SUMMARY

New rare earth oxide emitters show greater efficiency than previous selective emitters. As a result, based on a simple model the efficiency of these new emitters was calculated. Results indicate that the emission band of the selective emitter must be at relatively low energy ($\leq 0.52$ eV) to obtain maximum efficiency at moderate emitter temperatures ($\leq 1500$ K). Thus low bandgap energy PV materials are required to obtain an efficient thermophotovoltaic (TPV) system. Of the four specific rare earths (Nd, Ho, Er, Yb) studied, Ho has the largest efficiency at moderate temperatures (72 percent at 1500 K). A comparison was made between a selective emitter TPV system and a TPV system that uses a thermal emitter plus a band pass filter to make the thermal emitter behave like a selective emitter. Results of the comparison indicate that only for very optimistic filter and thermal emitter properties will the filter TPV system have a greater efficiency than the selective emitter system.

INTRODUCTION

The early work of White and Schwartz (ref. 1) recognized the benefits of selective emitters for efficient thermophotovoltaic (TPV) energy conversion. However, finding an efficient selective emitter has been a difficult task. The most promising solid selective emitters have been the rare earth elements (ref. 2). For doubly and triply charged ions of these elements in crystals the orbits of the valence 4f electrons, which account for emission and absorption, lie inside the 5s and 5p electron orbits. As a result, the rare earth ions in the solid state have radiative characteristics much like they would have if they were isolated. They emit in narrow bands rather than in a continuum as do most solids. The 5s and 5p electrons "shield" the 4f valence electrons from the surrounding ions in the crystal. The spectra of these rare earth ions in crystals have been extensively studied. Most of this work is summarized in the text of Dieke (ref. 3).

The rare earths to be considered in this study are neodymium, Nd, holmium, Ho, erbium, Er, and ytterbium, Yb in the oxide form ($\text{Nd}_2\text{O}_3$, $\text{Ho}_2\text{O}_3$, $\text{Er}_2\text{O}_3$ and $\text{Yb}_2\text{O}_3$).

Early spectral emittance work (ref. 2) on rare earth oxides that are suitable for TPV showed strong emission bands. However, the emittance for photon energies below the bandgap for PV materials was also significant. As a result, the efficiency of these emitters was low. In the last few years, however, Nelson and coworker (refs. 4 and 5) have reported a large improvement in rare earth oxide emitters. Their emitters are constructed of fine (5 to 10 $\mu$m) rare earth oxide fibers similar to the construction of the Welsbach mantle used in gas lanterns. The very small characteristic dimension of the
emitter results in low emittance for the low energy part of the spectrum, thus giving a much higher efficiency than previous emitters.

This study models the emissive properties of the rare earths in order to calculate the radiative efficiency. From the radiative efficiency results conclusions are made about where each of the considered rare earths is most appropriate for a TPV system. Finally, a selective emitter TPV system is compared to a TPV system that uses a band pass filter to make a thermal emitter behave like a selective emitter.

EMITTER EFFICIENCY ANALYSIS

As already mentioned, the new rare earth oxide emitters (refs. 4 and 5) show a single strong emission band centered around some photon energy, \( E_g \). For photon energies above and below this emission band the emissivity is greatly reduced. Therefore, the following model is used to describe the rare earth oxide emitters. There is a single emission band of width \( \Delta E_g \) centered about photon energy, \( E_g \). Outside this emission band the emissivity is \( \epsilon_l \) for \( E < E_I = E_g - 1/2 \Delta E_g \) and \( \epsilon_u \) for \( E > E_u = E_g + 1/2 \Delta E_g \). Now define the emitter radiative efficiency as follows,

\[
\eta_E = \frac{P_E}{P_{RAD}}
\]

where \( P_E \) is the useful emitted radiative power per unit area from emission band at \( E_g \) and \( P_{RAD} \) is the total emitted radiative power per unit area. Obviously, this efficiency does not include thermal conductive or convective heat loss. A photovoltaic (PV) material with bandgap energy just slightly less than \( E_g \) is capable of efficient conversion of this useful energy, \( P_E \).

The two powers in equation (1) can be written as follows:

\[
P_E = \epsilon_g \int_{E_I}^{E_u} e_b \, dE
\]

\[
P_{RAD} = \epsilon_I \int_0^{E_I} e_b \, dE + \epsilon_g \int_{E_I}^{E_u} e_b \, dE + \epsilon_u \int_{E_u}^{\infty} e_b \, dE
\]

Where, \( \epsilon(E) \) is the total hemispherical emissivity and \( e_b \) is the black body emissive power so that,

\[
\epsilon_I = \frac{\int_0^{E_I} \epsilon e_b \, dE}{\int_0^{E_I} e_b \, dE}
\]

(4a)
and,
\[
e_b \, dE = \frac{2\pi}{h^3 c_0} \left[ \frac{E^3}{\exp \left( \frac{E}{kT_E} \right) - 1} \right] \, dE
\]

where, \( h \) is the Planck constant, \( c_0 \) is the speed of light in vacuum, \( k \) is the Boltzmann constant and \( T_E \) is the emitter temperature (K). Substituting equations (2) and (3) in (1) yields the following.

In obtaining equation (6) the following result was used.

Where \( \sigma \) is the Stefan-Boltzmann constant \( (5.67 \times 10^8 \, \text{W/m}^2\text{K}^4) \). For the rare earths and emitter temperatures of interest the smallest value of \( E_1/kT_E \approx 1.9 \). Therefore, it is a good approximation to assume \( e^{E_1/kT_E} \approx e^{E/kT_E} \) in equation (5). As a result, the integrals in equation (6) can be carried out so that the emitter efficiency becomes the following.
\[ \eta_E = 1 + \left( \frac{\varepsilon_l}{\varepsilon_g} \right) G \left[ \frac{E_g}{kT_E}, \Delta E_g/E_g \right] + \left( \frac{\varepsilon_u}{\varepsilon_g} \right) H \left[ \frac{E_g}{kT_E}, \Delta E_g/E_g \right] \tag{8} \]

Where,

\[ G[u,z] = \frac{\pi^4}{15} \frac{\text{Exp}(x_l) - F[x_l]}{F[x_l] - F[x_u] \text{Exp}(-zu)} \tag{9a} \]

\[ H[u,z] = \frac{F[x_u] \text{Exp}(-zu)}{F[x_l] - F[x_u] \text{Exp}(-zu)} \tag{9b} \]

\[ x_l = \frac{E_l}{kT_E} = u(1 - \frac{z}{2}) \tag{9c} \]

\[ x_u = \frac{E_u}{kT_E} = u(1 + \frac{z}{2}) \tag{9d} \]

\[ z = \frac{\Delta E_g}{E_g} \tag{9e} \]

\[ u = \frac{E_g}{kT_E} \tag{9f} \]

\[ F(x) = x^3 + 3x^2 + 6x + 6 \tag{9g} \]

As equation (8) shows, there are four parameters that determine the efficiency; \( \Delta E_g/E_g \), \( E_g/kT_E \), \( \varepsilon_l/\varepsilon_g \) and \( \varepsilon_u/\varepsilon_g \). In figure 1 the efficiency is shown as a function of \( E_g/kT_E \) for several values of \( \varepsilon_u/\varepsilon_g = \varepsilon_l/\varepsilon_g \), and \( \Delta E_g/E_g = 0.1 \). As can be seen there is an optimum value for \( E_g/kT_E \) to obtain maximum \( \eta_E \). These results also show that it is essential to have small \( \varepsilon_l/\varepsilon_g \) and \( \varepsilon_u/\varepsilon_g \) in order to obtain maximum efficiency. This was not the case for the early rare earth oxide emitters and therefore they were inefficient.

The case of figure 1 where \( \varepsilon_u/\varepsilon_g = \varepsilon_l/\varepsilon_g \) and \( (E_g/kT_E)_{\text{opt}} = 4.0 \) leads to the result that an emitter with \( E_g \leq 0.69 \text{ eV} \) is required if \( T_E \leq 2000 \text{ K} \). Also, if it is desirable to have \( T_E \leq 1500 \text{ K} \) then \( E_g \leq 0.52 \text{ eV} \) is required to obtain maximum \( \eta_E \). Thus in order to obtain a high efficiency TPV system at moderate emitter temperatures relatively low bandgap PV materials are required.

In figure 2 the effect on efficiency of variable below emission band emissivity, \( \varepsilon_l \), is demonstrated. Reducing \( \varepsilon_l \) obviously increases \( \eta_E \). However, changing \( \varepsilon_l \) also causes the \( (E_g/kT_E)_{\text{opt}} \) to shift. As \( \varepsilon_l \) decreases, \( (E_g/kT_E)_{\text{opt}} \) increases. This is a desirable situation since maximum efficiency for a given \( E_g \) can be attained at lower temperature. As figure 2 shows, however, \( \varepsilon_l/\varepsilon_g \leq 0.05 \) in order to produce a significant increase in \( (E_g/kT_E)_{\text{opt}} \).
Efficiency dependence on the above emission band emissivity, $\epsilon_u$, is illustrated in figure 3. As expected, $\eta_E$ increases as $\epsilon_u$ decreases. However, the increase in $\eta_E$ is less than the increase that results from decreasing $\epsilon_l$. For $\epsilon_l/\epsilon_g = 0.01$ and $\epsilon_u/\epsilon_g = 0.1$, $[\eta_E]_{\text{MAX}} > 0.7$ but for $\epsilon_l/\epsilon_g = 0.1$ and $\epsilon_u/\epsilon_g = 0.01$, $[\eta_E]_{\text{MAX}} < 0.6$. Also, decreasing $\epsilon_u/\epsilon_g$ causes an undesirable shift in $(E_g/kT_E)_{\text{opt}}$ to lower values. Therefore, higher temperatures are required to obtain maximum efficiency.

The effect of dimensionless emission bandwidth, $\Delta E_g/E_g$, was also investigated. As expected, the emitter efficiency increases with increasing bandwidth. However, for $\Delta E_g/E_g \leq 0.5$ the location of $[\eta_E]_{\text{MAX}}$ is not changed. Also the width of the $\eta_E$ versus $E_g/kT_E$ curve increases as $\Delta E_g/E_g$ increases.

Based on the results of this model for the rare earth selective emitters the following two important conclusions can be made. First of all, to obtain maximum efficiency at moderate temperatures ($\leq 1500$ K), the emission band must be centered at relatively low energy ($E_u \leq 0.52$ eV). Thus low bandgap PV materials are required to obtain an efficient TPV system. Also to obtain high efficiency at moderate temperature, it is more important to reduce the below emission band emissivity, $\epsilon_l$, than the above band emissivity, $\epsilon_u$.

**EMITTER EFFICIENCY FOR SELECTED RARE EARTHS**

Now consider the emitter efficiency, $\eta_E$, for each of the rare earths shown in Table I. The relative spectral exitance data for the fibrous emitters of Nelson and coworkers (refs. 4 to 6) were used to obtain $\epsilon_l/\epsilon_g$, $\epsilon_u/\epsilon_g$ and $\Delta E_g/E_g$. Values for $\Delta E_g/E_g$ were calculated from these data, however, the emissivity ratios, $\epsilon_l/\epsilon_g$ and $\epsilon_u/\epsilon_g$, are only estimates rather than actual integrations of the data (see eq. (4)). The temperature dependence of the emissivity ratios was neglected. This should be a good approximation for the small temperature range (1000 to 3000 K) considered. Nelson's data was taken in the 1800 to 2000 K temperature range. The emissivity ratios used here are conservative estimates based on that data. However, since he presents no data for $E < 0.5$ eV ($\chi > 2.5$ µm) the $\epsilon_l/\epsilon_g$ ratios are not as reliable as the $\epsilon_u/\epsilon_g$ ratios. More will be said about the emissivity ratios when efficiencies of each of the 4 rare earths are discussed.

Ytterbia, Yb$_2$O$_3$, is of great interest for two reasons. First of all, the emission band at $E_u = 1.29$ eV is a good match to silicon, which has a bandgap energy of 1.12 eV at 300 K. Secondly, it has only a single strong emission band (refs. 2, 4, and 5). Ytterbium has only one observed energy level above the ground state (ref. 3). Figure 4 shows $\eta_E$ as a function of $T_E$ for $\epsilon_u/\epsilon_g = 0.01$ and $\epsilon_l/\epsilon_g = 0.07$. The value for $\epsilon_l/\epsilon_g$ was obtained from reference 5. Since the Yb spectrum shows negligible radiation for $E > E_g$ the low value of $\epsilon_l/\epsilon_g = 0.01$ was chosen. Also, the experimental value for $\eta_E$ of Parent and Nelson (ref. 5), which is close to the theoretical value, (ref. 5) is shown in figure 4. Note that for $T_E < 2000$ K the efficiency is far from the maximum. Thus, even though Yb has low values of $\epsilon_l/\epsilon_g$ and $\epsilon_u/\epsilon_g$ high efficiency is only possible if $T_E \approx 3000$ K can be attained.

The close match of erbium's emission band at $E_g = 0.827$ eV with germanium's bandgap of 0.66 eV makes Er$_2$O$_3$ a good candidate for a TPV system.
Also, the ternary semiconductor, Ga_{47}In_{53}As (ref. 9) has a bandgap of 0.75 eV, which matches Er very well. Nelson's (ref. 4) Er_{2O_3} data show a narrow bandwidth for Er, \( \Delta E_g/E_g = 0.05 \). Also, negligible emissivity above and below \( E_g \) is shown in Nelson's data (ref. 4). Therefore, \( \epsilon_u/e_g = 0.01 \) and \( \epsilon_1/e_g = 0.05 \) were chosen as representative of Er. With this input the emitter efficiency for Er was calculated and is shown in figure 5. The narrow bandwidth for Er limits the maximum efficiency to approximately 0.55. Also, for \( \eta_E \geq 0.5 \) the emitter temperature must be high (\( T_E > 2000 \text{ K} \)).

Holmium has a strong emission band at \( E_g = 0.62 \text{ eV} \), which is slightly below the bandgap of germanium (0.66 eV at 300 K.) However, increasing the germanium temperature to 408 K reduces the bandgap of germanium to 0.62 eV (ref. 8) although this would also decrease the PV efficiency. In addition the bandgap of the ternary semiconductor, Ga_{x}In_{1-x}As, can be varied by changing the ratio of Ga_{x} and In_{1-x}. This has been accomplished in the construction of infrared detectors (ref. 10). Nelson's (ref. 6) spectral data for Ho_{2O_3} above the emission band at 0.62 eV show a weak radiation band at ~1.0 eV with negligible emissivity everywhere else down to \( E = 0.5 \text{ eV} \). Therefore, it was assumed that \( \epsilon_u/e_g = 0.02 \) and \( \epsilon_1/e_g = 0.05 \). Using this data \( \eta_E \) was calculated and is shown in figure 6. As can be seen, \( \eta_E > 0.7 \) for \( T_E > 1500 \text{ K} \). Thus Ho has the potential for large efficiency at moderate emitter temperatures.

The final rare earth oxide considered is neodymia, Nd_{2O_3}. It is of interest because it has the potential for the highest efficiency at the lowest temperature. Neodymium has a strong emission band at 0.496 eV resulting from the \( ^4I_{12}/2 \rightarrow ^4I_{12}/2 \) transition (ref. 6). Nelson (ref. 6) also detects two much lower intensity emission bands at 1.5 and 0.74 eV. Nelson (ref. 6) has no data for photon energies less than the strong emission band at \( E_g = 0.496 \text{ eV} \). However there are possibilities for 0.25 eV (\( \lambda = 5 \mu m \)) photons from \( ^4I_{12}/2 \rightarrow ^4I_{12}/2 \) and \( ^4I_{12}/2 \rightarrow ^4I_{12}/2 \) transitions (ref. 3). Therefore, to model Nd the following emissivity ratios were chosen \( \epsilon_1/e_g = 0.1 \) and \( \epsilon_u/e_g = 0.1 \). Figure 7 shows the Nd efficiency results. Maximum efficiency occurs at \( T_E \approx 1400 \text{ K} \). Therefore, Nd is well suited for operation at moderate temperatures (\(<1500 \text{ K} \)). However, because Nd has larger \( \epsilon_u/e_g \) and \( \epsilon_1/e_g \) the maximum efficiency for Nd is less than the other rare earths.

The low energy emission band (\( E_g = 0.496 \text{ eV} \)) for Nd leads to \( \eta_E \) being attained at low temperature. However, the low \( E_g \) means that a new low energy bandgap PV cell must be developed in order for a Nd emitter to be used in a TPV system. Indium arsenide, InAs, has a bandgap of 0.36 eV and is a good candidate for matching with a Nd emitter in a TPV system. Again the ternary semiconductor, Ga_{x}In_{1-x}As, is also a possible PV material to match with a Nd emitter. One disadvantage of a low temperature (\(<1500 \text{ K} \)) TPV system is the resulting lower power density. Remember that the power density is proportional to \( T_E^4 \) and thus sensitive to emitter temperature changes.

COMPARISON OF FILTER TPV AND SELECTIVE EMITTER TPV

Rather than using a selective emitter a thermal emitter plus filter can also be used in a TPV system. In a thermal emitter system a narrow band filter is placed in front of the emitter to make it perform like a selective emitter.
The ideal filter allows all photons with \( E_1 < E < E_u \) to pass from the emitter to the PV cell and reflects all photons with \( E < E_1 \) and \( E > E_u \) back to the emitter. The filter recycles the inefficient photons back to the emitter. Such solar TPV systems have been considered by many researchers (refs. 11 to 15). The critical component in these systems is the filter. As Bell (ref. 12) and Sirkl and Ries (ref. 15) point out introducing only a 10 percent filter loss reduces the ideal (no filter losses) efficiency by more than a factor of 1.5. It should also be mentioned that a real emitter will not have perfect black body properties (emissivity = absorptivity = 1).

Now consider the following simple comparison of a TPV system that uses a thermal emitter with a bandpass filter to a TPV system that uses a selective emitter. Figure 8 is a schematic drawing of the two systems. The thermal input power, \( P_t \), is assumed the same for both systems. This thermal input could be from a solar concentrator, a chemical combustion process or a nuclear reactor.

In both systems the PV array will "see" mainly the useful photons that are in the energy interval, \( E_1 < E < E_u \). Therefore, it is assumed that the photovoltaic efficiency, \( \eta_{PV} \), is the same in both systems.

In the thermal emitter system a portion \( \tau_f P_{RAD}^0 \) of the emitted power, \( P_{RAD}^0 \), is transmitted to the PV array and a portion, \( \eta_f P_{RAD}^0 \), is reflected back to the emitter. Of the reflected power a portion, \( \alpha_f P_{RAD}^0 \), is absorbed by the emitter, where \( \tau_f \) is the total transmission of the filter, \( \eta_f \) is the total reflectivity of the filter and \( \alpha_f \) is the total absorptivity of the emitter.

Also, for conservation of energy,

\[
\tau_f + \eta_f + \alpha_f = 1
\]  
(10)

Where \( \alpha_f \) is the total absorptivity of the filter. An energy balance on the emitter yields the following.

\[
P_{RAD}^0 + P_L^0 = P_t^0 - \alpha_f \tau_f P_{RAD}^0
\]  
(11)

Where \( P_L^0 \) is the conductive and convective heat loss to the surroundings of the emitter.

Defining the emitter thermal efficiency as

\[
\eta_{th}^0 = \frac{P_{RAD}^0}{P_t^0} = 1 - \frac{P_L^0}{P_t^0}
\]  
(12)

and combining with equation (11) yields

\[
P_{RAD}^0 = \frac{\eta_{th}^0 P_t^0}{1 - \alpha_f \tau_f}
\]  
(13)
Therefore, if $\eta_{PV}$ is the PV efficiency the electrical power output is the following.

$$P_{EL}^O = \eta_{PV} \eta_f \eta_{th} P_t$$  \hspace{1cm} (14)

Where,

$$\eta_f = \frac{\bar{\tau}_f}{1 - \bar{\alpha}_E \bar{r}_f} = \frac{\bar{\tau}_f}{1 - \bar{\alpha}_E (1 - \bar{\alpha}_f - \bar{\tau}_f)}$$  \hspace{1cm} (15)

can be considered as the efficiency of the filter.

Now consider the selective emitter TPV system. In this case the electrical output power is the following.

$$P_{EL} = \eta_{PV} \eta_E \eta_{th} P_t$$  \hspace{1cm} (16)

Where $\eta_E$ is the emitter efficiency defined by equation (1) and

$$\eta_{th} = \frac{P_{RAD}}{P_t} = 1 - \frac{P_L}{P_t}$$  \hspace{1cm} (17)

is the thermal efficiency of the selective emitter, which includes the conductive and convective heat loss, $P_L$, of the emitter. For similar designed systems it is expected that $\eta_{th}^0 = \eta_{th}$.

Assuming $\eta_{th}^0 \approx \eta_{th}$ equations (13) and (15) yield the following,

$$\frac{P_{EL}^O}{P_{EL}} = \frac{\eta_f}{\eta_E}$$  \hspace{1cm} (18)

Thus if,

$$\eta_f > \eta_E$$  \hspace{1cm} (19)

then the filter TPV system electrical output, $P_{EL}^O$, will be greater than the selective emitter electrical output, $P_{EL}$. Obviously, if the emitter is a perfect black body ($\bar{\tau}_E = \bar{\alpha}_E = 1$) and there are no filter losses ($\bar{\alpha}_f = 0$) then $\eta_f = 1$ (see eq. (15)). In this case the filter system will always be superior to the selective emitter system.

For the filter system consider the filter to have the following spectral transmission, $\tau_f$.

$$\tau_f = 0 \quad \text{for} \quad E < E_l$$ \hspace{1cm} (20a)

$$\tau_f = \tau_g \quad \text{for} \quad E_l \leq E \leq E_u$$ \hspace{1cm} (20b)

$$\tau_f = 0 \quad \text{for} \quad E > E_u$$ \hspace{1cm} (20c)
Thus all the "inefficient" photons are not transmitted and a fraction, $\tau_g$ of the efficient photons are transmitted. The ideal filter results if $\tau_g = 1$. For $\tau_f$ given by equation (20) the total transmission of the filter is the following.

$$\bar{\tau}_f \equiv \frac{p_E^0}{p_{RAD}^0} = \tau_g \int_{E_1}^{E_u} \frac{E_u}{\varepsilon^0 \varepsilon_b \, dE}$$

Where $\varepsilon^0$ is the spectral hemispherical emissivity of the thermal emitter, $\varepsilon^0$ is the total hemispherical emissivity of the emitter and $T_E$ is the temperature of the thermal emitter.

By using the hemispherical emissivity in equation (21) to calculate $P_E$ we are assuming all radiation leaving the emitter reaches the PV array. Comparing equations (1) and (21) it can be seen that $\bar{\tau}_f$ for the filter TPV system is equivalent to $\eta_E$ for the selective emitter TPV system.

Define the emissivity in the "useful" energy band $E_1 \leq E \leq E_u$ similar to the selective emitter case (eq. (4b)). Therefore,

$$\varepsilon_g^0 = \int_{E_1}^{E_u} \frac{e^0 e_b \, dE}{E_b}$$

and equation (21) becomes the following,

$$\bar{\tau}_f = \frac{15}{\pi^4} \left[ \frac{\varepsilon_g^0}{\varepsilon^0} \right] \tau_g \exp(-x_1) [F(x_1) - F(x_u) \exp(-zu)]$$

where it has been assumed that $\exp\left(\frac{E}{kT_E^0}\right) - 1 \approx \exp\left(\frac{E}{kT_E^0}\right)$ in the black body emissive power, $e_b$ (eq. (5)) and $x_1$, $x_u$, $z$, $u$, and $F$ are given by equations (9c) to (9g). If the emitter is a perfect black body $\varepsilon_g^0 = \varepsilon^0 = 1$. For a nonblack body emitter $\varepsilon^0 < 1$ and is a function of $T_E$. Therefore, $\varepsilon_g^0/\varepsilon^0 < 1$ or $\varepsilon_g^0/\varepsilon^0 > 1$ depending on $T_E^0$. For unpolished tungsten, which is a good candidate for an emitter material, $\varepsilon^0 \approx 0.6$ for $1100 \leq T_E^0 \leq 2600$ K (ref. 16). Polished tungsten has much lower emissivity. Also, for the photon energy range $0.5 \leq E_g \leq 1.3$ eV ($2.5 \geq \lambda \geq 1$ μm) of interest for TPV systems the spectral emissivity of unpolished tungsten is less than 0.5 (ref. 15). Therefore, $\varepsilon^0 < 0.6$ and for $\varepsilon_g^0 \approx 0.6$ the ratio, $\varepsilon_g^0/\varepsilon^0 < 1$. However, in order to make $\tau_f$ as large
as possible for comparing the filter TPV and selective emitter TPV systems assume 
\( \varepsilon_{0} / \varepsilon_{0} = 1 \) in equation (23).

To compare the two TPV systems \( \eta_{E} \) and \( \eta_{F} \) were calculated as functions of \( \frac{E_{g}}{kT_{E}} \). When \( \eta_{F} > \eta_{E} \) the filter TPV system will be more efficient than the selective emitter system. In figure 9 results are shown for \( \varepsilon_{U} / \varepsilon_{g} = \varepsilon_{F} / \varepsilon_{g} = \Delta E_{g} / E_{g} = 0.1 \) for the selective emitter system. This is a conservative representation of the four rare earths in this study. For the filter TPV system in figure 9 the optimistic assumption of a black body emitter (\( \varepsilon_{0} = \frac{\varepsilon_{0}}{\varepsilon_{g}} = \frac{\varepsilon_{0}}{1} \)) was made. Also, an optimistic filter transmission in the emission band, \( \varepsilon_{g} = 0.95 \) was assumed. Results for three filter absorptivities, \( \alpha_{F} = 0.01, 0.05, 0.1 \) are shown in figure 9. As can be seen, for \( \alpha_{F} = 0.01 \) the filter system is significantly better than the selective emitter system. For \( \alpha_{F} = 0.05 \) the filter system is still more efficient than the selective emitter system. However, for \( \alpha_{F} = 0.1 \) the selective emitter system becomes more efficient than the filter system.

Even with a perfect black body emitter the filter TPV system efficiency will be less than the selective emitter system efficiency for a filter loss of 10 percent or more (\( \alpha_{F} > 0.1 \)). For a nonblack body emitter the superiority of the selective emitter system is even greater. This is illustrated in figure 10 where \( \eta_{E} \) and \( \eta_{F} \) are compared for three values of the filter system emitter emissivity (and absorptivity), \( \frac{\varepsilon_{0}}{\varepsilon_{E}} = \frac{\varepsilon_{0}}{\varepsilon_{0}} = 0.6, 0.7, 0.8, 0.9, \) and \( \frac{\varepsilon_{0}}{\varepsilon_{g}} = 1 \).

The selective emitter conditions are the same as figure 9 and optimistic values for the filter performance were chosen (\( \alpha_{F} = 0.01, \varepsilon_{g} = 0.95 \)). As can be seen, even for \( \frac{\varepsilon_{0}}{\varepsilon_{E}} = \varepsilon_{0} = 0.9 \) the selective emitter system has a larger efficiency.

Based on the results shown in figures 9 and 10, it appears that, \( \varepsilon_{g} > 0.95 \), and \( \alpha_{F} < 0.01 \) and \( \frac{\varepsilon_{0}}{\varepsilon_{0}} > 0.9 \) are required for the filter TPV system to have greater efficiency than the selective emitter TPV system.

CONCLUSION

The development of new high efficiency rare earth oxide emitters has caused renewed interest in TPV energy conversion. Theoretical emitter efficiency calculations yield two important conclusions. First of all, the emission band of the selective emitter must be centered at relatively low energy (\( E_{g} < 0.52 \) eV) to obtain maximum efficiency at moderate emitter temperatures (\( T_{E} < 1500 \) K). Thus low bandgap PV materials are required to obtain an efficient TPV system. Secondly to obtain high emitter efficiency at moderate temperatures, it is more important to reduce the off band radiation that lies below the emission band than the radiation that lies above the emission band. Theoretical efficiency calculations for Yb, Er, Ho, and Nd were made. Yb and Er are of interest because their emission bands are well matched to the bandgaps of silicon and germanium respectively. The experimental efficiency data of references 5 and 6 for Yb comes close to the theoretical efficiency. However, in order to approach the maximum efficiency for Yb, emitter temperatures approaching 3000 K are required. Erbium has a narrow emission band (\( \Delta E_{g} / E_{g} = 0.05 \)) which limits its efficiency. However, near maximum efficiency can be reached for \( T_{E} \approx 2000 \) K. Holmium is an excellent candidate for a
selective emitter since high efficiency is possible for moderate temperatures \( (hE = 0.72 \text{ for } T_E = 1500 \text{ K}) \). Neodymium is a low temperature candidate since its maximum efficiency occurs at 1450 K. However, Nd has larger off emission band emissivities so that its maximum efficiency \( ([hE]_{\text{MAX}} = 0.55) \) is lower than Ho maximum efficiency. Both Ho and Nd require new PV materials if they are to be used in a TPV system. However, there are good candidate PV materials that can be used with Ho and Nd.

Finally, a comparison was made between a rare earth selective emitter TPV system and a TPV system that uses a thermal emitter plus a band pass filter that makes the thermal emitter perform like a selective emitter. In order for the filter TPV system to have a greater efficiency than the selective emitter system nearly impossible filter and thermal emitter properties are required. The filter absorption must be 1 percent or less, filter transmission must be zero outside the photon energy band of interest and 95 percent or greater within the energy band. Also, the thermal emitter must have an emissivity of 0.9 or greater.

New rare earth oxide emitters show greater efficiency than previous selective emitters. As a result, based on a simple model the efficiency of these new emitters was calculated. Results indicate that the emission band of the selective emitter must be at relatively low energy (≤ .52 eV) to obtain maximum efficiency at moderate emitter temperatures (≤ 1500 K). Thus low bandgap energy PV materials are required to obtain an efficient thermophotovoltaic (TPV) system. Of the 4 specific rare earths (Nd, Ho, Er, Yb) studied Ho has the largest efficiency at moderate temperatures (72 percent at 1500 K). A comparison was made between a selective emitter TPV system and a TPV system that uses a thermal emitter plus a band pass filter to make the thermal emitter behave like a selective emitter. Results of the comparison indicate that only for very optimistic filter and thermal emitter properties will the filter TPV system have a greater efficiency than the selective emitter system.
