

VCSEL, designed to operate in the wavelength range of  $795 \pm 3$  nm, that was generating about 200  $\mu$ W of optical power. (The use of relatively high injection

power levels is a usual practice in injection locking of VCSELs.)

## Measuring Multiple Resistances Using Single-Point Excitation

*Lyndon B. Johnson Space Center, Houston, Texas*

In a proposed method of determining the resistances of individual DC electrical devices (e.g., batteries or fuel-cell stacks containing multiple electrochemical cells) connected in a series or parallel string, no attempt would be made to perform direct measurements on individual devices. Instead, (1) the devices would be instrumented by connecting reactive circuit components in parallel and/or in series with the devices, as appropriate; (2) a pulse or AC voltage excitation would be applied at a single point on the string; and (3) the transient or

AC steady-state current response of the string would be measured at that point only. Each reactive component(s) associated with each device would be distinct in order to associate a unique time-dependent response with that device.

Using the known time-varying voltage excitation, the known values of inductance and/or capacitance, and the standard equation predicting the response for the known circuit configuration, the time-varying current response would be subjected to nonlinear regression analysis. In essence, this analysis would yield in-

dividual device resistances that result in a best fit between the predicted and actual time-varying current responses.

## Improved-Bandwidth Transimpedance Amplifier

*NASA's Jet Propulsion Laboratory, Pasadena, California*

The widest available operational amplifier, with the best voltage and current noise characteristics, is considered for transimpedance amplifier (TIA) applications where wide bandwidth is required to handle fast rising input signals (as for time-of-flight measurement cases). The added amplifier inside the TIA feedback

loop can be configured to have slightly lower voltage gain than the bandwidth reduction factor (the ratio of the input capacitance plus the feedback capacitance to the feed capacitance). This innovation enables the optimization of design based on suitable space-approved operational amplifiers and provides better, stronger

performance under radiation and wide temperature variations. In many cases, this approach can eliminate the need to qualify new amplifiers.

## Inter-Symbol Guard Time for Synchronizing Optical PPM

**This method would involve less computation than does the pilot-symbol method.**

*NASA's Jet Propulsion Laboratory, Pasadena, California*

An inter-symbol guard time has been proposed as a means of synchronizing the symbol and slot clocks of an optical pulse-position modulation (PPM) receiver with the symbol and slot periods of an incoming optical PPM signal. (Such synchronization is necessary for correct identification of received symbols.) The proposal is applicable to the low-flux case in which the receiver photodetector operates in a photon-counting mode and the count can include contributions from incidental light sources and dark current. The use of the inter-symbol guard time would be an alternative to a prior syn-

chronization method based on the periodic transmission of a fixed pilot symbol.

The proposal involves a modification of conventional  $M$ -ary optical PPM, in which each successive symbol period is divided into  $M$  time slots (0, 1, 2, ...,  $M-1$ ), each slot being of duration  $T_s$ . Each time slot represents a different symbol in an alphabet of up to  $M$  symbols. At the transmitter, during each time slot, a laser either transmits a pulse or no pulse, depending on which symbol is to be sent. Synchronization of the receiver symbol and slot clocks is necessary because the task of the receiver is to determine which

of the  $M$  possible symbols has been received by observing the photon counts accumulated during each of the  $M$  time slots of a symbol period.

In both the prior method and the method now proposed, the basic idea is to estimate the symbol and slot timing boundaries of the received signal by correlating the received-signal counts with a known component of the transmitted signal while taking account of the fact that the received-signal counts are related to the received-signal intensity through a Poisson distribution. In the prior method, the known component of
