ABSTRACT
With a pilots’ increasing use of visual cue augmentation, much requiring extensive pre-processing, there is a need to establish criteria for new avionics/display design. The timeliness and synchronization of the augmented cues is vital to ensure the performance quality required for precision mission task elements (MTEs) where augmented cues are the primary source of information to the pilot. Processing delays incurred while transforming sensor-supplied flight information into visual cues are unavoidable. Relationships between maximum control system delays and associated flying qualities levels are documented in MIL-F-83300 and MIL-F-8785. While cues representing aircraft status may be just as vital to the pilot as prompt control response for operations in instrument meteorological conditions, presently, there are no specification requirements on avionics system latency. To produce data relating avionics system latency to degradations in flying qualities, the Navy conducted two simulation investigations. During the investigations, flying qualities and performance data were recorded as simulated avionics system latency was varied. Correlated results of the investigation indicate that there is a detrimental impact of latency on flying qualities. Analysis of these results and consideration of key factors influencing their application indicate that: (1) Task performance degrades and pilot workload increases as latency is increased. Inconsistency in task performance increases as latency increases. (2) Latency reduces the probability of achieving Level I handling qualities with avionic system latency as low as 70 ms. (3) The data suggest that the achievement of desired performance will be ensured only at display latency values below 120 ms. (4) These data also suggest that avoidance of inadequate performance will be ensured only at display latency values below 150 ms.

INTRODUCTION
This paper documents the results of two piloted simulations conducted to generate data regarding display latency effects on flying qualities. A theoretical foundation is presented first to facilitate discussion. In this introduction, latency, flying qualities and a general closed-loop system are defined. The predictions that provided the impetus for the simulation investigations are presented.

Definition of Latency
Latency associated with a system component can be viewed as a pure time delay between some input or change and the corresponding output. Avionics system latency can be defined as the time delay between aircraft motion and the corresponding indication of that motion on the aircraft displays. Based on this definition, the terms latency, time delay, and delay are considered equivalent and are interchanged throughout this paper.

Definition of Flying Qualities
The acceptability of aircraft dynamics and control characteristics can be quantified in terms of achievable mission task performance and resulting pilot workload. This quantification is typically performed using the Cooper-Harper pilot opinion scale shown in Figure 1. Aircraft flying qualities evaluations and specification development are based on results obtained from the use of this scale tempered with actual task performance data. Military flying qualities specifications typically quantify acceptability in terms of flying qualities levels. Explicit in the definition of these levels is not only pilot workload, but also mission task performance as indicated in Figure 1.

MIL-F-83300\textsuperscript{2} and MIL-F-8785C\textsuperscript{3} have been used to define the flying qualities requirements for many military V/STOL aircraft. These requirements are established with respect to the flying qualities levels as defined above. Most Navy aircraft in normal state conditions are required to exhibit Level I flying qualities. This level of flying qualities is required even during the more demanding tasks intended to be flown and in the more adverse environments expected to be encountered. In general Navy aircraft will be required to perform routine and tactical flight operations satisfactorily (including high-speed terrain following flight and shipboard operations) in adverse weather and combat conditions.\textsuperscript{4}

General Latency Effects and Flight Control System (FCS) Latency Specifications

The effect of time delays on flying qualities is common knowledge in the flying qualities community. In summary, data from numerous experiments indicates that time delays reduce closed-loop system stability, thereby increasing pilot workload and degrading task performance. These data further indicate that latency will have an increasingly detrimental effect as task difficulty, aggressiveness and precision requirements are increased.

The data referenced above was generated in experiments designed to identify the effects of FCS latency and has been used to define FCS latency limits. Shown in Table 1, these limits have been associated with handling qualities levels and incorporated into military flying qualities specifications.\textsuperscript{2,3}

The time delay limits shown are typical of delay limitations associated with high difficulty/high gain/high precision tasks and may appear conservative. However, it should be noted that most experiments used to support these limits have investigated delay effects with delays inserted in only a single axis of control. Delays in all axes, which is more representative of a real system may result in an even more severe degradation than that indicated above. In this sense, the specifications may be liberal.

**Definition of a Closed-Loop System**

A simplified closed-loop system is illustrated in Figure 2 and includes airframe, control, pilot and information components. A typical loop closure will involve pilot control of an aircraft state or flight parameter. During control, the pilot will attempt to minimize the difference or error between a reference or desired value of the selected state and the actual or perceived value of the selected state. Information on the reference value, controlled parameter and the error between the two will be available to the pilot through outside world visual cues, motion cues and displays. To close the loop, the pilot will apply control proportional to the error.

As an example, consider a precision approach to a ship. The pilot's goal is to track the instrument landing system (ILS) beacon, both vertically (glideslope) and laterally (localizer), with precision sufficient to allow a safe landing. Outer loop control is accomplished with closure around the pilot's reference parameters, glideslope angle, localizer and recovery heading. Inner loop control is accomplished with closure around descent rate, airspeed, and pitch and roll attitude.

Since precise glideslope and localizer error are available only from the displays, the displays can be considered the primary source of information in the above task. This is clearly the case during an approach with degraded visibility, where the displays are the pilot's only reliable source of flight information. Under these circumstances, the pilot would find it difficult, if not impossible, to distinguish between display dynamics, control dynamics and airframe dynamics. The effect of a delay in displayed information could, therefore, be considered equivalent to the effect of an airframe or control delay of the same magnitude.

The most severe delay-induced degradations in flying qualities are expected during high difficulty, high gain, high precision tasks requiring the use of displays as the primary source of flight information. In particular, the concern lies with the performance of manual, high frequency, precision control of aircraft attitude, position and vertical speed in degraded visual conditions (instrument meteorological conditions (IMC), visual meteorological conditions (VMC) with an obscured horizon, and night VMC). Under these circumstances, the head-down displays or helmet-mounted displays would most likely be used to provide the required flight information, either alone or superimposed on a Forward Looking Infra-red (FLIR) image.

**FLIGHT SIMULATION INVESTIGATIONS AND RESULTS**

Two manned flight simulations, one in an engineering simulator and one in a high fidelity developmental simulator, were conducted to generate data specific to avionics or display system latency effects on aircraft flying qualities. The first, conducted in a basic engineering simulator to generate initial data, simulated avionics system latency which was swept from 47 ms to 447 ms. The second, conducted in a high fidelity developmental simulator to produce high quality data, was conducted with latency values varying from 70 ms to 240 ms.

A precision approach task was selected as the primary task for the simulation. Performance constraints were established based on mission or safety requirements. Adequate performance constraints were based on maximum safe or
acceptable spatial deviations. Desired performance constraints were established as limits reflecting a desired margin of performance or safety beyond adequate performance constraints. The tasks and the corresponding performance constraints are described below.

Unless specified otherwise, "Latency", "Delay", "Display Delay" and are used in short for "Avionics System Latency" in the following text.

Engineering Simulation
Simulation Facility
This investigation utilized a fixed-base engineering research simulator. This simulator employs standard fixed-wing controls: center stick, pedals, and throttle. The computer generated outside-world image is projected onto a single, forward screen. For this investigation, primary flight information was superimposed on the outside-world image in a standard uncluttered format. This format presented glideslope as a fly-to horizontal bar and localizer as a fly-to vertical bar. Range and airspeed data were digitally represented. The symbology is shown in Figure 3.

The aircraft model used was a generic medium weight, medium agility fixed-wing aircraft with level I baseline handling qualities.

Evaluation Task
The primary task consisted of a precision approach on a 3.5 degree glideslope to a ship. Environmental conditions were extremely limited visibility and crosswinds up to 45 kt. Direction and magnitude were selected at random, prior to each evaluation run. The initial conditions were glideslope (GS) and localizer (LOC) offsets of 1 degree and 5 degrees, respectively. These were combined randomly to result in four initial positions: above GS and left of LOC, below GS and right of LOC, etc.. Range at the initial position was 24000 ft. Trim approach speed was 128 kt.

The pilot was instructed to capture GS/LOC prior to reaching a 15,000 ft range and to track GS/LOC to 1,500 ft range within the following performance tolerances:

- Desired
  - ± 5 kt
  - ± 1/4 degree GS
  - ± 1 degree LOC

- Adequate
  - ± 10 kt
  - ± 1/2 degree GS
  - ± 2 degrees LOC

A given level of performance was to be maintained for at least 80-percent of the approach (between 15,000 and 1,500 ft range) for that level to be considered achievable during evaluation.

A secondary task was used to examine the effect of side task workload on primary task performance. This secondary task consisted of the pilot physically setting and verbally repeating the barometric altitude pressure reference to random values called by the engineer every 3000 ft range (with the last call made at 4000 ft). No degradation in performance was tolerated in this task.

Latency Matrix and Evaluation Technique
Limited by hardware, minimum achievable simulated delays were 57 ms flight controls (from stick displacement to aircraft motion) and 47 ms displays (from aircraft motion to head-up display update). The matrix of delay configurations evaluated is shown in Table 2.

Two Marine Corps operational test and evaluation pilots performed as evaluation subjects. Each pilot was given between four and eight hours familiarization time. During evaluation, each pilot was given as many runs as necessary to confidently assess achievable task performance and his workload. This technique resulted in as many as eight flights per delay configuration evaluation (single pilot rating). Further, each pilot evaluated each configuration at least twice.

Results
Result are presented in the form of pilot ratings and sample time histories of stick activity and tracking error. Pilot ratings as a function of display delay are shown in Figure 4. Sample longitudinal and lateral stick activity with glideslope and localizer tracking error are shown in Figure 5 and 6, respectively.
Evaluation Task

Again, the evaluation involved the performance of a precision approach task. This task is similar to that of the engineering simulation. The precision approach task was flown at 85 kt (75° in) on a 3.5 degree glideslope. Environmental conditions consisted of mild-to-moderate turbulence with a mild (10 kt) windshear (between 1000 and 100 ft AGL) in addition to a moderate (20 kt) crosswind. A ceiling was simulated at 300 ft AGL. A constant altitude, 30 degree ILS intercept profile was flown from the initial conditions. Tracking constraints for evaluation were identical to those used in the engineering simulation, with one exception. The pilots were instructed to place emphasis on the performance and the workload near decision height, 200 AGL, which was the task termination point.

The approach configuration flown was at 120 kt, 60° nacelle angle (in) and represented a nominal combat or expedited recovery. Environmental conditions were fixed with mild-to-moderate turbulence, 10 kt windshear, 20 kt crosswind, 200 ft ceiling. As illustrated in Figure 7, initial positions were located at 5.9 nm range with randomly selected offsets of 1 degree in glideslope and 5 degrees in localizer. The initial heading corresponded to the recovery heading with a minor trim adjustment for the crosswind.

The pilot was instructed to maneuver from his initial position to intercept glideslope and localizer by 4.8 nm range and to track glideslope and localizer to decision height (300 ft AGL). For evaluation purposes the task began at initial glideslope and localizer intercept and terminated at decision height.

Tracking constraints were also similar to those used in the engineering simulation, with additional emphasis placed on the last half of the approach. Because of the evolution of these constraints, they are summarized in Table 3. Precision approach flight symbology was mildly cluttered with a vertical bar for localizer, and an arrow indicator for the glideslope and is shown in Figure 8. The above desired, geometric, GS and LOC constraints corresponded to 1/2 of a display tic and 2/3 of a display tic, respectively. Airspeed was indicated with a digital numeric display.

High Fidelity Simulation

Simulation Facility

The fixed-base simulator used in this investigation employs a representative tilt-rotor cockpit with a multi-window, high-resolution, computer-generated, outside-world image. The simulator mathematical model represents a low to medium agility medium weight tilt rotor aircraft.

Latency Matrix, Pilots, Evaluation Technique

i. Latency Matrix - The FCS latency was fixed at 50 ms. Three display latency configurations (73, 179, and 241 ms) were evaluated.

ii. Pilots - Four military test pilots served as evaluation subjects. The pilots and their backgrounds are listed in Table 4.

iii. Evaluation Technique - Each pilot underwent extensive familiarization prior to evaluations. This familiarization was accomplished with the mini-
mum latency and proceeded as follows. Each pilot took approximately 1 hour of free-flight without turbulence or wind to become familiar with the cockpit and math model. An additional 2 hours was taken by each pilot to fly approximately 20 precision approaches with and without turbulence and wind. During evaluations, the pilots provided an HQR following each run. A complete evaluation consisted of, at least, three runs. When both the pilot and the engineer were satisfied that the delay configuration had been adequately evaluated, the engineer informed the pilot that the delay configuration was to be changed and the next evaluation commenced. The pilot was not informed of the latency value during evaluations. Each pilot performed a minimum of two evaluations per latency configuration.

Results

Among all pilots, 254 approaches were flown during six days of simulation. Results presented here take the form of pilot ratings and tracking performance as a function of display delay. Pilot rating data is shown in Figure 9. Tracking performance, in terms of time outside desired glideslope envelope, weighted time outside desired glideslope envelope, and time outside adequate glideslope envelope, is shown in Figures 10, 11, and 12 respectively.

Localizer tracking and airspeed maintenance performance is not shown for the following reasons:

- with two exceptions in 254 runs, airspeed error was within desired performance constraints for all values of latency evaluated;

- even though lateral-axis workload seemed to increase as latency increased, no trend in localizer tracking error as a function of latency was apparent;

- glideslope tracking performance drove both pilot ratings and comments.

Returning to the glideslope tracking performance data shown in Figures 10, 11, 12, several issues are worth mentioning. First, these data represent the last 60 seconds of the task (from approximately 1000 to 300 ft. AGL). Following the time constraints and evaluation emphasis specified, 12 seconds (20% of 60 seconds) can be considered the time constraint associated with desired performance. Any runs with excursions outside of the desired glideslope envelope beyond 12 seconds, during the last 60 seconds of the task, were considered to have, at best, adequate performance. Second, examining time outside of constraints as an isolated performance metric may be misleading if the magnitude of the angular excursion is inversely related to the time of the excursion. To examine this possibility, the time of the excursions were weighted by the corresponding magnitude of the excursions outside of the desired glideslope envelope. These weighted values are plotted in Figure 11. A trend similar to that of the unweighted data exists. This indicates that time outside of constraints may legitimately be used as a measure of performance.

Finally, considering adequate performance (Figure 12) and following the time constraints and evaluation emphasis, 5 seconds can be considered the time constraint associated with adequate performance. With the time constraint defined, specifying that "exceedance of adequate performance constraints for 5 seconds or more could not be considered desired," any excursion beyond 5 seconds could legitimately be classified as either adequate or inadequate. Nearly all excursions outside of the adequate glideslope envelope occurred, however, just prior to decision height. The pilots, observing the emphasis on performance near decision height, typically classified the excursions beyond the adequate glideslope envelope of 5 seconds or more as inadequate.

Examining the results, one general observation can be made:

A handling qualities degradation with increasing display delay is apparent in both the pilot ratings and tracking performance.

The nature of this degradation and its applicability to defining an acceptable level of latency is discussed in the following section.

DEFINING AN ACCEPTABLE LATENCY LEVEL

When attempting to define a limit on any flying qualities parameter, several criteria may be considered:

- achievement of Level I handling qualities
- achievement of desired performance (note that achievement of desired performance does not mean that Level I handling qualities are achievable; Level II handling qualities (HQR 4) could result if workload is moderate or greater - see Figure 1)
- avoidance of inadequate performance

Regarding these criteria the results will first be considered in isolation. A discussion of the issues affecting the definition of delay limits will be discussed subsequently.
NOTE: The data shown above are the result of two modifications of the raw data. During the evaluation process pilots were permitted to give a rating of 4.5 for either of two reasons: desired performance was achievable with maximum pilot compensation only adequate performance was achievable but with minimal pilot compensation. Ratings of 4.5 with desired performance achievable and 4.5 with adequate performance achievable were redistributed to HQR 4 and 5 respectively. The other modification involved adjustment of ratings to reflect corresponding actual performance. In this case, the minimal possible adjustments were made only when the original rating clearly was not supported by actual performance. Here, 3, 1, and 8 ratings were adjusted at 70, 170, and 240 ms, respectively. Neither of these modifications altered the true nature of the results.

Figure 9. Handling Qualities Ratings for Precision Approach
tracking performance through a reduction in time outside of constraints is apparent with decreasing latency. A continuation of this trend, although shallow, is reasonable to assume if latency were dropped below 70 ms. It may also be reasonable to assume based on the available data that, as latency is reduced below 70 ms, workload would first incrementally decrease and then level off at some baseline. Taken together, these observations and assumptions lead to the conclusion that reducing latency below 70 ms should result in consistent Level I handling qualities.

Achievement of Desired Performance

Workload is not a consideration when applying this criteria. Tracking performance may therefore be examined directly. For this purpose, time outside of the desired glideslope envelope as a function of latency is shown in Figures 13 A, B, C.

The probability bands in Figure 13 are defined by the worst 10, 20, or 30 percent of the main body of the performance data. Examination of these bands reveals the nature of latency effects on flying qualities. The following observations are made regarding achievement of desired performance.

- As latency increases, an increasing rate of performance degradation is apparent.
- Extrapolating the bands below 70 ms, very little performance benefit is expected with a latency reduction below 70 ms.
- If an increased probability of exceeding overall desired performance constraints is tolerable, then a higher latency is acceptable. As an example, if a 10-percent probability of exceeding desired constraints is tolerable, then a latency of 120 ms is acceptable. If a 20 percent probability of exceeding desired constraints is tolerable, then a latency of 170 ms is acceptable.

However, noting that there are significant occurrences of inadequate performance at 170 and 240 ms (see Figure 9), avoidance of inadequate performance must be considered.

Achievement of Level I Handling Qualities

In applying the first criterion, pilot rating data (Figure 9) and performance data (Figure 10) must be examined. From Figure 9, it is apparent that, although there is a clear improvement in handling qualities between 170 and 70 ms, consistent Level I handling qualities are still not achievable at 70 ms. Further, from Figure 10, an improvement in
Avoidance of Inadequate Performance

Tracking performance can also be examined directly in this section. Here, however, time outside of adequate glideslope envelope is used in the analysis. As in Figure 13, the probability bands shown in Figures 14 A and B are defined by the worst 10 and 20 percent of the main body of the performance data.

Examination of these bands provides additional insight into the effects of latency on flying qualities. The following observations can be made regarding the avoidance of inadequate performance:

- A linear degradation in tracking performance and consistency with increased latency is apparent.
- Extrapolating the bands below 70 ms, a substantial performance benefit is expected with a latency reduction below 70 ms. This extrapolation indicates that below 10 to 20 ms no excursions outside of adequate constraints would occur.
- If an increased probability of exceeding overall adequate performance constraints is tolerable, then a higher latency is acceptable. As an example, if a 10-percent probability of exceeding adequate constraints is tolerable, then a latency of 150 ms is acceptable. If a 20-percent probability of exceeding adequate constraints is tolerable, then a latency of 240 ms is acceptable.
ISSUES AFFECTING DEFINITION OF A LATENCY LIMIT

Due to the origin and quantity of data used in the analysis, the following issues must be considered when applying the results of the previous section to definition of a latency limit:

- Data Quality
- Simulation vs. Actual Flight
- Simulation Fidelity
- Cues Available to the Pilot
- Pilot Gain
- Severity of Task/Environment
- Training

Data Quality

The data used in the previous analysis were generated under controlled conditions using accepted flying qualities evaluation techniques. The evaluation pilot population was diverse and representative of the general pilot population. Minor adjustments were made to the pilot rating data to better reflect actual performance; actual performance data were used "as is."

A general qualitative check on both the experiment and data validity can be made by examining the trends in Figures 10, 13, and 14. These trends are what is physically expected from the effects of latency on tracking performance and workload.

Based on the above, the data used in the analysis are considered to be "high quality."

Simulation vs Actual Flight

Motion cues are not available in a fixed-base simulator. As a result, lead information available through actual commanded aircraft acceleration was not available. In the task used in evaluation this is not a factor for several reasons. First, tracking error information is only available to the pilot from the display. Motion cues do not provide any tracking error information. Even though motion cues aid inner-loop control this provides only marginal benefit in a primary visual tracking task. Second, during precision approach in IMC, the displays are the only reliable source of flight information. Anomalous aircraft motion cues, from both the pilot's head orientation and turbulence, force the pilot to rely on display information for an accurate assessment of the flight condition. A detrimental effect, if any, is expected due to the display latency induced mismatch between actual dynamics and display dynamics.

Finally, pilot gain would be higher in flight than in the simulator. Pilots would be less tolerant of tracking errors. This tolerance change would manifest itself through an increase in control activity. In turn, this increase in control activity would accentuate the effects of latency.

Therefore, given the same task, configuration and conditions, tracking performance and workload in flight are expected to be worse than that in the simulator.

Severity of Task and Environment

The precision approach evaluation task used was representative of a nominal combat or expedited recovery in IMC. This task should be able to be performed with Level I handling qualities. Potentially more demanding tasks such as terrain following or target tracking have not been explored.

The wind and turbulent environment can be classified as mild to moderate. Much more severe environments are frequently encountered in the field.

A lower limit than that associated with a nominal precision approach may be required to ensure satisfactory performance of potentially more demanding tasks or nominal tasks in more severe environments.

Training and Pilot Compensation Techniques

Pilots, with sufficient training will develop delay compensation techniques. In compensation, the pilot would reduce his input magnitude and frequency. This technique would not only allow the aircraft and display to respond, but also limit the response magnitude to a controllable level. This technique, by its nature prohibits high frequency precision control, and requires the acceptance of task performance degradations.

Another technique that can be used is lead compensation. This technique involves an initial control overshoot by the pilot to quicken the response followed by a reduced steady state input to limit the response magnitude. As with lead compensation implemented with the avionics or FCS, pilot lead is effective, but only over a given frequency range. Furthermore, this technique, by its nature, requires the pilot to stay in the control loop, with his energy split between two primary control frequencies, one associated with his application of lead (high frequency), and one associated with the fundamental task requirements.

Under normal conditions, pilot compensation can be effective. In emergency conditions or during sudden severe disturbances, the pilot tends to abandon compensation techniques instinctive control. Under these circumstances, the pilot will increase input magnitude and frequency in an attempt to retain control of his aircraft. This, however, accentuates the detrimental effects of latency and only aggravates the control problem. In the extreme, an aircraft with large delays, but readily controllable with appropriate pilot compensation, will become uncontrollable in emergency conditions or during sudden severe disturbances.
Negative training is also an issue. Although the compensation techniques described above can be effective with large delays, they can be detrimental if applied to a system with low delays. If compensation techniques used in IMC are retained in performance of a visual task, a degradation in task performance and increase in workload are expected.

Integrating the above issues, the net impact on the application of the simulation data is minimal. Any latency limit, based on analysis of the previously presented simulation data, is expected to be applicable to an actual production aircraft.

CONCLUSIONS

The results from the Navy simulations correlate well. These studies further indicate that performance and flying qualities degradations can be expected to occur with increasing avionics system latency. Considering the simulation data, several latency limits are suggested.

- 70 ms or below to ensure Level I handling qualities.
- 120 ms or below to ensure desired performance (with a maximum 10-percent probability of exceeding constraints).
- 150 ms or below to ensure the avoidance of inadequate performance (with a maximum 10-percent probability of exceeding adequate performance constraints).

These limits were established from analysis of data generated during simulation where the flight control latency was 50 ms. If actual flight control latency differs significantly from 50 ms, the above limits must be examined from a system latency point of view.

ACKNOWLEDGEMENTS

The authors would like to thank pilots USAF Maj. Joe Bonin, USMC Majs. Kevin Dodge and Doug Isleib, and USA CW04 Reggie Murrell for participating in the study.
