ABSTRACT

An analytical method is presented to predict the shifts of the contact ellipses on spiral bevel gear teeth under load. The contact ellipse shift is the motion of the tooth contact position from the ideal pitch point to its location under load. The shifts are due to the elastic motions of the gear and pinion supporting shafts and bearings. The calculations include the elastic deflections of the gear shafts and the deflections of the four shaft bearings. The method assumes that the surface curvature of each tooth is constant near the unloaded pitch point. Results from these calculations will help designers reduce transmission weight without seriously reducing transmission performance.

NOMENCLATURE

O center of curvature
Pb base pitch of equivalent spur gear, m
r mid-plane pitch radius, m
R mid-cone pitch radius, m
Re effective pitch radius, m
Re' loaded effective pitch radius, m
T torque, N·m
U pitch point tangential motion, m
N force component, N
X bearing radial deflection, m
Y pitch point deflection, m
Z gear center deflection, m
β orthogonal coordinate frame
Γ cone angle, rad
θ pitch point slope, rad
ρ radius of curvature, m
Σ shaft angle, rad
ϕn normal pressure angle, rad
ϕ' n loaded normal pressure angle, rad
ψ spiral angle, rad

INTRODUCTION

Spiral bevel gears are important elements for transmitting power. In designing spiral bevel gear transmissions, the designer meets a tradeoff between a transmission's weight and its life and reliability. By removing weight from transmission components, one increases the overall flexibility of the transmission. This flexibility affects the deflections of the loaded components in the transmission.

The design of an efficient spiral bevel gear box includes the design of: gear and support geometry, bearing and shaft sizes, and material properties. The gear tooth interaction is more complex than that of spur or helical gears. The loaded region of the gear mesh shifts due to the deflections of the gear and the pinion. A primary cause of these motions is the flexibility of the gear support shaft and bearings. Although the teeth also deflect, tooth beam deflections are small in comparison to tooth gear support deflections. If the shift of the loaded region is large, the life of the gear mesh may reduce significantly.

The classic work of Wildhaber (Refs. 1 and 2) describes the kinematic operation and the generation of spiral bevel gears. More recently, Baxter (Ref. 3) and Coleman (Ref. 4) expanded on this fundamental theory. They described a Tooth Contact Analysis program which analyzes the kinematic action of two spiral bevel gears in mesh. The program considers effects of tooth manufacturing parameters on the gear mesh kinematics.

Litvin and Coy (Ref. 5), and Litvin, Rahamn and Goldrich (Ref. 6) also presented the theory of spiral bevel gear generation and design. These works describe kinematic errors induced in the transmission by errors in gear manufacturing and assembly. The papers also suggest tooth profile modifications to improve kinematic transmission. They give direct relationships for the generated curvatures and directions on the terms of the principal curvatures and directions on the bevel gear teeth surfaces. These relationships are in terms of the principal curvatures and directions of the tool generating surfaces.

Coleman (Ref. 7) described the experimental measurement of existing bevel and hypoid gear deflections under load. The paper cites the importance of these deflections for the capacity and noise level of the gear set. The test results also suggest gear mounting and tooth manufacturing changes which can improve the capacity and life of the gear set.

Wah, Ettles and MacPherson (Ref. 8) presented the interaction of structural rigidity and performance for a helicopter tail rotor gear box. They used a finite element model for the housing. The paper presents effects of deflections on: bearing roller load distribution, bearing fatigue life and the gear motions at the unloaded pitch point. Their work demonstrates the importance of rigidity to minimize deflections and maximize bearing life in a transmission.

Winter and Paul (Ref. 9) presented work on the influence of spiral bevel gear deflection on tooth root stresses. This paper presents an analytical method to predict the shift of the loaded region on the tooth. The method treats the shift as a result of the elastic deflections of the gear support shafting and bearings. The analysis is sequential.

The first stage defines the gear geometry and loading. The second stage determines the elastic deflections of the bearings and shafts and the slopes of the shafts at the gears. The third stage finds the motions of the gear teeth caused by each elastic deflection. The total deflections of the gear teeth are the algebraic sum of these motions. The fourth stage determines the geometry and curvatures of the gear and pinion teeth. These directions and curvatures combine with the separate motions of the gear teeth to produce the contact shift. The contact shift is the motion of the contact ellipses on the two tooth surfaces under load from the unloaded pitch point. The analysis assumes that the curvatures are constant over the affected surfaces of the teeth.

A gear box model similar to the main rotor bevel gear reduction of the U.S. Army OH-58 light duty helicopter serves as an example for the method. The gear box includes a single spiral bevel gear drive with a pinion input and the supporting shafts and bearings. The analysis includes a parametric study. The paper presents radial and tangential shifts of the contact ellipses on the pinion and gear teeth as functions of shaft stiffness.

GEOMETRY AND LOADING

Figure 1 shows the geometry of a spiral bevel gear mesh. The mid-cone distance, \(D_o\), is the distance from the apex of the bevel cones to the mid-plane pitch point. This distance is along the pitch line of the two pitch cones. It is equal to the outer-cone distance, \(A_o\), minus one half the tooth face width, \(f\). The mid-cone distance and the tooth face width describe the basic gear blank sizes. The cone pitch angles, \(g\), \(g_p\), and \(g_{pi}\), for the gear and pinion also contribute to the gear sizes. The shaft angle, \(\Sigma\), is the sum of the cone pitch angles. The shaft angle defines the relative orientation of the gear and pinion shafts. The pitch radius of the gear in its mid-plane, \(r_g\), is:

\[
r_g = D_o \cdot \sin g
\]
The cone pitch angle, $\gamma$, in terms of the numbers of teeth on the gear and pinion, $N_g$ and $N_p$, and the shaft angle, $\Sigma$, is:

$$\tan \gamma = \frac{\sin \Sigma}{N_p/N_g + \cos \Sigma}$$  \hspace{1cm} (2)

Similar equations define the pitch radius, $r_p$, and cone pitch angle, $\beta_p$, of the pinion with the subscripts $p$ and $g$ interchanged.

Figure 2 shows the spiral angle, $\psi$, and normal pressure angle, $\phi$. The spiral angle, $\psi$, is the angle of inclination of the teeth to the pitch ray. It is in the plane tangent to the two pitch cones. The gear of Figure 2 has a right hand spiral. The normal pressure angle, $\phi$, is the angle between a normal to the tooth and the tangent to the pitch cone surface in the tooth normal plane.

Figure 2 includes four orthogonal right handed coordinate frames. All four coordinate frames are at the mid-plane pitch point of the spiral bevel tooth. The first of these, $B_{di}$, has coordinates in the tangential, axial and radial directions of the gear body. The second coordinate frame, $B_{ei}$, is the first coordinate frame rotated through the cone angle, $\gamma$, in a negative direction about the $B_{di}$ vector. The unit vectors of this frame are in the tooth normal plane, tangent to the tooth in the cone tangent plane, and in the mid-cone radial direction respectively.

The third coordinate frame, $B_{fi}$, is the second coordinate frame rotated through the spiral angle, $\psi$, in a positive direction about the $B_{ei}$ vector for a right handed spiral angle. The unit vectors of this frame are tangent to the pitch cone in the tooth normal plane, tangent to the tooth in the cone tangent plane, and in the mid-cone radial direction respectively.

The fourth coordinate frame, $B_{gi}$, is the third coordinate frame rotated through the normal pressure angle, $\phi$, in a negative direction about the $B_{fi}$ vector. The unit vectors of this frame are in the tooth normal plane, tangent to the tooth in the cone tangent plane, and in the mid-cone radial direction respectively.

Figure 2 shows the mid-plane pitch radius of the gear, $r_g$, in the axial section plane. The mid-cone radius of the gear, $R_g$, is in the same view. This equivalent spur pitch radius is:

$$R_g = \frac{r_g}{\cos \gamma} \hspace{1cm} (3)$$

The gear assembly includes the support bearings and their locations. The position of the bearings relative to the gear or pinion describes the support system geometry. The two most common bearing configurations are straddle and overhung mountings. Figure 1 shows both. The pinion has a straddle mounting while the gear has an overhung mounting. In both cases, $A$ is the distance from the gear mid-plane to the bearing closest to the pitch cone apex. $B$ is the distance from the gear mid-plane to the bearing furthest from the apex. Distance $A$ is positive for an overhung mounting and negative for a straddle mounting. $B$ is always positive.

The normal force acts on the tooth at the mid-plane pitch point. The method assumes that the force is a concentrated force. The force has three orthogonal components in the directions of the $B_{di}$ coordinate frame relative to the tooth. The tangential component, $W_t$, produces the torque on the gear. It acts in the $B_{di}$ direction. The axial component, $W_a$, acts in the $B_{di}$ direction. And the radial component, $W_r$, acts in the $B_{di}$ direction.

Figure 3 shows these forces for both the gear and the pinion with their respective coordinate frames. For the gear, the components are:

$$W_t = \frac{T_g}{B_0 \cdot \sin \gamma} \hspace{1cm} (4)$$

$$W_a = \frac{W_t}{\cos \psi} \left[ \tan \phi \cdot \sin \gamma + \sin \psi \cdot \cos \gamma \right] \hspace{1cm} (5)$$

$$W_r = \frac{W_t}{\cos \psi} \left[ \tan \phi \cdot \cos \gamma - \sin \psi \cdot \sin \gamma \right] \hspace{1cm} (6)$$

where $T_g$ is the torque on the gear. Replacing the subscript $g$ with the subscript $p$ in Eq. (4) through (6) gives the equations for the pinion force components. In Eq. (5) and (6), the sign of the last term depends on: the direction of rotation, the hand of the spiral, and whether the gear is driving or being driven. These equations are valid for a right-handed spiral driving gear rotating counterclockwise about the $B_{d2}$ direction. Each change in the spiral hand, power direction or rotation direction reverses the signs.

The sign of the tangential load, $W_t$, also depends on the directions of the rotation and power flow. The tangential component is positive for a driving gear or pinion which is rotating counterclockwise. It is also positive for a driven gear or pinion which is rotating clockwise. The tangential load is negative otherwise. However, Eq. (5) and (6) use the absolute value of $W_t$.

**COMPONENT DEFLECTIONS**

Under load, the motion of the ideal pitch point of a spiral bevel gear is mainly the superposition of three elastic configurations resulting from: shaft deflects at the gear centers, shaft slopes at the gear centers, and the deflections of the support bearings.

Table I lists the results of a strength of materials shaft analysis for the deflections, $Y_{ci}$, and slopes (rotations), $\theta_{ci}$, of the gear at the pitch point in and about the $B_{di}$ directions. In the analysis, both the axial and radial forces contribute to both the radial deflection and the tangential rotation. The axial deflection is due to the tangential rotation and the radial deflection at the pitch point in this instance. The straddle and overhung cases require different formulas due to the different elastic configurations for the two cases. As before, interchanging gear and pinion subscripts yields valid equations for the pinion.

The bearings which support the shaft also deflect. Each bearing has a nonlinear stiffness and its own contact angle. Harris (Ref. 10) and Houghton (Ref. 11) present methods for determining the rolling element load sharing and resulting deflection. The method of this paper combines the radial and axial loads on each bearing to find the bearing deflections. The program then resolves each bearing deflection into its radial and axial components in the $B_{di}$ coordinate directions.

The deflections at the bearings are $X_{ao}$ and $X_{bo}$. Here, the subscript $a$ identifies the bearing located the distance $A$ from the gear. And the subscript $b$ identifies the bearing located the distance $B$ away. The last subscript, $i$, denotes the deflection direction in the $B_{di}$ coordinate frame.
For $i = 1, 2$, both bearings have the same axial deflection, $x_2$. Table II lists the deflections, $y_{bi}$, and the rotations, $\theta_{bi}$, of the gear pitch point caused by these bearing deflections. The motions are due to the rigid body motion of the gear and support shaft in the bearings.

The total motions of the gear pitch point in and about the $B_{bi}$ coordinate directions, neglecting any elastic motion of the transmission housing, are:

$$Y_{di} = y_{bi} + y_{ci} \quad \text{for } i = 1, 2, 3$$

$$\theta_{di} = \theta_{bi} + \theta_{ci} \quad \text{for } i = 1, 2, 3$$

Similar equations describe the motion of the pinion pitch point. The motions of the gear and pinion pitch points combine in the analysis for the shift of the contact ellipse under load.

**CONTACT ANALYSIS**

The principal curvatures of the teeth are needed in addition to the teeth deflections in the contact ellipse shift model. Unfortunately, no direct equations exist for the spiral bevel tooth surface due to the complexity of the surface geometry (Ref. 5 and 6). However, an indirect approach can determine the principal curvatures and directions of curvature. Litvin (Ref. 5 and 6) has developed equations to determine these principal curvatures and their directions at the pitch point.

The analysis assumes that direct conjugate relationships exist between the gear cutting tool surface curvatures and motion and the sought quantities. These are the principal curvatures and their directions on the gear tooth surface. The analysis uses the gear and pinion geometry along with the cutter machine settings for both the gear and pinion. The cutter machine's manufacturer provides the gear cutter settings. With this method, one can determine the curvatures of the gear tooth surface without equations for the surface.

The separate pitch point motions of the two gear teeth effect the shift of the contact ellipse under load. In addition, the motions of the centers of transverse curvature of the teeth surfaces effect the tangential contact ellipse shift. The motions of the mid-plane base circles of the teeth also effect the radial contact ellipse shift. In addition, the standard Hertzian contact stress formulas (Ref. 12) yield the size and orientation of the contact ellipse on the gears. All these calculations assume that the principal curvatures remain constant over the contacted portions of the spiral bevel gear teeth.

**RELATIVE MOTIONS**

The contact shift motion occurs in the plane tangent to the two teeth. Relative motions in the direction of the common normal to the teeth produce kinematic errors in the motion transmission. Kinematic error (Ref. 5) is a forward or backward rotation of the output gear from its ideal position relative to the input gear. This motion does not produce a shift of the contact ellipse. Only the radial shift of the teeth in the tooth normal plane and the tangential relative motion in the cone tangent plane are of interest. The radial shift of the teeth produces a radial shift in the contact ellipse locations on both teeth. The tangential motion produces a tangential shift in the contact ellipse locations as shown in Fig. 4.

In the motion analysis, the small pitch point deflections and rotations are vectors. One can obtain the vector components in any of the four coordinate frames by direct matrix rotations.

**Radial Shift**

The radial shift of the two teeth appears in the mid-cone plane and in the tooth normal plane. Fig. 5 shows the two equivalent spur gears in the tooth normal plane before and after application of the separating load. Equivalent spur gears have the tooth geometry of the spiral bevel tooth in its mid-cone plane. The involute action of these spur gears is the same as that of the spiral bevels in the mid-cone plane (Refs. 1 to 3). The radial shift of the two gears is due to an increase of the center distance in this parted mid-cone plane. The separating motion of each gear center is the pitch point motion in the $B_{e3}$ direction minus a small relative motion. The relative radial motion of the gear center is toward the pitch point. It is due to the gear rotation about the original tangential direction $B_{e1}$.

The displacement of the pitch point in the $B_{e3}$ direction is:

$$y_{e3,g} = y_{d2,g} \sin \Gamma + y_{d3,g} \cos \Gamma$$

The effective radius of the equivalent spur gear in the tooth normal plane, $R_{e3,g}$, is a function of the mid-cone radius, $R_g$, and the spiral angle, $\psi$:

$$R_{e3,g} = \frac{R_g}{\cos^2 \psi}$$

The motion of the center of the equivalent gear is thus:

$$y'_{e3,g} = y_{e3,g} - R_{e3,g}(1.0 - \cos \theta_{d1,g})$$

Due to the involute action on separation, the radial motion produces a new loaded pitch point. The normal pressure angle increases slightly. The gears rotate slightly. And a new loaded effective pitch radius results. The new pressure angle, $\phi'_n$, is:

$$\phi'_n = \cos^{-1} \left[ \frac{(R_{e3,g} + R_{e3,p}) \cos \phi_n}{R_{e3,g} + R_{e3,g} + R_{e3,p} + R_{e3,p}} \right]$$

The loaded effective gear pitch radius, $R'_{e3,g}$ is:

$$R'_{e3,g} = \frac{R_{e3,g} \cos \phi_n}{\cos \phi'_n}$$

The radial shift of the pitch point from the unloaded to the loaded position on the gear tooth, $D_{rg}$, is now:

$$D_{rg} = \frac{R'_{e3,g} - R_{e3,g}}{\cos \phi'_n}$$

Figure 6 shows this shift distance and the two pitch radii. Figure 6 is a normal view of the spiral...
bevel gear tooth. The analysis for the radial shift of the contact point on the pinion tooth is similar.

TOOTH CONTACT SHIFT

The radial and tangential components of tooth contact shift are valuable measures of the rigidity of a bevel gear mesh. Knowledge of the shift components can help a designer evaluate important properties of the gear mesh and support bearings. An interactive input Fortran 77 computer program (Ref. 13) calculates these tooth contact shifts for both the gear and pinion. The program, SLIDE.FOR, can run on a personal computer.

Figure 4 shows the shift of the nominal pitch point contact ellipse on a gear tooth. The principal radii of curvature of the teeth and the normal tooth load determine the size and orientation of the contact ellipse. One can compare the tangential shift to the difference between the half tooth width and the tangential radius of the ellipse. This comparison demonstrates whether edge loading can occur in the design. By subtracting the radial shifts from the tooth addenda, one also can evaluate the reduction in the ideal contact ratio.

This model can evaluate performance tradeoffs where transmission weight and transmission life are competing objectives. Figures 8 and 9 are dimensionless plots of contact shift as a function of support shaft stiffness for a single stage transmission. The plots vary both the gear and pinion shaft stiffnesses by the same percentage. The parametric study reduces the stiffnesses from the design values to show the effect of shaft stiffness on performance.

Figure 8 is a plot of the radial contact shift on both the gear and the pinion. Figure 9 is a plot of the tangential contact shift for the two gears. Both plots show the contact shift as a ratio to the mid-cone base pitch of the teeth. This gives a dimensionless comparison of the shift magnitudes. A second vertical axis on the radial plot shows the shift as a percent of the tooth addendum. This compares the shift of the contact point to the actual tooth size. In the tangential shift plot, the second vertical axis shows the tangential shift as a percent of the half tooth width. The horizontal axis of both plots is the ratio of the support shaft stiffness, EI, to the full support shaft stiffness, E1.0.

The figures demonstrate a definite hyperbolic relationship between the stiffnesses and the resulting pitch point contact shift. A valuable conclusion is that one may reduce the stiffnesses in the example to about 20 percent of the nominal design values. At this point, there is a significant increase in the contact position shift. With this information available at the design stage of a transmission's design, important weight savings may be possible. The weight savings will not sacrifice the transmission's life or power overload performance seriously.

SUMMARY AND CONCLUSION

This paper presents a method to predict the shift of the loaded region on the gear teeth in a spiral bevel reduction. This shift is a result of the elastic deflections of the gear support shafting and bearings under load. The reduction is a single spiral bevel gear drive with a pinion input and supporting shafts and bearings. The assumed deflections were caused by: the shaft deflections, the shaft slopes, and the bearing deflections. The analysis assumed that the curvatures of the teeth near the pitch point were constant. It determined the curvatures using the envelope of cutting tool positions.
The analysis was sequential. The first stage defined the gear geometry and loading. The second stage determined the elastic deflections of the bearings and shafts and the slopes of the shafts at the gears. The third stage determined the motions of the gear teeth caused by each elastic deflection. Superposition of these motions produced the total deflections of the gear teeth. The fourth stage analyzed the interaction between the tooth geometry and motion to predict the tooth contact ellipse motions under load. A Fortran 77 computer program determined the radial and tangential tooth contact shifts of the gear and pinion.

An example representative of the main rotor bevel gear reduction found in the U.S. Army OH-58 helicopter was modeled. A parametric study illustrated the determination of the radial and tangential tooth contact ellipse shifts. Graphs showed the variation in contact shift with reduction in support shaft stiffness. An important conclusion was that, for the example, one could reduce the shaft stiffnesses to about 20 percent of the present stiffnesses. At this level, significant changes in the shifts of the tooth contact positions occurred. Significant weight reductions may be possible without seriously affecting the gear action or the gear life.
