Optimum Data Weighting and Error Calibration for Estimation of

Gravitational Parameters

Francis J. Lerch
Geodynamics Branch, GSFC
Greenbelt, MD 20771

ABSTRACT

A new technique has been developed for the weighting of data from satellite tracking systems in order to obtain an optimum least-squares solution and an error calibration for the solution parameters. Data sets from optical, electronic, and laser systems on 17 satellites in GEM-T1 (Goddard Earth Model, 36x36 spherical harmonic field) have been employed toward application of this technique for gravity field parameters. Also GEM-T2 (31 satellites) was recently computed as a direct application of the method and is summarized here. The method employs subset solutions of the data associated with the complete solution and uses an algorithm to adjust the data weights by requiring the differences of parameters between solutions to agree with their error estimates. With the adjusted weights the process provides for an automatic calibration of the error estimates for the solution parameters. The data weights derived are generally much smaller than corresponding weights obtained from nominal values of observation accuracy or residuals. Independent tests show significant improvement for solutions with optimal weighting as compared to the nominal weighting. The technique is general and may be applied to orbit parameters, station coordinates, or other parameters than the gravity model.
1. INTRODUCTION

The method of data weighting has been an outgrowth of a calibration process for the error estimation of gravitational models that have been derived from satellite data, Lerch et al. (1985 and 1988) and Wagner and Lerch (1978). The principle of the new technique is to estimate the weighting of the data so as to produce realistic error estimates of the solution parameters from subset solutions of least squares normal equations. Application has generally been with use of a large set of satellites with inhomogeneous data from tracking systems of laser, electronic, and camera (optical) data. The gravity model of GEM-T1 (Marsh et al., 1988) using some 17 satellites has been tested with the new technique and the GEM-T2 (Marsh et al., 1989) solution with some 31 satellites has been derived with the new process of optimum weighting of the satellite data sets.

The accuracy estimation of the gravity model is particularly important for the TOPEX Project (1992 launch) for ocean application of its altimetry. It requires that the radial orbit error be accurate to better than 10 cm due to the uncertainty of the gravity field. Hence the estimation process for the errors, which are based upon the weights assigned to the data, must be reliable. The accuracy of the solutions, particularly the low degree field, is also important for the Lageos orbit. Accuracy is needed for the estimation of baseline motion of laser tracking sites at the centimeter per year level as part of the NASA Crustal Dynamics Project.
2. OBSERVATION WEIGHTING AND DATA CHARACTERISTICS

Observations obtained from geodetic satellite tracking systems generally have precision levels, particularly laser systems, much better than the observation residuals obtained from satellite orbital arcs in post fit analyses using the best models. This is true even though the orbital models employed were derived from the same satellite data and with the same arc lengths of several days. The problem here is that there are unmodeled systematic errors (biases) which need to be accounted for in the weighting system of the solution (Brown, 1988).

In Figure 1 an example of the characteristics of the residuals is shown for a pass of data from a typical laser tracking site. The precision error \( \sigma_o \) of the laser data is generally small (centimeter level) as compared to the rms \( \sigma_t \) of the residuals for a satellite data set \( t \). Values of \( \sigma_t \) are given in Tables 1A and 1B (GEM-TI and T2 data sets) for different satellite data types and for laser systems \( \sigma_t \) varies from 10 cm for Lageos orbits to over 50 cm on GEOS-1 orbital data in 1978.

Note in Figure 1 that the residuals of a tracking pass with noise removed fit very closely to a straight line as a function of a bias offset \( b_o \) and a timing error. The bias offset is the dominant part of the residuals. If the residuals were random with rms equal to \( \sigma_t \) the weight per observation point should be

\[
 w_t = 1/\sigma_t^2 ,
\]

but with a constant offset \( b_o \), say for \( N=50 \) points in a pass, the weight should be degraded by

\[
 w_t = 1/N\sigma_t^2 = .02/\sigma_t^2 .
\]
The latter case is characteristic of our situation particularly for the high precision laser data. The bias effects per pass tend to fluctuate randomly from pass to pass.

In general for a given satellite data type $t$ we have

$$w_t = f_t / \sigma_t^2$$

where $\sigma_t$ is the rms of residuals for the satellite data set and $f_t$ is a downweighting factor to account for the bias effects and the correlated effects of the residuals particularly within the pass. The weighting technique will obtain $w_t$ directly. Note from Table 1A (and 1B), $\sigma_t^2$ as well as $\sigma_t$ is given for each data type where

$$w_t = 1/\sigma_t^2$$

hence

$$f_t = (\sigma_t/\sigma_t)^2$$

which is approximately a constant

$$f_t = .01$$

for the satellites with the laser data. In Table 1B for the Starlette ('86) and AJISAI laser data, $f_t = .002$ where the data weight rates were 5 times faster (1 per second as compared to 1 per 5 seconds). Note also for the optical where systems with passive (non-flashing lamps) camera data, the degradation (factor) is much less, namely

$$f_t = .20$$
which may be expected since the number of points per pass are fewer and the ratio of noise to bias is relatively more significant than with the laser data.
3. LEAST SQUARES MINIMIZATION

The method of solution is a modified least squares process which minimizes the sum (Q) of signal and noise as follows:

\[ Q = \sum_{l,m} \frac{c_{l,m}^2 + s_{l,m}^2}{\sigma_l^2} + f \sum_t \sum_i \frac{r_{it}^2}{\sigma_t^2} f_t \]  

(1)

where the signal is given by

\[ c_{l,m}, s_{l,m}: \text{spherical harmonics comprising the solution coefficients; and} \]

\[ \sigma_l: \frac{1}{\sqrt{2}} \times 10^{-5} \frac{l^2}{l^2} \text{rms of the coefficients of degree } l \text{ (a priori rule) and is introduced to permit larger solutions to degree and order } 36x36. \text{ This law, based upon Kaula's rule, has been obtained independently from studies of the spectra of the Earth's gravity field and is used here to represent the observed power within the geopotential.} \]

and the noise by

\[ r_{it}: \text{observation residual (observed-computed)} \]
\[ f_t: \text{RMS of observation residuals (generally significantly greater than a priori data precision)} \]

The optimum weighting method estimates the combined weight directly, namely
When minimizing $Q$ above using the least squares method, the normal matrix equation and error covariance is obtained as follows:

$$w_t = t^2 / \sigma_t^2.$$  

are the normal equations, where $x$ is the solution, $R$ is the vector of residuals, and

$$V_{x} = N^{-1}$$

is the approximate form for the variance-covariance error matrix which must be calibrated by adjusting the weighting.

The process of minimizing both signal (Kaula constraints) plus noise in (1) is also known as collocation by Moritz (1978). With the normal least squares approach (noise-only minimization) there is a problem of separability due to the strong correlation between many of the high degree coefficients. The absence of collocation (GEM-T1 without the Kaula constraint) results in excessively large power in the adjustment of the potential coefficients. Figure 2 illustrates the instability of the least-squares solution when collocation is not used. A satellite-derived gravity solution has been solved without collocation which is evaluated using a global set of independent gravity anomalies. An unrestricted high degree field performs poorly due to excessively large adjustment in the coefficients which is normally circumvented in the standard least-squares method by solving for a smaller sized field. Unfortunately, by restricting the size of the field, one also is requiring the higher degree terms above the field limits to be constrained absolutely to zero. Figure 2 also shows the disadvantage of this approach where the smaller sized field (PGS-3067) contains aliasing in its coefficients and does not perform well. (The abbreviation PGS stands for Preliminary Gravity Solution.) The aliasing signal sensed in the data above the field limits is absorbed into the adjustment of the lower degree coefficients. The best approach is seen with the least squares collocation (or constrained) solution, GEM-T1, with a complete solution of a 36x36 field in harmonics.
4. LEAST SQUARES NORMAL EQUATIONS

In matrix form the observation equation is given by, assuming linearity,

\[ O - C = r = r_o - Ax \]

\[ x = X - X_R \]

where

- \( r = O - C \) --- residual, observation \( O \) minus computed value \( C \) from solution

- \( x = X - X_R \) --- adjustment of solution \( X \) from reference value \( X_R \) (for error analysis \( X_R \equiv X(true) \))

- \( A \) --- matrix of partials evaluated at \( X = X_R \)

- \( r_o \) --- residuals based upon a priori value \( X_R \).

For the gravity field, the linearity of perturbations may be seen for the spectrum of harmonics in Kaula (1966). The weighted normal equations are where \( W \) is a diagonal weight matrix (Lawson and Hanson, 1974)

\[ A^T W r = 0 \]

then from (1)

\[ A^T W A x = A^T W r_o \]  \hspace{1cm} (4)

For error analysis it is convenient to let the reference value
\[ X_R = X(\text{true}) \]

then from (3) \( x \) is the error in the solution \( X \), namely

\[ x = X - X(\text{true}) \]

Hence (4) becomes

\[ A^T W A x = A^T W e \]

where

\[ e \equiv r_o = 0 - C_R \]

\[ = 0 - C(\text{true}) \]

represents the errors due to all unmodeled systematic effects including random noise but excluding errors in the adjusted parameters. Instead these are the errors in \( x \) given by the solution to (5). Our solutions will be represented by the form (5) as we are interested in the difference between two solutions, \( x \) and \( \hat{x} \), namely

\[ x - \hat{x} = [X - X(\text{true})] - [\hat{X} - X(\text{true})] \]

\[ = X - \hat{X} \] (6)

The normal matrices for (5) are written compactly as

\[ N x = R \]

where
\[ N = A^T W A \quad (7) \]

\[ R = A^T W e \]

The normal matrices for each data subset \( t \) will be given as

\[ w_t N_t = w_t A_t^T A_t \quad (8) \]

\[ w_t R_t = w_t A_t^T e_t \]

where \( t=0 \) is a special case which corresponds to the signal constraints where the weight is fixed.
5. METHOD OF ESTIMATION OF WEIGHTS

The technique for estimating $w_t$ for each data set $t$ is based upon a complete solution ($S$) with all the data and a subset solution ($S_t$) where data set $t$ is removed. Let the normal equations for the complete solution $x$ and the subset solution $x_t$ be given as in (7) namely

$$N x = R$$

$$N_t x_t = R_t$$

where from (7)

$$\bar{N} = \sum_{j \neq t} w_j N_j \quad \bar{R} = \sum_{j \neq t} w_j R_j$$

(10)

$$N = \bar{N} + w_t N_t \quad R = \bar{R} + w_t R_t$$

The covariance (variance-covariance) matrices ($V$) for the errors $x$ and $x_t$ are obtained as

$$V(x) = N^{-1} \equiv E(xx^T)$$

$$V(x_t) = \bar{N}^{-1} \equiv E(x_t x_t^T)$$

(11)

As in (6)

$$x_t - x = [X_t - X(true)] - [X - X(true)]$$

$$= X_t - X$$

(12)

The covariance of the difference between the solutions is
\[ V(x_t - x) = E(x_t - x)(x_t - x)^T \]
\[ = V(x_t) - 2 E(x_t x_T^T) V(x) \]  
(13)
\[ = V(x_t) - V(x) \]

where as shown below
\[ E(x_t x_T^T) = V(x) \]  
(14)

From (9)
\[ E(x_t x_T^T) = N^{-1} E(R R^T) N^{-1} \]  
(15)

From (10) and (11)
\[ E(R R_T^T) = E[R(R + w_t R_t)^T] \]
\[ = E(R R_T^T) = N V(x_t) N \]  
(16)
\[ = N \]

since
\[ E(R R_t^T) = 0 \]

The latter result is true as from (10) the data set \( t \) is excluded from the subset solution, making \( R \) and \( R_t \) independent. Hence (14) results by substituting (16) into (15) and using (11).
5.1 WEIGHTING ALGORITHM

Using just the gravity parameters in \((X_t-X)\) the weighting algorithm is given by the calibration factor \(k_t\) obtained from

\[
(X_t-X)^T(X_t-X) = (x_t-x)^T(x_t-x) = k_t \text{ TR } V(x_t-x)
\]  

(17)

where TR denotes the trace of the matrix and where from (9) through (13)

\[
x_t-x = \bar{N}^{-1}R - N^{-1}R = X_t-X
\]  

(18)

\[
\bar{N} = \sum_{j \neq t} w_j N_j
\]  

(19)

\[
N = \bar{N} + w_t N_t
\]

\[
\bar{R} = \sum_{j \neq t} w_j R_j
\]  

(20)

\[
R = \bar{R} + w_t R_t
\]

\[
V(x_t-x) = \bar{N}^{-1} - N = V(x_t) - V(x)
\]  

(21)

Since \(k_t\) scales the error variances it will be inversely proportional for scaling the weight \(w_t\) to obtain the adjusted weight \(w_t^*\), namely

\[
w_t^* = \frac{w_t}{k_t}
\]  

(22)

This latter result will be derived more directly below. By iterating on the solutions \(x_t\) for each data set \(t\) and the complete solution \(x\) for all data sets until

\[
k_t = 1
\]
for each \( t \), the weights by (22) will then converge and the error estimates will automatically be calibrated from (17).

Results are given below to show how the weights and associated calibration factors converge. Because of the extensive computations for a large number of data sets a reasonable set of a priori values for the weights should be available for their refinement in the optimization process.

The gravity parameters of spherical harmonic coefficients are calibrated as a set by (17). Calibrations \( (k_t) \) are also given by subsets of spectral components from the harmonics of degree \( \ell \) and order \( m \). For all satellite data sets \( t \) (Lerch et al., 1988) relatively little variation is seen in the spectral calibrations.

5.1.1 Weighting Adjustment

The relation (18) for the weighting adjustment

\[
W_t^* = w_t / k_t
\]

is derived from use of (17) through (21). It is assumed that the data set \( t \) does not significantly change the solutions \( x \) and \( x_t \) beyond first order effects as follows:

\[
V(x_t-x) = \bar{N}^{-1} - N^{-1} = \bar{N}^{-1} - (\bar{N} + w_t N_t)^{-1}
\]

\[
= \bar{N}^{-1} - (I + w_t N_t)^{-1} \bar{N}^{-1}
\]

\[
= w_t \bar{N}^{-1} N_t \bar{N}^{-1}
\]

To the same approximation
\[ x_t - x = \omega_t \bar{N}^{-1} R_t \]

\[ E(x_t - x)(x_t - x)^T = \omega_t^2 \bar{N}^{-1} E(R_t R_t^T) \bar{N}^{-1} \]  \hspace{1cm} (24)

From (8)

\[ E(R_t R_t^T) = A_t^T E(e_t e_t^T) A_t \]  \hspace{1cm} (25)

\[ = \sigma_t^2 N_t \]

\[ = N_t/\omega_t^c \]

where \( \sigma_t \) accounts for the unmodeled systematic effects in \( e_t \) and the corresponding weighting effect is given as

\[ \omega_t^c = \frac{1}{\sigma_t^2} = f_t/\sigma_t^2 \]

Using (23) and (25) then (24) becomes

\[ E(x_t - x)(x_t - x)^T = \frac{\omega_t}{\omega_t^c} V(x_t - x) \]  \hspace{1cm} (26)

From (26) and (17)

\[ k_t = \omega_t/\omega_t^c \]

which gives the result (22).
6. TESTS AND RESULTS FOR OPTIMUM WEIGHTING TECHNIQUE

Sample tests of the weighting algorithm (22) were made using GEM-T1 plus additional data sets for several satellite data types of laser, optical, and electronic data. Results are given in Table 2 which show that the algorithm nearly converges in one step from the a priori starting weights. Plots of $w_t$ vs $k_t$ from (17) show a strong linear relationship from the origin ($w_t = k_t = 0$). Hence

$$\frac{w'}{k'} = \frac{w}{k}$$

and by setting $k' = 1$ for calibration the adjusted weight $w'$ should nearly converge from (22).

The above tests were made in preparing the weights for additional data sets to GEM-T1 that were combined for the GEM-T2 model. The convergence of these weights for GEM-T2 is shown in Table 3. In addition to the optimum weights the technique provides an automatic calibration of the error estimates based upon the satellite data types $t$ since each of the $k_t$ from (17) is required to converge to 1.

The data weights in GEM-T1 were derived primarily by requiring the weight for each data type $t$ to give the best overall agreement with independent mean gravity anomalies (Rapp, 1986) and with the satellite observation residuals on selected test arcs. The calibration factors $(k_t^{1/2})$ for several of the major data types (Lerch et al., 1988) are given in Table 4 which show that the weights converge ($k_t = 1$) except for the Lageos laser data. However, several additional tests were made in Table 4 for the calibration factor using independent data from Seasat altimetry (Rapp, 1986) and surface gravity data (Pavlis, 1988). All of the latter tests show good calibration of the error estimates, indicating optimum weighting was closely achieved. The last test deliberately increased the weighting for a subset of laser data by a
factor of 10 giving a value $k_t = (2.75)^2$. From (22) the adjusted weight should be reduced by a factor of $1/k_t$ which would nearly recover the original weight in one step of the iteration process. The gravity model with the increased weight naturally gives smaller error estimates but it also gave significantly worse agreement with independent surface gravity anomalies.
7. SUMMARY

The optimum weighting technique was shown to be important in the weighting of satellite data, particularly precise laser data where unmodeled systematic effects require a significant downweighting factor as shown in Table 1. The method of weighting was shown in Section 6.0 to provide realistic error estimates for GEM-T1 and T2. These models were calibrated using subset solutions based not only on data employed in their solutions but also upon independent data from altimetry and gravimetry. Because of the important application of the gravity model to ocean altimetry in the Topex Project, the gravity model errors were projected on the radial component of the TOPEX orbit and the result gave 10 cm for GEM-T2 which nearly meets the goal of the gravity model.

It was also shown in Section 6.0 that the model with the increased weight on the data over the optimum weighting gave much poorer agreement with independent surface gravity anomalies. The optimum weighting technique based upon the mathematical formulae is general and may be applied to other than gravitational parameters such as station coordinates and in particular orbit parameters where knowledge of accuracy estimation and refined solutions are needed.
ACKNOWLEDGMENTS

I wish to express my sincere thanks to Girish Patel of STX Corporation for his analysis and computation of the GEM-T1 and T2 data weights and calibrations of this report.

Characteristics of a Pass of Orbital Laser Residuals at a Tracking Site in Post Fit Analysis

\[ \text{rms} (10 \text{ cm}) \text{ varies with satellite} \]

\[ \text{Laser Residuals} r \]

\[ \text{cm} \]

\[ 50 \text{ Points} \]

\[ \text{rms} (r) = 7 \sigma \]

\[ \text{WEIGHT PER POINT} = \frac{1}{50} \left( \frac{1}{(\text{rms})^2} \right) \]

\[ = \frac{0.02}{(\text{rms})^2} \]

\[ = \frac{0.003}{\sigma^2} \]
Models show three modes of solution. The 25 x 25 field solves GEM-T1 tracking data without the Kaula constraint showing misclosure for high degree terms. PGS-3167 solves GEM-T1 data (with Kaula constraint) to the GEM-L2 size field (20 x 20), showing no improvement over our previous model. GEM-T1 uses the Kaula constraint with a high degree field (36 x 36) and is free of the above problems.

1. **UNDERLINED WEIGHTS ARE THE ADJUSTED ONES IN THE ITERATED SOLUTIONS**
2. **CALIBRATION FACTORS ARE CONSERVATIVE BUT SUFICIENTLY CONVERGED**
3. **ATS SST WEIGHT DELIBERATELY UNDERWEIGHTED BASED UPON COMPARISON WITH SEASAT ALTIMETER ANOMALIES**

* 4-LASER dataset is laser data from GEOS-1, GEOS-2, GEOS-3 and BE-C satellites
3-LASER dataset is laser data from DI-C, DI-D, and PEOLE satellites
OPTICAL dataset is the camera data from 20 satellites shown in TABLE 1A and 1B
