We present the first observation of magnetic fluctuations consistent with 5 Short Large-Amplitude Magnetic Structures (SLAMS) in the foreshock of 6 the planet Venus. Three monolithic magnetic field spikes were observed by 7 the Venus Express on the 11th of April 2009. The structures were  $\sim 1.5 \rightarrow 11s$ 8 in duration, had magnetic compression ratios between  $\sim 3 \rightarrow 6$ , and exhibited 9 elliptical polarization. These characteristics are consistent with the SLAMS 10 observed at Earth, Jupiter, and Comet Giacobini-Zinner, and thus we hy-11 pothesize that it is possible SLAMS may be found at any celestial body with 12 a foreshock. 13

14

## 1. Introduction

The foreshock is the region of space upstream from a celestial body which is magnet-15 ically connected to the bow shock [Eastwood et al., 2005]. It is pervaded by a field of 16 ULF waves [Fairfield, 1969; Scarf et al., 1970] which are thought to be driven by field-17 aligned ion beams reflected at the bow shock [Tsurutani and Rodriguez, 1981; Hoppe and 18 Russell, 1983], or produced locally [Hellinger and Mangeney, 1999; Mazelle et al., 2003; 19 Meziane et al., 2004]. ULF waves have been observed at many planets including Venus 20 [Hoppe and Russell, 1981], Jupiter [Tsurutani et al., 1993b], and at interplanetary shocks 21 Tsurutani et al., 1983]. The waves attempt to propagate upstream, but are convected 22 back toward the bow shock by the solar wind. As they convect deeper into the foreshock, 23 they enter regions of higher diffuse ion density. These ions alter the index of refraction 24 for the medium causing transverse modes to become compressive, and thus the waves can 25 steepen [e.g. Wilson et al., 2009; Tsubouchi and Lembèqe, 2004; Tsurutani et al., 1987, 26 and references therein]. They become more oblique and compressional the deeper they go. 27

28

One of the possible resulting foreshock phenomena are Short Large-Amplitude Magnetic Structures (SLAMS), pulsations believed to steepen out of the background ULF wave field due to the interaction with diffuse ions [e.g. *Scholer et al.*, 2003; *Dubouloz and Scholer*, 1995]. As the waves convected back toward the bow shock, the different wave fronts (i.e. wave crests and troughs) cause a differential slowing of the incident solar wind flow which leads to the refraction of the waves. As the amplitude of the SLAMS increases, their phase speed also increases. *Dubouloz and Scholer* [1995] found that SLAMS are left hand

DRAFT

August 27, 2012, 1:05pm

polarized in the plasma frame, that both upstream and downstream edges steepen, and that some pulsations appear to nearly stand against the incident flow. SLAMS are distributed over a transition region of 2-3  $R_E$ , with individual scale sizes of  $\sim 700 \rightarrow 1000 km$ , or  $\sim 10 \rightarrow 15$  ion inertial lengths.

40

<sup>41</sup> SLAMS are elliptically polarized and compressive characterized by brief (5 - 20s) mono-<sup>42</sup> lithic spikes in magnetic field magnitude (|B|), with compression ratio ( $\delta B/B_0$ ) between 2 <sup>43</sup> to 5 times the background field [*Schwartz*, 1991; *Tsurutani et al.*, 1993a; *Schwartz et al.*, <sup>44</sup> 1992; *Dubouloz and Scholer*, 1993]. They are commonly observed in the quasi-parallel <sup>45</sup> (i.e. where the angle between the magnetic field vector and the normal to the bow shock, <sup>46</sup>  $\theta_{Bn} < 45^{\circ}$ ) foreshock when and where the Interplanetary Magnetic Field (IMF) lies quasi-<sup>47</sup> parallel to the bow shock normal [*Schwartz*, 1991].

48

As SLAMS convect Earthwards, their phase speed increases as their amplitude increases [*Omidi and Winske*, 1990]. Thus their motion relative to the planet decreases, and they coalese together to form the complex three-dimensional patchwork of the quasi-parallel shock [*Schwartz and Burgess*, 1991; *Lucek et al.*, 2008] (although not all observations of quasi-parallel shocks are thought to obey this paradigm [*Burgess*, 1995]). Thus, understanding SLAMS is crucial to understanding how the Earth's shock forms under certain IMF conditions.

56

<sup>57</sup> The first extra-terrestrial observation of "steepened magnetosonic waves" consistent with <sup>58</sup> SLAMS was made by *Tsurutani et al.* [1990] at Comet Giacobini-Zinner. The pulses ex-

DRAFT

hibited compression ratios ( $\delta B/B_0$ ) of 2.3 to 7.0, had full-width half-maximum durations 59 from 12 to 72s, comparable to the  $H_2O$  group ion gyroperiod (67s in a 15nT field), and 60 were circularly polarized with right-hand rotation in the spacecraft frame. Later Tsuru-61 tani et al. [1993a, b] reported the discovery of large-amplitude magnetic pulses upstream 62 of the Jovian bow shock by *Ulysses*. The magnetic pulses they reported were similar to 63 SLAMS in that they were planar elliptically polarized structures, although their peak am-64 plitudes were lower  $(0.5 \rightarrow 2 |B_0|)$  than typically observed at the Earth, and the duration 65 of the pulses was much longer ( $\sim 1$  minute). 66

67

In this paper we present the first observations of magnetic pulsations consistent with 68 SLAMS in the Cytherean foreshock by the ESA Venus Express [Svedhem et al., 2007] 69 magnetometer [Zhang et al., 2006]. We also present supplementary data from the Anal-70 yser of Space Plasmas and Energetic Atoms (ASPERA) Electron Spectrometer (ELS) 71 [Barabash et al., 2007], although direct measurement of the plasma properties of the 72 SLAMS were not possible due to limits in the temporal resolution, and low sensitivity 73 [Collinson et al., 2009] owing to a reduced geometric factor [Collinson et al., 2012b] of 74 ASPERA-ELS. 75

76

<sup>77</sup> Our paper is outlined as follows: In section 2 we present a global overview of the Cytherean <sup>78</sup> foreshock encounter by the *Venus Express* on the 11th of April 2009; In section 3.1 we <sup>79</sup> present observations of the  $\sim$ 2 minute period in which three SLAMS were observed; In <sup>80</sup> section 3.3 we present an example of our analysis of the magnetic field data from an <sup>81</sup>  $\sim$ 11 second period containing three SLAMS; and in section 4 we summarize our find-

DRAFT

August 27, 2012, 1:05pm

<sup>82</sup> ings and compare the Cytherean SLAMS with their Terrestrial, Jovian, and Cometary
 <sup>83</sup> counterparts.

## 2. Overview of Cytherean upstream conditions on the 11th of April 2009

In this section we present data from the  $\sim 12$  minute period that begins in the distant foreshock region where magnetic fluctuations consistent with SLAMS were observed, continues through the three bow shock crossings observed that day, and ends when the *Venus Express* goes into the magnetosheath for the third and final time. This global overview puts our later description of Cytherean SLAMS into context.

## 2.1. Review of Cytherean induced magnetosphere

Although Venus has no intrinsic magnetic field [Smith et al., 1965], its conductive iono-89 sphere creates an impassable barrier to the IMF [Zhang et al., 1991]. Magnetic field lines 90 frozen into the solar wind flow collide with the planetary ionosphere and pile up on the 91 day-side, resulting in the generation of an induced magnetosphere [Zhang et al., 2008]. 92 This induced magnetic field is an obstacle to the supersonic solar wind and thus a su-93 personic bow shock is generated [Ness et al., 1974; Russell et al., 1979]. The stand-off 94 distance of the Cytherean bow shock is much less than that at the Earth, with a closest 95 altitude of ~1.5 Venus Radii ( $R_V$ ) [Slavin et al., 1980], as compared to  $\approx 15 R_E$  [Fairfield, 96 1971]. The Venus Express is in an elliptical quasi-polar orbit with a period of  $\sim 24$  hours, 97 with an apogee over the south pole of  $\approx 12R_V$  [*Titov et al.*, 2006] and perigee inside the 98 ionosphere over the north pole of  $\approx 1.04 R_V$ . 99

## 2.2. Map of Orbit 1086

Figure 1 shows a map of the relevant orbit (1086) on the 11th of April 2009. Panels A, 100 B, and C show the orbital encounter in Venus Solar Orbital (VSO) coordinates, where x101 points towards the sun, y points back along the orbital path of the planet, and z points 102 out of the plane of the ecliptic completing the right-hand set. Panel D shows the course 103 of the Venus Express in cylindrical coordinates, where the x-axis points towards the sun, 104 and the y-axis represents the radial distance from the planet ( $R = \sqrt{(y^2 + z^2)}$ ). This 2D 105 cylindrical projection allows us to plot the positions of the observed bow shock crossings 106 and SLAMS in relation to the idealised bow shock (black line) of *Slavin et al.* [1980]. The 107 blue line represents the path of the Venus Express, the pink circles denote the locations 108 of observed bow shock crossings, the vellow stars denote the location where SLAMS were 109 observed, and the light blue line running parallel to the orbit for a distance between 110  $\sim 2.5 R_V \rightarrow 1.9 R_V$  shows the part of the orbit from which we present data in this section. 111 112

As can be seen from Figure 1, Venus Express was approaching the planet along the flanks, from a latitude of ~78°. The position of the Cytherean bow shock is known to be highly variable [Slavin et al., 1980; Russell et al., 1988; Martinecz et al., 2008], and three distinct bow shock crossings were observed on the 11th of April 2009. The furthest crossing was significantly further away from the planet than expected from an idealized hyperbolic model  $(2.3R_V \text{ vs. } 1.8R_V)$ .

#### 2.3. Magnetometer and Electron Spectrometer observations

Figure 2 shows magnetometer and ASPERA-ELS measurements from between 02:42:30 and 02:54:30 (The period of the orbit highlighted by the light blue line in Figure 1).

Panel A presents a color-coded timeline showing which of the three regions of space (solar 121 wind, foreshock, magnetosheath) the spacecraft was occupying at any given time. The 122 three bow shock crossings are highlighted with pink circles and vertical dotted lines that 123 have been extended throughout the Figure. The magnetic pulsations which we examine 124 in detail are denoted by yellow stars. The light blue track (in Panel A) running parallel 125 to the timeline from 02:43:00 to 02:45:10 highlights the period of the main event where 126 these magnetic pulsations were observed, and will be covered in more detail in Figure 3 127 and accompanying Section 3.1. 128

129

Panels B through E present the four magnetic field components  $(|B|, B_x, B_y, B_z)$  in VSO 130 coordinates, respectively. The black line is the full 32 samples per second resolution data 131 and the red line is the same data set averaged at  $\frac{1}{4}$  samples per second so that trends can 132 be more easily identified. Panel F shows a plot of the shock normal angle,  $\theta_{Bn}$ , between 133 an extension of the local magnetic field vector to a model bow shock drawn according 134 to Slavin et al. [1980]. Periods when there is no data in panel F indicate when there 135 was no connection between the magnetic field and the model bow shock. Panel G shows 136 an electron spectrogram of the plasma observed by ASPERA-ELS. We have over-plotted 137 |B| (y-axis is arbitrary) to highlight trends between magnetic field magnitude and the 138 electron flux. 139

140

There were three encounters with the magnetosheath (marked in pink on the timeline) and associated bow shock crossings (pink circles). The clearest and best example is the final (right most in Figure 2) bow shock crossing at  $\sim 02:53:45$ , after which the magnetosheath

DRAFT

is clearly visible in panel G by an increase in |B|, and an increase in flux of electrons 144 over a broad range of energies, consistent with heating at the bow shock *Pérez-de-Tejada* 145 et al., 2011]. The two other transitions into the sheath at  $\sim 02:45:00$  and  $\sim 02:52:30$  were 146 brief, but are evident by the change the orientation of the magnetic field, an increase in 147 |B|, and an increase in electron flux consistent with that of the final bow shock crossing. 148 Thus the magnetic pulsations of interest (marked by yellow stars on the timeline, although 149 not yet visible at this scale) were observed shortly before a distant bow shock crossing at 150  $\sim 02:45:00.$ 151

152

The period preceding the earliest transition into the sheath from  $\sim 02:42:30$  until  $\sim 02:45:00$ 153 is much more turbulent than the solar wind. There was magnetic connectivity to the bow 154 shock, with  $(\theta_{Bn})$  initially near ~60°, and then fluctuating due to magnetic turbulence. 155 It is very important to recall that these angles are based on an idealised nominal bow 156 shock, and the distant bow shock crossing was  $\sim 0.5 R_V$  further away than predicted by 157 this model (see Figure 1). Given that this most distant magnetosheath crossing was very 158 brief (6.4s), and that it occurred so far from the nominal bow shock, this suggests that 159 this brief shift in the position of the bow shock was due a reaction to some unknown 160 external solar wind stimuli. 161

162

One possible explanation for this outward shift is a Hot Flow Anomaly (HFA) [*Collinson et al.*, 2012b]. HFAs are features that form in close proximity to the bow shock at the intersection of certain interplanetary discontinuities with the bow shock. The brief reductions in pressure associated with HFAs can enable both bow shock and magnetopause to

DRAFT

August 27, 2012, 1:05pm

move outward far beyond their mean positions [Sibeck et al., 1999]. HFAs exhibit greatly 167 heated populations of ions and electrons, as well as highly deflected flows. Consistent with 168 this interpretation, our event exhibited electron signatures consistent with heating, and a 169 rotation in the magnetic field. In the absence of high time resolution ion measurements, 170 we cannot comment on any concomitant flow deflections or ion heating. Regardless of the 171 presence or absence of an HFA, the turbulent magnetic field, magnetic connection to the 172 bow shock, and shock-like crossing at  $\sim 02:45:00$  suggest that the Venus Express was in 173 the foreshock, the region where SLAMS are expected at Earth. We will now take a closer 174 look at the period covered by the light blue parallel track on the timeline (Panel A.) of 175 Figure 2. 176

## 3. SLAMS at Venus

## 3.1. Overview of distant foreshock crossing containing SLAMS

Figure 3 shows the period when we observed the three magnetic fluctuations which we identify as SLAMS. We have highlighted three such fluctuations using a yellow bar and star on the timeline (Panel A) because they also exhibit a brief spike in |B|. The periods when the spacecraft was in the foreshock are marked by a purple bar on the timeline, and the brief ~6s Magnetosheath crossing is marked in pink with associated bow shock crossings marked by pink circles.

## 3.2. Observed properties of Cytherean SLAMS

The most obvious feature of the three magnetic pulsations highlighted in Figure 3 is the brief monolithic spikes in |B| at ~02:43:51, ~44:44, and ~44:58. The average compression ratio was ~4 times the background field. The pulsations had durations between

DRAFT

X - 12

 $\sim 1.5 \rightarrow 11$  seconds. Additionally, the  $(\delta B/B_0)$  of the leading edge of each increases from 186  $\sim 3 \Rightarrow 6$ , as Venus Express approaches the bow shock (or vice-versa). These magnetic 187 compression ratios are greater than 2, consistent with observations of SLAMS at the Earth 188 [Mann et al., 1994]. The compression ratios of the two later pulsations was greater than 189 the maximum factor of four for simple compression [Gurnett and Bhattacharjee, 2005], 190 which is also consistent with observations of SLAMS [Schwartz et al., 1992]. During the 191 pulsations, the magnetic fields rotate from a quasi-parallel orientation to a locally quasi-192 perpendicular orientation, consistent with observations of SLAMS by Mann et al. [1994]. 193 At and near the time of the pulsations there are intervals of nearly quasi-parallel bow shock 194 configurations, although the degree of turbulence is so great that there also disconnections. 195 As a whole, during the time of the events, we believe this to be a quasi-parallel bow shock. 196 197

## 3.3. Minimum variance analysis of Cytherean SLAMS

We performed minimum variance analysis (MVA) on subintervals of the time series 198 using multiple frequency filters to determine the propagation characteristics of the wave. 199 For more details about this technique, see *Wilson et al.* [2009]. This process was per-200 formed on the steepened leading (upstream) edge of the magnetic pulsations. Figure 4 201 shows magnetometer data from the eleven second period (02:43:50 to 02:44:01) showing 202 an example of a Short Large-Amplitude Magnetic Structure (SLAMS) at Venus. Panels 203 A to D show the data in VSO coordinates, where the black line is 32 samples per second 204 resolution, and the red line is the appropriate subinterval of this data with a 0.2 - 1Hz205 filter applied. Panels E and F of Figure 4 show hodograms of this filtered subinterval 206 of magnetic field data. Panel E is in VSO co-ordinates, and Panel F is the same data 207

DRAFT

<sup>208</sup> after MVA. All three of the magnetic structures analyzed were left-hand polarized in <sup>209</sup> the minimum variance direction. However, with only single spacecraft magnetic field ob-<sup>210</sup> servations, we cannot define the correct sign of this vector [*Khrabrov and Sonnerup*, 1998].

The magnetic field was rotated into field-aligned co-ordinates (not shown) to investigate 212 the polarization of the fluctuations with respect to the quasi-static magnetic field. The 213 first structure was highly complex. The leading edge spike (as shown in Figure 4) was 214 both right and left-hand polarized, whereas the trailing edge of the larger structure was 215 left-hand polarized in the spacecraft frame. The second (far shorter) structure was left-216 hand polarized in the spacecraft frame, and the third structure exhibited both left and 217 right handed components. These results are consistent with simulations [e.g. Dubouloz 218 and Scholer, 1995] and previous observations [e.g. Schwartz et al., 1992; Mann et al., 1994] 219 who found that pulsations showed left-hand and right-hand polarization in the simulation 220 (i.e. spacecraft) frame, with left-hand polarization in the plasma frame. However, it is not 221 possible to determine the wave polarization in the spacecraft frame using only magnetic 222 field observations with a single spacecraft. 223

224

<sup>225</sup> Panel F shows that the leading (upstream) edge of the structure was elliptically po-<sup>226</sup> larized, consistent with previous observations [Schwartz et al., 1992; Tsurutani et al., <sup>227</sup> 1993a; Dubouloz and Scholer, 1993]. Note that previous studies have referred to this <sup>228</sup> edge as the "trailing" edge [e.g. Schwartz et al., 1992]. The eigenvalues of the MVA were <sup>229</sup>  $(\lambda_{mid}/\lambda_{min}) = 101$ , and  $(\lambda_{max}/\lambda_{min}) = 1.6$ , which shows we have a nearly circularly polar-<sup>230</sup> ized wave. Our MVA analysis showed an average  $\theta_{\hat{\mathbf{k}}.\langle\hat{\mathbf{b}}\rangle} \approx \underline{61.7}^{\circ}$ , consistent with previous

DRAFT

August 27, 2012, 1:05pm

X - 14

<sup>231</sup> observations in the terrestrial foreshock [e.g. *Mann et al.*, 1994], and upstream of Comet <sup>232</sup> Giacobini-Zinner [*Tsurutani et al.*, 1990].

## 4. Summary and Discussion

In this paper we have reported the first observation of Cytherean Short Large-Amplitude Magnetic Structures (SLAMS) by the *Venus Express* Magnetometer. SLAMS are common features of the Earth's foreshock, and can be part of the 3D patchwork of magnetic structures that compose the quasi-parallel bow shock. We believe these magnetic pulsations to be SLAMS because they share the following properties with their terrestrial equivalents:

1. They were observed on interplanetary magnetic field lines connected to the bow
 shock, i.e. the foreshock, the region where SLAMS are observed at Earth.

241 2. We observed large-amplitude monolithic spikes in |B| that have compression ratios 242 greater than a factor of 2 above the background field,  $((\delta B/B_0)$  between  $\sim 3 \Rightarrow 6)$ , with 243 an average of  $\sim 4$ , consistent with previous observations [e.g. Schwartz et al., 1992; Mann 244 et al., 1994].

3. On the whole, the pulsations had higher compression ratios than can be explained by simple compression, consistent with pervious observations [Schwartz et al., 1992].

4. They exhibit left-hand elliptical polarization in the spacecraft frame, consistent with previous observations [*Lucek et al.*, 2004, 2008].

5. MVA analysis of one example revealed that it propagated obliquely to the ambient field with  $\theta_{\hat{\mathbf{k}}\cdot\langle\hat{\mathbf{b}}\rangle} \approx 61.7^{\circ}$ , consistent with SLAMS [Mann et al., 1994].

DRAFT

251

Our findings are consistent with *Tsurutani et al.* [1990], who reported solitary circularly 252 polarized magnetic pulses at comet Giacobini-Zinner, with typical peak-to-background 253 compression ratios of ~4, with  $\theta_{\hat{\mathbf{k}},\langle\hat{\mathbf{b}}\rangle}$  between 55° to 75°. The durations of the Cytherean 254 SLAMS were consistent with the  $\sim 10s$  typically reported at the Earth [Schwartz, 1991], 255 and shorter than the ~60s structures observed at Jupiter and  $12s \Rightarrow 72s$  at the Comet 256 (which *Tsurutani et al.* [1990] reported was comparable to the local H<sub>2</sub>O group gyroperiod 257 of 67s in a 15nT field). The duration of the monolithic peaks was  $\sim 1.5s \Rightarrow 11s$ , similar 258 to the local proton gyroperiod of 9.4s in a 7nT field. 259

260

Our calculation of  $\theta_{\hat{\mathbf{k}},\langle\hat{\mathbf{b}}\rangle} \approx 61.7^{\circ}$  is consistent with SLAMS acting like a local quasi perpendicular shock, consistent with previous interpretations [*Mann et al.*, 1994]. Compressional waves like this perturb the medium, increasing both |B| and plasma density which are in phase with one another [*Hellinger and Mangeney*, 1999]. However, it is not possible for us to compare any plasma perturbations with those known to occur at terrestrial SLAMS [*Giacalone et al.*, 1993; *Behlke et al.*, 2003; *Dubouloz and Scholer*, 1993] due to the limitations of ASPERA.

268

Though only three SLAMS were observed, the short period of the compressive leading edges  $(0.4s \Rightarrow 0.7s)$  means that they are only clearly visible in the full 32 sample per second resolution data, and are therefore not evident in browse plots. The three SLAMS presented here were discovered by chance during a survey of Cytherean Hot Flow Anomalies [*Collinson et al.*, 2012a], and further study is needed to determine if SLAMS are a

Figure 1. Map of the encounter on the 11th of April 2009, showing the trajectory of *Venus Express* (dark blue line), idealized bow shock according to *Slavin et al.* [1980] (black line), actual bow shock crossings, and the distance covered by the spacecraft during the period covered by Figure 2. Panels A-C are in VSO co-ordinates, Panel D in Cylindrical co-ordinates, where the x-axis points towards the sun, and the y-axis is the radial distance  $(R = \sqrt{y^2 + z^2})$  from the Venus/Sun line. All units are in Venus Radii.

COLLINSON ET AL.: SLAMS AT VENUS

2:42:30 to 2:54:30 Greenwich Mean Time.

Figure 3. Data from the *Venus Express* on the 11th of April 2009 covering a period from 2:43:00 to 2:45:10 GMT.

August 27, 2012, 1:05pm

Figure 4. Panels A-D: The magnetic signature of the elliptically polarized field spike within an example of Cytherean SLAMS, at ~02:43:51 GMT. Panel E: Hodograms of the same data after it has been processed with a  $0.2 \rightarrow 1Hz$  filter. Panel F: Hodogram of the same data in minimum variance coordinates showing the elliptical polarization of the SLAMS and full 360° rotation.
