frac{\partial \gamma_i, \bar{x}}{\partial p_s} \bar{y}_j \tan \Lambda + b^5 \gamma_i, \bar{x} \frac{\partial \bar{y}_j}{\partial p_s}) \tan \Lambda \nonumber \\
+ \frac{b^5}{\cos^2 \Lambda} \bar{y}_i, \bar{x} \bar{y}_j \frac{\partial \Lambda}{\partial p_s} \right] A_{at} \nonumber \tag{5.4.2} \\
+ (b^2 \gamma_i, \bar{y}_j - \frac{ib^3}{k_n} \tan \Lambda \bar{y}_i, \bar{x}) \frac{\partial A_{ch}}{\partial p_s} + \frac{b^3 \gamma_i, \bar{x} \bar{y}_j}{\partial p_s} \right] A_{cs} \nonumber \\
+ (b^4 \tan \Lambda \bar{y}_i, \bar{x} \bar{y}_j) \frac{\partial A_{ct}}{\partial p_s} + (b^4 \gamma_i, \bar{x} - \frac{ib^4}{k_n} \tan \Lambda \bar{y}_i, \bar{x} \bar{y}_j, \bar{x}) \frac{\partial A_{ah}}{\partial p_s} \nonumber \\
+ b^4 \gamma_i, \bar{x} \bar{y}_j \frac{\partial A_{ax}}{\partial p_s} + b^5 \tan \Lambda \bar{y}_i, \bar{x} \bar{y}_j \bar{y}_j \frac{\partial A_{at}}{\partial p_s} \right] B^r \nonumber \\
\text{Sensitivity Analysis} \text{ 56}
The derivatives of the displacement function with respect to a general shape parameter \( p_i \) are given as follows:

\[
\frac{\partial}{\partial p_i} \left[ \frac{1}{k_n} \tan \Lambda \tilde{y}_i \tilde{y}_j \right] A_{ch} + b^3 \tilde{y}_i \tilde{y}_j A_{ca} \\
+ (b^4 \tan \Lambda \tilde{y}_i \tilde{y}_j) A_{ce} + \left[ b^3 \tilde{y}_i \tilde{y}_j \tilde{z} + \tan \Lambda \tilde{y}_i \tilde{y}_j \right] A_{ah} \\
+ b^4 \tilde{y}_i \tilde{z} A_{ac} + b^5 \tan \Lambda \tilde{y}_i \tilde{y}_j \tilde{z} A_{as} + \frac{\partial B'}{2\partial p_i} \right] d\eta
\]

The global coordinates \( x \) and \( y \) are given in terms of the local coordinates and the geometric shape parameters in equations 5.3.5 and 5.3.6. The derivatives of \( x \) and \( y \) with respect to various geometric shape parameters are as follows:

\[
\frac{\partial y}{\partial A R} = \frac{S(\eta + 1)}{4(\sqrt{A R S})} \quad [5.4.4]
\]

\[
\frac{\partial y}{\partial S} = \frac{A R(\eta + 1)}{4(\sqrt{A R S})} \quad [5.4.5]
\]

\[
\frac{\partial y}{\partial \eta} = 0.0 \quad [5.4.6]
\]

\[
\frac{\partial y}{\partial \lambda} = 0.0 \quad [5.4.7]
\]
The derivatives of the halfchord with respect to the shape parameters are:

\[
\frac{\partial x}{\partial AR} = -\frac{S^2}{2(1 + tp)AR S \frac{3}{2}} + \frac{\partial y}{\partial AR} \tan \Lambda \tag{5.4.8}
\]

\[
\frac{\partial x}{\partial S} = \frac{1}{2(1 + tp)\sqrt{AR S}} + \frac{\partial y}{\partial AR} \tan \Lambda \tag{5.4.9}
\]

\[
\frac{\partial x}{\partial tp} = -\frac{S\sqrt{AR S}}{[(1 + tp)^2]^{\frac{3}{2}}} \tag{5.4.10}
\]

\[
\frac{\partial x}{\partial \Lambda} = \frac{\sqrt{AR S}(r + 1)}{2 \cos^2 \Lambda} \tag{5.4.11}
\]

The aerodynamic coefficients, $C_{A1}$, $A_{m1}$, $A_{m2}$, $A_{m3}$, $A_{m4}$, and $A_{m5}$, are functions of the reduced frequency. The reduced frequency changes as the shape parameters change therefore these terms are functions of the shape parameters and must be included in the formulation. They are defined as:

\[
\text{Sensitivity Analysis}
\]

58
\[
\frac{\partial}{\partial p_s} = \frac{\partial}{\partial k_n} \frac{dk_n}{dp_s}
\]  
[5.4.16]

\[
\frac{\partial A_{ch}}{\partial k_n} = \left( \frac{iC_{ls}}{\pi} \right) \frac{k_n \frac{dC(k_n)}{dk_n} - C(k_n)}{k_n^2}
\]  
[5.4.17]

\[
\frac{\partial A_{c3}}{\partial k_n} = -\frac{i}{2} + \left( \frac{iC_{ls}}{\pi} \right) \frac{k_n \frac{dC(k_n)}{dk_n} - C(k_n)}{k_n^2} \left( \frac{1}{2} - a \right)
\]  
[5.4.18]

\[
\frac{\partial A_{c3}}{\partial k_n} = -i + \left( \frac{iC_{ls}}{\pi} \right) \frac{k_n \frac{dC(k_n)}{dk_n} - C(k_n)}{k_n^2} \left( \frac{C_{ls}}{\pi} (-a - a) \right)
\]  
[5.4.19]

\[
\frac{\partial A_{oh}}{\partial k_n} = -\left( \frac{k_n \frac{dC(k_n)}{dk_n} - C(k_n)}{k_n^2} \right) \left( \frac{iC_{ls}}{\pi} \right) \left( -a + a \right)
\]  
[5.4.20]

\[
\frac{\partial A_{ax}}{\partial k_n} = -\frac{i}{2} \left( \frac{1}{2} - a \right) + \left( \frac{iC_{ls}}{\pi} \right) \frac{k_n \frac{dC(k_n)}{dk_n} - 2C(k_n)}{k_n^3} \left( \frac{C_{ls}}{\pi} (-a + a) \right)
\]  
[5.4.21]

Sensitivity Analysis
The derivative of Theodorsen's circulation function, as given in equation (3.1.3), is:

$$\frac{\partial A_{aq}}{\partial k_n} = -\frac{i}{k_n} \left[ -\frac{2i}{4k_n^2} + (-a_n^2 + a^2)(\frac{k_n^2 \frac{dC(k_n)}{dk_n}}{k_n^2} - C(k_n)) \left( \frac{C_{iz}}{\pi} \right) \right] - \frac{1}{k_n} A_{aq}[5.4.22]$$

The derivative of the eigenvalue with respect to various parameters, namely the surface area $S$, the aspect ratio $AR$, the taper ratio $t_p$ and sweep were compared with those obtained using the two previously described methods, namely: (i) the purely finite difference method and (ii) a semi-analytic approach in which the desired derivatives were obtained using a forward finite difference scheme. The results are shown in Table 5. An excellent agreement exists between the various sets of results. However, the values of the derivative of the eigenvalue, with respect to sweep, see fourth row of Table 4, obtained using the three methods appear to be different from each other. For example, the "analytically obtained " derivative ( case (iii)) is about 6.95 percent more than that obtained using a purely finite difference approach (case (i)). Similarly, the value of the same derivative obtained using a semi-analytic approach (case (ii)), is about 9.36 percent less than that obtained using the analytic approach. The reasons for this discrepancy are not entirely clear at this stage. However, Figure 28 shows that the analytic method gives the best results.

Figures 18 through 29 show the flutter speed, frequency, and reduced frequency analytically based values versus the values which where reanalyzed at different configurations.
These are called reanalysis values because the v-g method was used to solve for the flutter speed at the perturbed value. These show excellent agreement over a range which can be useful to the designer in the initial design phase.

However, close attention should be paid to any mode shifting. For instance, in smaller aspect ratio configurations the flutter frequency predominant mode changes from the third mode to the second mode. This evident in Figure 21, where the flutter frequency drops for the lower values of the aspect ratio.

6.0 Conclusions and Suggestions for Future Work

A method for analyzing the dynamic aeroelastic behavior of a laminated wing has been developed. The aerodynamic formulation was taken from Yates' modified finite strip method. This was combined with Giles' equivalent plate model which is capable of analyzing cranked wing box structures. Three different approaches were used to obtain the sensitivity of the flutter speed, frequency, and reduced frequency. The first was a purely numerical approach using finite difference method. The second used the analytic expressions for the derivative of the eigenvalue as originally derived by Lancaster [19], and a finite difference method to calculate the derivatives of the aerodynamic, mass and stiffness matrices. The third method also used Lancaster's [19] expression for the eigenvalue derivative but the derivative of the aerodynamic matrix is computed analytically.

It was shown that the eigenvalue derivatives for all three cases are in good agreement with each other. Also the results for flutter speed and reduced frequency obtained using sensitivity based analysis, for a significant range of parameters, are found to be in good agreement with those obtained using a complete reanalysis.
There is ample room for additional work in the area of Aerodynamic sensitivity analysis. This work can be extended to include the analytical derivatives of the mass and stiffness matrices. This will eliminate any uncertainties in choosing a finite difference step size and be of great use to the present optimization codes.

An improved aerodynamic code could be added to include the effect of chordwise bending of the box structure. This can be achieved by using the aerodynamic coefficients developed by Spielberg [26] to modify the present analysis.

The variation of the curvature of the flutter speed, flutter frequency, and reduced frequency could be predicted more accurately by a second order derivative. For a general complex matrix, efficient calculations of these derivatives are present by Murthy and Haftka [19].

The aerodynamic sensitivity calculations of a wing with mass stores is needed in the industry. The changing mass configurations of a wing with missiles and bombs is a typical example for the need of such an analysis capability.

This work can be extended to include the sensitivities of the flutter speed, flutter frequency, and reduced frequency to a simultaneous change in several shape parameters. For example, the sensitivity of flutter speed with the changes in sweep and aspect ratio would be useful. The structural code used in this analysis is extremely versatile and can be extended with the present aerodynamic formulation to analyze cranked wing boxes.
7.0 References

A method is presented for calculating the shape sensitivity of a wing aeroelastic response with respect to changes in geometric shape. Yates’ modified strip method is used in conjunction with Giles’ equivalent plate analysis to predict the flutter speed, frequency, and reduced frequency of the wing. Three methods are used to calculate the sensitivity of the eigenvalue. The first method is purely a finite difference calculation of the eigenvalue derivative directly from the solution of the flutter problem corresponding to the two different values of the shape parameters. The second method uses an analytic expression for the eigenvalue sensitivities of a general complex matrix, where the derivatives of the aerodynamic, mass, and stiffness matrices are computed using a finite difference approximation. The third method also uses an analytic expression for the eigenvalue sensitivities, but the aerodynamic matrix is computed analytically. All three methods are found to be in good agreement with each other. The sensitivities of the eigenvalues were used to predict flutter speed, frequency, and reduced frequency. These approximations were found to be in good agreement with those obtained using a complete reanalysis. However, it is recommended that higher order terms be used in the calculations in order to assure greater accuracy.
