INTRODUCTION

Noble metals, when used as electrocatalysts for oxygen reduction in metal-air batteries and fuel cells, suffer from the disadvantages of high cost, susceptibility to poisoning and sintering. Carbons activated with macrocyclics have attracted increasing attention as alternative electrocatalysts for oxygen reduction (Yeager, 1984). Initial activity of these catalysts is good, but performance declines rapidly. Pyrolyzing the macrocyclic on the carbon support leads to enhanced stability and the catalyst retains good activity (Wiesener, 1986). The exact nature of the catalytic sites after pyrolysis is still under investigation (Scherson, et al., 1983; McBreen, et al., 1987).

Despite this promising method of treating macrocyclic activated carbon catalysts, the performance decay is still too large to be acceptable. Part of the stability problem occurs because the catalytic layer on the carbon surface is, at most, a few monolayers thick. The approach described here is designed to develop bulk doped catalysts with similar structures to pyrolyzed macrocyclic catalysts. The transition metal and coordinated ligands are dispersed throughout the bulk of the conductive carbon skeleton.

Two approaches to realizing this concept are being pursued, both involving the doping of a carbon precursor followed by high temperature pyrolysis to form a M-N-C catalyst. In one approach, the precursor is a solid phase ion exchange resin. Two resins have been selected for doping. One is IRC-50 (Figure 1a) which is a weak cation exchange resin that contains no nitrogen in its backbone or exchange groups. The transition metal and nitrogen are introduced by either exchanging a transition-metal (such as Fe$^{3+}$ from FeCl$_3$) and nitrogen (from NH$_4$OH) sequentially or exchanging a chelation compound (such as Fe(bipy)$_3^{2+}$). The other ion exchange resin chosen was Chelite-C (Figure 1b) which contains a nitrogen-containing iminodiacetic acid exchange group. Exchange of a simple transition metal salt results in metal-nitrogen coordination before pyrolysis.

In the second approach, gas phase precursors are mixed in a reactor and pyrolyzed to form the catalyst. Acetylene (C$_2$H$_2$) is used as the carbon source, ammonia (NH$_3$) as the nitrogen source, and an iron-containing organometallic as the transition metal source.
EXPERIMENTAL METHODS

Chelation compounds for doping the IRC-50 resin have included Fe(bipy)₃SO₄, Co(bipy)₃Cl₂, Fe(phen)₃SO₄, Co(NH₃)₆Cl₂, and Co(en)₃Cl₃. Doping is carried out by mixing the resin with a solution of the dopant and agitating the mixture at 80°C for 3 hours. The doped resin is dried and then placed in a tube furnace. The resin is pyrolyzed under an NH₃ atmosphere at temperatures near 900°C.

The gas phase precursors are pyrolyzed in a vertical tube furnace at temperatures near 1100°C. The C₂H₂, NH₃, and iron-containing organometallic are introduced at the top of the furnace. Product is collected in a water trap at the bottom of the furnace or inside the tube.

Electrodes are prepared from the bulk doped carbons by mixing the catalyst with PTFE and spreading onto a Ag-plated Ni screen.

Electrochemical tests are performed using the floating electrode technique (Giner and Smith, 1967). The electrolyte is 30% KOH and the temperature is held at 80°C. The electrodes are tested galvanostatically and the measurements are corrected for external ohmic losses. Potentials are reported versus a dynamic hydrogen electrode (DHE).

The catalysts are analyzed for their carbon, hydrogen, nitrogen, and metal content. Some catalysts have also had BET surface areas determined using a Micromeritics Flowsorb II surface area analyzer.

Mossbauer spectroscopy has been used in an attempt to identify the species present in the iron-containing catalysts. This work is being done in conjunction with Professor Daniel Scherson at Case Western Reserve University.

RESULTS AND DISCUSSION

A. Electrochemical Tests

Figure 2 compares the electrochemical performance of catalysts prepared from IRC-50 doped from solutions of Fe(bipy)₃SO₄, Co(en)₃Cl₃, Co(bipy)₃SO₄, Co(NH₃)₆Cl₂, and FeCl₃-NH₄OH with CoTMPP adsorbed and pyrolyzed on Vulcan XC-72. There is a large improvement in performance on changing the dopant solution from FeCl₃-NH₄OH to Fe(bipy)₃SO₄ with the same resin and pyrolysis conditions. The Fe(bipy), Co(en), and Co(hex) systems show a performance that is 50-80 mV less at 100 mA/cm² than the CoTMPP on Vulcan XC-72. The surface areas of Co(en), Co(hex) and Fe(bipy), doped carbons are in the same range as CoTMPP doped Vulcan XC-72. The differences in the kinetic region may be attributed to the differences in the surface concentrations of the catalyst. The earlier dropoff of performance may be due to either ohmic losses in the structure or hindrance to oxygen transport. The Co(bipy) system shows somewhat poorer performance; stoichiometric analysis of the Co(bipy) system showed that only 1% Co was incorporated in the final catalyst (compared to 10% for iron) and, therefore, doping conditions need to be adjusted.

The next set of experiments examines two different approaches for the synthesis of "Fe-N" complexes. Figure 3 compares the performance of the IRC-50 Fe(bipy) system with Chelite-C doped with FeCl₃. In the first system, the Fe is
already coordinated with nitrogen in the bipyridine complex. Introducing this complex into the ion exchange resin, allows bulk-doping and ensures molecular level interaction between the carbon and the "Fe-N" complex. In the second system, the resin has a backbone that contains nitrogen and coordinates with the iron. In addition to differences in the density of the exchange sites (which determines the metal/nitrogen ratio) in these two systems, the molecular interactions are bound to be different which may result in differences in oxygen reduction performance. The carbon prepared from the chelating resin shows essentially the same performance in the kinetic region, indicating that the nature of the Fe-N complexes may be similar regardless of their method of preparation, as long as covalent type interactions are ensured as opposed to purely ionic type interactions. At higher current densities, there are some differences in the performance of these systems, which may be attributed to the non-optimized electrode preparation. It is also quite possible that the stabilities of these complexes may vary widely. Preliminary examination of the catalysts using Mossbauer spectroscopy indicates that the IRC-50 and Chelite-C systems contain one species in common and one species each that is unique to that catalyst.

Figure 4 shows the results of performance measurements on catalysts from gas phase precursors. The undoped carbon prepared from gas pyrolysis shows very poor performance. Addition of the Fe and N has a dramatic effect on performance. The surface area of the Fe/N doped carbon in this figure, is only 19 m²/g and the nitrogen/metal mole ratio is 0.46. Studies are in progress to improve both these factors.

B. Characterization of Catalysts

The catalysts are routinely analyzed for carbon, hydrogen, nitrogen, and metal content. Table I shows the stoichiometry calculated for some typical catalysts. There is still some unknown that is not accounted for in the C, H, N, M. Some of this unknown is oxygen which comes from the COO⁻ groups in the resin and exposure of catalyst to the atmosphere. The oxygen is present in the form of metal oxides. However, a calculation of the maximum weight percentage of oxygen present in this form shows that it is not enough to account for all of the unknown. The sample of IRC/Fe(bipy) was also sent for Si analysis. Some Si is present, but Si or SiO₂ does not account for all of the unknown. Emission spectroscopy was conducted to determine if any other heavy metals are present. Only minor amounts were present. The sample was sent for sulfur analysis which showed that some sulfur was present. This sulfur is probably from the sulfate group in the Fe(bipy)₃SO₄. This is because some of the dopant is imbibed in the pores of the IRC-50 instead of being ionically bound to the COO⁻ groups.

BET surface areas of catalysts prepared from the doped ion-exchange resin precursors are in the range of 100-300 m²/g. When the IRC-50 resin with no dopant was pyrolyzed, the surface area was less than 5 m²/g. This is consistent with work in progress which indicates that the presence of the metal dopant has a large effect on the nature of the pyrolysis process.
CONCLUSIONS

The doping of solid phase precursors followed by pyrolysis or the co-
pyrolysis of gas phase precursors has allowed us to produce catalysts with good
activity toward oxygen reduction. Efforts are currently underway to better
understand the reasons for the catalytic activity of the bulk doped catalysts
with a view toward further improving their activity.

ACKNOWLEDGEMENT

This work is supported by the United States Department of Energy under
Contract No. DE-AC02-87ER80500.M001. We would like to thank Professor
Daniel Scherson for providing the sample of CoTMPP adsorbed on Vulcan XC-72 and
performing the Mossbauer spectroscopy on the catalyst samples.
