19. ABSTRACT *(Continue on reverse if necessary and identify by block number)*

The lake acidification in Northern Ontario has been investigated using Landsat TM to sense lake volume reflectance and also to provide important vegetation and terrain characteristics. The purpose of this project was to determine the ability of Landsat to assess water quality characteristics associated with lake acidification. Results from this study demonstrate that a remote sensor can discriminate lake clarity based upon reflection. Our basic hypothesis is that seasonal and multi-year changes in lake optical transparency are indicative of sensitivity to acidic deposition. In many acid-sensitive lakes optical transparency is controlled by the amount of dissolved organic carbon (DOC) present. Seasonal changes in the optical transparency of lakes can potentially provide an indication of the stress due to acid deposition and loading.

1.0 TECHNICAL SUMMARY

The lake acidification in Northern Ontario has been investigated using Landsat TM to sense lake volume reflectance and also to provide important vegetation and terrain characteristics. The purpose of this project was to determine the ability of Landsat to assess water quality characteristics associated with lake acidification. Our basic hypothesis is that seasonal and multi-year changes in lake optical transparency are indicative of reaction to acidic deposition. Results from this study demonstrate that a remote sensor can discriminate lake transparency based upon measured reflectance. In many acid sensitive lakes, optical transparency is controlled by the amount of dissolved organic carbon (DOC) present. DOC is a strong absorbing non-scattering material which has the greatest impact at short visible wavelengths including TM band one. Acid sensitive lakes have high concentrations of aluminum, which have been mobilized by acidic components contained in the runoff. Aluminum complexing with DOC is considered to be the primary mechanism to account for increased lake transparency.

When eco-physical properties developed from vegetation, soil/bedrock, sulfate deposition, and topographic relief characteristics were stratified across the study regions, it was determined that these regions could be described as ten separate environments based upon a simple acid sensitivity index model. This classification of the environment predicts location of regions containing acid sensitive lakes. The spatial co-occurrence of acid sensitive eco-physical parameters showed that acidification of a lake is driven mostly by local geology and soil conditions and less by the rate of sulfate deposition. Geologies which are weather resistant containing quartz rich sandstones and other quartz rock with bare or shallow sandy soils are most susceptible to regional acid deposition. These geologies produce naturally very low buffered acid sensitive lakes, contain very low amounts of DOC, and tend to have lower values of pH.

This study involved gathering an extensive amount of supporting data from 1986 and 1987. During August 1986, data were gathered from several sites representative of the range of ecosystems found in Northern Ontario. These data include limnological parameters, subsurface spectral irradiance, subsurface beam attenuation, airborne radiometry, and Landsat TM coverage. Based on these data, lake reflectance was modelled in terms of DOC and chlorophyll-a pigment concentrations. It was demonstrated that acid lakes having abnormally small amounts of DOC show greater reflectance than lakes with normal pH and DOC values. Significant correlation was found between in-situ and above surface lake volume reflectances. The model-predicted changes in TM band one signal response were consistent with observed values.

A second data set was gathered during May and June of 1987 on eight lakes to observe possible seasonal changes in subsurface and Landsat TM reflectance measurements. It was expected that spring runoff would produce decreases in DOC concentration and an increase in reflectance as a result of aluminum complexing. Actually, seasonal changes in TM observations of the lakes were very small as were the changes in the subsurface reflectance data. The significance of these changes was doubtful. In addition, little seasonal change could be demonstrated in lake water chemistry from May to June for this data set. Many of these latter constituent concentrations were near the reported lower limit of detection. During the winter of 1986 and 1987, the precipitation was particularly anomalous. Lack of snow during the winter left water levels down an average of three to four feet in the Sudbury area during spring, 1987. The lack of snow and subsequent runoff may explain the absence of a seasonal change in TM reflectance. More extensive seasonal observations are necessary to validate the season transparency hypothesis.

An historical TM scene pair (1985-1986), however, did demonstrate multi-year changes that were consistent with expected changes in water chemistry, but lacks the chemistry and in situ optical data needed for hypothesis validation. Lakes displaying the greatest TM changes are also the ones which were identified to be in acid sensitive strata. We conclude that there is likely some seasonal changes in transparency which can be related to the acidification process but it is also likely that year to year variability is significant. Strong relationships were found between chemical and optical properties of sampled lakes and the eco-physical strata within a single date. Optical transparency in clear acidified lakes is sensitive to water quality changes.

Results show that a remote sensor can discriminate clear acid lakes from colored high DOC lakes based upon reflection. The clear acid lakes may be naturally clear. TM signals were found to be generally higher for these lakes due to higher volume reflectance and greater effective transparency. Subsurface and airborne spectral reflectance measurements confirm this result. High DOC lakes in the same sensitive environments are less prone to pH change and certainly to changes in reflectance. Many of these lakes were originally acidic and will remain so but seem to be less impacted by acid deposition than the clearer low DOC lakes. Both lake types can be distinguished by remote sensing but it is necessary to first stratify the region to identify the acid sensitive environments. When stratification of eco-physical properties is used to identify acid sensitive areas TM can be used to pick lakes which are likely to be most sensitive to acid deposition and which also are indicators of temporal change.

The opportunities for using TM to monitor multitemporal lake reflectance changes remains positive but additional data collections are considered necessary to confirm or deny the interpretations made in the present study. However, it is apparent that remote sensing of lake reflectance provides a means to identify many of these lakes and to possibly monitor their decline or recovery over extended period of time.

2.0 INTRODUCTION

2.1 STATEMENT OF THE PROBLEM

The acidification of lake waters from airborne pollutants is of continental proportions both in North America and Europe. A major problem with acid deposition is the cumulative ecosystem damage to lakes and forests. The number of lakes affected by this in northeastern United States and on the Canadian Shield is thought to be enormous.

2.2 STATEMENT OF THE OBJECTIVES

This research had three principal objectives. First, determine how lake constituent concentration and lake transparency are related to annual acidic load. Second, investigate the utility of Thematic Mapper (TM) based observations to measure changes in the optical transparency in acid lakes. Third, examine the relationships between variations in lake acidification and eco-physical properties.

2.3 BACKGROUND

Previous investigations have suggested that DOC, which originates from the dissolution of humic substances, controls transparency in many Canadian Shield Lakes (Howard and Perley, 1982). It has also been established that aluminum, which is abundant in the local rocks and soils, is easily mobilized by acidic components contained in spring runoff (Hendry and Brezonik, 1984). The presence of any significant amount of aluminum induces a loss of DOC from the water column by coagulation and complexing resulting in increased optical transparency. This process has not been observed in lakes with normal pH levels associated with buffered geologies. In a normal lake, transparency would tend to decrease in time with the seasonal phytoplankton productivity cycle. Thus seasonal changes in the optical transparency of lakes should potentially provide an indication of the stress due to acid deposition.

The potential for this optical response is related to a number of local eco-physical features with soil/geology being, perhaps, the most important. Other important factors include sulfate deposition, vegetation type, vegetation cover, and topographic relief. The area of northern Ontario under study contains a wide variety of geologies from acid-sensitive quartzite to acid-insensitive dolomite. Annual sulfate deposition ranges from 1.0 to 4.0 grams per square meter (Environmental '82 Committee, 1982).

An acidifying lake undergoes a process of decay known as oligotrophication. Fewer and fewer ions of acid within the lake can be neutralized by the biological community. Increasing acidity further hampers the normal biological processes. Even though the acidity is not yet fatal to most fish, the lake is considered acid-sensitive and scientists would most like to monitor a lake at this delicate point. An acid-sensitive lake is thought to have, in general, high aluminum ion concentrations, low pH values, low alkalinity concentrations, and low DOC concentrations.

Several investigators including Almer [1974], Malley [1982], Schofield [1972], and Yan [1983] have reported a reduction in water attenuation with acidification. Almer proposed that the changes resulted from probable interaction between aluminum mobilized in the watershed and DOC and argued that an aqueous solution with pH below 5 will result in the precipitation of humic substances (such as DOC) from the water column. At pH's above 5.5 the aluminum, as aluminum hydroxide, will precipitate from the water column. The concentration of soluble aluminum will increase significantly if watershed soils are acidified and thus there is correlation between dissolved aluminum and lake pH. Acidified lakes with high concentrations of aluminum should also be relatively clear because of the complexing reductions of DOC. Almer, however, suggests in lakes with very high humus the aluminum complexing does not result in precipitation. Effler's [et.al., 1985] description of experiments in Dart Lake not only confirm the strong relationship between DOC and lake transparency but also demonstrate the coagulation/adsorption of DOC by aluminum. The following discussions relate how chemical and optical properties will be effected by the acidification process.

2.3.1 PH

Many lakes in the Northern Ontario region have experienced a 100-fold increase in acidity (i.e., from pH=6.8 to pH=4.4) in one decade. Much of this is due to abnormally acidic atmospheric deposition and the low buffering capacity of the Shield. The present average acid deposition over Ontario has a pH level of 4, which is ten times more acidic than normal rain and 1000 times more acidic than neutral water. Two classifications of lakes based on pH are made most often. Lakes with pH's less than 6.5 are typically acid-sensitive lakes. These lakes have severe pH fluctuations, especially during spring thaw, resulting in obvious negative biotic impacts. Lakes with a pH of 5.0 or less can only support a few acid-insensitive plankton and are generally considered "acidified". Near pH 6.5 the effects are not as noticeable, but the pH fluctuations kill off most of the young biotic generations. The process leading to an "acidified" lake begins at a pH of 6.5. Those lakes with pH's greater than 6.5 are considered more or less "normal" and the water chemistry remains fairly stable (Environment '82 Committee, 1982).

2.3.2 Aluminum

Acidification transforms organic weak-acid dominated lakes to mineral strong-acid dominated lakes. More specifically, acidification decreases the availability of organic ligands for binding metals such as aluminum (Davis et al., 1985). As a result, aluminum ions are usually found in high concentrations in acid lakes, and aluminum ion data could be used to predict acid-sensitive lakes. High concentrations of aluminum ions will ensure the absence of fish since aluminum hydroxide forms on their gills, making it difficult for the fish to intake oxygen. In general, if the aluminum concentrations reach 200

$\mu g/l$, the lake becomes toxic to fish (Environment '82 Committee, 1982).

Since precipitation has a very low aluminum concentration, the aluminum found in a lake's water column reflects mineral weathering within watersheds or mineral dissolution from lake sediments. Therefore, we would expect that a relationship would exist between surrounding terrain and within-lake concentrations.

2.3.3 Dissolved Organic Carbon

Acidified lakes found in Norway undergo a precipitation of the colored organic matter (DOC) in the water by acid-mobilized metals such as aluminum (Davis, Anderson and Berge, 1985). Increasing mineral acids actually protonate organic molecules and increase their tendency to aggregate and precipitate. The mobilization of aluminum in inorganic form provides further charge neutralization of organic functional groups leading to their precipitation. Dissolved organic carbon measured from lake samples represents the amount of organics still within the water column and may reflect the nutrient status of the lake.

2.3.4 Alkalinity

Alkalinity is a measure of the ability of water to neutralize acid. The presence or absence of hydroxide, bicarbonate, and carbonate strongly influence the alkalinity or "buffering capacity" of a lake. Alkalinity is determined by measuring the amounts of acid required to neutralize alkaline water to pH 8.2 and pH 4.5 (pH 8.2 indicates the conversion of the carbonate to bicarbonate ions and pH 4.5 indicates the conversion of the bicarbonate ions to carbonic acid). These two acid levels determine the buffering capacity of the lake. A pH of 7.0, that of neutral water, bears little significance in the determination or expression of alkalinity (Chow, 1964). Therefore, alkalinity levels provide information not acquired with pH data alone.

When using Total Inflection Point (TIP) as a measure of alkalinity, an acidified lake is indicated when the TIP is less than or equal to zero (Keller and Pitblado, 1985).

A review of the literature shows that in-lake pH levels, and concentrations of DOC, aluminum and alkalinity all indicate the acid sensitivities of a lake. These parameters, however, are not just a function of in-lake processes and atmospheric loading; they are also a function of terrigenous loading, i.e., a function of bedrock, soil, vegetation, and possibly terrain relief (Effler, Schafran, and Driscoll, 1985).

2.3.5 Optical Effects

The bio-optical state is a measure of the total effect of biological and chemical processes on the lake optical properties. This concept maintains that diverse constituents in natural waters can be described by a few optical parameters which represent a meaningful average estimate of the material present at any time and place.

The reflectance of a lake is optically determined from the scattering and absorption processes which occur in the epilimnion (i.e. to the depth where the downward irradiance medium can be predicted by means of the radiative transfer equation). The absorption and scattering properties are inherent optical properties and do not depend on the light field external to the medium. There are three inherent properties which together are sufficient to describe the behavior of light in the medium. The absorption coefficient is the fraction of energy absorbed from the collimated beam per unit distance traversed in the medium. The scattering coefficient is the fraction of energy which is scattered out of a collimated beam per unit distance traversed by the beam. The volume scattering function describes the fraction of energy scattered in a specific direction per unit scattering volume. These three inherent properties can be used to predict the subsurface irradiance reflectance which is described as an apparent property of the medium. The subsurface reflectance can in turn be related to the above surface upwelling radiance which is also controlled by the radiance distribution parameters and the Fresnel transmittance. This latter radiance is a component of the radiance observed by an airborne radiometer or by Landsat TM.

The scattering and absorbing agents in natural waters can be divided into three categories: water, dissolved materials, and suspended materials. If the absorption and scattering characteristics of the medium are known, the behavior of light with the suspended and dissolved materials in the water column can be estimated. The reflectance can be related to the constituent concentrations using a simple model described later in Section 7.0 since the absorption and scattering coefficients for constituents are additive.

For lakes in slow-weathering soil/rock conditions the amount of suspended mineral content is minimal. The remaining components in these lakes which have an optical impact are chlorophyll-a pigment and DOC. Both of these components have large absorption coefficients in the blue-green spectral region. Scattering by chlorophyll-based phytoplankton is small so we are essentially dealing, in many cases, with an aquatic medium which is dominated by absorption. An increase in DOC results in increased absorption and a decrease in reflectance. Since the absorption cross section for DOC is large in the blue-green spectral region, small changes in the DOC concentration may produce significant changes in reflectance especially when the base concentration is low.

2.4 DATA COLLECTED

Water quality parameters were measured along with in-situ optical data in representative lakes of the Canadian Shield. This was done to calibrate a Bio-Optical Model which defines the linkages between the acid-deposition induced chemical lake processes and the upwelling radiometric signals measured by the Landsat Thematic Mapper sensor. A spring/summer TM scene pair and companion field measurements were obtained for the selected study sites located in northern Ontario.

These data will be used to investigate possible formulations of the multitemporal remote sensing causal relationships between water chemistry and observed changes in water transparency.

2.5 DESCRIPTION OF THE STUDY REGION

The study region of Northern Ontario consisted of four principal sites located within the following three Landsat scenes: Sudbury, Algoma, and Dorset. Relative locations of the study sites are shown in Figure 2.1 and their general characteristics are described in the section below.

2.5.1 Sudbury Site

Location: The Sudbury Site is located within the Landsat TM scene 19-27 and has the following coordinates:

Upper Left: 47^{o} 40.05' -80^{o} 49.40'
Lower Right: 46^{o} 16.51' -80^{o} 36.50'

Geology: The geology of the Sudbury site is dominated by the Lorrain formation which consists of quartzite, arkose, quartz sandstone, micaceous and aluminous quartz sandstone, quartz feldspar sandstone, and minor conglomerate and siltstone. Mafic intrusive diabase and granophyte dikes and sheets are distributed evenly throughout the site except near lake Wanaptei Significant amounts of conglomerate, sandstone, siltstone and argillite are found in the southern half and northern tip of the site. In addition scattered areas of felsic intrusive and metamorphic rocks, and felsic to intermediate metavolcanics occur.

Vegetation: Approximately 65% of the test site has conifer forest cover and approximately 35% is classified as mixed forest.

Soil Sensitivity: Approximately 90% of this site has low potential to reduce acidity and the soil is predominantly shallow. The remaining 10% of the site has a moderate potential to reduce acidity with shallow soils and ultramafic bedrock.

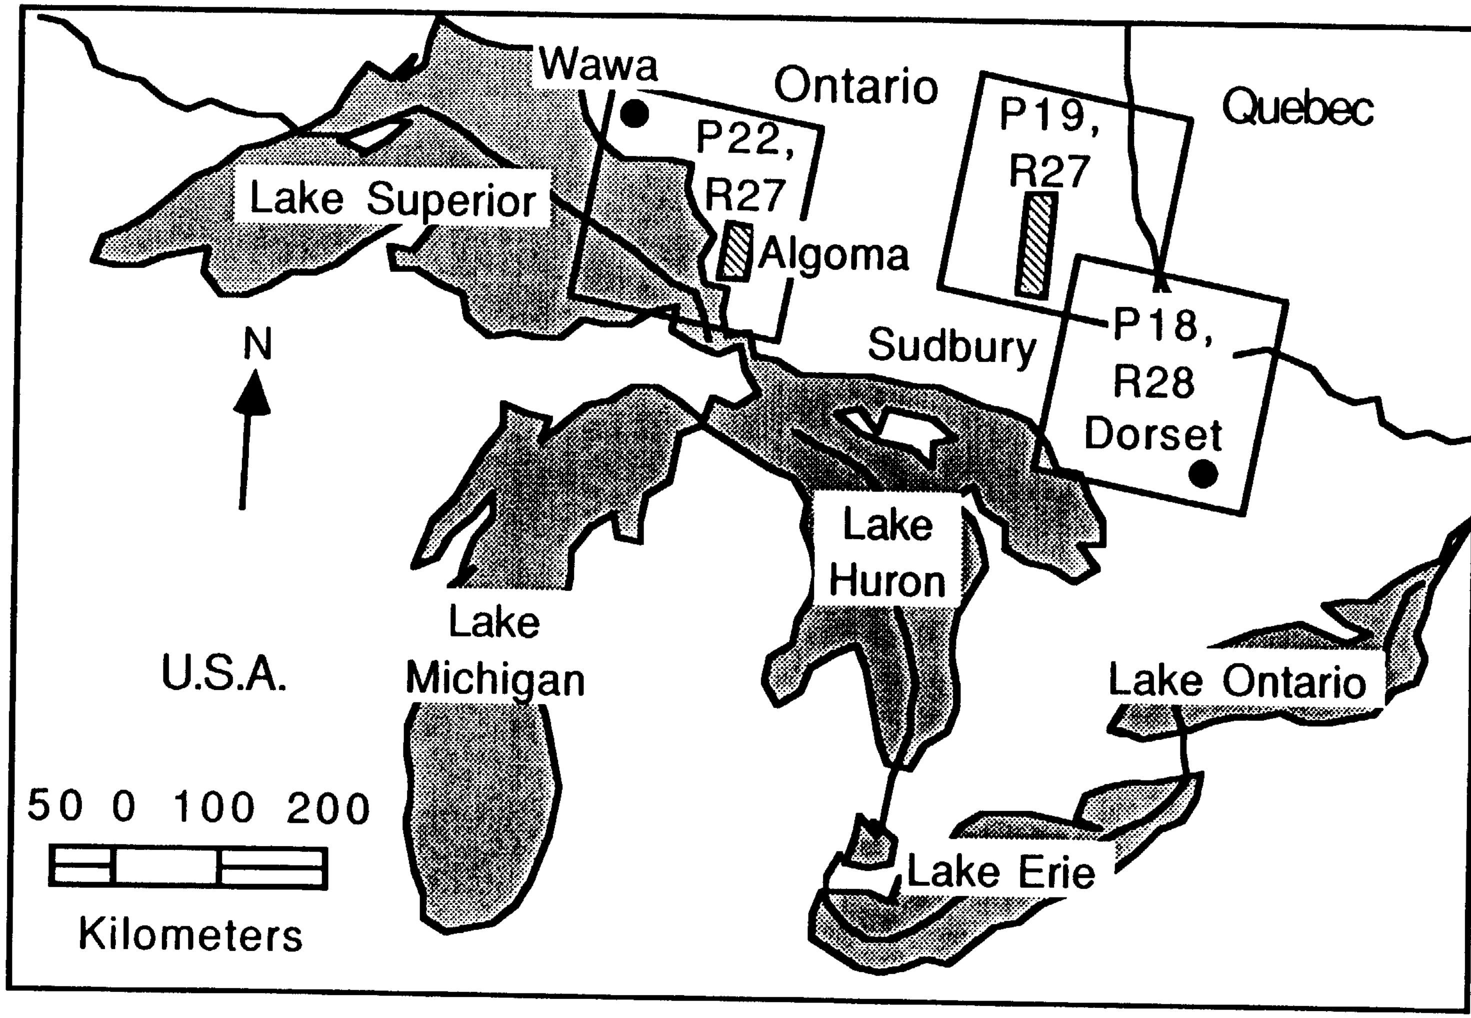

Figure 2.I. The Location of the Three Study Areas

Limnology/Water Chemistry: The quartzite regions have very transparent lakes (e.g., Sunnywater has a Secchi depth of 25-30 meters) with high concentrations of aluminum, low pH values (4-5.5), low DOC concentrations, and metal fallout from the Sudbury smelter. The dark humic lakes tend to have higher pH values.

Acid Deposition: Annual deposition in 1982 was 1.24 g/m^2 of sulfate

2.5.2 Algoma Site

Location: The Algoma site is located within the TM scene 22-27 and has the following coordinates:

Upper Left: 47^o 21.5', -84^o 25.8'
Lower Right: 47^o 00.0', -84^o 13.8'

Geology: Granitic rock predominates (60%) in the Algoma site and is concentrated in the northeast and southwest corners. Approximately 25% of the geology consists of acid to intermediate metavolcanics and 15% is basic and undifferentiated metavolcanics. Several lakes are situated in greywacke-slate-arkose and grabbro formations.

Vegetation: Hardwood forests predominate (Sugar Maple, Birch, Trembling Aspen) with a few mixed stands in the lowland areas (White Birch, Black Spruce, and White Spruce).

Soil Sensitivity: The northern half (approximately 55%) of the site has a high sensitivity to acid deposition with 0.25 to 1 meter soil depth with sandy texture and granite and associated alkalic bedrock. The southern corner(5%) is the same as the northern half of the site. A moderate potential to reduce acidity is found in the southern part of the test site (35%), which stems from a differing bedrock (ultramafic serpentine, non-calcareous silicic sediments and anorthosite)

Limnology/Water Chemistry: Lakes in this region are less transparent due to a higher DOC content. Levels of pH are typically between 5 and 6.

Acid deposition: Annual deposition of sulfate 1.5-2.0 g/m^2

2.5.3 Dorset Site

Location: the Dorset site is located near the southern edge of TM scene 18-28.

Geology: Acid intrusives occur throughout this area including granite, syenite, granite gneiss, grantized sedimentary and volcanic rocks.

Vegetation: Predominantly hardwoods (Sugar Maple, Red Maple, Yellow Birch, Trembling Aspen) occur in this area. Hemlock and Eastern white pine are found in selected areas.

Soil Sensitivity: The Dorset area is in the center of a large region of high deposition. West of Dorset there is less than 50% exposed bedrock and to the east 50 to 75% is exposed.

Limnology/Water Chemistry: Lakes in this region are poorly buffered. DOC levels are higher and secchi depths are lower compared to the Sudbury area.

Acid Deposition: Annual deposition of sulfate 2.90 g/m^2.

2.5.4 Wawa Site

Location: The Wawa site is located northeast of Wawa, Ontario near Michipicoten Bay.

Geology: The northern third of the Wawa site consists of mafic metavolcanics. Felsic metavolcanics occur in the southern tip of the site and are also interspersed with metasediments (conglomerate, greywacke, shale, arkose, and quartzite) near the middle of the site.

Vegetation: This site contains large non-vegetated areas which have been impacted by the smelter fumes from Wawa.

Soil Sensitivity: This area is primarily moderately sensitive to acid deposition. A small area of high sensitivity exists along the Maple River in the southern part of the Wawa plume.

Limnology/Water Chemistry

Lakes in this region are buffered , have higher pH values, high DOC levels, and relatively low transparency except in the immediate vicinity of the Wawa smelter plume where the lakes are acid and clear and highly contaminated with smelter waste.

Acid Deposition: Annual deposition in 1982 was 1.5 g/m^2

2.6 SUPPORTING RESEARCH

An historical water quality database, has been obtained from the Ministry of Environment for all of Ontario which contains many lakes within our proposed field sites. A second database is being acquired for approximately 300 lakes in the Sudbury area, many of which are located within the proposed sampling sites. The most important parameters within this database are those which have impact on the optical transparency of the water. These parameters are chlorophyll pigments, suspended mineral particles, and dissolved organic carbon. Of these DOC is considered to have the greatest influence on optical properties in Northern Ontario.

One obvious feature indicating a declining lake is low pH, but a low pH is not the only characteristic of an acidified lake. Chemical levels within a lake can also indicate its health. A study involving lake classification near Sudbury, Ontario used principal component analysis to show that chemical variability of acidified lakes is attributed to three main components: nutrient status, buffering status, and atmospheric deposition status (Pitblado et al., 1980). Nutrient status of a lake could be indicated by levels of dissolved organic carbon, while buffering status could be indicated by the alkalinity of a lake. Atmospheric deposition status might be indicated by the annual rate of sulfate deposition within an area.

Some historical data collected by John Fortescue at OGS, using the PROBAR/helicopter over a portion of the Algoma site, were made available to be analyzed with coincident limnological data. These data were collected on August 22, 1984 and on September 6, 1985. Fortescue had attempted to used these data to separate clear and colored acidic and normal pH lakes within the site [Fortescue, 1986]. Since many of the same lakes were to be sampled during the August 1986 field work using the PROBAR radiometer, it seem reasonable to examine these data for potential relationships between the PROBAR measurements in TM bands and the measured values of DOC, pH, etc. The data set consisted of 113 sample locations and a representative subset was selected for data reduction. The reported reflectances at 10 nm intervals were first reduced to simulate TM band reflectances in bands 1 through 4. These data were then statistically correlated to the available limnological data.

Attempts to run analyses on the combined 1984/1985 data set yielded very poor correlations. The 1985 data were found to be suspect because of reported instrumentation problems and further analysis of the 1985 PROBAR data set was therefore discontinued. The pH values of the 1984 data set ranged from 4.9 to 5.57 with a mean value of 5.24. DOC values were high and ranged from 3.1 to 14.1 mg/l with a mean value of 6.7 mg/l. Correlations with estimated TM reflectance values were considered modest (-0.73 for pH and TM band 3, -0.71 for pH and TM band 4). Similarly, coefficients of 0.62 and 0.64 were determined between the two TM bands and measured DOC. Correlations of comparable magnitude were observed between pH, DOC, and Secchi depth transparency. The lack of strong correlation was attributed to the relatively high levels of DOC which almost completely absorb the radiation in TM bands 1 and 2.

2.7 STUDY ORGANIZATION

This study was divided it into four types of activities: 1) stratification of eco-physical sensitivity, 2) water quality measurements, 3) lake optical measurements, and 4) remote sensing measurements. These activities in turn supported calibration of an optical model which would describe the reflectance sensitivity to changes in water parameters and relationships between spatial eco-physical features. These eco-physical features describe the environmental sensitivity to acidification. Our approach is outlined with the organizational flow chart contained in Figure 2.2. The desired result from this effort was to be able to identify which environments contain lakes which are sensitive to acidification and can be monitored using Landsat TM data.

2.8 STUDY PARTICIPANTS

A cooperative program with Canadian agencies and Universities interested in the remote sensing aspects of the acid deposition problem have resulted in an informal joint program which includes four major Canadian participants. These are Professor Roger Pitblado of Laurentian University in Sudbury, Ontario, Dr. John Fortescue of the Ontario Geological Survey (OGS), Dr. Vernon Singroy of the Ontario Centre for Remote Sensing (OCRS), and Professor Michael Dickman from Brock University in Saint Catherine, Ontario.

The Canadians are funded through the Ministry of Environment (MOE) and the Ontario Geological Survey for a one year period to work collaboratively on the program. These funds were budgeted to support equally remote sensing data collection and analysis and a geochemical survey.

The Canadian effort was based on meeting two separate but highly complementary objectives. The OGS objective was designed to look the relationships between environmental and geochemical studies involving lake acidification and remote sensing. The geochemical survey techniques developed by John Fortescue of the OGS involve analysis of chemical constituents in lake water samples and in bottom sediment cores. A mineral resource appraisal was a specific objective of the OGS. The MOE support was directed at examining the role remote sensing can play in the study of lake acidification in both the short and in the long term. The MOE had stressed that effort be placed on the Sudbury site where there exists an extensive limnological database.

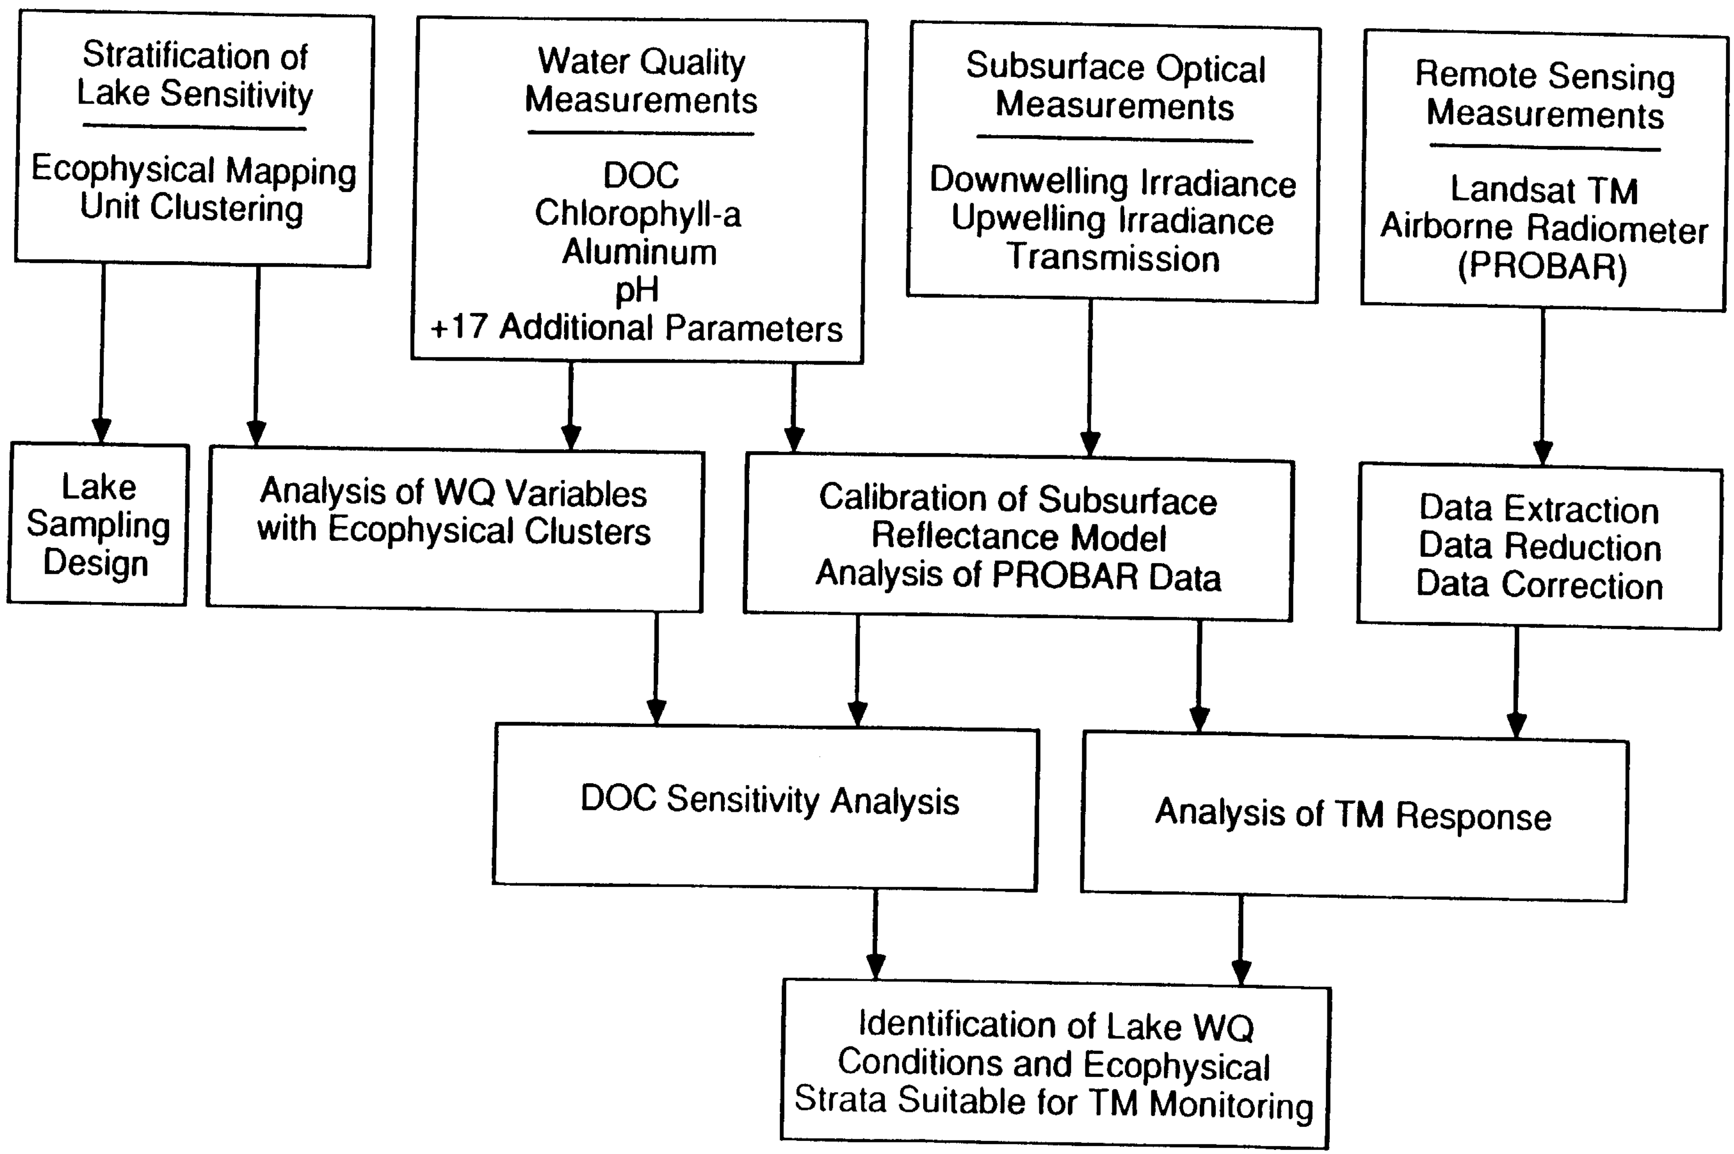

Figure 2.2. Study Organization

The MOE plan includes examination of several historical Landsat TM and MSS collections.

3.0 ECO-PHYSICAL CHARACTERIZATION

3.1 OBJECTIVE

The objective of the eco-physical stratification and characterization of acid-sensitive parameters was to reveal the location and co-occurrence of environmental attributes that influence lake acidification. The study areas were stratified into the following four parameters:

1. type and percent cover of vegetation,
2. soil and bedrock buffering capacity,
3. topographic relief,
4. sulfate deposition rate.

The acid sensitivities of these areas were then determined, based on these four parameters. Each of these parameters affects the sensitivity of the ecosystem a lake is found in and ultimately affects the water chemistry and optical signature of that lake. Stratification also provided a basis to characterize lakes within study areas which aided in the sampling design.

3.2 PROCEDURE

The three Landsat scenes were stratified into eco-physical units, or "polygons", based upon soil/bedrock sensitivity, vegetation sensitivity, topographic-relief sensitivity and acid- deposition sensitivity. Sensitivity values were assigned to each polygon and combined in a linear function which produced a "sensitivity index" for each polygon using a sensitivity model. Maximum-likelihood clustering of these sensitivity indexes then revealed the location and co-occurrence of similar polygons.

3.3 STRATIFICATION OF ECO-PHYSICAL FEATURES

The Algoma, Sudbury, and Dorset study areas were stratified in terms of bedrock/soil, vegetation, relief and sulfate deposition.

Four mylar overlays were constructed, one for each of the variables, at a scale of 1:250,000.

3.3.1 Vegetation and Percent Cover

The lowest pH values are found in coniferous forests. Fir trees are often found growing on weathering-resistant soils and bedrock. When precipitation falls on this type of area, the acidic water flows largely unaltered into nearby lakes at a pH of 5.6. Broadleaf forests are generally found in terrain of higher pH, so precipitation is neutralized more before it enters a lake. A much higher rate of sulfate deposition would be necessary to make the pH of runoff from a deciduous forest reach that of a coniferous forest (Environment '82 Committee, 1982).

Percent cover of vegetation also plays a factor in lake acidification. If percent cover is low, the extent and volume of surface runoff is frequently higher than for average cover conditions increases. Under these conditions, very little of the precipitation has time to penetrate into the rock and/or soil and become neutralized by the buffering systems.

TM satellite images were used for vegetation classification and lines were drawn between areas of different vegetation types and different percent covers of these types. Vegetation was categorized as conifer, hardwood, mixed or barren. If an area's vegetation consisted of 80% or more of either conifer forest or hardwood forest, then it was classified hardwood or conifer, otherwise it was classified as a mixed forest.

Percent cover for an area was derived using existing soil and bedrock sensitivity maps published by the Environment Canada Lands Directorate in 1983. These maps outline percent exposed bedrock at three levels: 0-24%, 25-50%, and 50-99%. Since there were no extensive areas of low vegetation, such as prairies, marshes, etc., the following equation was used:

$$(\text{Percent forest cover}) = 1 - (\text{Percent exposed bedrock}) \ .$$

Percent forest cover was divided into three classifications:

1. 0 - 49 % cover,
2. 50 - 74 % cover,
3. 75 - 99 % cover.

Vegetation and percent cover sensitivities were derived from the literature (Environment '82 Committee) and are shown in Table 3.1.

TABLE 3.1. VEGETATION AND PERCENT COVER SENSITIVITIES

Cover	Percent	Sensitivity Value
hardwood	0 - 49 %	3.33 x .75
hardwood	50 - 74 %	3.33 x .5
hardwood	75 - 99 %	3.33 x .25
mixed	0 - 49 %	6.67 x .75
mixed	50 - 74 %	6.67 x .5
mixed	75 - 99 %	6.67 x .25
conifer	0 - 49 %	10 x .75
conifer	50 - 74 %	10 x .5
conifer	75 - 99 %	10 x .25

These sensitivity values rank the combinations of vegetation type and percent cover on a scale from 1 to 10. Terrain with conifer forest cover was rated most sensitive and terrain with hardwood forest cover was rated least sensitive. The higher the percent cover the less sensitive the polygon was rated for potential damage.

3.3.2 Sulfate Deposition

Large emissions of sulfur dioxide and nitrogen oxide from combustion (usually within coal burning industries) lead to their oxidation in the atmosphere to sulfuric acid and nitric acid. These acids dissolve in water droplets and fall to the ground via some form of precipitation. The presence of sulfuric acid in precipitation over the Continental Shield results in 100 times more acid entering these already poorly buffered ecosystems (Hendry and Brezonick, 1984).

The sulfate deposition overlay was drawn from enlarged 1981 meteorologic maps (Chan, et al. 1983) provided by the Ontario Ministry of the Environment (see Figure 3.1) Sulfate deposition was measured in grams/m^2/year. Across all three areas, the following six classifications were derived from the maps in terms of deposition rates:

1. 1.0-1.5,
2. 1.5-2.0,
3. 2.0-2.5,
4. 2.5-3.0,
5. 3.0-3.5,
6. 3.5-4.0.

Sulfate deposition was assigned sensitivity values based on amount of sulfate deposited. Each of the six levels was assigned equally spaced sensitivity values on a scale from 1 to 10. The highest sulfate deposition was given the highest sensitivity value. The results are given below in Table 3.2.

TABLE 3.2. SENSITIVITY VALUES OF SULFATE DEPOSITION LEVELS

gm/m^2/year	Sensitivity Value
1.0-1.5	1.67
1.5-2.0	3.33
2.0-2.5	5.00
2.5-3.0	6.67
3.0-3.5	8.33
3.5-4.0	10.00

3.3.3 Bedrock and Soil

In general, the easier the ground materials around a lake weather, the less susceptible that lake is to acidification. Thus, weatherability of the lake's surrounding bedrock and soil play a large factor

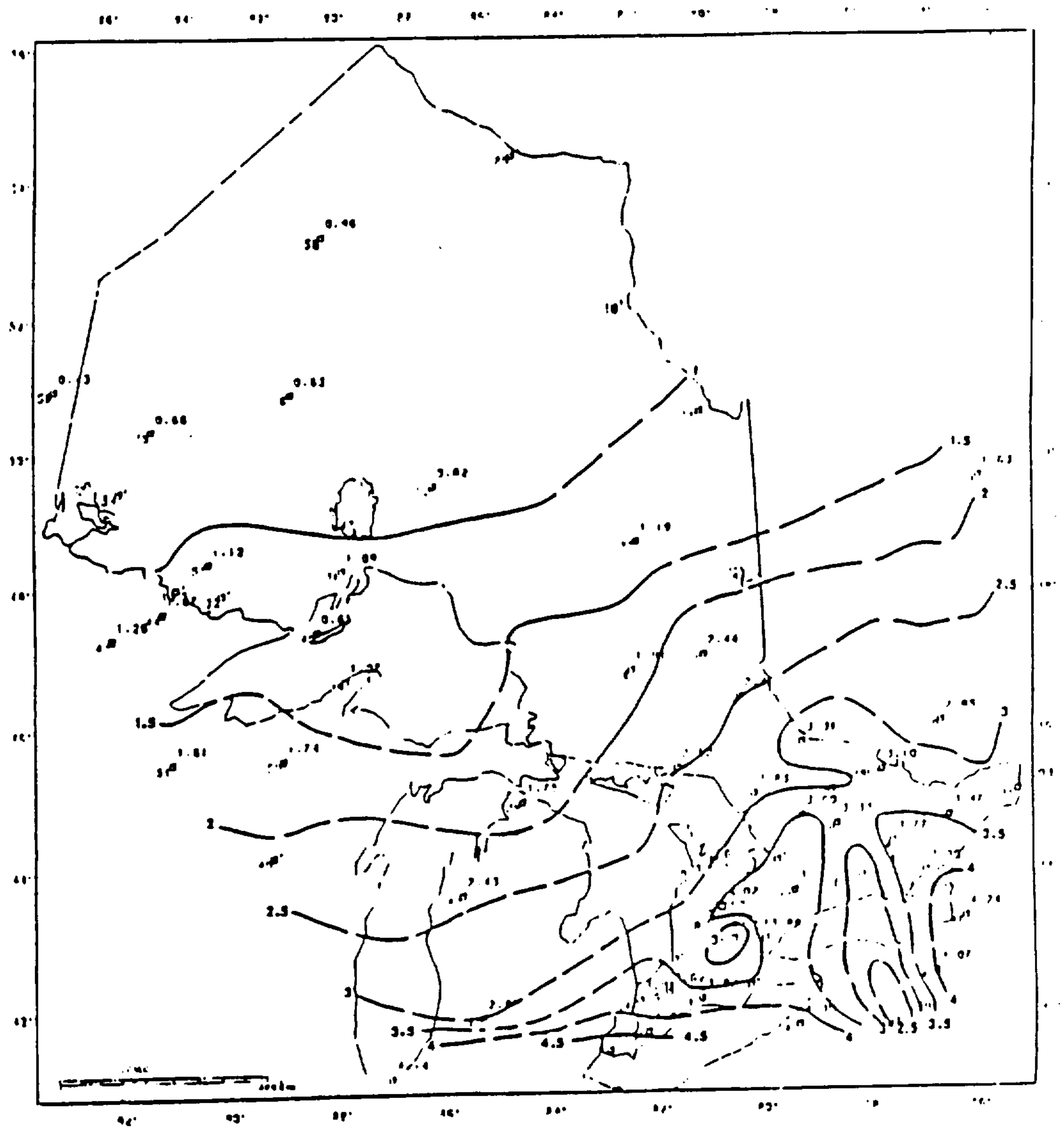

Figure 3.1. The Annual Deposition (G/M**2) of Sulfate in Ontario (from Chan, Tang and Lusis, 1983).

on the lake's acidity. The rate at which bedrock and soil weather depend on their hardness and their ability to release buffering ions which counter lake acidification by reducing the impact of the water runoff.

Bedrock resistant to weathering does not neutralize acid rainwater therefore it is associated with acidic lake systems. Sensitivities for bedrock/soil combinations were derived from the Environment Canada Sensitivity Maps. Bedrock was divided into four categories based on its sensitivity. These four categories are found in Table 3.3.

TABLE 3.3 BEDROCK SENSITIVITY CATEGORIES

Type	Description
1	limestone, marble, dolomite
2	carbonate-rich siliceous sedimentary: shale, limestone; noncalcareous siliceous with carbonate interbeds: shale, siltstone, dolomite; quartzose sandstone with carbonates.
3	ultramafic rocks, serpentine, noncalcareous siliceous sedimentary rocks: black shale, slate, chert; gabbro, anorthosite: gabbro, diorite; basaltic and associated sedimentary: mafic volcanic rocks.
4	granite, gneiss, quartzose sandstone, syenitic and associated alkalic rocks.

The ability of the soil to neutralize the acid was found to be the most important factor influencing the susceptibility of a lake to acidification. Lime-rich, easy-weathering soils protected the lakes, but lakes surrounded with sandy soil and expanses of flat bare rock are mostly acid (Environment '82 Committee, 1982). Basically three categories of soil can be defined: easy-weathering clay, normal-weathering loam, and resistant-weathering sand.

The soil's depth also affects the neutralization of precipitation. A deeper soil will contain larger quantities of weatherable minerals and other buffering substances. Thin soils are often leached of such buffering substances. In the stratification, one of the soil types (clay, loam or sand) was assigned to each polygon. Each polygon was also assigned a unique soil depth. The soil depth categories used are shown in Table 3.4.

TABLE 3.4. SOIL DEPTH CATEGORIES

Category	Definition
deep:	> 1 m average soil thickness
shallow:	25 cm - 1 m average soil thickness
bare:	< 25 cm average soil thickness

Different combinations of bedrock type, soil type, and soil depth were already ranked on the Environment Canada maps from most to least sensitive. Since there were 28 soil/bedrock combinations, the most sensitive combination was assigned a 10.0. The other combinations were assigned sensitivities ranging from 1 to 10 separated by units of 10/28. These combinations are shown in Table 3.5.

TABLE 3.5. BEDROCK/SOIL SENSITIVITY INDEX VALUES

ROCK TYPE	SOIL TYPE	SOIL DEPTH	SENSITIVITY VALUE
1	clay	deep	.36
1	loam	deep	.71
1	sand	deep	1.07
1	clay	shallow	1.43
1	loam	shallow	1.79
1	sand	shallow	2.14
1	none	bare	2.5
2	clay	shallow	2.86
3	clay	shallow	3.21
2	clay	deep	3.57
3	clay	deep	3.93
4	clay	deep	4.29
2	loam	deep	4.64
3	loam	deep	5.
2	sand	deep	5.36
3	sand	deep	5.71
2	loam	shallow	6.07
3	loam	shallow	6.43
2	sand	shallow	6.79
3	sand	shallow	7.14
2	none	bare	7.5
3	none	bare	7.86
4	clay	shallow	8.21
4	loam	shallow	8.57
4	loam	deep	8.93
4	sand	deep	9.29
4	none	bare	9.64
4	sand	shallow	10.00

3.3.4 Relief

Since the extent and volume of surface runoff plays an important factor in lake acidification, the topographic relief of the terrain surrounding a lake would help determine its acidification state. An area with steep topographic relief would allow less time for precipitation to penetrate the soil and bedrock and become neutralized. Flat topographic relief would contribute more to the neutralization of precipitation since the extent and volume of surface runoff would be less.

Relief was divided into three categories: steep, rolling, and level. This information was extracted from standard topographic maps at a scale of 1:250,000. Change in elevation across unit distances was measured perpendicular to elevation contours and categorized into one of three types for each polygon. These categories are shown in Table 3.6.

TABLE 3.6. TOPOGRAPHIC RELIEF CATEGORIES

Category	Definition
level:	< 400 ft change in 2 kilometers
rolling:	> 400 ft < 800 ft change in 2 km
steep:	> 800 ft change in 2 kilometers

Topographic relief levels were assigned three sensitivity values, equally spaced from 1 to 10. These three values are shown below in Table 3.7.

TABLE 3.7. RELIEF SENSITIVITY VALUES

Relief	Sensitivity Value
level	3.33
rolling	6.7
steep	10.00

3.4 COMPOSITE MAP CONSTRUCTION

The four maps were produced for each of the ecosystem parameters (bedrock and soil, sulfate deposition, terrain relief, and vegetation type and percent cover). Each map consisted of polygons that represented uniform ecosystem parameters and that were assigned corresponding sensitivity values. A composite map was then produced for each of the study areas by overlaying the four ecosystem parameter maps, and tracing them on to one overlay (see Figure 3.2). Ultimately, the new polygons created with the composite map had four sensitivity values:

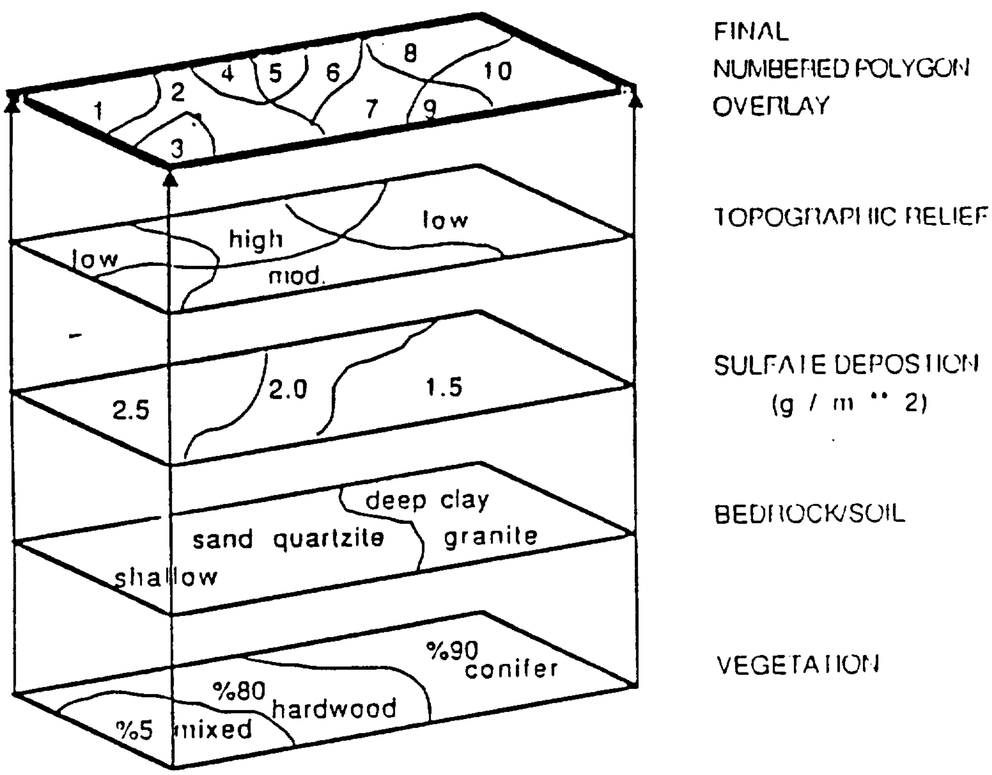

Figure 3.2. The Stratification Procedure.

one for bedrock/soil, one for vegetation, one for relief and one for the sulfate deposition.

The three composite maps produced 694 polygons with a minimum polygon size of 25 square kilometers. Each polygon was numbered from 1 to 694. A computer program was written and used to read the polygon number, forest type, percent cover, bedrock type, soil type, soil depth, topographic relief and sulfate deposition into computer memory. A program subroutine was used to assign four ecosystem sensitivity values, ranging from 1 to 10, to each polygon and compute the sensitivity index for each polygon using the sensitivity index model.

A list of the polygons with eco-physical characteristics and sensitivity index values is found in Appendix A.

3.5 SENSITIVITY INDEX MODEL

A sensitivity index model was developed which assigned a sensitivity index to each composite map polygon. The sensitivity index, SI, is a function of a linear combination of the four ecosystem parameters within the polygon:

SI = A x (bedrock/soil sensitivity value)
B x (vegetation sensitivity value)
C x (sulfate deposition sensitivity value)
D x (topographic relief sensitivity value).

The coefficients A, B, C and D were derived from the literature, but in the absence of quantitative information. An ecosystem sensitivity study in Sweden concluded that bedrock and soil were found to be the most important factors influencing the susceptibility of a lake to acidification (Environment '82 Committee). Also, areas of nearly equal rates of sulfate deposition, but differing types of bedrock and soil, have been found to contain lakes of different buffering capacities, supporting the idea that bedrock and soil are the most important eco-physical parameters in terms of lake sensitivity. Therefore the coefficient "A" equals four, the highest number assigned to a coefficient. A review of the literature indicated that vegetation type was highly correlated with soil and bedrock type in terms of sensitivity, so the vegetation sensitivity value was weighted as the second most important variable.

If the vegetation and soil/bedrock sensitivity values were identical in two areas, it is assumed that sulfate deposition would affect the sensitivity of a lake within the area more than topographic relief would. Therefore the following equation was developed:

SI = 4 x (bedrock/soil sensitivity value)
3 x (vegetation sensitivity value)
2 x (sulfate deposition sensitivity value)
1 x (topographic relief sensitivity value).

The sensitivity index of an eco-physical polygon is driven by the bedrock/soil and vegetation sensitivity values. The sulfate deposition and topographic relief sensitivity values still contribute to an area's sensitivity, so they are included in the model but weighted as less important. Therefore, it is hypothesized that the sensitivity index rates the acid sensitivity of an eco-physical area on a scale from 1 to 10.

3.6 CLUSTERING OF MODEL SENSITIVITY VALUES

The sensitivity indexes of the polygons (approximately 694) were then clustered using a maximum likelihood hierarchical clustering procedure. The results of this clustering procedure has produced 10 significantly ($p > .95$) different clusters (see Appendix B). These clusters are summarized in Table 3.8.

TABLE 3.8 SENSITIVITY RATINGS AND TYPE VALUES FOR THE TEN SIGNIFICANTLY DIFFERENT CLUSTERS

CLUSTER RATING	BEDROCK/SOIL	VEGETATION	RELIEF	SULFATE	DEPOSITION
1	5.66	7.04	4.67	5.57	4.40
2	6.36	8.05	4.65	5.78	5.82
3	6.74	8.16	5.83	5.28	5.00
4	6.02	7.67	4.63	5.25	5.18
5	7.41	8.47	7.13	5.62	6.59
6	3.55	3.28	2.08	5.57	5.27
7	7.07	8.50	6.37	5.36	6.10
8	5.14	5.96	4.71	5.46	3.97
9	7.83	8.71	8.53	5.20	6.29
10	4.34	5.21	3.82	5.01	3.05

The ten clusters are described in terms of their mean eco-physical sensitivity values in the following paragraphs.

Cluster 1 is characterized by shallow sandy soils over rock types 3 and 4 with less than 50% cropping out. Vegetative cover is a mixture of conifers and hardwoods with a dominance of the hardwoods. The terrain is level to rolling. The average acid deposition is approximately 2.0 $g/m^2/yr$.

Cluster 2 is characterized by moderate depth soils over rock type 4 with less than 50% cropping out. Vegetative cover is a mixture of conifers and hardwoods with a dominance of the hardwoods. The terrain is level to rolling. The average acid deposition is approximately 2.5 $g/m^2/yr$.

Cluster 3 is characterized by deep sandy soils over rock type 4 with less than 50% cropping out. Vegetative cover is a mixture of conifers and hardwoods with a dominance of the hardwoods. The terrain is level to rolling. The average acid deposition is approximately 2.5 $g/m^2/yr$.

Cluster 4 is characterized by moderately deep soils over rock type 4 with less than 50% cropping out. Vegetative cover is a mixture of conifers and hardwoods with a dominance of the hardwoods. The terrain is level to rolling. The average acid deposition is approximately 2.25 $g/m^2/yr$.

Cluster 5 is characterized by moderately deep sandy soils over rock type 4 with less than 50% cropping out. Vegetative cover is a mixture of conifers and hardwoods with a dominance of the hardwoods. The terrain is level to rolling. The average acid deposition is approximately 2.75 $g/m^2/yr$.

Cluster 6 is characterized by deep clay soils over rock type 3 with less than 30% cropping out. Vegetative cover is mostly hardwood. The terrain is level to rolling. The average acid deposition is approximately 2.25 $g/m^2/yr$.

Cluster 7 is characterized by shallow sandy soils over rock type 4 with less than 50% cropping out. Vegetative cover is a mixture of conifers and hardwoods with a dominance of the conifers. The terrain is level to rolling. The average acid deposition is approximately 2.5 $g/m^2/yr$.

Cluster 8 is characterized by moderately deep sandy soils over rock type 3 with less than 50% cropping out. Vegetative cover is a mixture of conifers and hardwoods. The terrain is level to rolling. The average acid deposition is approximately 2.0 $g/m^2/yr$.

Cluster 9 is characterized by shallow sandy soils over rock type 4 with less than 25% cropping out. Vegetative cover is dominated by conifers. The terrain is level to rolling. The average acid deposition is approximately 2.5 $g/m^2/yr$.

Cluster 10 is characterized by deep sandy soils over rock types 3 and 4 with less than 50% cropping out. Vegetative cover is a mixture of conifers and hardwoods with a dominance of the hardwoods. The terrain is level to rolling. The average acid deposition is approximately 1.5 $g/m^2/yr$.

These clusters are separated by only small changes in the mean value for each sensitivity index. The standard deviations of the above mean sensitivity index values was typically only one or two percent. Each cluster was color coded as shown in Figure 3.3. Color coded maps that show the location of the polygons within each cluster are shown in Figures 3.4 3.5 and 3.6. The listing of all eco-physical polygons by cluster with the strata descriptors is given as Appendix A. The summary statistics for the clusters is given in Appendix C.

The above clusters were further grouped into three classes which are shown in Table 3.9.

TABLE 3.9. CLUSTER CLASSES

Class	Clusters
insensitive	1, 6, 8, 10
mildly sensitive	2, 3, 4
sensitive	5, 7, 9

3.7 SAMPLE SITE SELECTION

Site selection for in situ lake measurements was based upon the stratification and clustering analysis described above and each of the following considerations: (1) availability of historical water quality and remote sensing data, (2) existing Canadian initiatives to collect site-specific data, (3) accessibility, and (4) coverage of eco-physical lake types. Sites selected included (1) Algoma, (2) Sudbury, (3) Wawa, and (4) Dorset. Nine of the ten clusters were represented by the selected sites.

The Canadian program recommended the use of the Algoma and Sudbury sites, each comprising approximately 1000 sq. km. Priorities were set

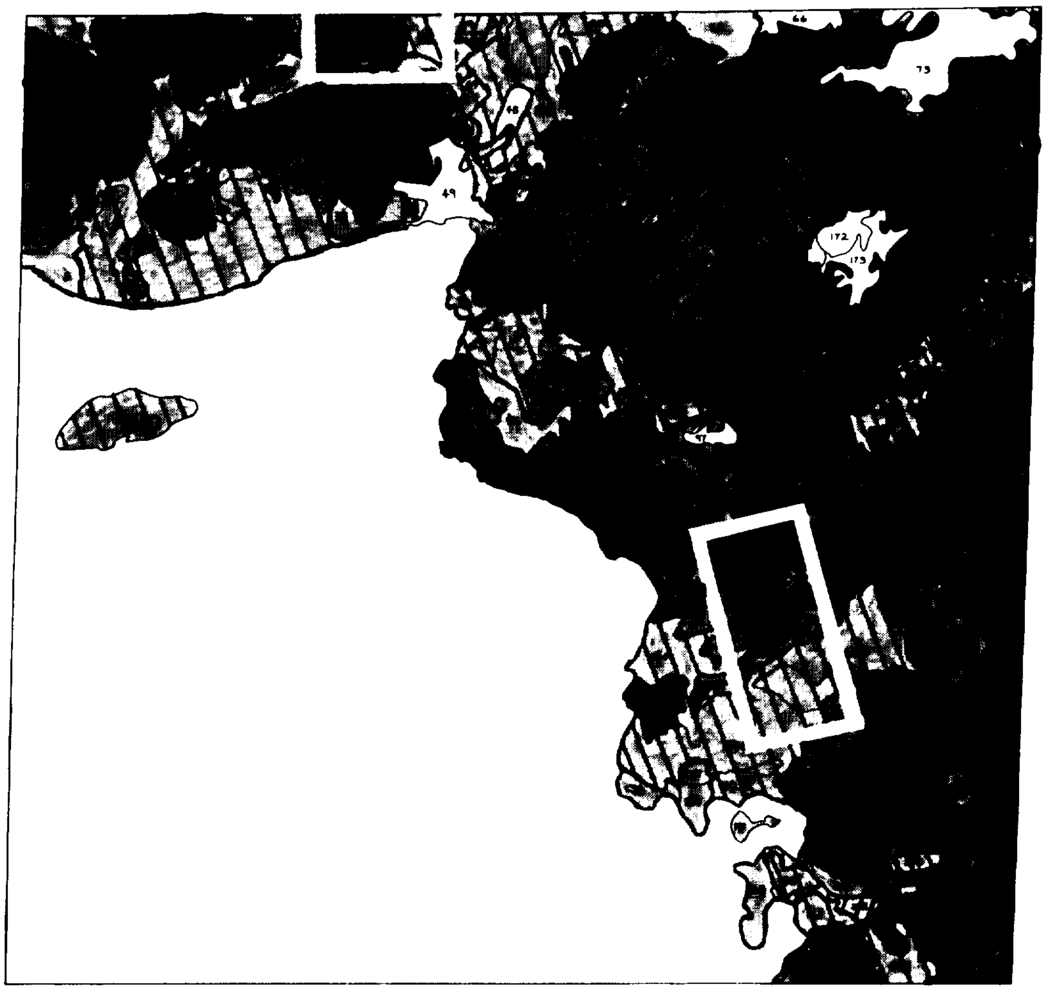

Figure 3.4 The Algoma Area Clusters and Sampling Sites

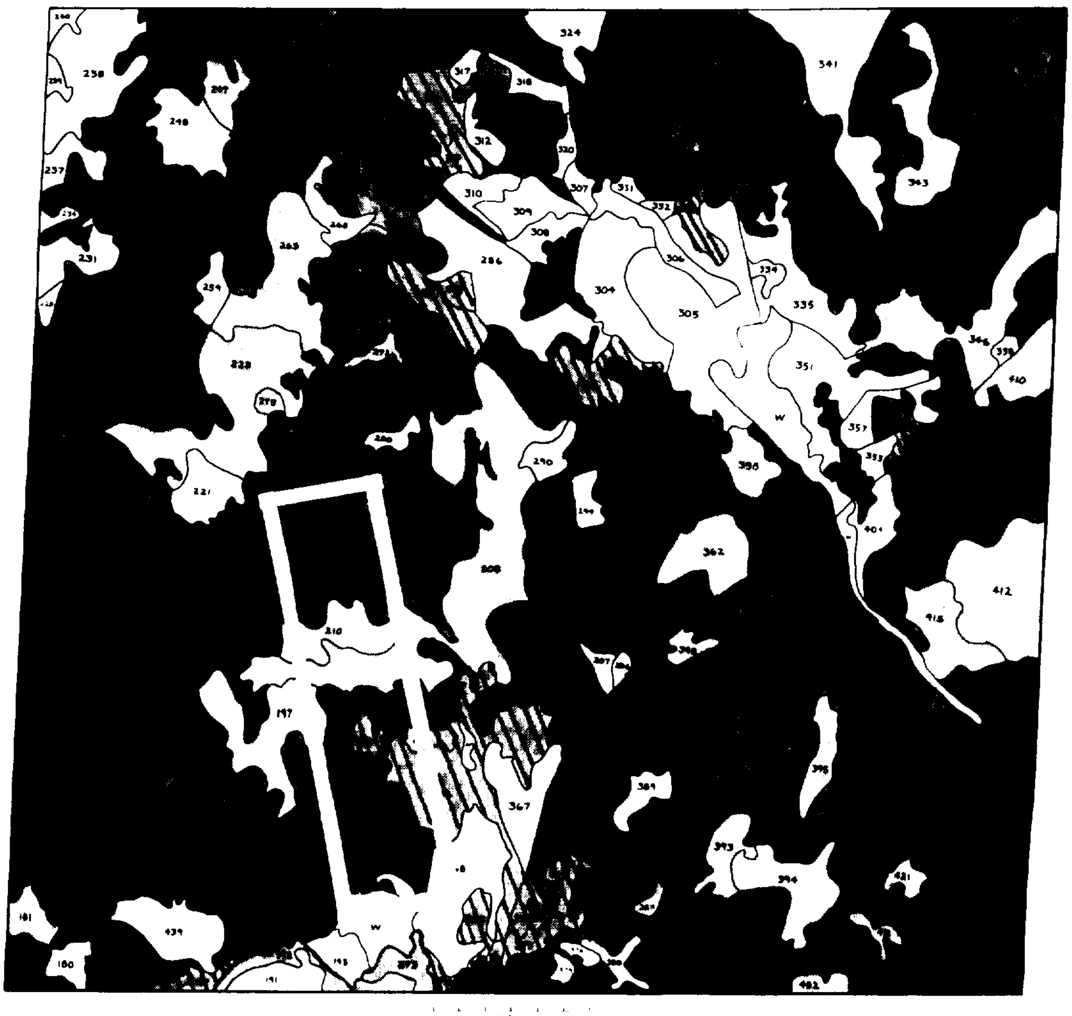

Figure 3.5 The Sudbury Area Clusters and Sampling Site

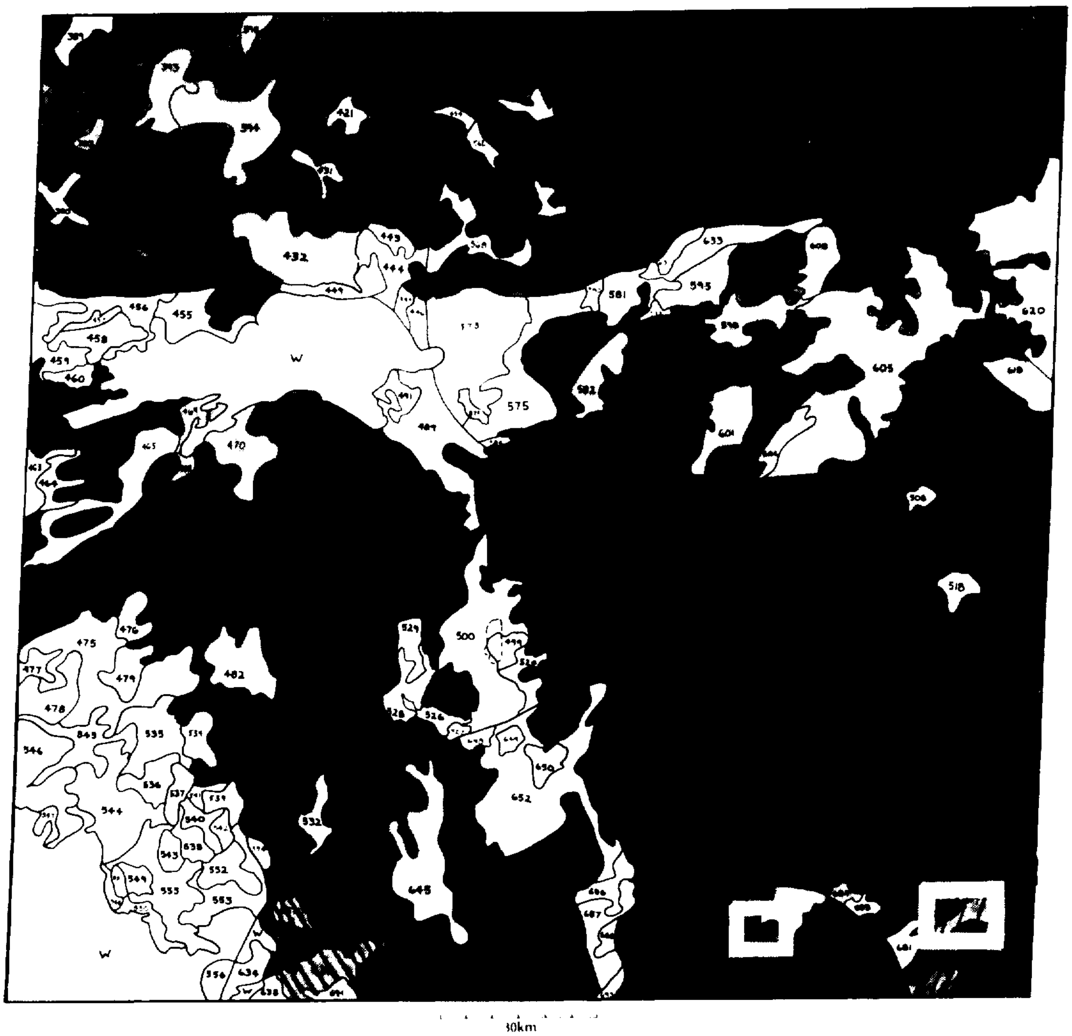

Figure 3.6 The Algonquin Area Clusters and Sampling Sites

for each of the four collection sites based upon group interests and availability of resources. First priority was given to the Sudbury site, second to Algoma, and third to Wawa. The Dorset site was viewed to be largely beyond the reach of a one-month field program and would only be addressed after the other data objectives had all been met. A lake sampling budget of approximately 300 samples was divided between the first three sites with 150 samples allocated to Sudbury, 130 allocated to Algoma, and 20 to Wawa. An additional 25 samples would be taken to support the Dorset sampling if resources were available.

4.0 DATA COLLECTION METHODS

4.1 LAKE SAMPLING STRATEGY

The ERIM field plan specified sampling at three different levels and with three different optical measurements. Field data collections were made during the summer of 1986 and spring of 1987. The August 1986 collections included three sites: Sudbury, Algoma, and Wawa. At each of these sites, water samples were gathered from a well distributed set of lakes using a helicopter. Radiometric measurements were made using Landsat TM, a helicopter (BELL-206) spectral radiometer (PROBAR), a subsurface spectral irradiance meter, and a subsurface beam transmissometer. The sampling strategy was to gather subsurface measurements from a small number of lakes and in sufficient number to calibrate a subsurface reflectance model. Airborne spectral measurements were gathered over a much larger set to be used to extend the subsurface results to a broader set of lake conditions. Finally these lake reflectance spectral characteristics were used to predict the reflectance characteristics of the still larger TM lake sample data set. The strategy in this three-tier sampling scheme was to develop a model/relationship from the in situ optical measurements and the measured limnological parameters. This "optical response model", once validated, was extended to the PROBAR data set and finally to the Landsat data set where it aided in the interpretation of TM observations.

During August 1986 field data were gathered from each of the three sites which included 21 water quality parameters (296 lakes), detailed subsurface optical measurements (12 lakes), airborne spectral radiometer measurements (102 lakes), and Landsat data. Most of these measurements were made in the Algoma and Sudbury sites (shown as Figures D.1 and D.2). All water chemistry data are compiled as Appendix D. PROBAR spectral radiometer measurements were made in most of the lakes that were larger than 20 hectares. The subsurface optical measurements were made in a representative set of lakes at each site. Water parameters were determined from collected samples by the MOE on-site or at the Toronto Laboratory. Water parameters especially important to this study included DOC, conductivity, total chlorophyll-a pigment concentration, pH, sulfate, alkalinity, TIP, turbidity, suspended solids, and aluminum.

The May-June 1987 field effort involved collecting subsurface MER reflectance and transmissometer data on four separate dates from eight lakes. Water samples were also collected and were processed by the MOE. Field data collections were made on 5 May, 14 May, 13 June, and 29 June at four to eight lakes in the Sudbury site. These data were collected coincident with the TM overpass on each of those dates. Two of these TM acquisitions (12 May and 13 June) were of excellent quality and were requested from NASA GSFC. No PROBAR airborne radiometer data were collected during the spring period because the unit was not available for project use.

4.2 SUBSURFACE OPTICAL MEASUREMENTS

Two instruments were used to make the subsurface optical measurements: a subsurface spectroradiometer (Biospherical Inc. MER-1000) with 11 narrow spectral bands (410, 441, 488, 520, 540, 560, 589, 625, 671 and 694 nm) and a transmissometer (SEATECH Inc.) with a single wavelength at 664 nm. These instruments were used to characterize the optical properties in several of the PROBAR-sampled lakes.

The MER-1000 subsurface upwelling and downwelling spectral spectral scans were collected in the field at variable sampling depths below the lake-water surface. MER data collections were made from a canoe (August 1986) and from a float plane pontoon (May-June 1987). The canoe measurements each consisted of 20 scans and the float plane measurements consisted of 10 scans. Fewer scans were used during the plane measurements since the instrument was allowed to drop through the water column at a faster rate. At each station a series of upwelling and downwelling irradiance measurements were made in succession. A pressure sensor in the MER recorded the depth of each spectral scan.

4.3 AIRBORNE RADIOMETER MEASUREMENTS

A helicopter-mounted (BELL 206) spectroradiometer (PROBAR) was used to collect radiometric data in each of 10 narrow spectral bands (443, 470, 520, 550, 580, 610, 640, 670, 700 and 732 nm) at the center of each sample lake.

PROBAR data was collected on four days in 1986:

August 12	15 Lakes
August 13	54 Lakes
August 14	18 Lakes
August 18	46 Lakes

Lakes sampled with the PROBAR were limited to those large enough to be visible in TM imagery and sufficiently deep not to produce a bottom reflected signal. The PROBAR unit had been rented from Moniteq Ltd., Toronto, Ontario and was controlled with an IBM PC that also was mounted in the helicopter. The PC logged the radiometer data and allowed easy transfer to the DEC VAX780 for data analysis.

4.4 LANDSAT TM ACQUISITIONS

All possible Landsat TM acquisitions were requested for the Algoma, Sudbury, and Dorset scenes for the month of August 1986. Algoma and Sudbury coverage were requested for May and June 1987. Of the scenes collected, four were considered sufficiently cloud- free to be useful. Image tapes were obtained from NASA GSFC Landsat office and are listed in Table 4.1.

TABLE 4.1. IMAGE TAPES REQUESTED FROM NASA GSFC LANDSAT OFFICE

Path/Row	Date
19/27	August 13, 1986
19/27	May 12, 1987
19/27	June 13, 1987
22/28	August 18, 1986

All of the other acquisitions were considered non-usable based upon the positive print of TM band one received from GSFC.

4.5 DATA QUALITY MEASURES

Provisions were made to ensure the quality of the data measurements. During the MER data collection, deck cell measurements of downwelling hemispherical irradiance were taken coincidentally. This ensured that the MER downwelling and upwelling profile measurements were taken while the downwelling irradiance remained constant.

When TM signals were being extracted, band four signals of water surfaces were examined for high standard deviations (> 0.5). If the standard deviation was higher than 0.5, it was assumed that the data were contaminated with either bottom or land reflectance, and they were not used.

Before transmissometer measurements were made, the air voltage was checked and recorded. The transmissometer measurement was only made if the air voltage was in the appropriate range. This air voltage was later used for calibration when calculating attenuation coefficients.

PROBAR measurements were corrected for the time of day and were calibrated using a white card of known reflectance. Instrument calibration was also done in the lab before the field work.

5.0 SUBSURFACE AND AIRBORNE RADIOMETRIC DATA REDUCTION

Radiometric data collected with the Biospherical MER-1000 radiometer, the SeaTECH transmissometer, the PROBAR spectral radiometer, and Landsat TM were reduced as described in the following sections.

5.1 MER DATA REDUCTION

MER-1000 data were first used to interpolate the irradiance data to common depths on a logarithmic scale before computing values of subsurface reflectance. The slope of the depth log-irradiance regression equation defines the average irradiance attenuation coefficient (K). The irradiance attenuation coefficient changes very little within the mixed layer, but rapidly within the transition zone (thermocline). The thickness of the mixed layer was easily determined from the temperature depth profile. Therefore only irradiance measurements from the mixed layer were used to determine K. Downwelling irradiance attenuation for low DOC lakes (Sunnywater and Wolf) and high DOC lakes (Whitepine and Barbara) are shown in Figure 5.1.

Subsurface spectral reflectances were calculated at 2, 4, 6, and 8 meters below the surface. Example reflectance curves are shown in Figure 5.2, along with the DOC and Chlorophyll-a measurements. The impact of DOC and Chlorophyll-a on reflectance is apparent. As DOC increases the blue-green portion of the reflectance spectrum is diminished due to highly selective absorption. Chlorophyll-a also diminishes the measured reflectance below 520 nm, due to absorption. Wavelengths greater than 520 nm absorption are reduced and backscattering is increased. The reflectance calculations at 700 nm are not considered valid since the irradiances are very small and contaminated by sensor noise.

In the spring of 1987 the MER pressure sensor was calibrated so measurement depths were available without depth correction. The pressure sensor in August 1986 sampling period was precise but it was not accurate. A control profile was made during which actual and measured

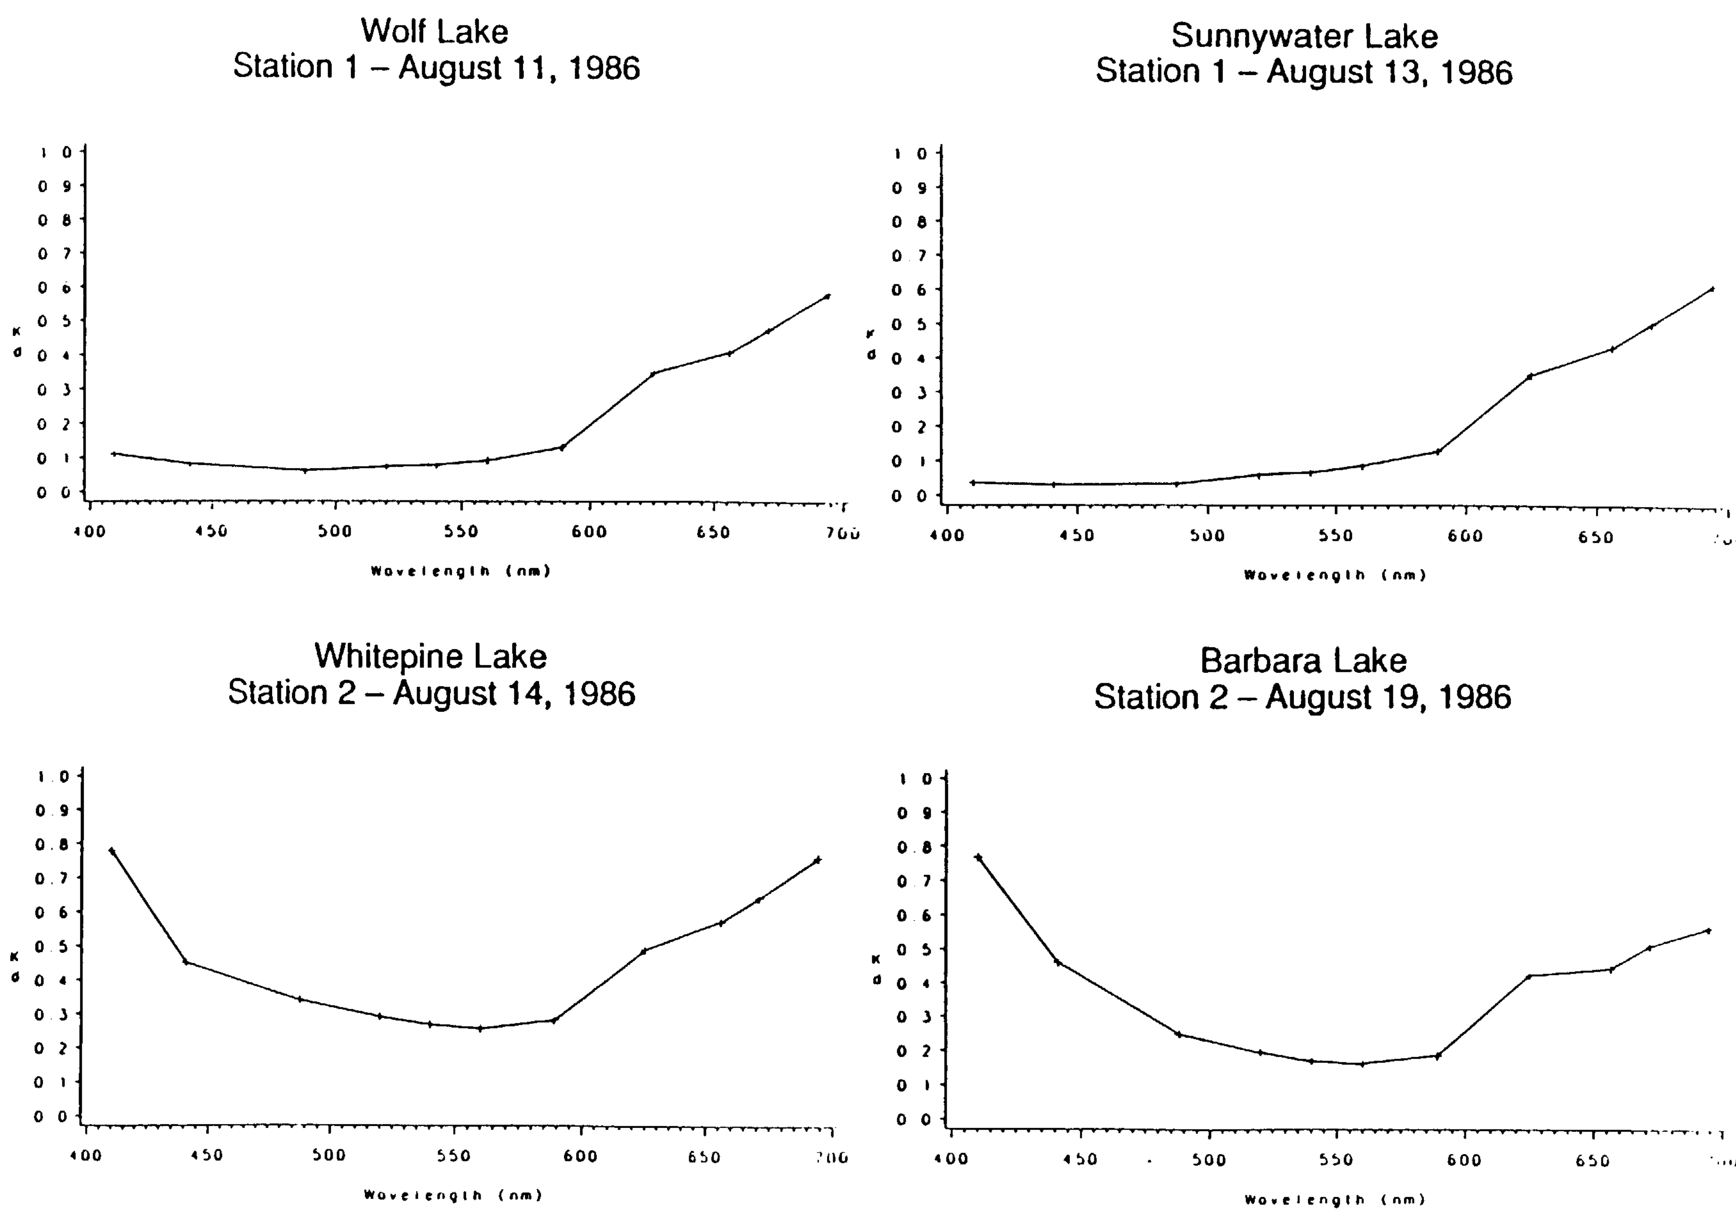

Figure 5.1 Downwelling Irradiance Attenuation $K_d(\lambda)$

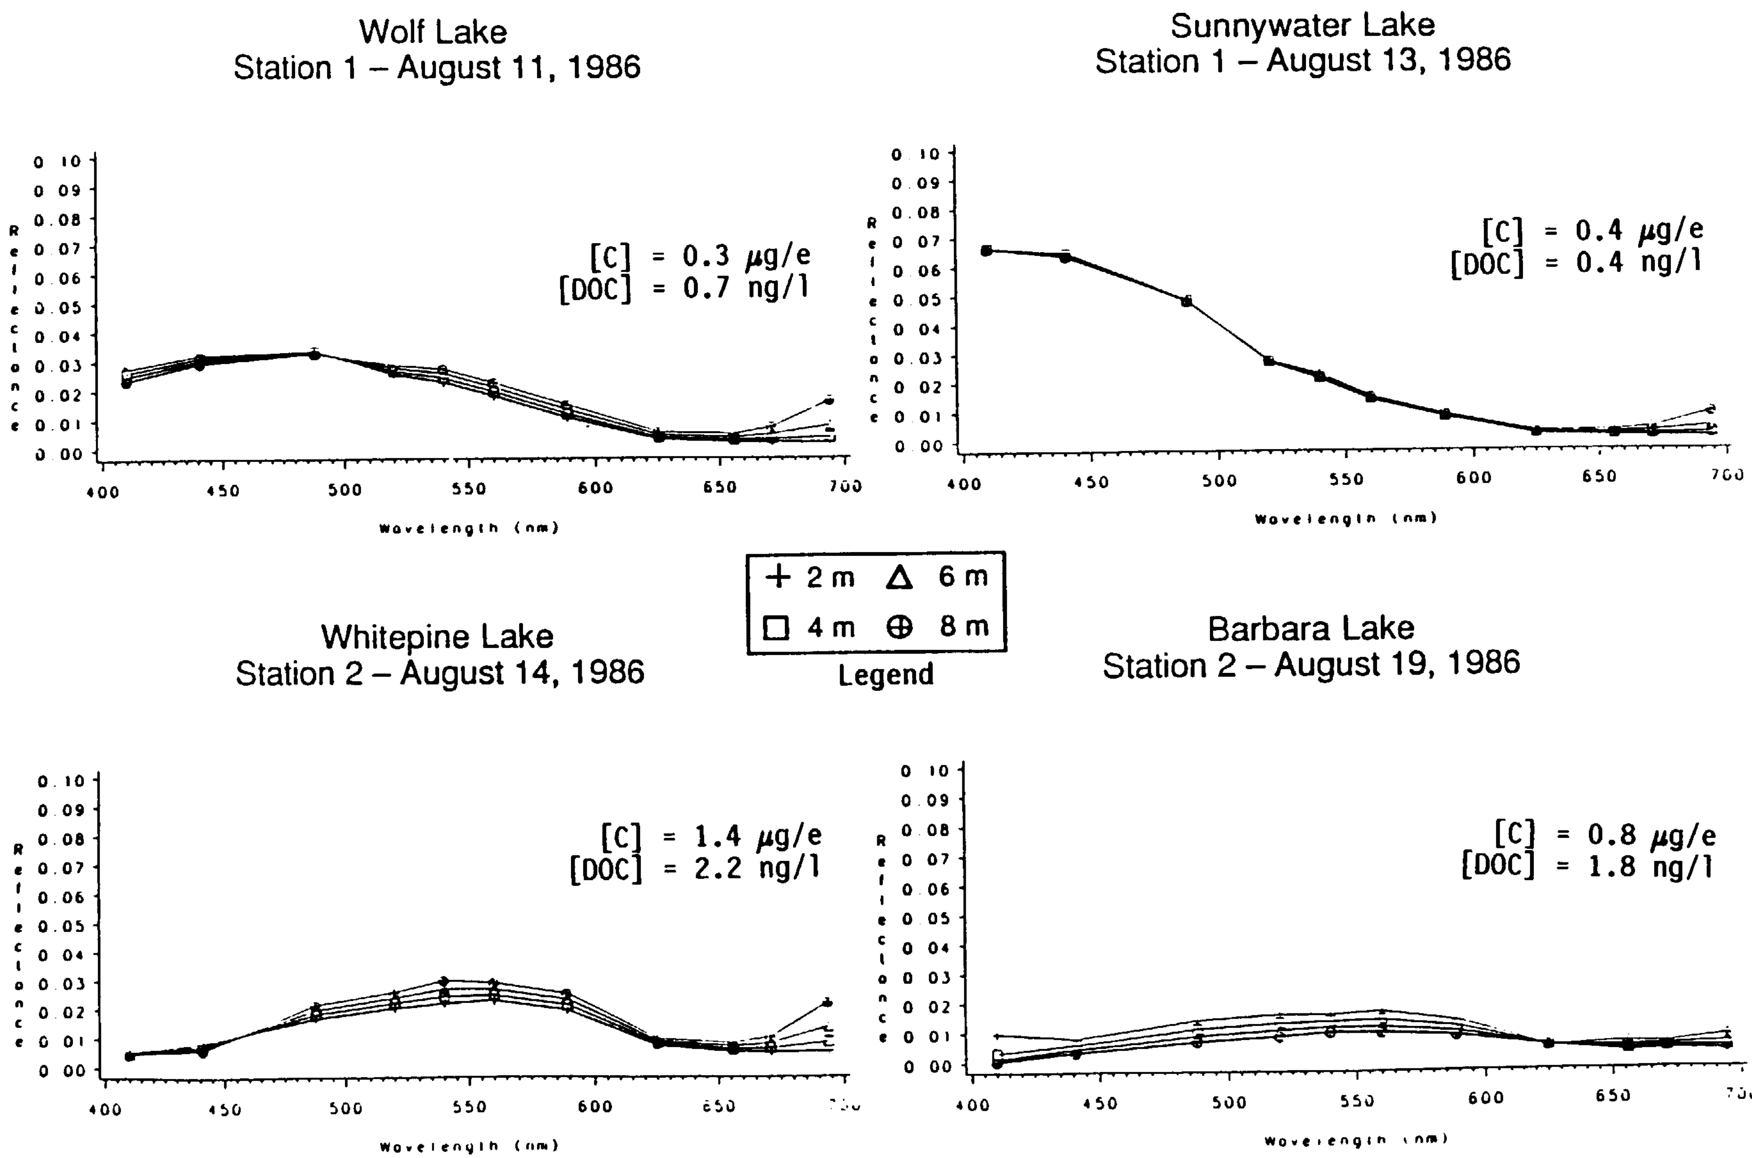

Figure 5.2 Subsurface Reflectance $R(\lambda)$

depths were recorded and a simple linear relationship was found between them.

$$\text{Depth} = \text{Measured Depth} / .567$$

To obtain reflectance values it was necessary to develop two linear equations describing the relationship between the natural logarithm of irradiance (ln(E)) and corrected depth for both the upwelling and downwelling profiles. The diffuse attenuation coefficient determines the rate of irradiance loss through the water column and is defined by the following equation.

$$K(\lambda) = \frac{-1}{E(\lambda,z)} \frac{dE}{dz}$$

The irradiance data collect at multiple depths were first used to estimate K from the solution to the above equation as given by the following linear form.

$$\ln(E(\lambda,z)) = K(\lambda)*z + \text{intercept}$$

Depths of 2, 4, 6 and 8 meters were then entered into the linear equation to estimate $\ln(E_u)$ and $\ln(E_d)$. Reflectance at these four depths were then produced using the following equation:

$$R(\lambda,z) = \text{EXP}(\ln(E_u(\lambda,z)) - \ln(E_d(\lambda,z))$$

Where $E_u(\lambda,z)$ = upwelling irradiance at z meters
  and $Ed(\lambda,z)$ = downwelling irradiance at z meters.

5.2 TRANSMISSOMETER DATA REDUCTION

SeaTECH transmissometer profiles were made at every station coincident with the MER measurements. Voltage measurements were made usually at 2, 4, 6, and 8 meters after an air reading was made at each station.

Corrected voltage was then obtained using the following equation:

$$\text{Cvolt} = (\text{Lab Air}/\text{Field Air}) \times (\text{Mvolt} - .003)$$

where Cvolt = Corrected voltage
Lab Air = Lab air reading = 4.775 volts
Field Air = Field air reading
Mvolt = Measured voltage

Fractional transmission could be determined since it is known that 100% transmission through 25 cm of pure water has a corrected voltage of 5 volts. Fractional transmission through 25 cm of lake water is found using the following relationship:

$$T(664\text{nm}) = (\text{Cvolt}) / 5 \text{ volts.}$$

The beam attenuation coefficient (c) can be derived using the fractional transmission in the following equation:

$$c(664\text{nm}) = -4 \text{ LOG}(T(664\text{nm})$$

The reduced transmission and beam attenuation coefficients for all SeaTECH measurements are given as Appendix E.

5.3 PROBAR DATA REDUCTION

One objective in reducing the PROBAR data was to estimate illumination independent reflectance values which could be compared to the MER data derived values. The airborne PROBAR measurements, however, were made complicated by the helicopter blade motion and by the need for irradiance reflectance given the PROBAR is a radiance device. The rotating blade interfered with the downwelling irradiance meter and also possibly with the upwelling radiance measurements as well. The raw data from several dates showed a significant change in downwelling irradiance between measurements taken on the ground using a standardized white reflectance card. This effect was dependent on time of day and date illumination conditions. These conditions necessitated a series of five corrections be made to these data in order to make them compatible to the MER reflectance data. These corrections were (1) for standardized white card reflectance, (2) for airborne conditions, (3) for time of day, (4) for day-to-day variations in sky illumination, and (5) for surface reflectance.

Upwelling radiance, $L_u(\lambda)$, and downwelling irradiance values were read for ten 20 nm - wide bands ranging from 433 nm to 710 nm. Reflectance was computed in the following manner:

$$R(\lambda,0) = M(\lambda,0)/E_d(\lambda,0)$$

$$\text{where } M(\lambda,0) = L_u(\lambda) * \pi$$

All dates show a large change in downwelling irradiance between measurements taken on the ground (white card measurements) and measurements taken when the helicopter was airborne (all lake measurements). This discrepancy was accounted for in the change in helicopter blade tilt. When the instrument was airborne, the blades were tilted at a higher angle, thus allowing more light to reach the downwelling irradiance sensor. A correction was made by producing a second order regression equation of all airborne downwelling irradiances as a function of time. The true white card downwelling irradiance was then estimated using the resultant equation. This correction was made for each PROBAR band.

All data needed to be normalized to one unique white card reflectance for each band. The white card used for correcting the data was known to have a nearly constant reflectance value (.989) for the bands being studied. The white card reflectances were fit to a second order equation using time as the independent variable producing the measured white card reflectance curve. The true lake reflectance is adjusted by the same percent difference as that between the measured white card reflectance (MWCR) the known white card reflectance curve.

$$R(\text{true}) = R(\text{measured}) \times \left[1 - \left[\frac{\text{MWCR} - .989}{\text{MWCR}}\right]\right]$$

A final correction was made to PROBAR measurements which was lake-dependent. The assumption was made that no internal lake reflectance was measured in the band centered at 700 nm. This measurement was assumed to be an indication of wave induced surface reflected noise and thus was subtracted at all wavelengths. This correction only changed the offset of the spectral reflectance curve, not its shape.

The above and below surface corrected PROBAR reflectances are given as Appendix B.

6.0 LANDSAT TM PROCESSING METHODS

6.1 LAKE SIGNATURE EXTRACTION

Extraction software was applied to all three TM scenes. Lake signals were extracted from the TM images by finding the latitude and longitude of lakes of interest on topographic maps and using these latitudes and longitude to extract lake signatures from geometrically corrected imagery using extraction software. Nine brightness values were extracted from each lake and their means were used in subsequent processing. A three by three pixel area was extracted and the mean signal and its standard deviation for each band were recorded. To ensure that the spectral signatures represented water and not cloud, shoreline or bottom reflectance, TM band 4 signals were inspected. Average signals in TM band four were found to range between 11.0 and 14.0 with a standard deviation for values within an individual samples of less than 1.0. Thus for samples which had mean values outside this range or with sample standard deviations greater than 1.0 the sample was rejected and considered to indicate a non-water mixed reflectance. The rejected samples were replaced with values extracted from another part of the lake surface. Brightness values were extracted from the approximate center of each lake based upon the latitude and longitude of each lake center. These extracted mean values were then correlated to historical water chemistry data available for the same lakes as discussed in Section 8.0.

The TM data extracted is summarized in Table 6.1.

TABLE 6.1. THEMATIC MAPPER DATA EXTRACTED

Path/Row	Quad	Date
22/27	1	8/18/86
22/27	4	8/18/86
22/27	4	5/27/85
19/27	3	8/13/86
19/27	3	5/22/85

6.2 SOLAR ELEVATION ANGLE CORRECTION

All lake data were corrected for the solar elevation angle of each scene. This correction simply involved dividing each brightness value mean by the cosine of the solar zenith angle.

6.3 ATMOSPHERIC HAZE CORRECTIONS

A haze correction needed to be applied to the TM data so that real comparisons could be made between lakes within and between scenes which had varying amounts of haze distorting the signals. Lakes of equivalent Dissolved Organic Carbon (DOC) concentrations should have similar TM signals in band one but these data showed instead wide variations. The lakes with elevated TM band one counts also had elevated counts in bands two, three, and four. Since band 4 counts represent virtually no internal lake reflectance, it was hypothesized that relative differences between lakes in band four represented differences in atmospheric haze. Linear regression analyses between bands one and four, bands two and four, and bands three and four showed nearly linear behavior but with different slope and a small intercept. Also, these derived slope values were found to be scene dependent. The slopes between bands were derived using regression analyses and used directly in the haze correction algorithms. Thus the correction for haze was both wavelength dependent and scene dependent. The following three equations are the haze correction algorithms for the three TM bands used:

$$\text{TM-1(corr)} = \text{TM-1} - (\text{TM-4} \times M_1)$$
$$\text{TM-2(corr)} = \text{TM-2} - (\text{TM-4} \times M_2)$$
$$\text{TM 3(corr)} = \text{TM 3} - (\text{TM 4} \times M_3)$$

M_1, M_2, and M_3 are the slopes between bands one and four, bands two and four, and bands three and four, respectively.

This procedure reduced the impact of haze as indicated by the improved correlation between TM band one signals and DOC (i.e. from 0.62 to 0.83).

7.0 DEVELOPMENT OF A BIO-OPTICAL REFLECTANCE MODEL

7.1 REFLECTANCE MODEL

A TM radiative transfer model was developed to predict possible changes in radiometer signal levels which result from field-measured changes in chemical properties. Work on this model included specific calibration for the Landsat TM sensor. The model treats atmospheric optics, water optics, and the wind ruffled air-water interface. A solar ephemeral model has also been implemented to provide a capability to simulate the entire sun-sensor geometry. For many of the lakes involved in this study absorbing effects of DOC dominate the scattering effects of suspended minerals and organic particles. Under these conditions subsurface reflectance can be estimated as the ratio of backscattered radiation to the total lost by both backscattering (Bb) and absorption (a).

The specific values of a and Bb will depend on the concentrations of silt (mineral particles), chlorophyll-a pigments (C), and DOC. The absorption and scattering cross sections used in the present study were those derived by Bukata [1985] in his detailed optical analysis of Lake Ontario waters. These cross sections are shown in Figures 7.1 and 7.2.

The specific concentrations of each component were used together with these cross sections to estimate the absorption and backscattering coefficient. The following equation gives the general subsurface reflectance model:

$$R(\lambda) = C_o(\lambda) \bullet \frac{Bb(\lambda)}{a(\lambda) + Bb(\lambda)}$$

where $R(\lambda)$ = Subsurface irradiance reflectance

$C_o(\lambda)$ = Constant (typical value = .33)

$Bb(\lambda)$ = Total backscattering coefficient

$a(\lambda)$ = Total absorption coefficient

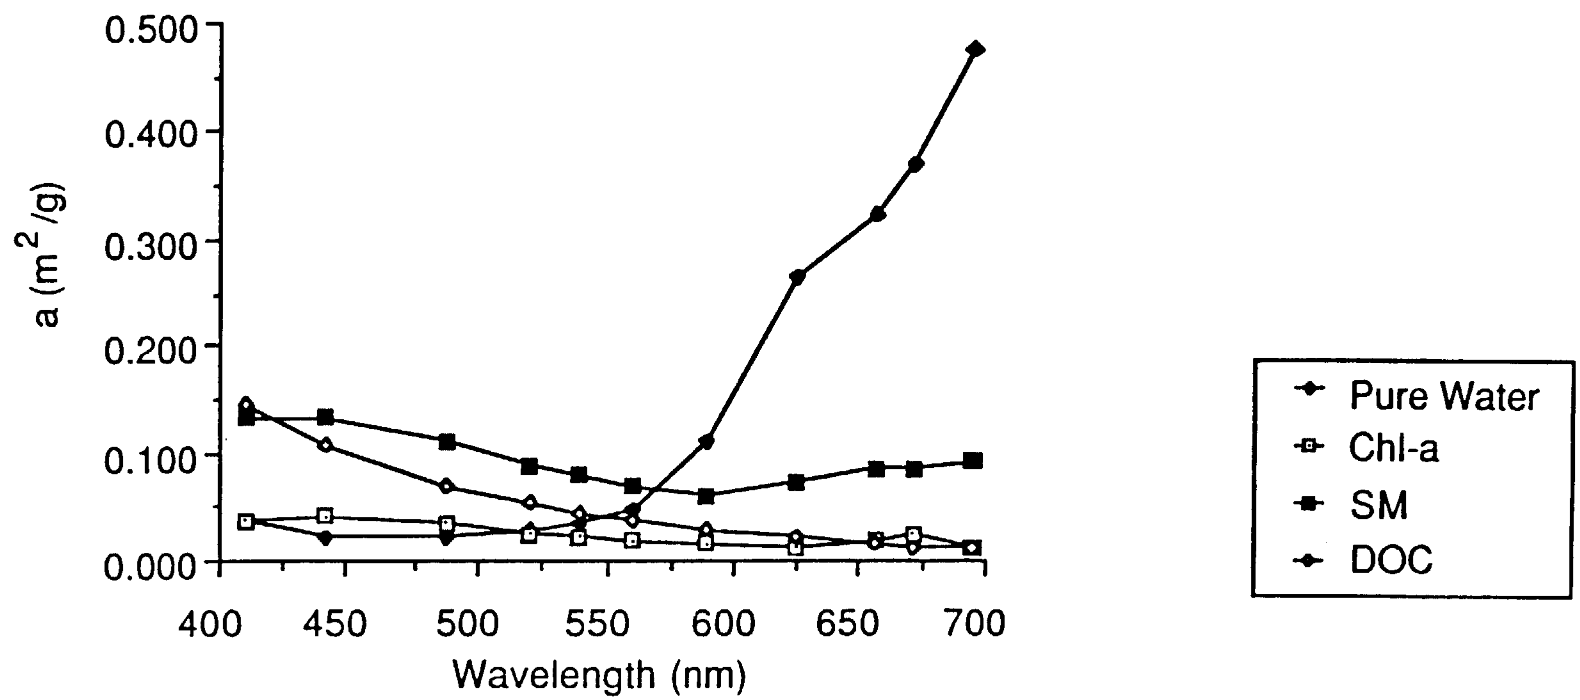

Figure 7.1. Absorption Cross Sections for Chlorophyll-a, DOC, Suspended Minerals, and the Absorption Coefficient of Pure Water.

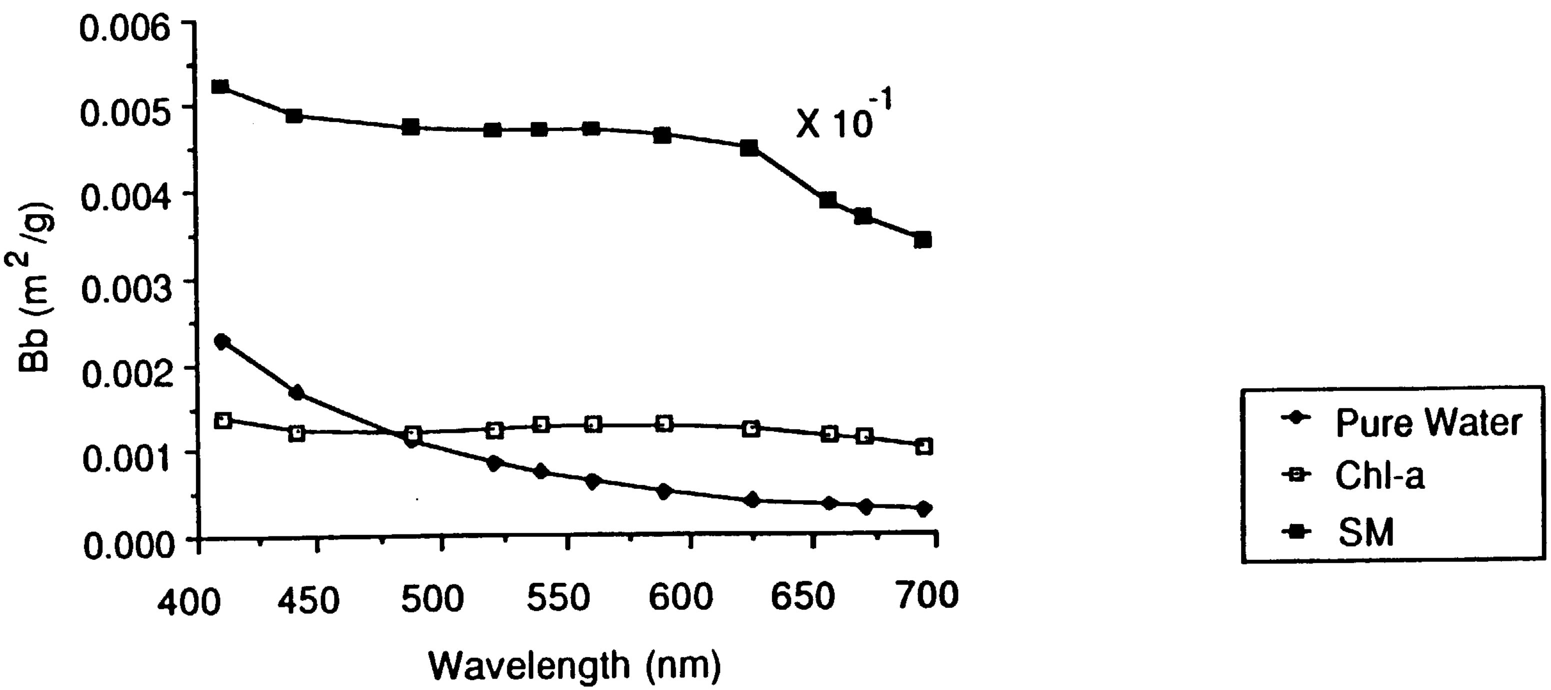

Figure 7.2. Backscatter Cross Sections for Chlorophyll-a, Suspended Minerals, and the Backscatter Coefficient of Pure Water.

This model calculates subsurface reflectances (at the wavelengths measured by the MER) given the concentrations of chlorophyll, DOC, and suspended solids as shown in the following equation:

$$R(\lambda) = C_o(\lambda) \bullet \frac{(Bb_w(\lambda) + Bb_C(\lambda)\bullet[C] + Bb_{SM}(\lambda)\bullet[SM])}{(a_w(\lambda) + a_C(\lambda)\bullet[C] + a_{SM}(\lambda)\bullet[SM] + a_{DOC}(\lambda)\bullet[DOC] + Bb's)}$$

where R = Subsurface hemispherical reflectance
SM = suspended solid concentration (mg/l)
C = chlorophyll concentration (μg/l)
DOC = Dissolved organic carbon concentration (mg/l)

7.2 MODEL CALIBRATION

Backscattering and absorption values were regressed with the MER-1000 estimated subsurface reflectance at each wavelength producing an estimate of constant coefficient (C_o) which is listed in Table 7.1. The resulting set of reflectance equations can be used to examine the spectral reflectance dependence on DOC and other constituents. The mineral particle concentrations were found to be extremely small, on the order of 0.1 mg/l. If one assumes a chlorophyll-a concentration of 1.0 μg/l (a typical value) then the DOC reflectance varies between 1% and 6% in TM band one as depicted in Figure 7.3.

7.3 MODEL EXTENSION WITH PROBAR DATA

The PROBAR above-surface reflectance data were collected in August 1986. These data were converted to subsurface reflectances for over one-hundred lakes using a regression procedure (described in Section 8.5).

The model developed for the MER subsurface reflectance data was tested using the PROBAR-predicted subsurface reflectance data. The Marquardt method was used for developing the non-linear model. This method is equivalent to performing a series of ridge regressions and is most useful when the parameter estimates are highly correlated.

Table 7.1.

Reflectance Model Coefficients

λ (nm)	C_o	Std. Error
410	0.731	0.1382
441	0.678	0.1193
488	0.525	0.0063
520	0.360	0.0318
540	0.319	0.0373
560	0.301	0.0520
589	0.374	0.0679
625	0.300	0.0753
656	0.345	0.0930
671	0.383	0.0936
694	0.519	0.1156

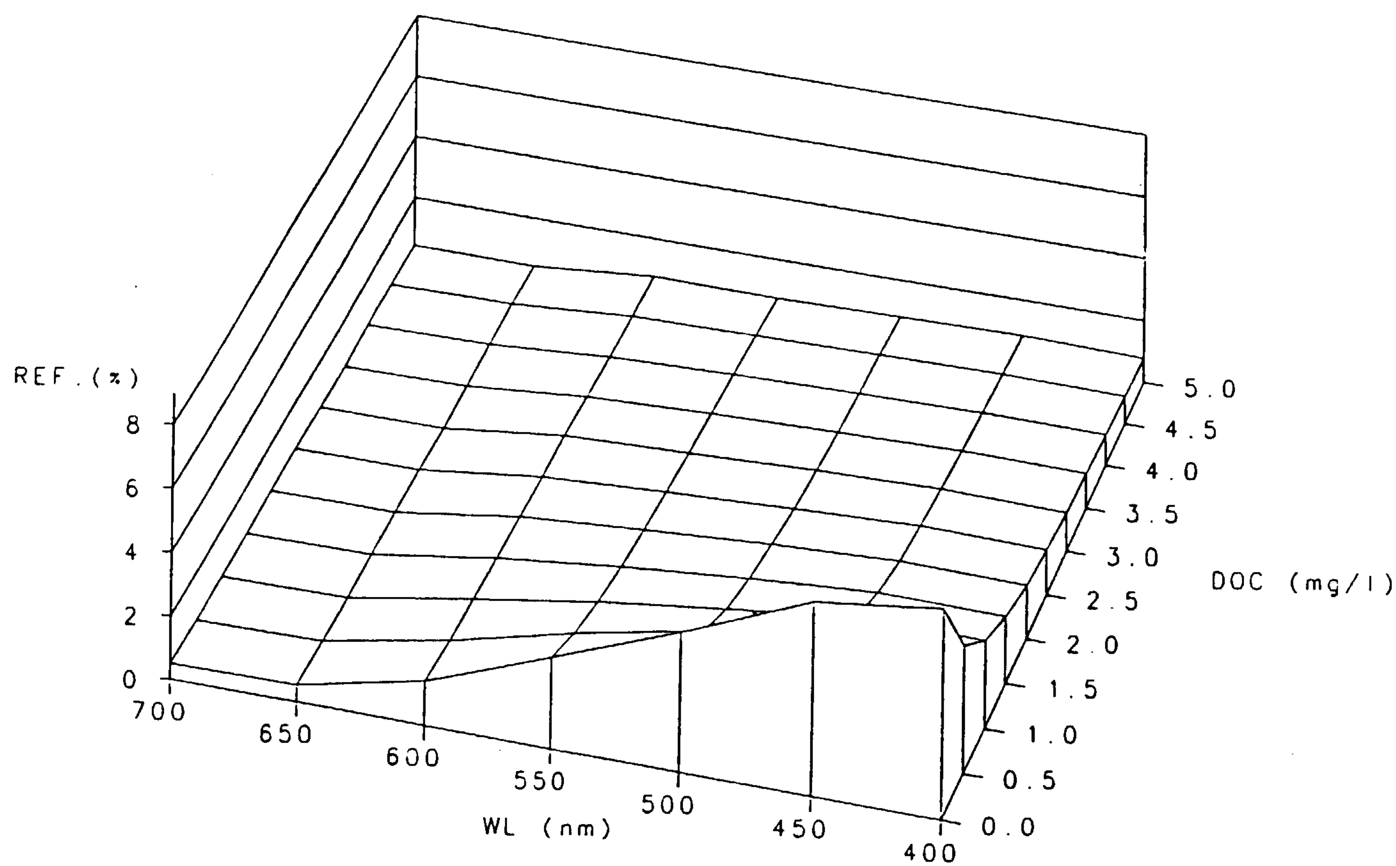

Figure 7.3. Reflectance Model for Dissolved Organic Carbon (DOC)

Since DOC and chlorophyll, (the two model parameters), have a correlation coefficient of about 0.73, the Marquardt method seemed appropriate.

To estimate how well this model fit the PROBAR predicted subsurface reflectance data, the coefficients produced using these data were compared to those produced using the MER data. The results of using the non-linear model on data from wavelengths of 443, 470, 520 and 540 μm are listed in Table 7.2.

TABLE 7.2. COMPARISON OF PROBAR AND MER MODEL COEFFICIENTS

	PROBAR	MER
C_{443}	.51	.73
C_{470}	.48	.68
C_{520}	.42	.36
C_{550}	.32	.32

The model fits the data best in the longer wavelengths. At worst, the model coefficients are different by .22, or approximately 30% (for λ=443 nm). At best, there is no difference between the coefficients (λ=550 nm).

A comparison of the actual PROBAR predicted subsurface reflectance and the model-predicted subsurface reflectance was made to test the performance of the reflectance model. The correlation between the predicted and actual subsurface reflectance models was quite high, ranging from .81 to .89, depending on the wavelength. Model-predicted versus PROBAR-predicted subsurface reflectances at 440 nm and 470 nm are shown in Figures 7.4 and 7.5, respectively.

7.4 REFLECTANCE SENSITIVITY TO CHANGES IN WATER CHEMISTRY

The sensitivity of reflectance to changes in DOC is given by the following derivative of the model equation:

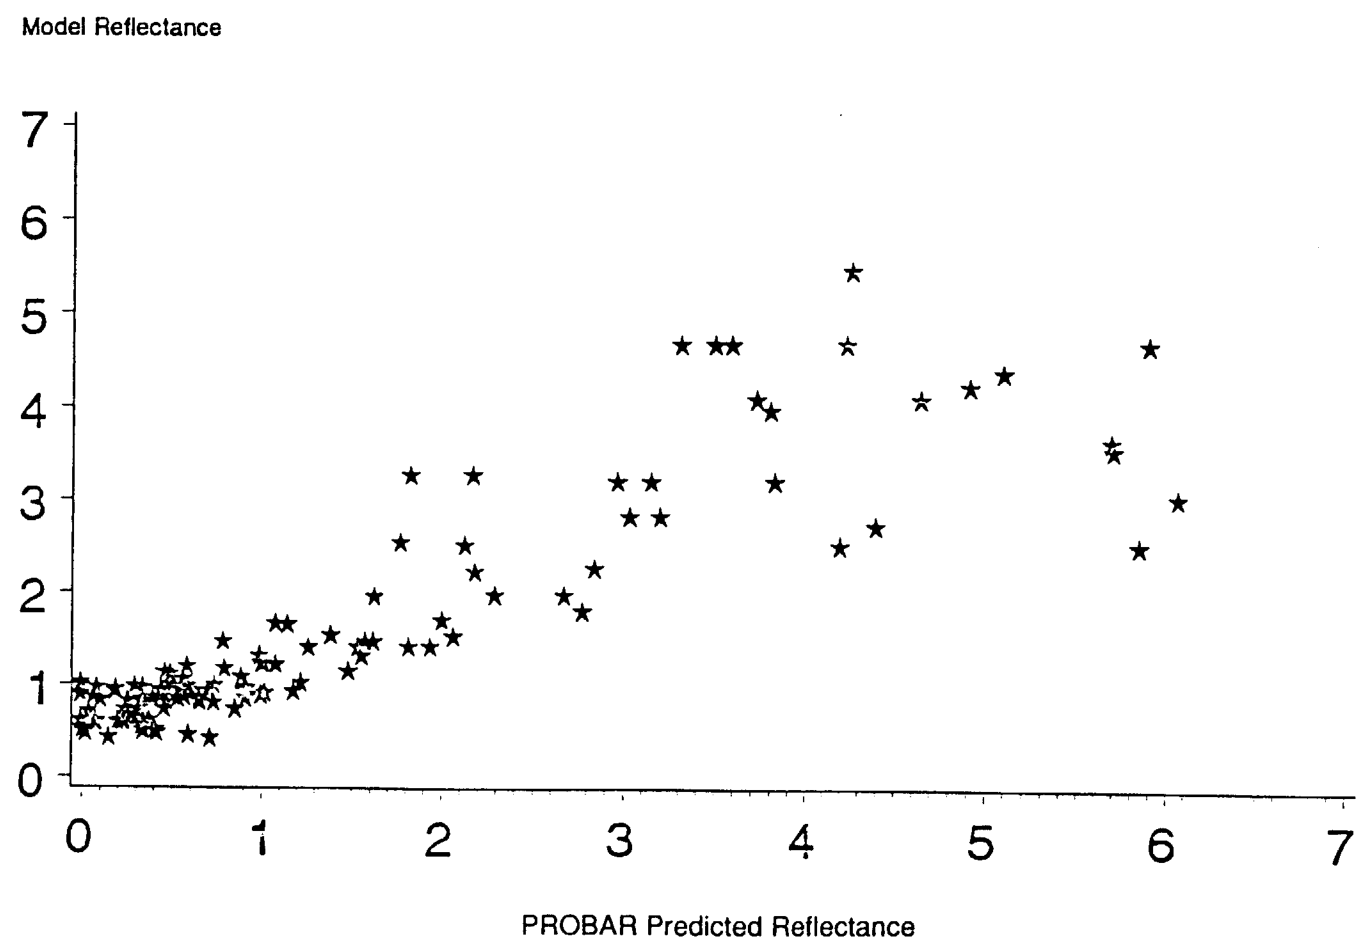

Figure 7.4. Model Predicted Versus PROBAR Predicted Subsurface Reflectance at 440nm. PROBAR Data Collected From Algoma and Sudbury Site, August 1986.

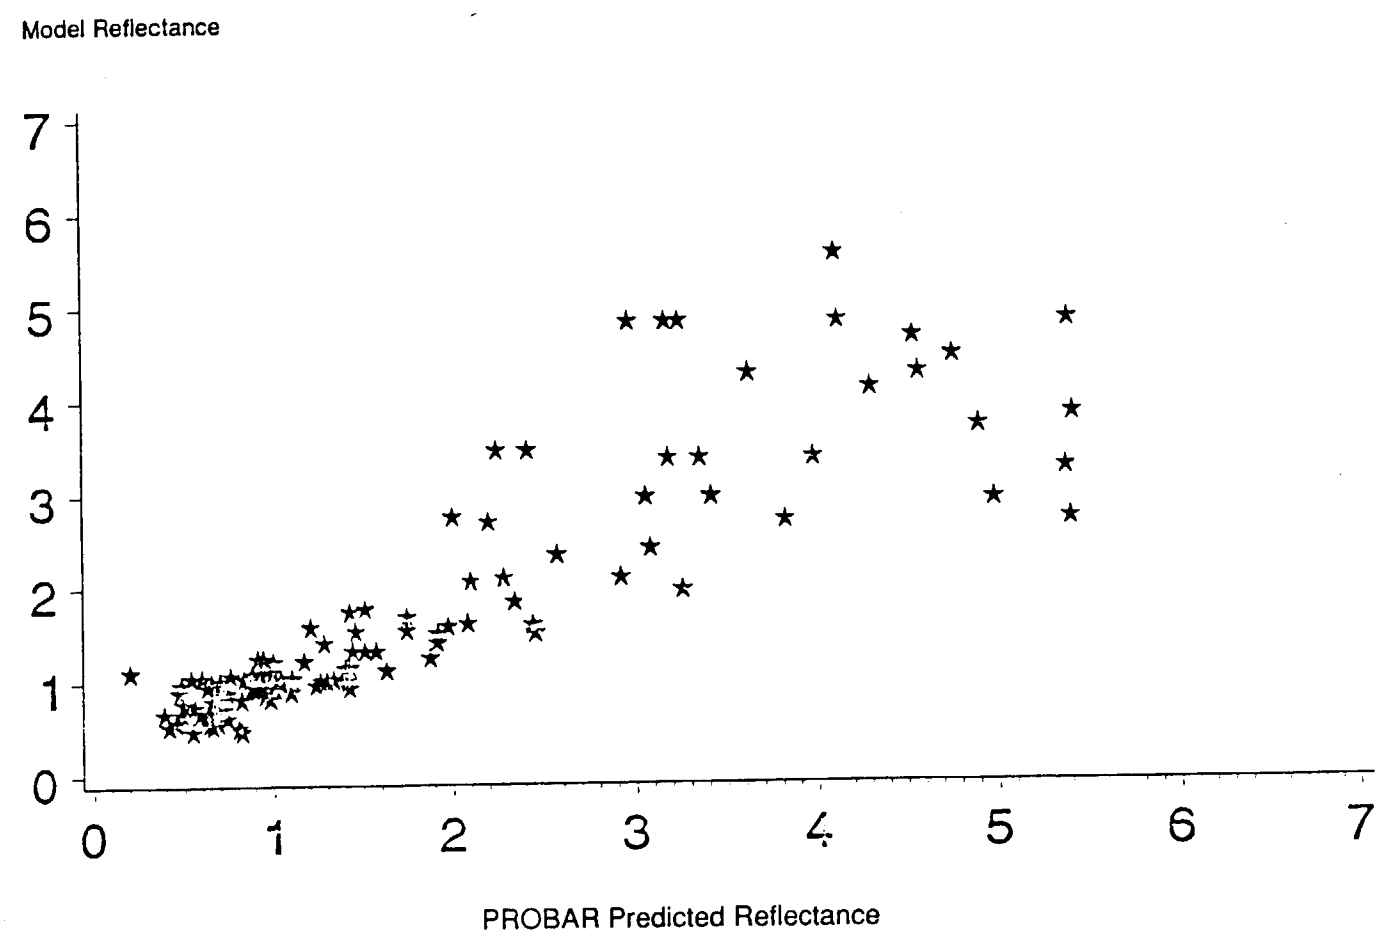

Figure 7.5. Model Prdicted Versus PROBAR Predicted Subsurface Reflectance at 470nm. PROBAR Data Collected From Algoma and Sudbury Site, August 1986.

$$\frac{dR(\lambda)}{d[DOC]} = \frac{a_{DOC}(\lambda)\bullet(Bb_{w}(\lambda)+Bb_{SM}(\lambda)\bullet[SM]+Bb_{C}(\lambda)\bullet[C]\bullet Co(\lambda)}{(a_{DOC}(\lambda)\bullet[DOC]+a_{C}(\lambda)\bullet[C]+a_{SM}(\lambda)\bullet[SM]+a_{w}(\lambda))^{2}}$$

Figure 7.6 shows the change in reflectance sensitivity for a given DOC concentration. The plotted sensitivity values are for the Sudbury site, calculated using the above equation and measured values of DOC and chlorophyll-a.

7.5 MODEL-PREDICTED SENSITIVITY OF TM

The ability to detect a seasonal change using depended on the measured TM reflectance changes, and on the sensitivity of reflectance to changes in DOC and chlorophyll-a pigment concentration.

The impact of DOC changes on reflectance can be calculated using the sensitivity equation in Section 7.4. The expected TM band one signal change per percent subsurface reflectance change was estimated previously to be 2.86 counts/percent. If it is assumed that seasonal changes in DOC are on the order of 50%, then background levels of two to three count changes are projected in the TM response. These predictions are summarized as Table 7.3.

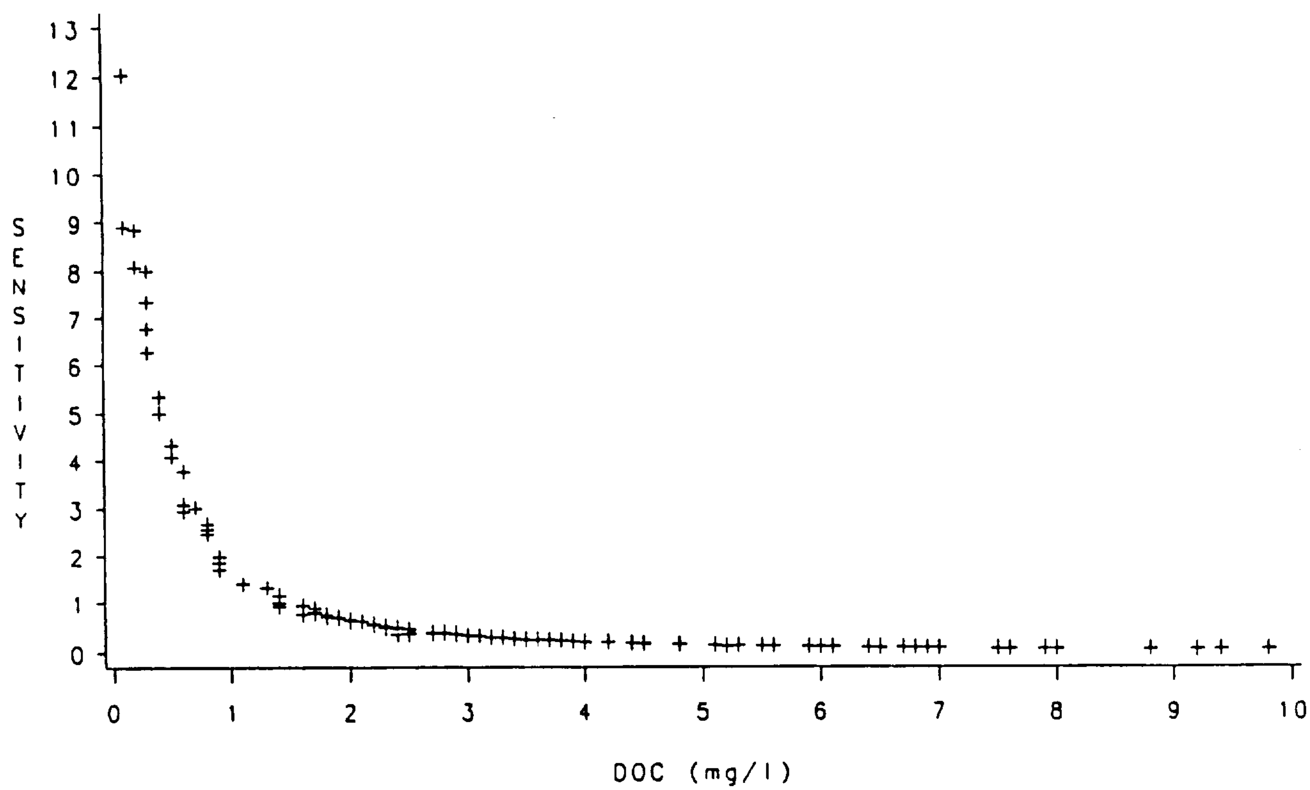

Figure 7.6. Sensitivity of Reflectance to Changes in DOC Concentration for a Clear Lake Typical of the Sudbury Site.

Table 7.3.

PREDICTED CHANGES IN REFLECTANCE AND TM BAND 1 COUNTS

DOC Sensitivity	DOC(mg/l)	ΔDOC (mg/l)	ΔR(%)	ΔTM Counts
5.6	0.3	0.15	0.84	1.7
4.0	0.5	0.25	1.00	2.0
1.6	1.0	0.50	0.80	1.6
0.8	2.0	1.00	0.80	1.6
0.3	3.0	1.00	0.30	0.6

8.0 ANALYSIS OF RADIOMETRIC DATA RELATIONSHIPS

8.1 CHARACTERIZATION OF WATER CHEMISTRY OF STUDY AREA LAKES

The August 1986 water chemistry data collected in this experiment contain twenty-eight in-lake water parameters for 300 lakes across Ontario. Pearson correlation coefficients and their significance probabilities were produced for a subset of these data set and are listed in Table 8.1. There were strong correlations between pH and total inflection point alkalinity and aluminum (.88 and -.75, respectively). The correlation between pH and DOC was found to be much lower at 0.61 but which still indicates a significant relationship exists. A scatter plot of pH and DOC is shown as Figure 8.1. It is evident from these data that the strongest relationship exists for DOC values less than 3.0 mg/1.

8.2 ANALYSIS OF SUBSURFACE IRRADIANCE MEASUREMENTS

Based upon the reflectance model analysis high correlations were expected between lake water chemistry and MER optical measurements. The Pearson correlation coefficients and their significant probabilities are tabulated in Table 8.2 for the August 1986 water chemistry data. In general, there is a high correlation between the short wavelength reflectances (λ < 540 nm) with Secchi depth (SD), chlorophyll-a (CHLOR), DOC, aluminum (AL), and pH. The high correlations with SD, DOC, and AL support the phenomenological relationships between water chemistry parameters and optical properties as discussed previously in Chapter 2.0. The lower correlations with chlorophyll-a values were expected since pigment concentrations measured in many of these lakes was so small.

Mer spectral reflectances were plotted for selected lakes which are given as Appendix F. The clear acid lakes were found to have spectral reflectances with peaks in the 400-450 nm range and shape similar to that obtained for Sunnywater Lake (see Figure 8.2). By contrast the high DOC lakes have spectral reflectance curves which

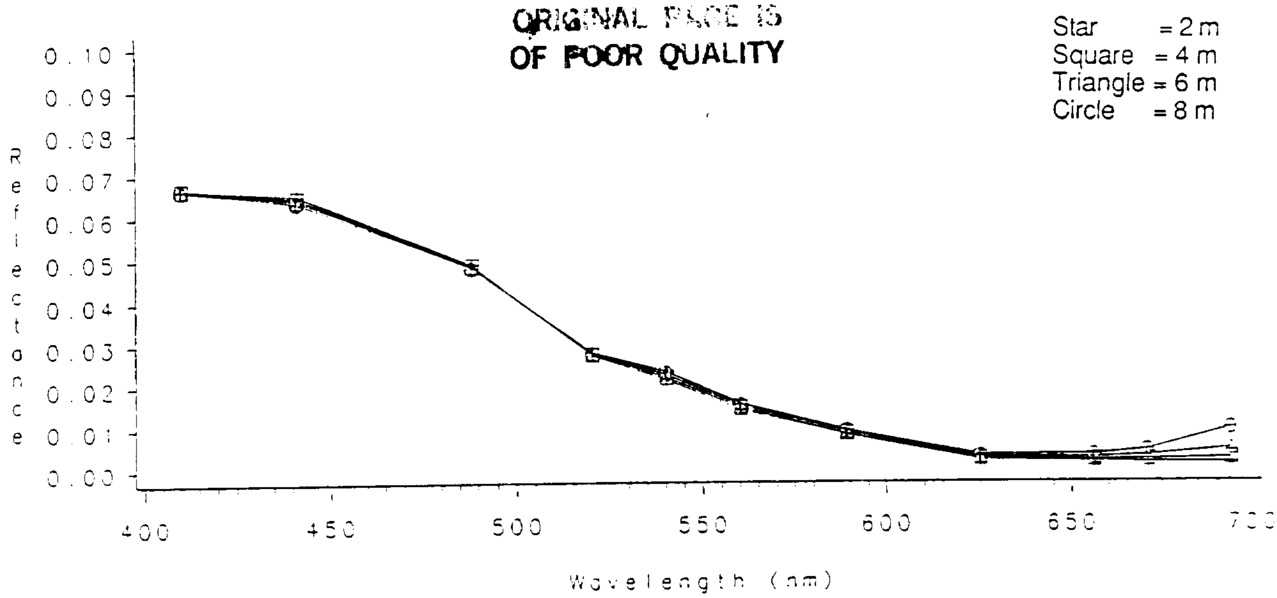

Figure 8.2. Spectral Reflectance for Sunnywater Lake as Derived From MER Data Collected 13 August 1986.

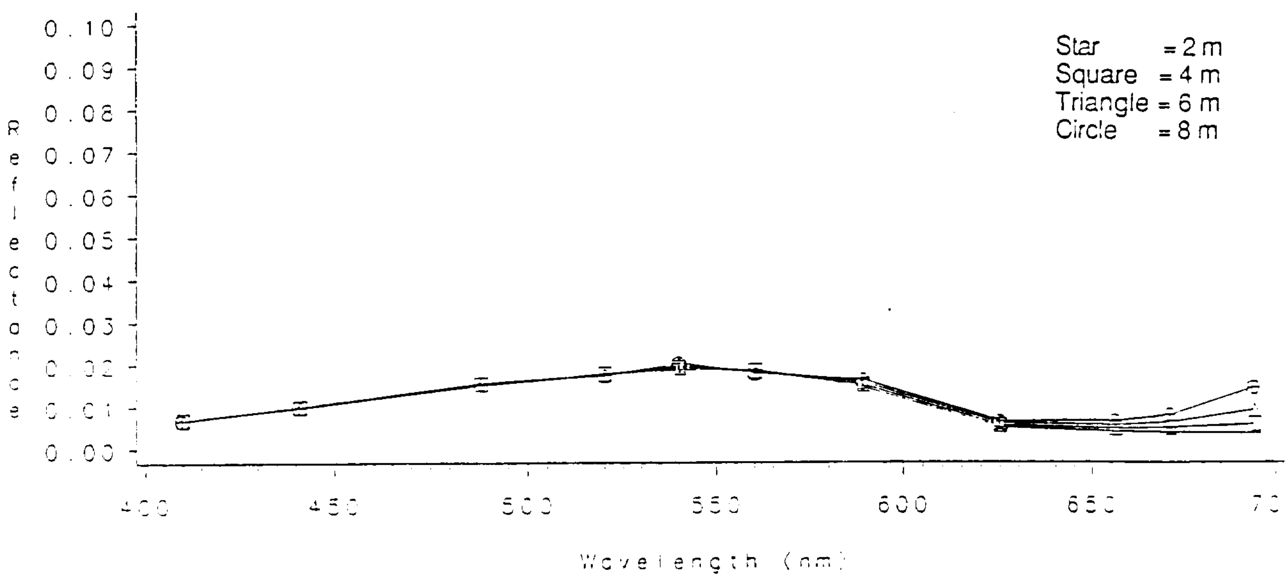

Figure 8.3. Spectral Reflectance for Center Lake as Derived From MER Data Collected 22 August 1986.

have generally lower reflectances values and a spectral peak at approximately 550 nm. For these lakes, the high DOC concentrations (2.0 - 4.0 mg/1) are consistent with the low reflectance values derived for the shorter wavelengths.

The high-DOC basic lakes have curves shaped more like Center Lake (see Figure 8.4). Therefore, the following indicator for characterizing acid and basic lakes using these spectral data could be calculated:

$$I = \frac{\text{Reflectance } (500\ \mu m)}{\text{Reflectance } (560\ \mu m)}$$

This suggested indicator, I, which takes advantage of the difference in the shapes of spectral curves, is greater than 1.0 for acidified lakes and is less than 1.0 for buffered, high DOC lakes.

The MER reflectances were also analyzed using the non-linear reflectance model described in Section 7.0. The suspended solids were assumed to be constant at 0.1 mg/1. The model converged for all the MER data collected and the following coefficients $C_0(\lambda)$ are shown in Table 8.3.

TABLE 8.3. COEFFICIENTS FOR SUBSURFACE REFLECTANCE MODEL USING MER DATA

	1986	1987			
Wavelength (μm)	Aug	May 5	May 12	June 13	June 30
488	.524	.388	.523	.779	.89
560	.302	.338	.332	.523	.667

The August data were collected under the best conditions, so the coefficients produced for these data were used as standards to compare the other dates. The May 12 data produced coefficients nearly equal to those produced using the August data. The June reflectance data do not seem to fit the same model suggesting that the water chemistry had

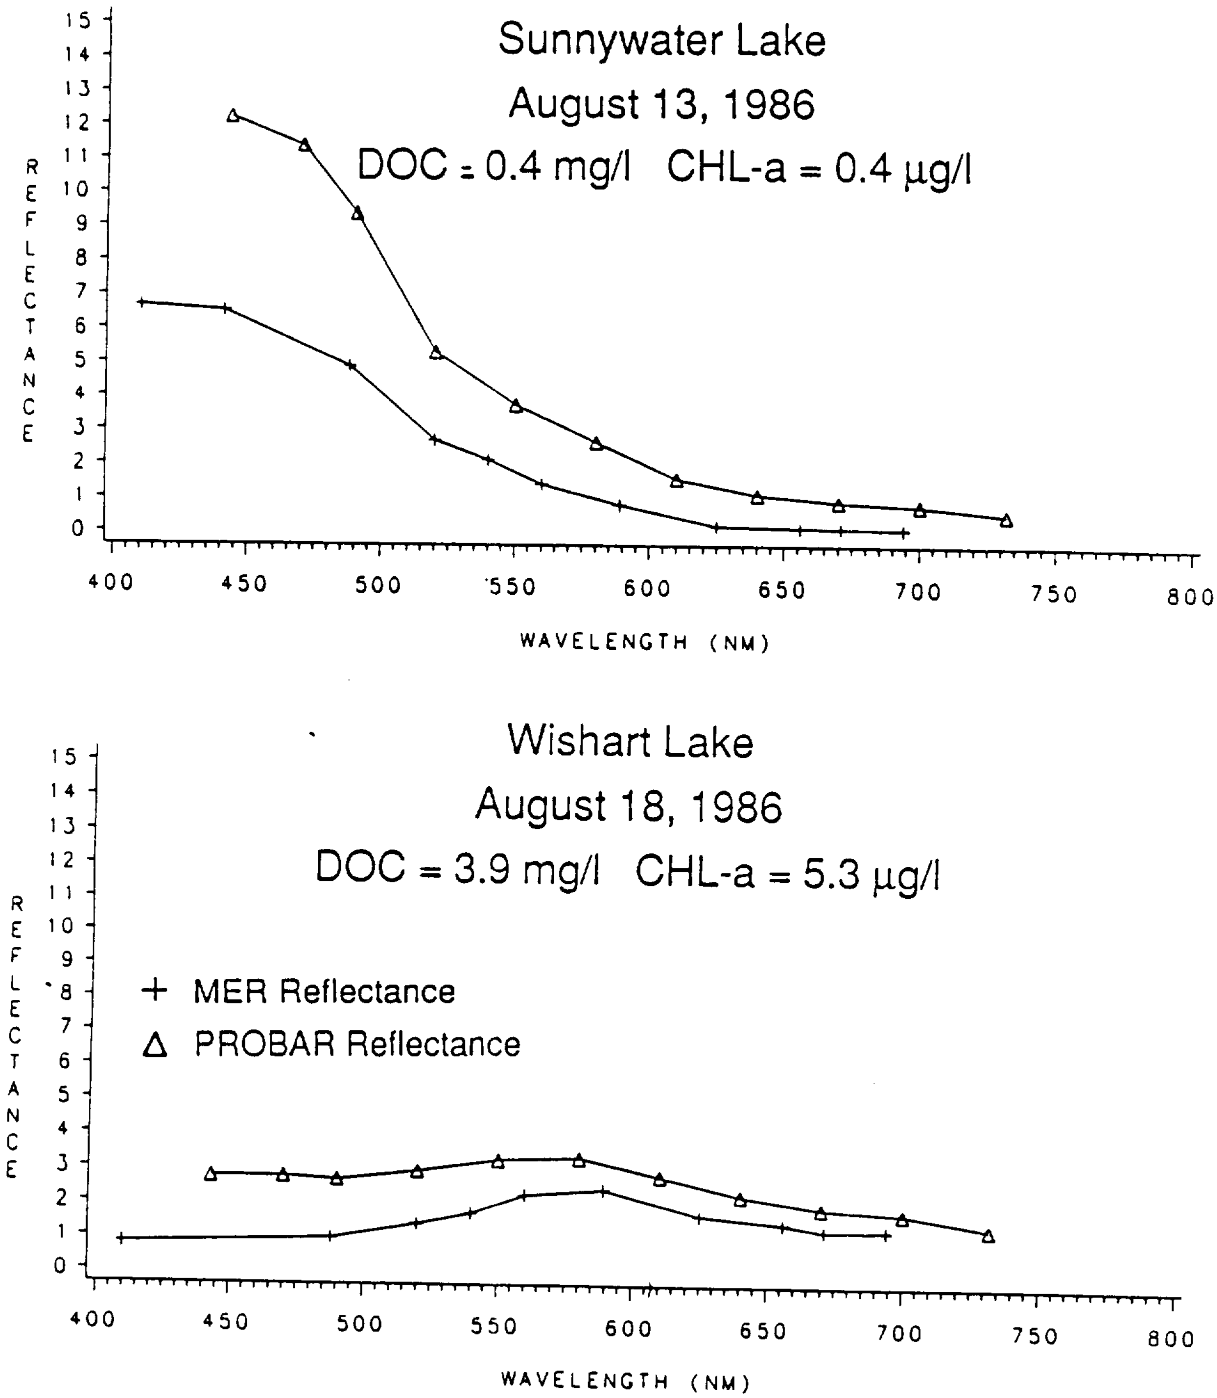

Figure 8.4. Comparison of MER and PROBAR Derived Spectral Reflectances.

changed dramatically and the DOC reflectance model assumptions were no longer valid.

To find out how well the model worked for each date, the correlations between actual and model-predicted subsurface reflectances were calculated. There was no correlation between actual and predicted subsurface reflectance for any of the spring data at 560 μm. For 488 μm the correlation between actual and predicted reflectances was less than .24 for the two June dates. However, the same correlations for May 5 and May 12 are .93 and .97, respectively. The reflectance differences between actual and predicted reflectances were less than 1.15% for these two dates.

8.3 ANALYSIS OF SURFACE MEASUREMENT DATA

The PROBAR-derived surface reflectance data were found to be highly correlated with the MER subsurface reflectance data as shown by the examples in Figure 8.3. To determine if the correlations of water chemistry with PROBAR data were similar to those with the MER data, another correlation matrix was calculated. Table 8.4 contains PROBAR correlations with water chemistry at multiple wavelengths. The correlations of reflectance with the water chemistry are much lower, but still reach -.80, -.68, and -.64 for DOC, pH and chlorophyll. This was expected, however, since varying lake surface waves and atmospheric haze introduced more noise in the signal measured by the PROBAR.

8.4 THE COMPARISON OF SURFACE AND SUBSURFACE MEASUREMENTS

An experiment was conducted to determine the relationship between the surface and the subsurface measurements of lake volume reflectance. The surface reflectance was measured using the PROBAR spectral radiometer mounted in a helicopter and the subsurface reflectance was measured using the MER submersible radiometer. Modeling theory predicted that the relationship between these two measurements would be

Table 8.4. Pearson Correlation Coefficient for Water Chemistry Parameters With PROBAR Derived Reflectances.

	PH	DOC	TIP	TTLCHL_A	AL	S04
R443	-0.64108	-0.73158	-0.44737	-0.62890	0.57202	0.57597
	0.0001	0.0001	0.0001	0.0001	0.0001	0.0001
R470	-0.65695	-0.75080	-0.46922	-0.63443	0.57275	0.58581
	0.0001	0.0001	0.0001	0.0001	0.0001	0.0001
R490	-0.66094	-0.75960	-0.47927	-0.63707	0.56906	0.58866
	0.0001	0.0001	0.0001	0.0001	0.0001	0.0001
R520	-0.68095	-0.79678	-0.50436	-0.64002	0.58672	0.62239
	0.0001	0.0001	0.0001	0.0001	0.0001	0.0001
R550	-0.62813	-0.78275	-0.47444	-0.58288	0.54829	0.59749
	0.0001	0.0001	0.0001	0.0001	0.0001	0.0001

linear. Therefore, the relationship between PROBAR and MER measurements could be described using the equation:

$$R_i(\text{mer}) = m \times R_1(\text{PROBAR}) + b$$

where m = slope

b = y-axis intercept

R_i = reflectance at band i

The results of a linear regression analysis of each spectral band and the corresponding statistical significance (α = .05) of each regression are found in the following table:

Wavelength	b	m	Significant (α < .05)
443	- .33	.53	yes
470	.215	.44	yes
490	.43	.42	yes
520	.55	.44	yes
550	1.17	.19	no (p = .36)
580	1.04	.14	no (p = .76)
610	-1.11	1.59	yes
640	- .57	1.86	yes
670	- .27	1.49	yes
700	0.0	1.0	yes

The results shown in Section 5.5 support the hypothesis that there is a linear relationship between the MER and the PROBAR data for all but wavelengths 550 and 580 nm. At most wavelengths, then, subsurface lake volume reflectance can be predicted with reasonable accuracy when only the PROBAR reflectance data are available. This result is significant since acquiring lake reflectance data with the PROBAR is less expensive and quicker that with the in situ measurements.

8.5 ANALYSIS OF TM MEASUREMENTS

The haze normalized TM data for August 1986 show sensitivity to lake DOC concentrations as indicated by the data plotted in Figure 8.5. These results confirm the model predicted sensitivity of the TM band on signals to changes in DOC. The model predicted a DOC reflectance range of about 5% which corresponds to a 14.3 signal count spread in the TM band one data. TM data from the Sudbury site are consistent with the predicted spread in DN counts. The Algoma data appear to lack sensitivity to changes in DOC which is likely due to the fact that most lakes in the Algoma region have high values of DOC and chlorophyll-a.

8.6 MULTITEMPORAL RELATIONSHIPS

Multitemporal analyses could be made for TM and MER data only since these were the only measurements made in the spring of 1987. PROBAR multitemporal relationships could not be examined since this instrument was not available to the project in 1987.

8.6.1 MER Multitemporal Analysis

The corrected MER data yielded several multitemporal trends. These trends differed depending on the buffering capacity of the lake. Acidified lakes, such as Dougherty and Wolf, (TIP < 0), had small multitemporal reflectance changes from 500 μm to 600 μm (< .4% reflectance). All the acid lakes showed large reflectance differences in to 400 μm to 500 μm region. Each lake showed a decrease in reflectance form August, 1986 to May 5, 1987, and then an increase in reflectance from May 5, 1987 to May 12, 1987 between 400 μm to 500 μm. These data for three lakes' reflectances at 441 μm are tabulated below:

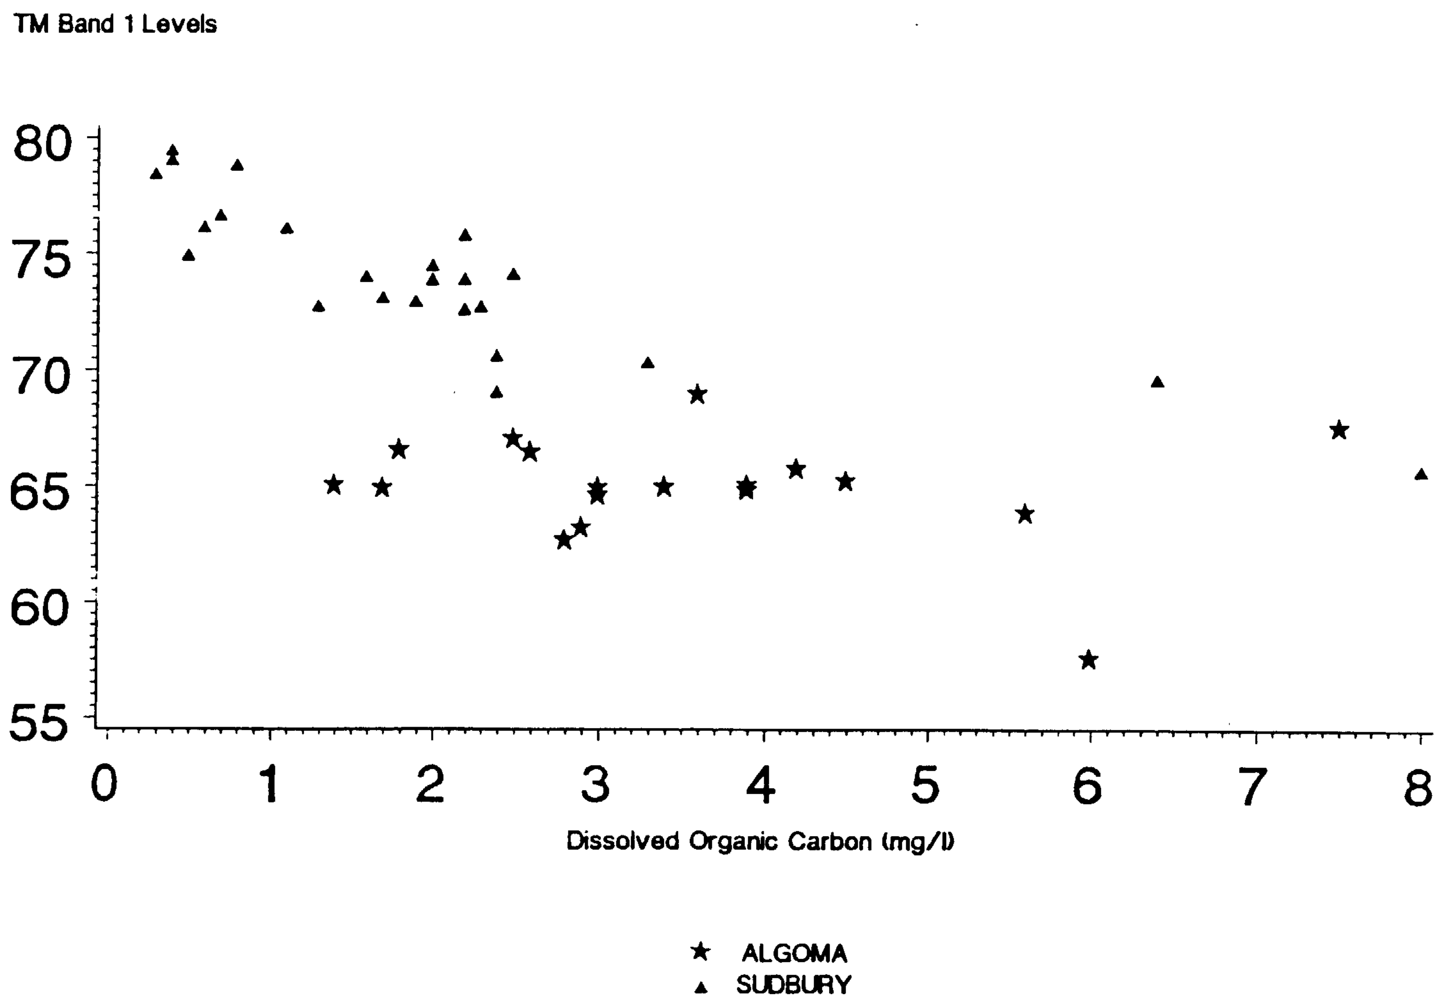

Figure 8.5. TM Band 1 Versus Dissolved Organic Carbon Using the August 13, 1986 (P19, R27) and August 18, 1986 (P22, R27) Data Sets.

Name	8/86	5/5/87	5/12/87
Sunnywater	6.5	-	7.4
Wolf	3.2	2.1	3.2
Dougherty	3.8	2.3	2.6

In contrast, the buffered lakes, (TIP > 0), did not show a large difference (> .4% reflectance) in the 400 μm to 500 μm region but did show large multitemporal differences from 500 μm to 600 μm. At 560 μm, the basic lakes increased in reflectance form August 1986 to May 5, 1987. No consistent change in reflectance from May 5, 1987 to May 12, 1987 was found for the buffered lakes. The reflectance data for 560 μm measured from buffered lakes are found below:

Name	8/86	5/5/87	5/12/87
Centre	1.8	2.6	1.7
Whitepine 2	1.2	1.6	2.0

In conclusion, differences in multitemporal MER reflectance trends between buffered and acidified lakes were found. Acidified lakes had a decrease in reflectance for the 400 μm to 500 μm region and relatively no change for the 500 μm to 600 μm region. Buffered lakes had an increase in reflectance for the 500 μm to 600 μm region and relatively no change to the 400 μm to 500 μm region.

8.6.2 TM Multitemporal Analysis

The TM band one seasonal change patterns are similar to those indicated for the August 1986 data. The August low DOC lakes were found to have larger TM DN values than with the May 12, 1987 and June 13, 1987 collection dates. These data are shown in Figures 8.6 and 8.7, respectively. The extracted and atmospherically normalized TM data are given as Appendix G. The size of the TM band one count changes for Sudbury are substantially larger than predicted. Furthermore,

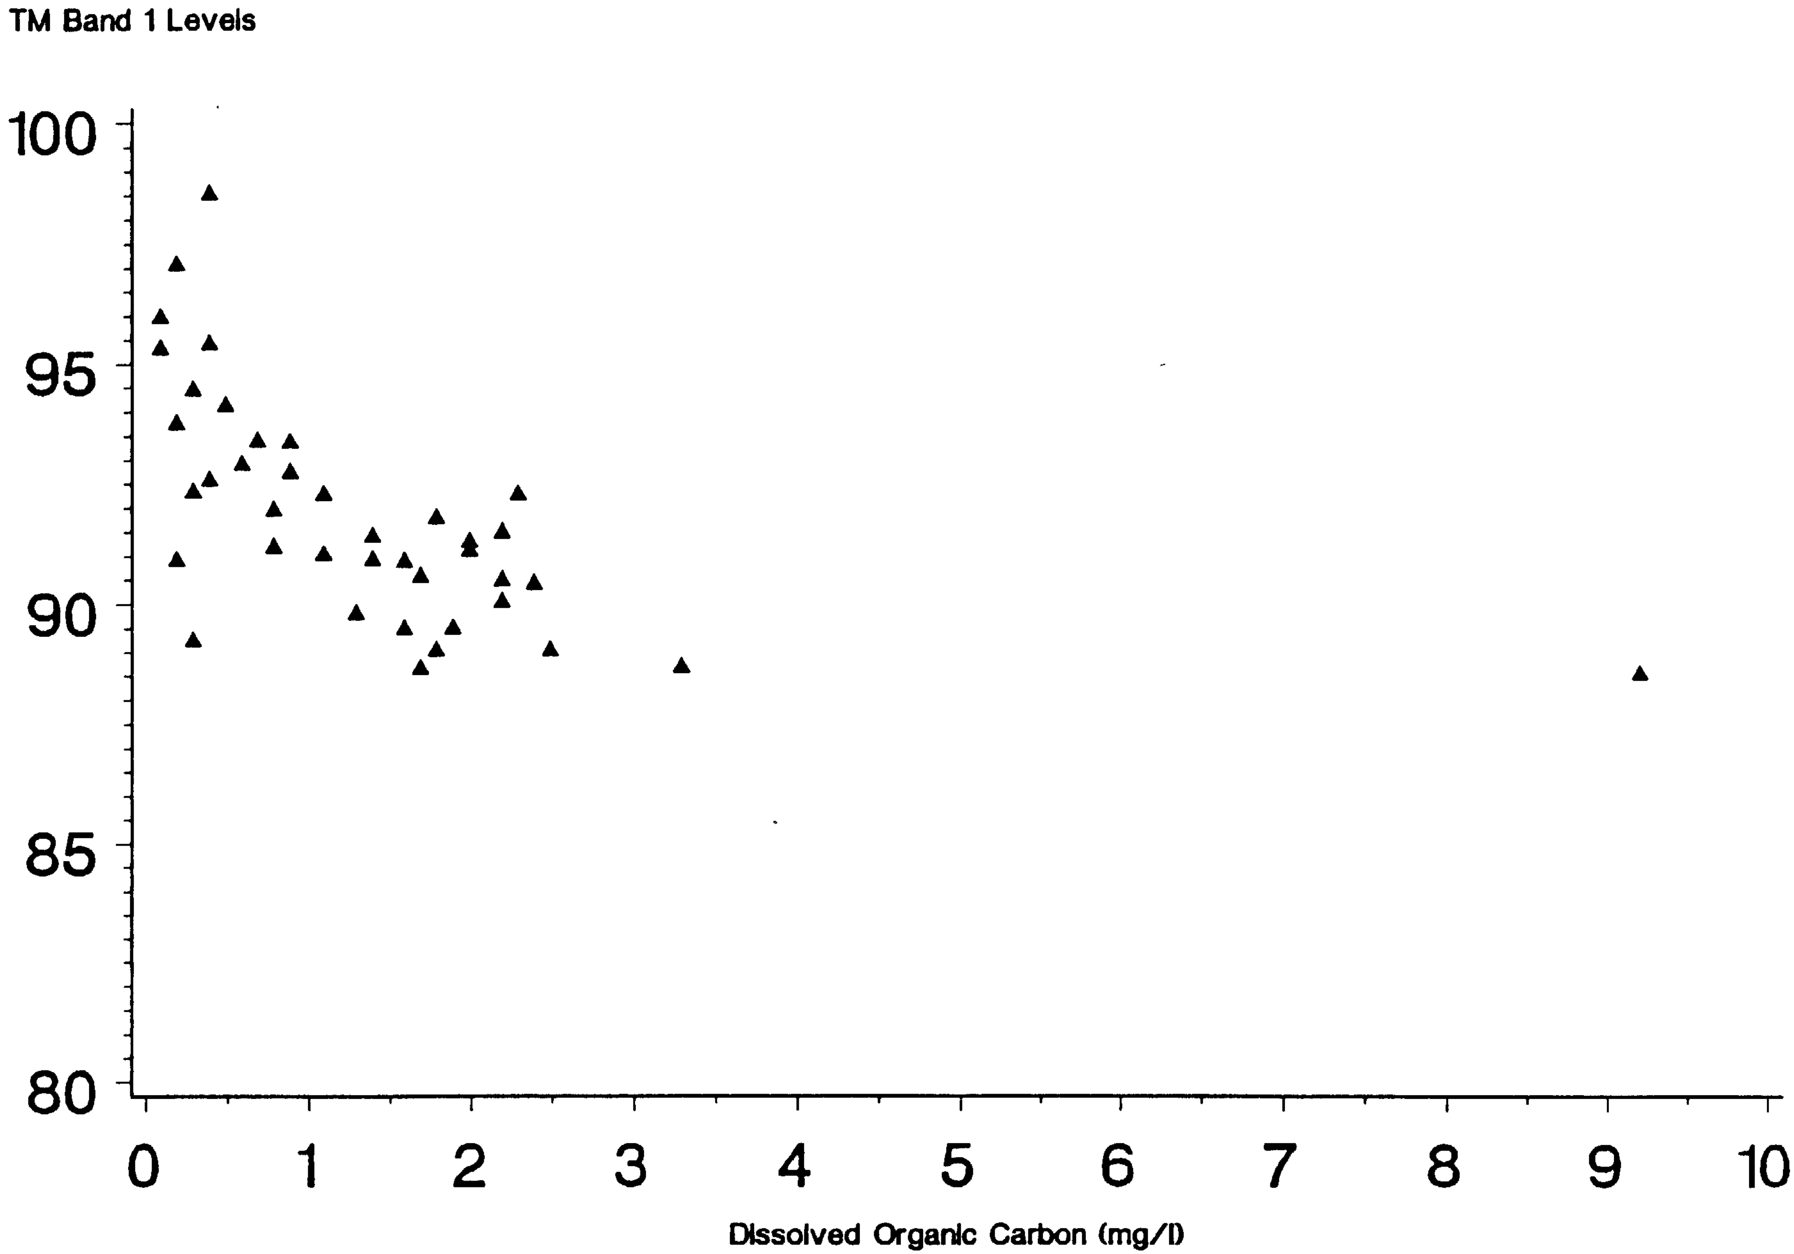

Figure 8.6. TM Band 1 Versus Dissolved Organic Carbon Using the May 12, 1987 (P19, R27) Scene Data.

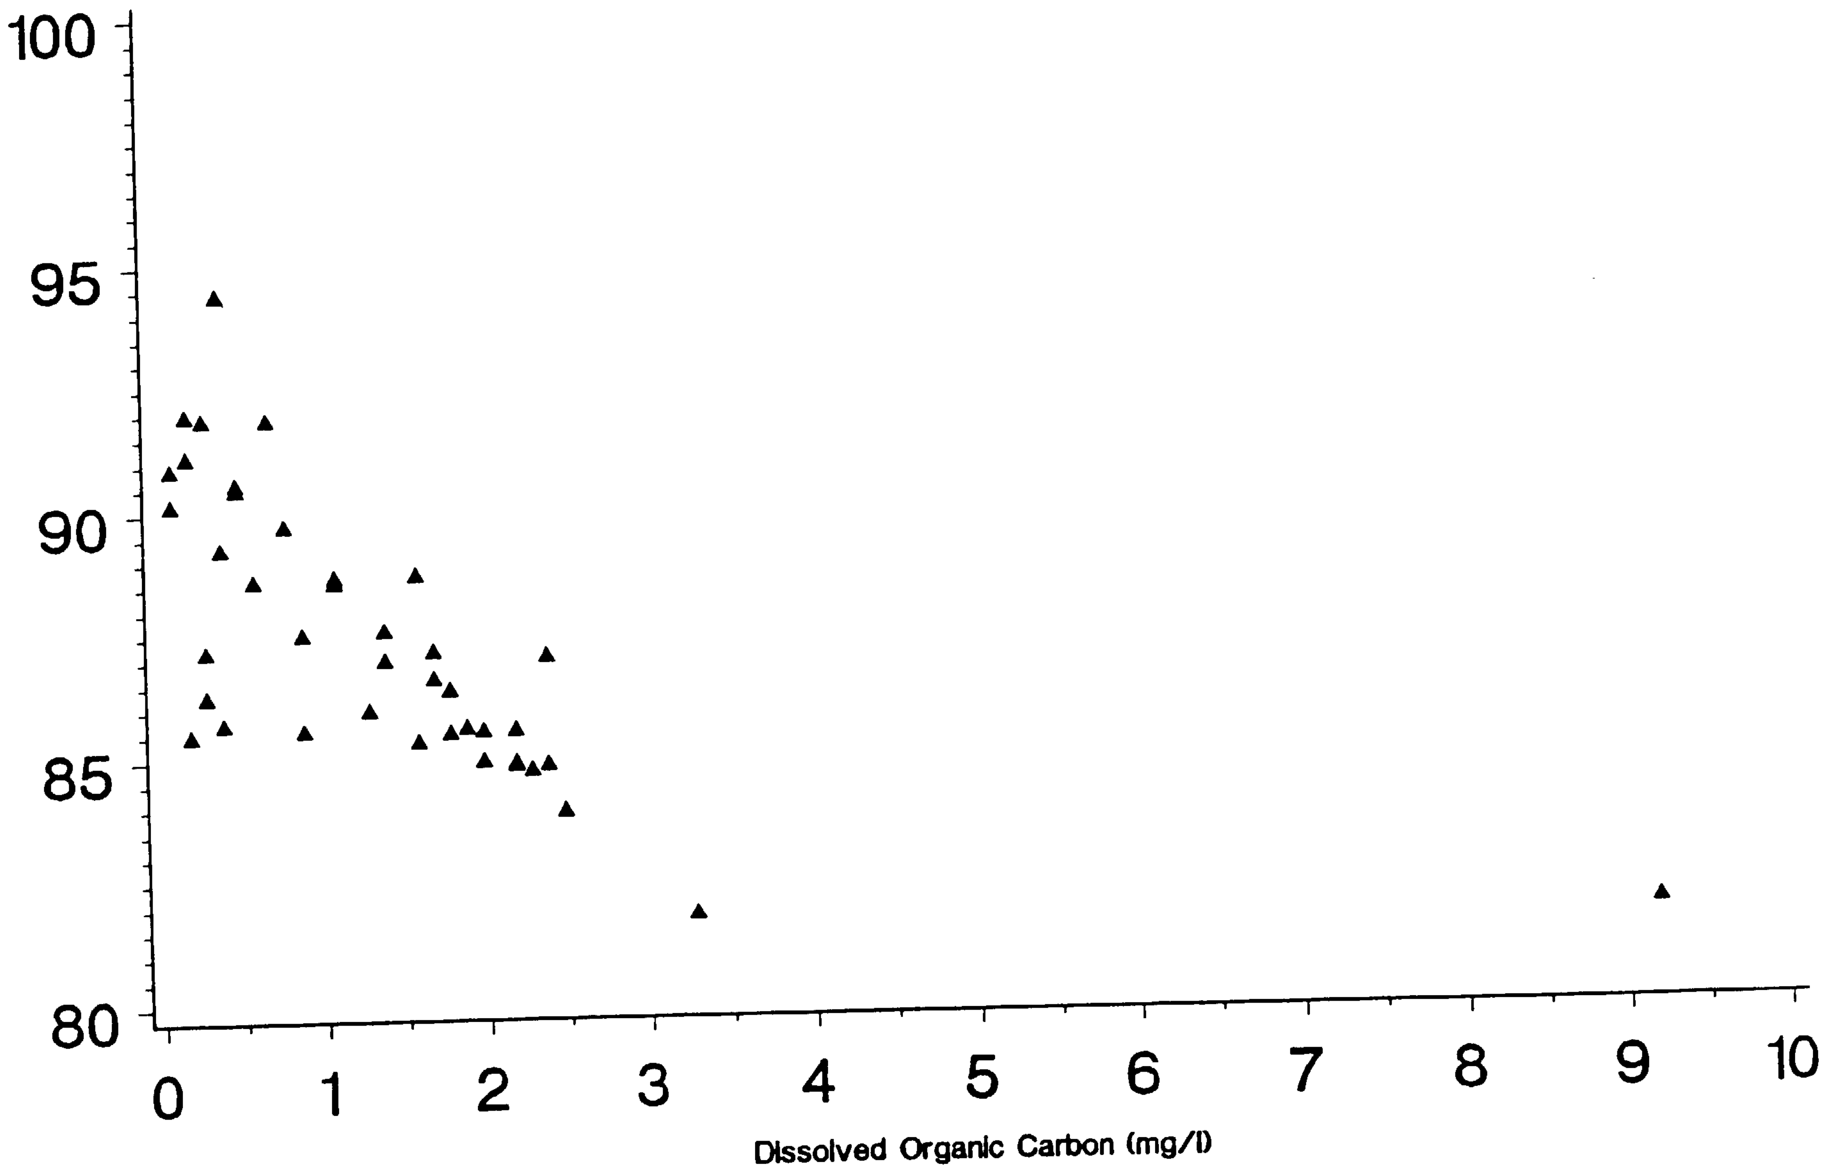

Figure 8.7 TM Band 1 Versus Dissolved Organic Carbon Using the June 13, 1987 (P19, R27) Scene Data.

these count differences suggest a two to three percent change in subsurface reflectance, needed a greater DOC change sensitivity than predicted in Table 7.3.

Multitemporal differences were calculated for the following pairs of dates:

August 1986 - May 1987
August 1986 - June 1987
June 1987 - May 1987

These differences were analyzed to determine whether or not they aided in identifying acidified and buffered lakes.

The multitemporal changes in MER-derived subsurface reflectance were used to determine the expected changes in TM signal counts for bands one and two using the conversion factors given in Section 2.5. The expected changes in TM signal counts for band two were all found to be within the noise level for band two data. Therefore, the band two multitemporal differences were insignificant for the 1986-1987 scene pair. Furthermore, approximately 90% of the TM band 1 differences were also in the noise level. As a result, obvious multitemporal differences using TM data were not found.

The majority of the multitemporal analyses were based on the August - May scene pair. When all of the lakes ($n = 41$) are analyzed for significant differences ($\alpha = .1$) between August and May reflectance changes, no difference is found between acidified and buffered lakes.

Another test was made to determine if the August - May TM band one differences were a function of DOC, TIP, chlorophyll and/or aluminum levels measured in 1986. A multivariate regression analysis was done and all of the parameter estimates were insignificant ($\alpha = .5$). These results lead to conclusion that the TM band one differences were not a function of water chemistry.

Data were also extracted from a May 22, 1985 scene for the Sudbury site and the differences in TM band 1 were formed with the August 13, 1986 scene. These differences were then compared to DOC values collected in August 1986. The results are shown in Figure 8.8 and indicated a possibly strong seasonal relationship to DOC concentrations and especially for those lakes with less than 3.0 mg/1 DOC.

8.7 ANALYSIS OF TRANSMISSOMETER ATTENUATION DATA

A study was conducted which examined the relationship between the water attenuation coefficient (α) at 600 μm and the suspended solid concentrations in eight lakes. The attenuation coefficient correlates positively with the suspended solids (ρ = .845). These data are shown in Figure 8.9 and shows and a linear relationship between the attenuation coefficient and the suspended solids. This further supported the possibility of suspended solid concentrations affecting the accuracy of the subsurface reflectance model since the suspended solids concentration correlates with the attenuation coefficient and the attenuation coefficient affects lake volume reflectance.

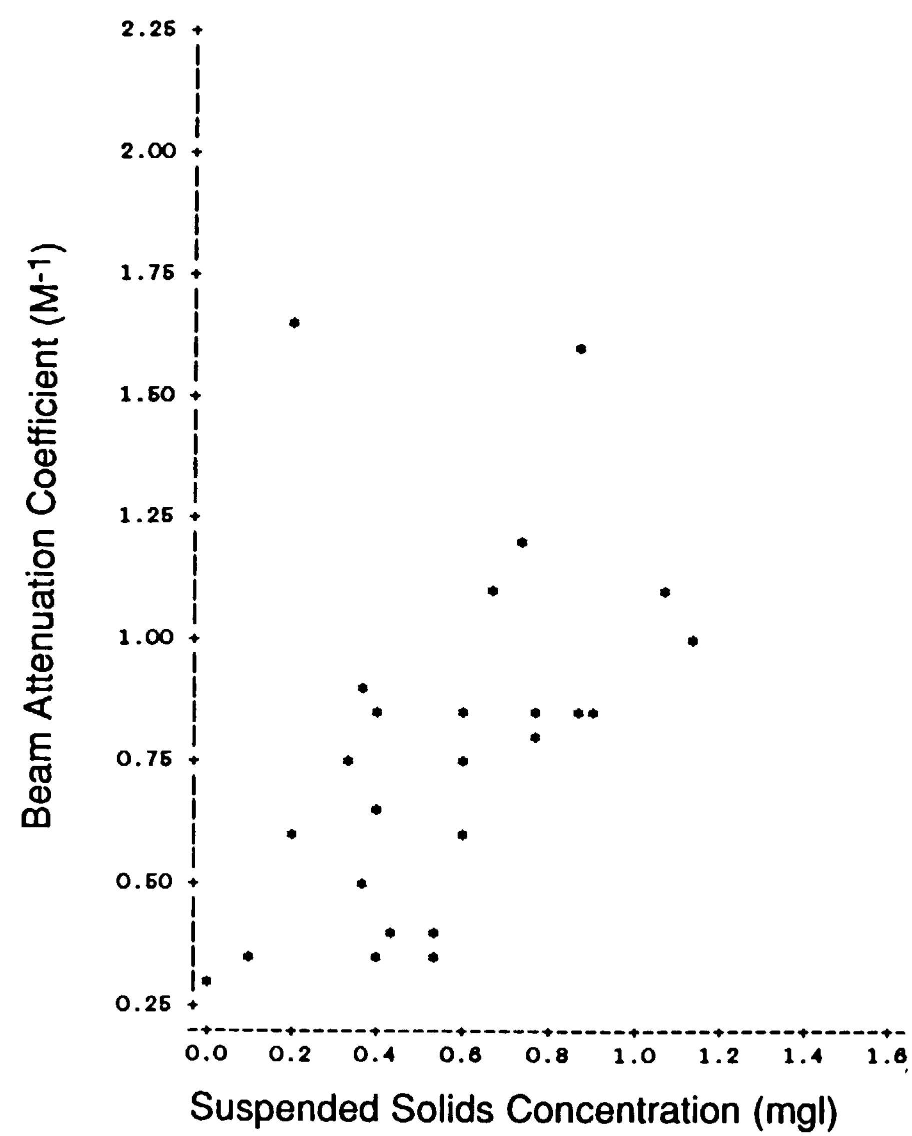

Figure 8.9. Beam Attenuation Coefficient Versus Suspended Solids Concentration 1987 Spring/Summer Data.

9.0 ANALYSIS OF ECO-PHYSICAL CLUSTERS

9.1 RELATIONSHIP OF WATER CHEMISTRY WITH ECO-PHYSICAL CLUSTERS

Since the eco-physical clusters represented unique acid-sensitivities across the Ontario test sites, it is reasonable to expect to find significantly different water-quality parameters for lakes that occurred in different clusters. An analysis was performed to test the hypothesis that the mean water-quality parameters were different at the 5% significance level between clusters. The following water variables were analyzed: dissolved organic carbon (DOC), Secchi depth, sulfate concentration, aluminum ion concentration, pH and total chlorophyll-a concentration. This analysis is summarized in Table 9.1.

TABLE 9.1. RESULTS FOR TUKEY'S STUDENTIZED RANGE TEST FOR SIGNIFICANTLY DIFFERENT MEAN WATER-QUALITY PARAMETERS

Chlorophyll-a	DOC	Secchi Depth	Sulfate	Aluminum	pH	
1-7	2-5	1-7	7-1	7-5	1-2	8-2
1-9	2-9	2-7	7-2	3-7	1-3	8-3
1-8	2-7	2-9	7-3	4-5	1-4	8-5
1-5	4-5	4-7	7-4	5-9	1-5	8-7
	4-7	5-7	8-9	7-8	1-6	3-9
	7-5		1-2		1-7	2-7

					10-7	
					10-9	

PRECEDING PAGE BLANK NOT FILMED

PAGE 92 INTENTIONALLY BLANK

Clustering was especially successful in separating different levels of lake pH. For significantly different clusters, the most acid-sensitive clusters (5,7,9) had lake waters with lower DOC and pH values and a higher sulfate concentration than those with less sensitivity (1,2,3,4). Thus, the clustering analysis appears to have produced significant eco-physical clusters that contain lakes that also have some significantly different water-quality parameters. Of the three most significantly different water-quality parameters (DOC, pH and sulfate), changes in DOC provide the basis for remote sensing monitoring and identification.

9.2 RELATIONSHIP BETWEEN TM SIGNALS AND ECO-PHYSICAL CLUSTERS

An analysis was performed to determine if significant differences existed among the eco-physical clusters based on the TM signals of lakes within the clusters. For the August 1986 Algoma and Sudbury data sets, two groupings were identified. Group A (lakes in clusters 5, 7 and 9) had mean signals (73.5 to 75.9) that were significantly different (α= .05) than signals (64.8 to 67.5) from lakes in group B (clusters 2, 4 and 8). The results are shown in Table 9.2.

TABLE 9.2. TM RELATIONSHIPS TO ECO-PHYSICAL SENSITIVITY -- AUGUST TM 1 DATA

Group	Mean TM 1	Cluster	Significantly Different at 5%
A	75.86	7	2, 4, 8
A	74.14	9	2, 4, 8
A	73.47	5	2, 4, 8
B	67.50	8	5, 7, 9
B	66.37	2	5, 7, 9
B	64.77	4	5, 7, 9

The mean eco-physical sensitivity of group A clusters was 7.44 and group B mean sensitivity was 5.85. The largest signals measured were from cluster 7 with a mean sensitivity index of 7.07 and the smallest from cluster 4 with a sensitivity index of 6.07. The primary difference in these two eco-physical clusters was the soil type and soil depth over the underlying bedrock. Cluster 7 had shallow (i.e. less than one meter) sandy soils while cluster 4 had soils of mixed types (sand, clay, loam) that had depths greater than one meter.

9.3 RELATIONSHIP BETWEEN TM MULTITEMPORAL DIFFERENCES AND ECO-PHYSICAL CLUSTERS

Examination of the August 1986 - May 1985 difference signals for TM band one produced similar results which are shown in Table 9.3. Group A and group B contained the same clusters as in Section 9.2 and the largest and smallest mean differences were found in clusters 7 and 4, respectively.

TABLE 9.3 TM RELATIONSHIPS TO ECO-PHYSICAL SENSITIVITY ANALYSIS OF VARIANCE OF AUGUST-MAY DIFFERENCE

Group	Mean Diff	Cluster	Significantly Diff. at 5%
A	4.94	7	2, 4, 8
A	2.91	9	2, 4, 8
A	2.68	5	2, 4, 8
B	0.61	8	5, 7, 9
B	-0.96	2	5, 7, 9
B	-2.45	4	5, 7, 9

9.4 Analysis of TM Signal Changes Due to Acid Deposition Changes

This analysis examined the relationship between the August - May signal differences from polygons that have similar eco-physical properties with the exception of sulfate deposition. For this case, lakes were selected from polygons with sandy soils over granitic rock types and the sulfate deposition was 1.5 or 2.5 g/m2/yr. The TM band one signals were found to be significantly different (at 5% level) based upon deposition level alone. This preliminary analysis suggests that

TM signal seasonal changes may be dependent upon changes in acid deposition.

9.5 ANALYSIS OF DOC REFLECTANCE SENSITIVITY

In addition to seasonal analyses, the spatial aspects of DOC reflectance sensitivity were investigated. Measured water-quality parameters were used together with the equation given Section 7.4 to calculate a lake value of reflectance sensitivity based to change in DOC concentration. The larger the derivative of reflectance with respect to DOC the more sensitive lake reflectance is to changes in DOC. As shown in Table 7.3, a reflectance sensitivity value of 4.0 corresponds to an expected count change in TM band 1 of at least two counts. The lake DOC sensitivity values were analyzed with the eco-physical clusters and the mean sensitivity was determined for each cluster as shown in Figure 9.1. These results indicated that clusters 5, 7, 8 and 9 have lakes most sensitive to DOC changes. These clusters also have the higher stratification sensitivity index values.

This preliminary analysis shows that TM band one seasonal difference signals will differentiate acid-sensitive from acid-insensitive areas.

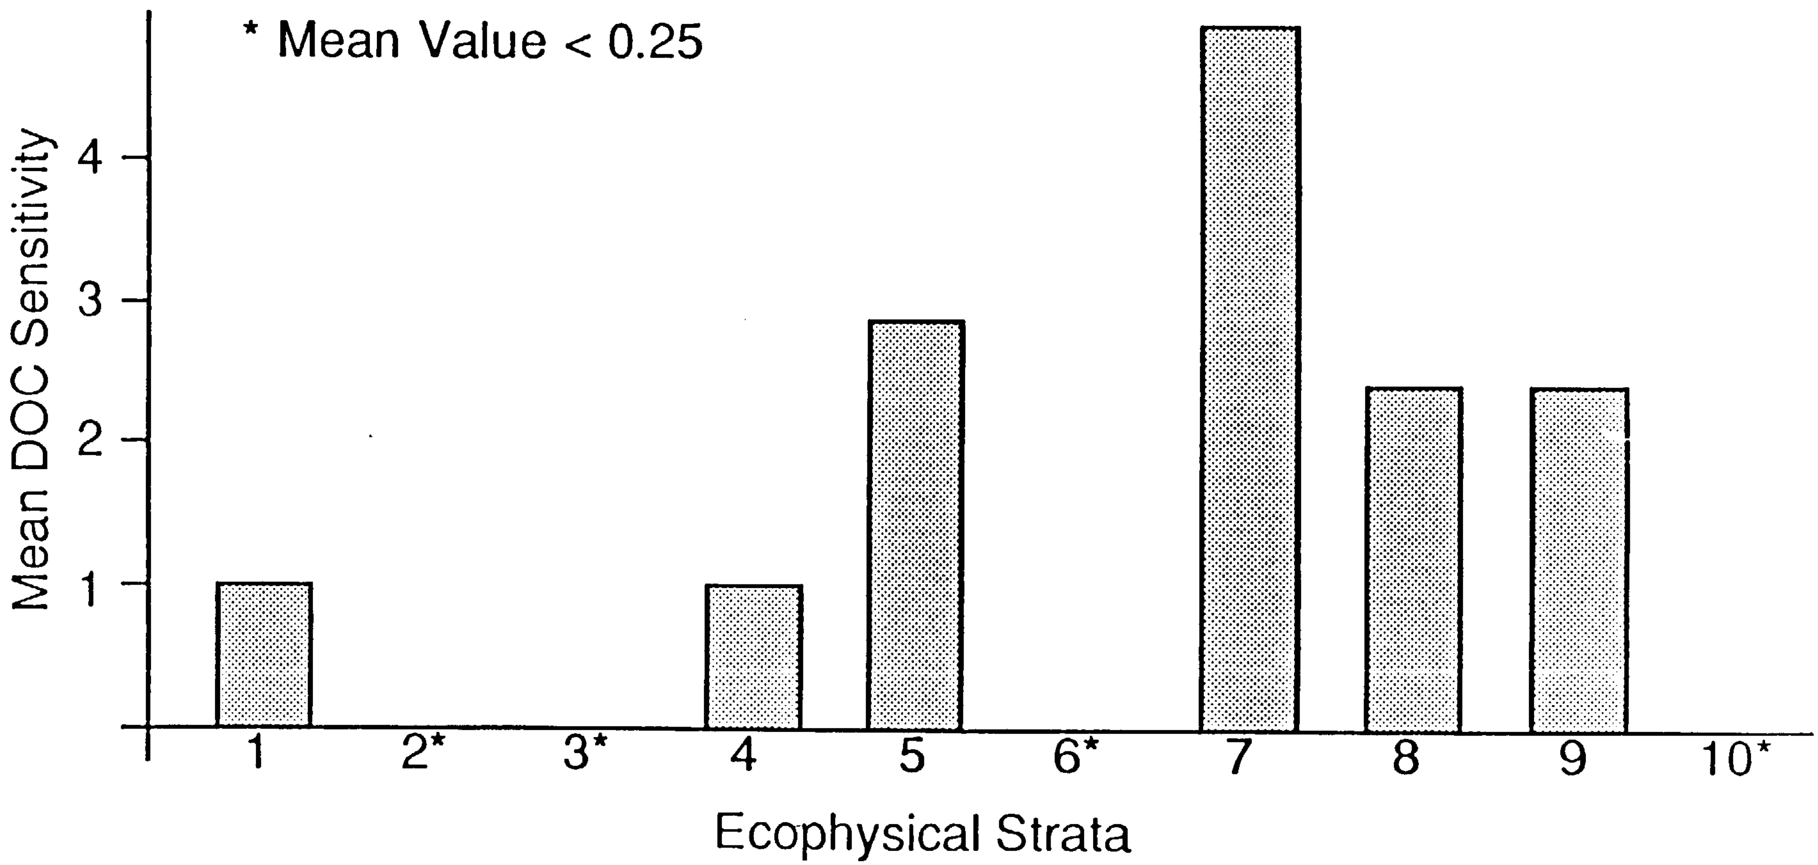

Figure 9.1. Mean DOC Induced Reflectance Sensitivity for Each Ecophysical Strata Estimates Based Upon August 1986 Water Chemistry Measurements.

10.0 CONCLUSIONS AND RECOMMENDATIONS

10.1 GENERAL CONCLUSION

Modeling, field measurements, and TM observations suggest that TM is useful to identify acid sensitive lakes and to monitor water quality changes associated with lake acidification.

10.2 SPECIFIC CONCLUSIONS

1. Modeling surface and subsurface reflectance measurements have shown the important relationships between lake optical properties and water chemistry.

   a. A simple DOC reflectance model accounts for observed subsurface hemispherical reflectance and also for the companion airborne (PROBAR) reflectance measurements.

   b. We found that clear acid sensitive lakes can be distinguished from the colored high DOC lakes using PROBAR data. The colored lakes tend to have greater buffering capacity than clear lakes in acid sensitive areas.

   c. The blue-green reflectance of clear lakes is highly sensitive to the presence of DOC. Modeling predicts a one percent change in subsurface reflectance for an expected seasonal fluctuation of about 50% in DOC concentration.

2. Modeling has shown that TM is sufficiently sensitive to monitor expected lake reflectance associated with acid deposition and acidification.

   a. An historical TM seasonal pair (August 1986 - May 1985) for the same Sudbury Lakes in a normal snowfall year supports our expectations but lacks the chemistry and in situ optical data needed for hypothesis validation.

   b. The expected seasonal changes (August 1986 to May/June 1987) in water chemistry did not occur nor did we observe

PRECEDING PAGE BLANK NOT FILMED

PAGE 98 INTENTIONALLY BLANK

a significant change in TM response. This lack of change may be due to the unusually small snow pack and spring runoff. While these TM data and water chemistry are consistent with our hypothesis, they do not validate it.

c. In areas of high acid deposition Landsat TM DN values were found to separate high DOC lakes (moderate acidity) found to separate high DOC lakes (moderate acidity) from low DOC lakes (high acidity). The expected TM band one signal change per percent subsurface reflectance change was estimated to be 2.86 counts/percent. In clear acid lakes seasonal change of two or three counts are expected from DOc fluctuations.

3. Stratification of eco-physical properties provides a way to locate areas which are sensitive to acid deposition.

a. When stratification of eco-physical properties was applied to our study sites, we could identify acid sensitive areas and use TM to pick lakes which are likely to be sensitive to acid deposition.

b. Clustering of eco-physical strata suggests that areas with shallow sandy soils over slow weathering granitic bedrock types are most sensitive to acid deposition and lakes located within these areas will have lower concentrations of DOC and lower pH values than for other soil and bedrock types.

c. TM band one lake response was found to be related to eco-physical sensitivity. The (August 1986 - May 1985) TM seasonal pair produced signal differences in eco-physically sensitive strata (1-6 DN) but not so in non-sensitive strata (-2 to 0 DN).

d. Nearly identical and sensitive eco-physical strata with different sulfate deposition rates were found to have different TM lake signal response.

10.3 RECOMMENDATIONS

While studies thus far are consistent with our seasonal change hypothesis they do not confirm its validity. Further study is needed to provide confirmation to the above results.

1. Collect lake chemistry and TM data in years of typical snowfall to demonstrate the capability of using TM data to monitor acidification under a wider range of environmental conditions (i.e., normal snowfall years).

2. Develop a TM based capability for assessing effects of acid deposition on terrestrial vegetation. Apply the vegetation monitoring technique and compare with lake monitoring technique.

APPENDIX A
ECO-PHYSICAL CLUSTER ANALYSIS

The maximum likelihood method was used to produce 10 clusters of polygons based on the sensitivity values for percent cover, vegetation type, soil depth, soil texture, bedrock type, relief and sulfate deposition. The data are sorted by cluster. Descriptions for each polygon are in the printout. The "cluster" data are either missing data or have vegetation types which were not used in the data.

APPENDIX C
SUMMARY STATISTICS FOR THE ECO-PHYSICAL POLYGON CLUSTER ANALYSIS

The following table shows the computer mean and standard deviation estimates for the set of Eco-physical polygons within each cluster. Estimates are computed for the total sensitivity rating (STRATRAT), vegetation sensitivity (VEGVAL), bedrock and soil sensitivity (SENSVAL), relief sensitivity (RELVAL), and sulfate deposition sensitivity (SO4VAL).

TABLE C-1

SUMMARY STATISTICS ON EACH CLUSTER
MAXIMUM LIKELIHOOD CLUSTER ANALYSIS

VARIABLE	MEAN	STANDARD DEVIATION
Cluster=		
STRATRAT

APPENDIX G

LAKE EXTRACTED TM SIGNAL VALUES AND ATMOSPHERIC CORRECTED VALUES

Thematic mapper (TM) signal digital count value for lake extracted samples are listed in the following tables. Also listed are the standard deviation estimates for each sample.

Table G.1. August 13, 1986 (P19,R27)
Table G.2. August 18, 1986 (P22,R27)
Table G.3. May 12, 1987 (P19,R22)
Table G.4. June 13, 1987 (P19,R27)

Atmospherically normalized value are listed in the following tables.

Table G.5. August 13, 1986 (P19,R27)
Table G.6. August 18, 1986 (P22,R27)
Table G.7. May 12, 1987 (P19,R27)
Table G.8. June 13, 1987 (P19,R27)
