Abstract

Methods are considered of reducing a non-random fatigue loading history to a concise description and then of reconstructing a time history similar to the original. In particular, three methods of reconstruction based on a rain-flow cycle counting matrix are presented. A rain-flow matrix consist of the numbers of cycles at various peak and valley combinations. Two methods are based on a two dimensional rain-flow matrix, and the third on a three dimensional rain-flow matrix. Histories reconstructed by any of these methods produce a rain-flow matrix identical to that of the original history, and as a result the resulting time history is expected to produce a fatigue life similar to that for the original. The procedures described allow lengthy loading histories to be stored in compact form.

Introduction

The study of lengthy irregular time histories is of interest for analysis of fatigue damage. In order to make the recorded data manageable for future use, it is desirable to summarize a lengthy irregular loading history by a concise description. This concise description is needed to provide sufficient information to estimate fatigue life and also to reconstruct a loading history similar to the original one, in the form of a time sequence, which can then be used in component testing. The goal of this paper is to use loading histories described in concise form to reconstruct histories that produce fatigue lives similar to those for the original history.

(a) Reconstruction Methods

A variety of methods exist for reconstruction purposes, such as power spectral density (PSD) [1], the to-from matrix [2-4], and cycle counting [5-11]. The first two of these have the advantage of having a probabilistic basis, but they have a disadvantage in handling loads with a deterministic mean variation. Also, these methods may not produce the same life as the original history if it is not a random process. For example, Refs. [4,11] report that to-from reconstructed histories may produce lives which are excessively conservative.

Reconstruction based on cycle counting can be done using a variety of cycle counting methods, such as level crossing [6,10,12,13], peak-valley [6,9,14,15], or the rain-flow method [7-9]. In the past, the most popular reconstruction method was the programmed step test, which is based on a level crossing histogram. In the simplest version of a level crossing method [16], all positive slope level crossings above a reference (mean) load, and all negative slope level crossing below the reference load are counted. Figure 1(a) shows the results of a level crossing count. A loading history is reconstructed from the level crossing count by first constructing the largest possible cycle, using the highest level and lowest level, followed by the second largest cycle, and so on, until all level crossings in the histogram are used. Figure 1(b) shows this method. However, forming the largest possible cycles first is the most conservative choice, and other procedures may be used. Literature survey reveals that this method gives lives that often vary considerably from those for the original history. In fact, lives can be either

conservative or non-conservative depending on the details of the loading history and the exact method of reconstruction.

Another method of reconstruction based on cycle counting is the peak-valley reconstruction method. In the simplest version of the peak-valley cycle counting method, all peaks above the reference load, and all valleys below the reference load, are counted. Figure 2(a) shows this method. A reconstructed history can be obtained by first combining the highest peak and lowest valley to form a cycle, and the second highest and second lowest, and so on, until all events are used. Figure 2(b) shows this method. Again, a different and less conservative procedure could be adopted, such as randomly chosen pairings of peaks and valleys to form cycles. In our previous work [9,14], the peak-valley reconstruction method in the version of Fig. 2 was used for the reconstruction of two helicopter load histories. It was found that this method produced histories which could have excessively conservative calculated fatigue lives. Therefore, a need was identified to use a method of reconstruction that produced histories which had expected fatigue lives similar to those for the original history.

A third method of reconstruction based on cycle counting is to use rain-flow cycle counting. This more complex cycle counting method is illustrated in Figs. 3 and 4 and will be described in some detail below. It has been found in all of a limited number of cases studied [7-9,11] that reconstruction based on this method gives similar lives to those for the original history, so that this is a promising reconstruction method. It's success appears to be due to the reconstructed history producing the same rain-flow cycles as the original history.

The concise description that is proposed above is obtained by applying the rain-flow cycle counting method to the loading history and recording the result in a matrix which gives numbers of rain-flow cycles at various combinations of peak and valley loads. Although some detail is lost, such a matrix can be used with the aid of the local strain approach to place upper and lower bounds on the fatigue crack initiation life that would result from analysis of the original, unsummarized history. (The procedure is described in Ref. [14]). As such bounds are reasonably tight for most loading histories of practical interest, rain-flow cycle counting appears to preserve sufficient information from the sequence of loads so that the crack initiation

life depends mainly on the peak-valley matrix of rain-flow cycles. In a noteworthy paper, Perrett [8] experimentally studied the success of rain-flow reconstructions and considered both crack initiation and crack growth. Based on the available evidence, reordered loading histories appear to all have approximately the same life for both crack initiation and crack growth, as long as the rain-flow cycle count of the original is reproduced. Thus, rain-flow cycle counting has definite advantages as a means of reconstructing a fatigue-equivalent loading history from a concise description which involves much less data storage than the entire original history.

(b) Rain-Flow Cycle Counting

In the rain-flow counting method, cycles are counted depending on the comparison of two adjacent ranges as illustrated in Fig. 3, which also defines the range and mean of a cycle. If the first range is less than or equal to the second, a cycle is counted and the corresponding peak and valley are discarded for purposes of further cycle counting. This procedure continues until all the peaks and valleys in the history are considered. Figure 4 illustrates this process for a simple loading history, and the result is given in Table 1. Based on Table 1, a history can be reconstructed which gives the same rain-flow matrix as the original history. Figure 5(b) shows one such history.

For lengthy histories, a practical method of presenting the result of rain-flow cycle counting is to form a matrix which gives numbers of cycles at various combinations of peak and valley loads. This is illustrated in Fig. 6, where rain-flow cycle counting of the short history of (a) is given by the matrix of (b). Matrix (b) only has entries below the diagonal. In (c), the result is presented in a different form which makes a distinction whether the cycle is ordered peak-valley or valley-peak. In this matrix, there are entries on both sides of diagonal depending on the direction of the cycle, that is, on whether the peak or valley occurs first.

Based on the equations in Fig. 3, a peak-valley matrix can be converted to a matrix which gives numbers of cycles at various combinations of range and mean loads. However, any in-

formation on cycle directions is lost. Hence, a matrix of the type of Fig. 6(c) preserves more information than a range-mean matrix, whereas 6(b) provides equivalent information.

In this paper, three methods of reconstruction based on a rain-flow matrix are discussed. Two methods are based on a two dimensional rain-flow matrix, one of which considers cycle directions, and the third on a three dimensional rain-flow matrix. Note that the two dimensional matrix is a peak-valley matrix, while the three dimensional matrix is a peak-valley-peak matrix. Reconstructed histories by any of these methods will not have the same sequence as the original history. However, all such reconstructed histories produce a rain-flow matrix identical to that for the original history; therefore, the fatigue lives are expected to be similar.

Rain-flow Reconstruction Method Based on a 2-D Matrix

In this method a loading history is first summarized by applying the rain-flow cycle counting method to obtain a compact matrix giving combinations of peak and valley values which correspond to the rain-flow cycles. As already noted, such a matrix can be defined in the two forms illustrated in Fig. 6. In one form, all values above the diagonal line are zero, which indicates that the directions of the cycles are not considered. The other form of the matrix considers the directions of the cycles and has values on both sides of the diagonal. The differences between these the two matrices can be seen in cycles b-c and g-h. If the directions are not considered, these cycles are identical. But if directions are considered, b-c is plotted in the matrix as 2-3, whereas g-h is plotted as 3-2. The detailed procedures employed for reconstruction based on these two types of matrix are explained below.

In Fig. 6, a 5 by 5 matrix is used for illustration purpose only. A higher resolution matrix is needed in practical work. A 32 by 32 matrix is a good compromise in most cases, as this reproduces load levels to within 3% of the largest range and is still relatively compact. Noting that all entries on the diagonal are zero, a 32 by 32 matrix involves 992 numerical values if cycle directions are considered. If the first storage method is applied, that is, if the cycle directions are not considered, then the matrix has a triangular form as in Fig. 6(b). In order to

reconstruct, first the largest cycle, which is in the first (left) column and last (bottom) row, is considered, and then all the columns corresponding to the same row are considered in order. Then the preceding row and corresponding columns are considered in order. This procedure continues until all the elements of the matrix are covered. A cycle can be placed within any cycle in the matrix with equal or more extreme peak and valley, that is, greater or equal row number and less or equal column number. A random location is chosen among all the possibilities, and then the partially reconstructed sequence is rearranged accordingly. The simplest reconstructed history can be formed by placing all the cycles having the same peak and valley in a single location. However, if a more irregular history is desired, the number of cycles for a given peak-valley combination is divided into "n" groups, and each group is placed in a possible location randomly. The value of " n " is optional, with larger values producing a more irregular history but causing computational costs to be greater.

For the other type of matrix where the information retained includes the directions of the cycles, a potentially full 32 by 32 matrix is formed. The elements within the matrix are chosen in the order given by the numbers in Fig. 7 so that the largest cycles are employed first. In Fig. 7, an 8 by 8 matrix is used for illustration only; the same procedure is extended for a 32 by 32 matrix. Four rules for inserting a cycle into a partially reconstructed history are illustrated in Fig. 8 and described below.

If the cycle that is being inserted (inserting cycle) has a greater row than column, that is, if it is ordered peak-valley, then it can be placed within any cycle (receiving cycle), provided:

1. If the receiving cycle is ordered valley-peak, that is, if it has a row less than the column, then the receiving row must be less than or equal to the inserting column, and the receiving column must be greater than or equal to the inserting row. Figure 8(a) illustrates this case.

2. If the receiving cycle is ordered peak-valley, that is, if it has a row greater than column, then the receiving row must be greater than or equal to the inserting row, and the re-

ceiving column must be less than or equal to the inserting column. Figure 8(b) illustrates this case.

On the other hand, if the inserting cycle has a greater column than row, that is, if it is ordered valley-peak, then it can be placed within any cycle, provided:

3. If the receiving cycle is ordered peak-valley, that is, if it has a row greater than the column, then the receiving row must be greater than or equal to the inserting column, and the receiving column must be less than or equal to the inserting row. Figure 8(c) illustrates this case.

4. If the receiving cycle is ordered valley-peak, that is, if it has a row less than column, then the receiving row must be less than or equal to the inserting row, and the receiving column must be greater than or equal to the inserting column. Figure 8(d) illustrates this case.

In addition, the reconstruction must alternate between peaks and valleys. This results in the insertion being made in the rising branch of the receiving cycle for cases (1) and (2), and in the falling branch for (3) and (4). Also, the major cycle could be considered to be either a peak-valley or a valley-peak cycle; the latter is arbitrarily chosen here.

These rules simply ensure that the inserting cycle is within the bounds of the receiving cycle. As an example, consider the history of Fig. 9(a). The inserting cycle 5-4 has a row 5 and a column 4. The partially reconstructed history has the following four rain-flow cycles as identified by the peak-valley or valley-peak levels: 2-6, 6-3, 7-2, and the major cycle, 1-7. Figure 9(b) shows these cycles. If rule number 1 is applied, then the possible receiving cycles would be 2-6 and 1-7. These cycles satisfy rule (1); therefore a random location is chosen between these two possibilities. Figure 9(c) shows the history if 2-6 is chosen as the receiving cycle, while Fig. 9(d) shows the history if 1-7 is chosen as the receiving cycle.

If rule number 2 is applied, then the possible receiving cycle would be 6-3 and 7-2. Note that both cycles satisfy rule number 2. Figures 9(e) and 9(f) show the history with the receiving cycle being 6-3 and 7-2, respectively.

Consider the history in Fig. 10(a). The inserting cycle is 4-5, and the partially reconstructed history is the same as for Fig. 9(a), having the same cycles 2-6, 6-3, 7-2 and 1-7, as already shown in Fig 9(b). If rule number 3 is applied, then the possible receiving cycles would be 6-3 and 7-2. Note that both cycles satisfy rule number 3. Figures 10(b) and (c) show the history with receiving cycles 6-3 and 7-2, respectively.

If rule number 4 is applied, then the possible receiving cycles would be 2-6 and 1-7. Both cycles satisfy rule (4). Figures 10(d) and (e) show the history with the receiving cycle 2-6 and 1-7, respectively.

Note that the location for the cycle under consideration is chosen among all the possibilities, and as before there exist two general options for the reconstructed history, namely, the simplest form and the irregular form. In the latter case, the number of cycles for a given peak-valley combination is divided into "n" groups, and each group is placed in a possible location randomly.

The reconstructed histories by either of the above described procedures will not have the same sequence as the original history. The reason is that a given minor cycle can be placed in a variety of locations, as its original location was not preserved by the peak-valley matrix of the rain-flow cycles. However, all reconstructed histories produce a rain-flow matrix identical to that for original history.

For the first method of reconstruction, that is , for the method not considering cycle directions, recall that all cycles in a given row were used for reconstruction before the next row was considered. Other orders of using cycles could have been employed, with the only absolute requirement being that the largest cycle be used first. The procedure used for the second method, where successively smaller ranges are considered, is preferable. The reason is that

this approach maximizes the number of possible locations where a given cycle can be placed as all larger cycles are already present.

Rain-flow Reconstruction Method Based on a 3-D Peak-Valley-Peak Matrix

This method is similar to the two dimensional reconstruction method (cycle directions considered), except another dimension is added to the matrix. Also, the rain-flow matrix was used with a size of 16 by 16 by 16. Greater resolution, say 32 by 32 by 32, could be used subject to limitations on computational time and cost. This method follows rules 2 and 4 plus an additional rule which must also be introduced. The new rule states that if the inserting cycle is ordered peak-valley, then the receiving cycle must also be ordered peak-valley, and the receiving peak must be equal to the third dimension of the inserting cycle. However, if the inserting cycle is ordered valley-peak, then the receiving cycle must also be ordered valley-peak, and the receiving valley must be equal to the third dimension of the inserting cycle.

For example, consider Fig. 6(c). In the two dimensional approach, cycle g-h, has a starting level of 3 and a target level of 2, while in the three dimensional approach, this cycle is stored as g-h-a, which has a starting level of 3, an intermediate level of 2, and a target level of 5.

Rain-Flow Reconstruction of Maneuver History

A loading history for the tail rotor pitch beam of an AUH-76 helicopter was selected as representative, and loading histories from each of 30 distinct severe maneuver were assumed to occur once in a specific sequence. This produced a loading history containing 33,470 cycles, which was then modified by the University of Dayton Research Institute (UDRI) to eliminate minor events, shortening it to 8777 cycles, that is 8777 peaks and 8777 valleys.

In addition, the modified history was further shortened by filtering all the rain-flow cycles with the range less than 0.45 units. Note that the history is scaled so that the highest peak is 1 unit, which results in the lowest valley being -0.517 units, and the largest rain-flow range 1.517 units. This filtered history contains 510 cycles and is shown in Fig. 11(a). Figure 12 shows the peak-valley matrix of this history, specifically the matrix with cycle directions considered. This history is explained in detail in Refs. [9,11].

Computer programs based on the above descriptions were developed and used for reconstruction of the filtered maneuver history. The filtered history was first summarized using rain-flow cycle counting into the compact form of a 32 by 32 matrix giving combinations of peak and valley values which correspond to rain-flow cycles. Recall that a history can be reconstructed in two ways depending on two variations of the rain-flow matrix.

Figures 11(b) and 11(c) show reconstructed histories where the cycle directions are not considered. The simplest reconstructed history is 11(b), and a more irregular reconstructed history is 11(c). The simplest history is obtained by placing all the cycles having the same peak and valley in a single location. The more irregular version can be formed by simply dividing the number of cycles for a given peak-valley combination into "n" groups, and each group is placed into a possible location randomly. For Fig. 11(c), a value of $n=3$ was used. Figure 11(d) shows the simplest reconstructed history where the directions of the cycles are retained.

The filtered history was also summarized by using the rain-flow method in the compact form of a three dimensional 16 by 16 by 16 matrix giving combinations of peak, valley, and peak, or valley, peak, and valley. Figure 13 shows the simplest form of the reconstructed history.

Discussion

Based on the discussion presented in this paper, it appears that a promising reconstruction method is some version of a rain-flow reconstruction. Although rain-flow reconstructed histories do not generally produce the same loading sequence as the original history, this is not

expected to affect the life significantly. This occurs because the rain-flow matrix will be identical to the original rain-flow matrix; therefore, a similar life is expected.

As already noted, Perrett's work [8] suggests that reconstructed histories producing identical rain-flow cycles give similar lives as original histories. This argument is strengthened by [11] based on the comparison of calculated fatigue lives of original and reconstructed histories. Note that Perrett's conclusion is based on test data for total life for crack initiation plus growth, and also on analysis of crack growth for standard aircraft spectra. He also suggests that, in all cases where the reconstruction process has been randomized, there is not a significant load interaction effect beyond that accounted for by rain-flow counting. The evidence to date suggests that all of the possible rain-flow reconstructions from a given rain-flow matrix cause similar lives for both crack initiation and growth.

Availability of testing equipment is important in determining the best method of rain-flow reconstruction. If the test equipment is limited to constant amplitude cycling, it would be the best choice if the rain-flow directions are not considered, and if all cycles with the same peak and valley are put in one location. However, for a more advanced equipment, where there is no restriction on the irregularity of the loading history, the realism of the reconstructed history can be increased by retaining the rain-flow cycles directions, and putting cycles with the same peak and valley in more than one location.

Comparison between the three dimensional and two dimensional methods indicates that the three dimensional method involves additional complexities, greater storage by a factor of 32, and greater computational time without any apparent benefit. Therefore, the two dimensional approach appears to be sufficient.

This work on rain-flow reconstruction is currently being extended to obtain experimental verification.

Conclusion

Reconstruction of loading histories from a concise description based on rain-flow cycle counting appears to be a promising approach. This produces a history with an altered ordering of events but with a rain-flow cycle counting matrix identical to the one for the original history. As a result of reproducing the rain-flow cycles, similar fatigue lives are expected for original and reconstructed histories.

Appendix A. Computer Program RAINF2 for Rain-flow Cycle Counting Analysis

A computer program for rain-flow cycle counting is provided. The program can take a lengthy load history and reduce it to a compact form of a matrix giving combinations of range and mean or peak and valley values. This information can be used for fatigue analysis. The input values are defined, and two examples using different options of the program are provided. The differences with an earlier version (RAINF1) are minor and are confined to two areas of the program as indicated by comment statements.

Program Logic

The following logic is used consistent with the ASTM Standard E1049 (Ref. 16 of this report): Let x denote the absolute value of the range under consideration, and y the previous absolute range adjacent to x.

Step 1: Determine the maximum absolute value in the history. (Note that this value can be either a peak or a valley.)

Step 2: Arrange the history to start with the maximum absolute value. Move all peaks and valleys which occur prior to the maximum load to the end as illustrated in Fig. A.1(b).

Step 3: Read the next value. If out of data, go to step 9.

Step 4: Three points are needed to define x and y. If there are less than three points, go back to step 3. Define x and y using the three most recent peaks and valleys that have not been discarded.

Step 5: Compare the two ranges, namely x and y. If x is less than y, go to step 3; otherwise go to step 6.

Step 6. If a rain-flow filtered history is not desired, go to step 8.

Step 7: If y is less than or equal to the filter level specified in the program input, discard the peak and valley of the range y in the array in memory, which is the original history of step 2.

Step 8: Count range y as one cycle, determine the mean value of the peak and valley of y, discard the peak and valley of y in the array set up in step 3, and go to step 4.

Step 9: Stop.

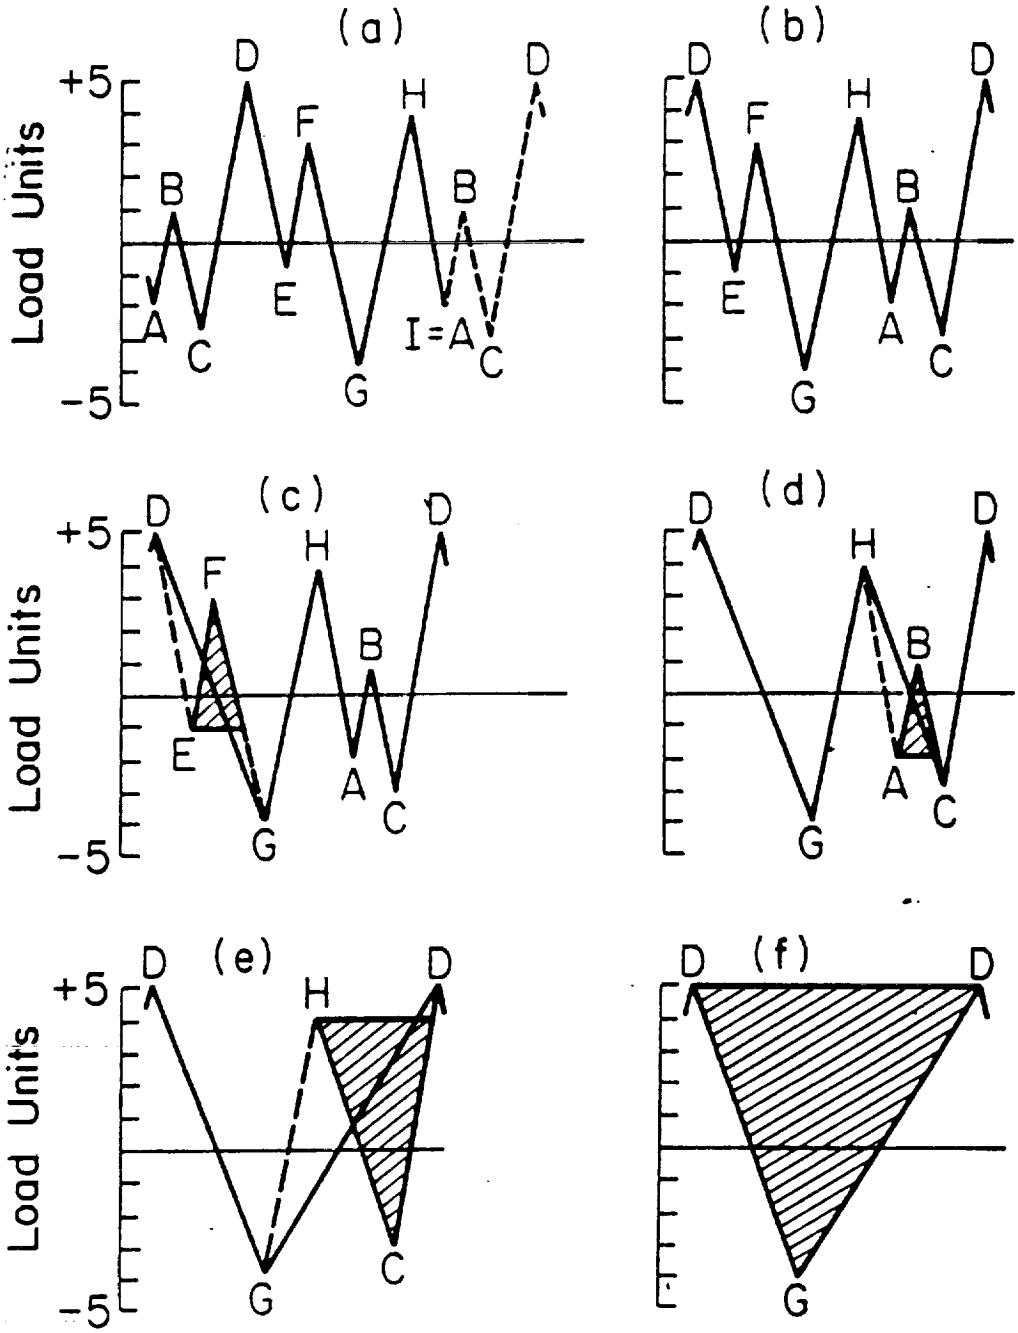

Figure A.1. Example of rain-flow program logic.

Definition of Input Data

Data line 1: OPTION = 1 List filtered history as peak-valley sequence; also print range-mean matrix of rain-flow cycles for original history.

2 List range, mean, minimum, and maximum of rain-flow cycles not in matrix form.

3 Print range-mean matrix of rain-flow cycles.

4 Print starting versus target level, 32 by 32, matrix of rain-flow cycles. Note the directions of cycles are stored in this matrix. The starting level for a cycle is either a peak (max) value or a valley (min) value, whichever occurs first, and the target level is the other peak or valley that defines the cycle. Also, the history is converted to a minimum value of 1 and maximum value of 32.

Data line 2: FL = Filter level as a range value. Note that this data is required only for OPTION = 1, and is otherwise omitted.

Data line 3: NN = Number of peak-valley points in the history. The history must start and end with the same value, so that this starting/ending value is counted twice in NN, and NN must be an odd number.

Data line 4: XIM = Constant increment between mean values in the range-mean matrix. Note that this data is required only if OPTION = 1 or 3, and is otherwise omitted.

XIR = Constant increment between range values in the range-mean matrix. Note that this data is required only if OPTION = 1 or 3, and is otherwise omitted.

Data line 5: P( ) = Input load history as peaks and valleys in sequence. Note that the history must start and end with the same value, and the direction of loading must reverse at each value.

Example 1

The history of Fig. A.1 is used for this rain-flow cycle counting example. Option 2 of the program is used; Therefore, the result is shown as a list of range, mean, minimum(valley), and maximum (peak) values. The entire program listing and program input and output for this example follow.

PROGRAM OUTPUT:

RANGES COUNTED AS CYCLES BY RAINFLOW CYCLE COUNTING METHOD.

RANGE	MEAN	MAX	MIN
4.000	1.000	3.000	-1.000
3.000	-0.500	1.000	-2.000
7.000	0.500	4.000	-3.000
9.000	0.500	5.000	-4.000

Example 2

The history of Fig. A.1 is again used for the rain-flow cycle counting example. Option 4 is used; therefore, the results are given in the form of a compact 32 by 32 matrix containing the peak and valley values of rain-flow cycles. Also, the directions of the cycles are stored in this matrix. Note that the history is converted using linear interpolation to have a minimum value of 1 and a maximum value of 32.

This option of the cycle counting program produces the output needed for use in a separate program (RECON2) that reconstructs a loading sequence having the same rain-flow cycles as the original sequence. The reconstructed history also produces rain-flow cycles with directions the same as in the original history. RECON2 is described in Appendix B.

In scaling to 32 levels, the level number, P_m, is related to any peak or valley value from the original history, P_0, as follows:

$$P_m = \frac{31 \times (P_0 - P_{0min})}{(P_{0max} - P_{0min})} + 1 \qquad (B-1)$$

except that P_m is rounded to the nearest integer. P_{0min} and P_{0max} are the lowest valley and highest peak, respectively, in the original history. For this example, $P_{0min} = -4$, and $P_{0max} = 5$. Cycle EF, which starts at $P_0 = -1$, and goes to $P_0 = 3$, has a starting level of 11 and a target level of 25.

Appendix B. Computer Program RECON2 for Two Dimensional Rain-flow Reconstruction

A computer program for reconstructing a load history from the result of rain-flow cycle counting in matrix form is provided. Note that the directions of the cycles are indicated by the position in the matrix. The numbers in the matrix , that is, the " matrix elements", are the numbers of cycles at the various peak-valley-direction combinations. The program takes the results of rain-flow cycle counting in the form of such a matrix and uses this information to reconstruct a load history. The resulting history has the same rain-flow matrix as the original history but is not generally identical as to ordering of the cycles. The program logic is explained in detail in the main text of this report, with a few examples.

Note that in its simplest application, the program places all cycles having the same peak, valley and direction in a single location in the history. If a more irregular version is desired, then the number of cycles for a given peak-valley-direction combination is divided into n groups. In this program n is called NOC. This is done only if the number of cycles is greater than a specific value (NP). The group size is then rounded down to the nearest whole number, and this many cycles are placed in the first location, the same in the second location, etc., except that the number in the last location includes the rounded down number plus all of the

residual from rounding. If NOC=NP=1, then cycles are placed individually, but this choice may be costly due to computer run time for lengthy histories.

Definition of Input Data

Data line 1: NP= Largest matrix element which is placed in a single location. If a given row and column has this value or less, then all of these cycles are placed in one location.

Data line 2: NOC= The number of different locations in which cycles from a matrix element are placed. If the number of cycles for a given row and column is greater than NP, then these cycles are placed in this many randomly chosen locations.

Data line 3: AB(,)= The rain-flow matrix elements themselves, where directions of rain-flow cycles are considered.

Note that the rain-flow peak-valley matrix AB(,) is read into a two dimensional array, starting with the first row, moving left to right, and completing each row before going to the next row. This data can be obtained using the RAINF2 computer program (OPTION=4). The standard size of the matrix for this program is 32 by 32. However, if a different size is desired, say 16 by 16, then the LEVEL value inside the program should be changed from 32 to 16. The columns are starting levels (peaks or valleys) of cycles, and the rows are target levels.

Example 1

A history containing 9 peak-valley points is used with NP = NOC = 1. Figure B.1 shows this history. The input is the rain-flow matrix of this history, with directions of rain-flow cycles considered, as obtained using the RAINF2 computer program (Appendix A, OPTION 4). Note that the reconstructed history gives the same rain-flow peak-valley matrix (with directions considered) as the original history; however, it does not have the same sequence as the original history. Figure B.1 compares the original and reconstructed histories. Note that the user must convert the history obtained (min = 1, max = 32) using linear interpolation to get a history compatible with the original history. The entire program listing and program input and output for this example follow.

GENERATED HISTORY

32 11 25 8 18 1 29 4 32

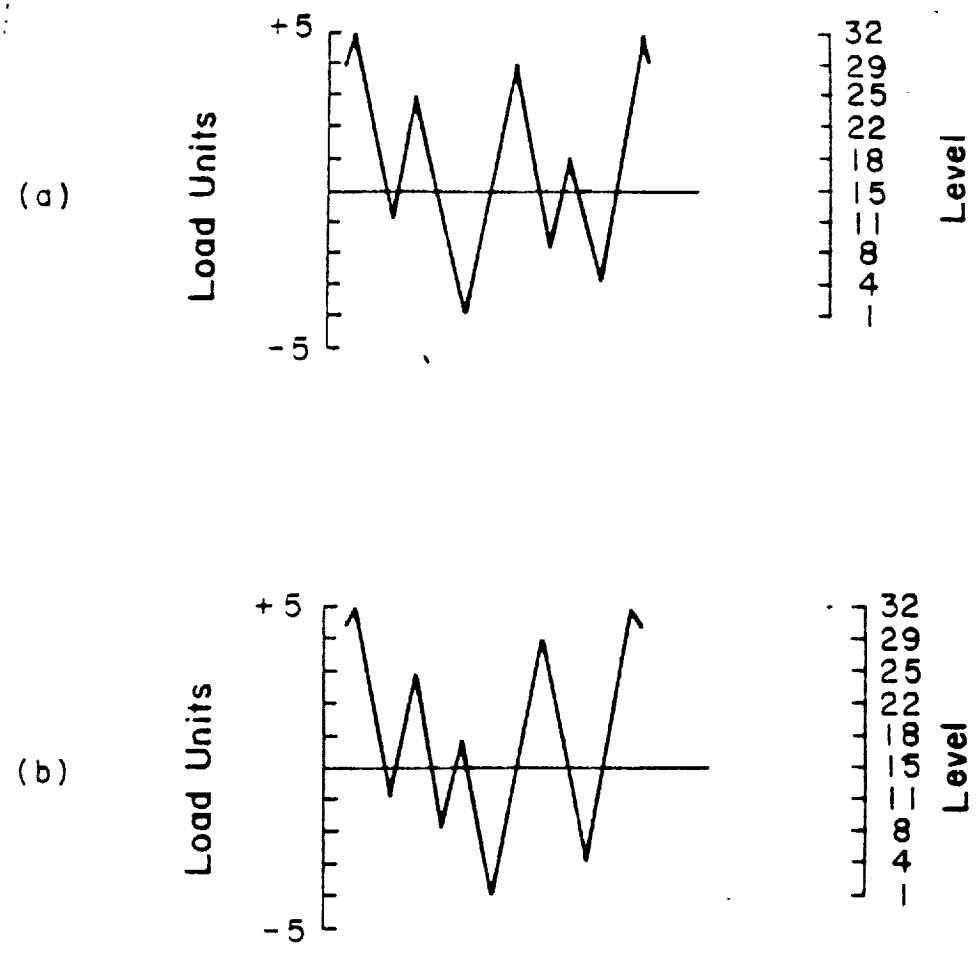

Figure B.1. Comparison of original (a), and reconstructed (b) histories.

Example 2

A history (Maneuver History) containing 1021 peak-valley points is used. This history is explained in detail in the main text of this report. The input is the rain-flow matrix of this history with directions of rain-flow cycles considered, as obtained using the RAINF2 computer program (Appendix A, OPTION 4). Note that the reconstructed history gives the same rain-flow peak-valley matrix as the original history, and also the directions of the cycles are preserved. Note that as mentioned before, the user must convert the history obtained (min = 1, max = 32) using linear interpolation to get a history on a scale compatible with the original history. The program input and output are attached. Cycles from each matrix element are placed in two randomly chosen locations (NOC = 2), provided these are more than eight (NP = 8). Figure B.2 shows the original and the reconstructed histories.

Input for the Reconstruction Program

16. Abstract

Methods are considered of reducing a non-random fatigue loading history to a concise description and then of reconstructing a time history similar to the original. In particular, three methods of reconstruction based on a rain-flow cycle counting matrix are presented. A rain-flow matrix consists of the numbers of cycles at various peak and valley combinations. Two methods are based on a two dimensional rain-flow matrix, and the third on a three dimensional rain-flow matrix. Histories reconstructed by any of these methods produce a rain-flow matrix identical to that of the original history, and as a result the resulting time history is expected to produce a fatigue life similar to that for the original. The procedures described allow lengthy loading histories to be stored in compact form.
