NASA STI Program . . . in Profile

Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) program plays a key part in helping NASA maintain this important role.

The NASA STI Program operates under the auspices of the Agency Chief Information Officer. It collects, organizes, provides for archiving, and disseminates NASA's STI. The NASA STI program provides access to the NASA Aeronautics and Space Database and its public interface, the NASA Technical Reports Server, thus providing one of the largest collections of aeronautical and space science STI in the world. Results are published in both non-NASA channels and by NASA in the NASA STI Report Series, which includes the following report types:

- TECHNICAL PUBLICATION. Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- TECHNICAL MEMORANDUM. Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- CONTRACTOR REPORT. Scientific and technical findings by NASA-sponsored contractors and grantees.

- CONFERENCE PUBLICATION. Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- SPECIAL PUBLICATION. Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

- TECHNICAL TRANSLATION. English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services also include creating custom thesauri, building customized databases, organizing and publishing research results.

For more information about the NASA STI program, see the following:

- Access the NASA STI program home page at *http://www.sti.nasa.gov*

- E-mail your question to *help@sti.nasa.gov*

- Fax your question to the NASA STI Information Desk at 443–757–5803

- Phone the NASA STI Information Desk at 443–757–5802

Abstract

The occurrence of ice accretion within commercial high bypass aircraft turbine engines has been reported under certain atmospheric conditions. Engine anomalies have taken place at high altitudes that were attributed to ice crystal ingestion, partially melting, and ice accretion on the compression system components. The result was one or more of the following anomalies: degraded engine performance, engine roll back, compressor surge and stall, and flameout of the combustor. The main focus of this research is the development of a computational tool that can estimate whether there is a risk of ice accretion by tracking key parameters through the compression system blade rows at all engine operating points within the flight trajectory. The tool has an engine system thermodynamic cycle code, coupled with a compressor flow analysis code, and an ice particle melt code that has the capability of determining the rate of sublimation, melting, and evaporation through the compressor blade rows. Assumptions are made to predict the complex physics involved in engine icing. Specifically, the code does not directly estimate ice accretion and does not have models for particle breakup or erosion. Two key parameters have been suggested as conditions that must be met at the same location for ice accretion to occur: the local wet-bulb temperature to be near freezing or below and the local melt ratio must be above 10%. These parameters were deduced from analyzing laboratory icing test data and are the criteria used to predict the possibility of ice accretion within an engine including the specific blade row where it could occur. Once the possibility of accretion is determined from these parameters, the degree of blockage due to ice accretion on the local stator vane can be estimated from an empirical model of ice growth rate and time spent at that operating point in the flight trajectory. The computational tool can be used to assess specific turbine engines to their susceptibility to ice accretion in an ice crystal environment.

Nomenclature

A = Area, ft^2

c_{p_w}, c_{p_a} = Specific heat of water vapor, air, BTU/(lb_m-R)

$c_{p_{wet}}$ = Specific heat air-water vapor mix, BTU/(lb_m-R)

c_{p_i} = Specific heat of ice, BTU/(lb_m-R)

C = Blade chord, in

C_U = Tangential velocity of air, ft/s

D_v = Diffusion coeff. of water vapor into air

d = Ice particle size, diameter, μm

F_w, F_a = Molar flow rates of water vapor, air, mole/s

G = Ice growth rate, in/s

g_c = Unit conversion, 32.2 lb_m-ft/(lbf-sec^2)

h_m = Mass transfer coefficient, ft/hr

h = Convective heat transfer coefficient, BTU/(hr-ft^2-R)

ΔH_{melt} = Enthalpy change of ice and air

IWC = Ice water content, kg/m^3

J = Units conversion, 778.28 ft-lb_f / BTU

k = Thermal conductivity, BTU/(hr-ft-R)

L_v = Latent heat of evaporation, BTU/lb_m

Le = Lewis Number

L_f = Latent heat of freezing, BTU/lb_m

L_s = Latent heat of sublimation, BTU/lb_m

LWC = Liquid Water Content, kg/m^3

M_a,M_w = Molecular weight of air, water vapor

M_{wet} = Molecular weight of air-water mixture

$\dot{m}_w$ = Evaporation rate of water, lb_m/hr

N = Compressor rotational speed (RPM)

n_{melt} = Melt fraction

Nu = Nusselt number

P_a, P_w = Partial pressure of air, water vapor, psia

$P_{w,s}$, $P_{w,\infty}$ = Partial pressure of water vapor at surface, and in free stream, psia

P_{SAT} = Saturation pressure, psia

Pr = Prandtl number

$\dot{q}$ = Heat flux, BTU/(sec-in^2)

r_2 = Blade tip radius, in

r_C = Arc radius of blade at mid-chord, in

R = Gas constant, ft-lb_f/(lb_m-R)

$\Re$ = Universal Gas constant, 1545.5 ft-lb_f/(lb-mole-R)

Re = Reynolds number

R_{wet} = Gas constant of air-water vapor mixture, ft-lb_f/(lb_m-R)

S = Blade spacing, baseline, in

S' = Reduced blade spacing, in

Sc = Schmidt number

Sh = Sherwood Number

T_s = Surface temperature, R

T_{Stat} = Static air temperature, R

T_{Tot} = Total air temperature, R

T_{WB} = Wet-bulb temperature; surface, R

T_∞ = Free-stream temperature, R

T_M = Averaged temperature of control volume, R

TWC = Total water content = $LWC + IWC$

t = Time, s

U = Rotor peripheral velocity, ft/s

V_d = Ice particle velocity, ft/s

V_∞ = Free-stream air velocity, ft/s

$\tilde{V}$ = Control volume

W_w, W_a = Flow rates of water vapor and air, lb_m/s

w_a,w_w = Mass fraction of air, water vapor

w_∞,w_s = Mass fraction of water vapor in dry air in the free-stream, and at the surface

X, = Axial gap between rotor and stator, in

X_0, Y_0 = Blade circular arc center point x, y

X_2, Y_2 = Blade trailing edge coordinate, in

x_0, x = Initial location ice particle, current location of ice particle, in

Y_1 = Blade leading edge y coordinate, in

Z = Axial distance, in

Greek:

α = Thermal diffusivity, ft^2/s

β_1, β_2 = Angles, leading; trailing edge, degrees

γ_{wet} = Ratio of specific heats of air-water mix

θ = Blade arc angle, degrees

μ = Viscosity of air, absolute, lb_m/(ft-s)

τ = Thermal response time, s

ϕ = Relative humidity

ρ_i,ρ_w,ρ_a, = Density of ice, water vapor, air, lb_m/ft^3

σ = Blade tip solidity

χ_a, χ_w = Mole fraction of air, water vapor

ω = Specific humidity

I. Introduction

The purpose of this study is to document the development of a computational tool to estimate the risk of ice accretion and its effect on turbofan engine performance. Ice crystals ingested into the engines during the operation of an aircraft at high altitudes in high ice water content (HIWC) environments can result in ice accretion in the low pressure compression system. As ice crystals are ingested into the fan and low pressure compression system, the air temperature increases and a portion of the ice crystals melt. This allows the ice-water mixture to stick to the metal surfaces of the compressor components. The resulting accretion causes a blockage on stationary components such as the stator vanes, and subsequently results in the deterioration in performance of the compressor and engine. There have been numerous reported engine icing events[1, 2] that have occurred on commercial airlines (Figure 1). The total number of engine icing events per year, that were attributed to high ice water clouds, appear to be increasing since 2002[3].

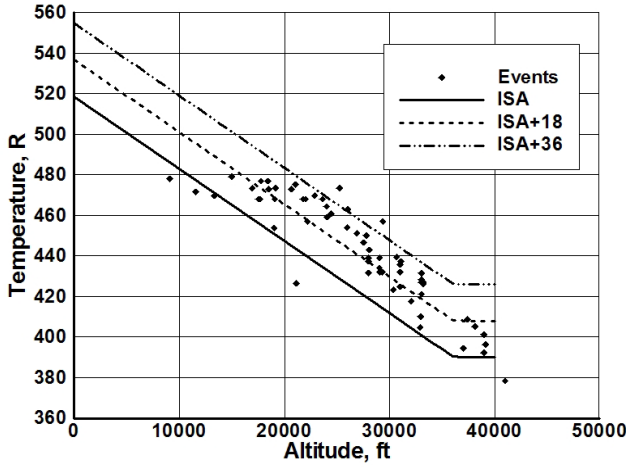

Figure 1: Reported engine icing events. *The engine events occurred at altitudes between 10K and 40K feet and at temperatures between ISA and +36 R).*

The computational tool that was developed in this study provides the capability to analyze a turbine engine through an ice cloud along a vehicle flight trajectory from takeoff, climb, cruise, and descent modes, and to evaluate the susceptibility of the engine to ice accretion. The tool has an engine system thermodynamic cycle code, coupled with a compressor flow analysis code, a fluid properties code, and an ice particle melt code. The mixed fidelity computational tool provides details of the flow conditions within each blade row of the fan and low pressure compression system during operation in the engine system environment. This work leverages from the previous code development effort and parametric study of the effects of blockage due to ice on engine and compressor performance reported in References 4, 5.

Ice accretion in the low pressure compression system can result in deteriorating the performance of the compressor, and consequently on the overall performance of the engine. In this study we utilize a representative notional engine in the 40K lb_f thrust class and a typical flight trajectory that is appropriate for a commercial aircraft equipped with this class of engine.

In order to perform the study, it was necessary to have the details of the low pressure compressor (LPC) geometry to compute the flow conditions between each blade row with the mean line compressor flow analysis code. To that end, a conceptual design of a notional fan-core and LPC was completed to determine the key dimensions that define the blade and flow path. Details of the LPC design are provided in the appendix of this paper. The engine system analysis was performed by the Numerical Propulsion System Simulation (NPSS) code[6]. This code has been coupled with a mean line compressor analysis code (COMDES[7]) such that blade row flow details of the LPC can be extracted. The baseline engine performance was computed with the NPSS-COMDES code, across the complete flight trajectory. The locations within the LPC where there is a risk of ice accretion were determined. At those operating points and locations within the LPC, a parametric analysis with additional blockage due to ice accretion could be performed, as was demonstrated in References 4, 5. These previous parametric analyses completed in

References 4, 5 predicted that as the amount of blockage is increased, the LPC pressure ratio, choke margin, efficiency, and stall margin are reduced. All of these have a net detrimental effect on engine performance that can potentially cause an increase in turbine inlet temperature for a given thrust setting, or a reduced level of thrust, or rollback, for a given maximum turbine temperature. Additionally both of these possible scenarios result in an increase in the specific fuel consumption.

II. Code Enhancements

The computational tool that has been developed for this study leverages from the coupled Numerical Propulsion System Simulation engine thermodynamic cycle code and the mean line compressor flow analysis code (COMDES). A fluid properties model has been added to the COMDES code to account for supplemental water vapor in the air. Additionally, a code named MELT has been developed to model the melting of ice particles. This code leverages capabilities from the LEWICE2D code[8, 9]. Modifications to account for water and ice crystals in the airflow have been made to the compressor code. These codes have been coupled together such that they exchange boundary conditions at each iteration. The compressor analysis code computes the detailed blade row by blade row flow conditions, as well as the overall compressor performance, thus the code is utilized by the system modeling code directly, and takes the place of a characteristic performance map. The mean line compressor code effectively eliminates the need for a map in the NPSS engine system modeling code for the fan-core and LPC components. A code named MELT has been developed that computes the melting rate of ice crystals, as they pass through the engine inlet, fan and low pressure compressor blade rows. The models for sublimation, melting, and evaporation in the MELT code have been adapted from the LEWICE2D code. However, there are no models for ice accretion, particle breakup, shedding, or erosion in MELT. The compressor code and MELT have been coupled to exchange boundary conditions at the blade leading and trailing edges. The compressor code has several additional capabilities, including the ability to calculate the effects of water vapor on the fluid properties of the air–water vapor mixture based on the mole fraction of air to water vapor. The specific humidity at the engine inlet is obtained from the NPSS code, and the local relative humidity is estimated through each component of the inlet-fan-LPC, taking the sublimation, melting, and evaporation into consideration, as well as the local air temperature. The resulting effect of the humid air on the performance of the compressor is computed.

A. Numerical Propulsion System Simulation (NPSS)

NPSS[6] is an advanced thermodynamic cycle code written in an object-oriented language for system modeling of gas turbine engines. The code provides the overall component-level performance and flow conditions of pressures and temperatures. However, the NPSS system modeling code alone does not have the fidelity to provide the flow conditions within the stages and blade rows. Therefore COMDES[7], a mean line compressor flow code, was coupled to NPSS to provide the flow conditions at a higher fidelity, that is, within each blade row of the multi-stage fan-core and low pressure compressor. The block diagram in Figure 2 illustrates the turbofan engine model and its components as modeled with the NPSS-COMDES codes.

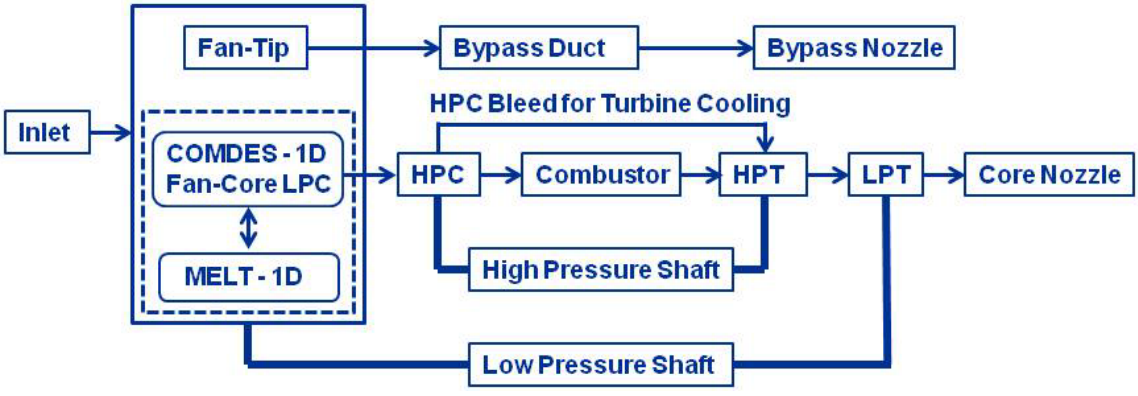

Figure 2: The NPSS engine system model of the two spool turbofan engine with the coupled COMDES compressor flow analysis code and MELT ice melting models. *The fan-core performance (dashed box) is computed with the COMDES mean line flow code and the MELT code.*

The COMDES and the NPSS codes were coupled such that they exchange boundary conditions iteratively at each operating point through the flight trajectory. The fan-core and LPC performance illustrated in Figure 2 with the dashed box is not obtained from component characteristic maps, but rather is calculated with the COMDES mean line flow analysis code, and the MELT code. This process is illustrated in more detail in Figure 3, where the codes and their functionalities that have been developed for this study are described in more detail. The codes are outlined with the rectangular shaped border, while the boundary condition information passed between the codes have borders with rounded corners.

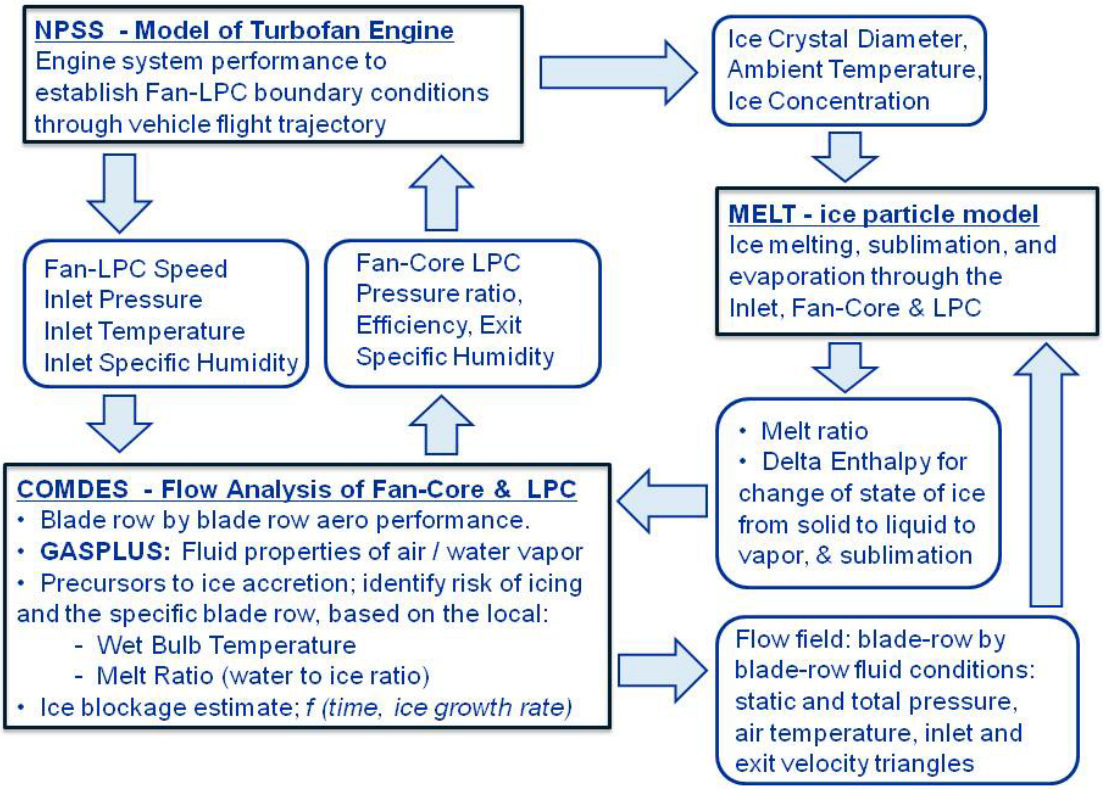

Figure 3: The NPSS engine system model, COMDES compressor flow model and MELT ice melting computer model boundary exchange strategy for the fan-core and LPC. *The fan-core and LPC performance is computed with the COMDES code, and the MELT code.*

While the fan-core and LPC performance is evaluated by means of the results from the COMDES code, the rest of the turbine engine components are modeled in NPSS with the use of traditional component characteristic performance maps. With this combined engine-compressor performance modeling tool, the detailed blade row conditions are determined while operating in an engine system environment. The notional engine is analyzed though the notional flight trajectory of a commercial carrier to determine the flow conditions, including the local pressure and temperature between each rotor and stator blade row of the multistage low pressure compressor (LPC).

Based on preliminary experimental results of ice accretion on a wedge shaped airfoil performed jointly by NASA and the National Research Council of Canada (NRCC)[10], well-adhered ice accretions with rapid growth were observed to occur when the wet-bulb temperature was near freezing or below. Another key parameter was to have sufficient liquid water which is characterized in this study using the melt ratio, or the local value of the liquid water to the total water ratio (ice + water). For icing to occur, this study utilized a melt ratio of 10% based on observations that were made from the analysis of laboratory test data[10]. As a side note, the experiments conducted by NASA and NRCC showed that ice accretion could also occur at wet-bulb temperatures above freezing, particularly at higher ice water concentrations. However, this ice did not appear to be well-adhered and had a tendency to shed periodically. This shedding can also pose a hazard in the engine but is not considered in this study.

The critical values of wet-bulb temperature and the melt ratio are the two key parameters that together are the necessary conditions which must be met simultaneously, at the same calculating station in the compressor, in order for there to be a high risk of ice accretion. Since the wet-bulb temperature and the melt ratio both change through each blade row, this technique also identifies the blade row where there is a high risk of ice accretion. However, it is recognized that other parameters such as the heat transfer rate through the blades may need to be considered as well, but are not included in the current version of the NPSS-COMDES codes. It is assumed in this study that accretion does not occur on the rotors, since the water/ice mixture would likely not have enough time to accrete on the high speed blade surface due to high centrifugal forces. Therefore the assumption is that accretion can only occur on the stator vanes and flow path walls.

Once a stator has been located in which the two parameters simultaneously indicate a risk of ice accretion, the amount of blockage at that stator vane location can be estimated as a function of time spent at that operating condition, and the measured ice accretion growth rate obtained from laboratory experiments[10]. The growth rate in terms of inches per second is converted to a value of additional blockage at that stator location, and the performance of the compressor with the additional blockage can then be computed with the compressor flow analysis code as a function of time spent at that operating condition. Parametric blockage is not addressed in this study, but was detailed in previous studies[4, 5]. The updated performance of the iced compressor is then passed to the engine cycle code, and the engine performance with the iced compressor is aero-thermodynamically rebalanced.

B. Compressor Flow Analysis Code Enhancements

The compressor flow analysis code utilized in this study is the COMDES mean line flow code. The code computes the velocity, pressure, temperature, and flow angles at the leading edge and trailing edge of each blade row, at the hub, mean, and tip sections. The mean line compressor design and flow analysis code has been modified to include the effects of relative humidity on the fluid properties of air and water vapor mixture, and the subsequent effects on compressor performance. The capability of calculating the local relative humidity in each blade row is based on the initial value of specific humidity (mass of water/mass of air) at the compressor inlet. Additional modifications have been made to enable calculating the two key parameters which have been identified as early indicators of ice accretion: the local wet-bulb temperature and the percent of melt ratio within each blade row. If the limiting values of these key parameters are met, there is a risk that ice will accrete on the surfaces of the compressor. With these parameters as the precursors to ice accretion, the blade row within the compression system can be identified that is likely to experience ice buildup at a particular engine operating condition in the vehicle flight trajectory. The local wet-bulb temperature is calculated at each blade row. The geometry section of the code was improved with the addition of simple circular arc blades and vanes. An ice particle melting and evaporation model was coupled to the compressor code to compute the local melt ratio through each blade row.

Water Vapor

Additional modification to the COMDES code includes the capability of modeling the effects of water vapor on the gas properties of air. The model is based on a specified value of specific humidity at the inlet of the engine/compressor. The values for fluid properties of the water vapor and air are obtained in COMDES from the GASPLUS[11] code. The mole fraction of water vapor to air is used to compute the average mole weight of the fluid, the average gas constant, and the average specific heat ratios for water vapor (c_{p_w}) and air (c_{p_a}). Molar flow rates (F_w, F_a) are given by:

$$F_w = \frac{W_w}{M_w} \tag{1}$$

$$F_a = \frac{W_a}{M_a} \tag{2}$$

Mole fractions (χ_w, χ_a) are given by:

$$\chi_w = \frac{F_w}{\left(F_w + F_a\right)} \tag{3}$$

$$\chi_a = 1 - \chi_w = \frac{F_a}{\left(F_w + F_a\right)} \tag{4}$$

Mass fractions (w_w, w_a) are given by:

$$w_w = 1 - w_a = \frac{\chi_w M_w}{\chi_a M_a + \chi_w M_w} \tag{5}$$

$$w_a = \frac{\chi_a M_a}{\chi_a M_a + \chi_w M_w} \tag{6}$$

Average molar mass of the mixture:

$$M_{wet} = \chi_a M_a + \chi_w M_w \tag{7}$$

The specific heat of the air-water vapor mixture ($c_{p\,wet}$) is calculated with the following formula:

$$c_{p\,wet} = w_a \; c_{p\,a} \; + w_w \; c_{p\,w} \tag{8}$$

Average gas constant (R_{wet}) of the air-water vapor mixture, in terms of the universal gas constant ($\Re$):

$$R_{wet} = \frac{\Re}{(\chi_a M_a \; + \chi_w M_w \;)} = \frac{\Re}{M_{wet}} \tag{9}$$

The ratio of specific heats for the air-water vapor mixture:

$$\gamma_{wet} = \frac{1}{(1 - R_{wet}/(J \;\; c_{p\,wet}))} \tag{10}$$

Rotor and Stator Blade Geometry

The geometry portion of the compressor code has been improved with the addition of a circular arc blade geometry generator. The code generates rotor blades and stator vanes based on the values of the blade angles at the leading and training edges, the tip solidity, and the flow path radii. The circular arc shaped mean camber lines of the blades are created at the hub, mean, and tip section of each rotor and stator of the stage. When used in the analysis mode, the circular arc blades act as reasonable approximations of the actual rotors and stators, Figure 4. This represents one stage of the five stage fan-core and LPC that are analyzed in this study, as will be illustrated in a later figure. With this method, the blade-to-blade distances and passage chord lengths can be computed with reasonable accuracy.

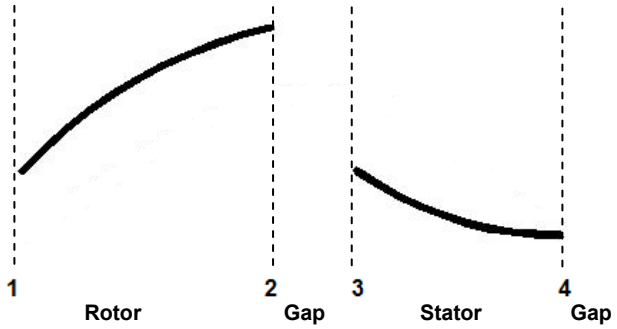

Figure 4: Rotor and stator blade mean camber line chords at the mid-span section for a typical stage. *The station numbers 1 and 2 refer to the rotor leading and training edges respectively, while stations 3 and 4 refer to the stator leading and trailing edges respectively.*

The lengths are used to estimate ice particle residence time and for calculating the sublimation, melt, and evaporation rates which will be addressed in the subsequent "Ice Particle Melting and Evaporation" section. The circular arc blade generation methodology that was used to determine the compressor rotor and stator blade dimensions are detailed below and the compressor geometry used in this study is provided in a later section on fan and low pressure compressor conceptual design.

The geometry section of the compressor code includes the capability to generate approximate blade shapes based on a simple circular arc blade camber line profile. The compressor code is run in the analysis mode, and the blade angles at the leading and trailing edges are specified. For rotors, the design point incidence, flow rate, and shaft rotational speed provides the blade angle at the leading edge. At the trailing edge, the work, or flow turning angle defines the blade angle at the blade exit. The tip solidity, number of blades, and flow path inner and outer radii are input parameters. The simple circular arc blade camber line is generated by the code at the hub, mean, and tip sections. The same procedure is followed to provide the stator vane camber line with simple circular arc shape. The following equations define the rotor blade and stator vane (referred to as airfoils in the following) camber geometric shape. The chord, C, is determined from the tip solidity, σ, the tip radius, r_2, and the number of airfoils, N, by the following equation.

$$C = \frac{2\ \pi\ r_2\ \sigma}{N} \tag{11}$$

The true chord can be closely approximated by the following equation which is for the isosceles triangle in Figure 5.

$$C = 2r_C\ Sin\frac{\theta}{2} \tag{12}$$

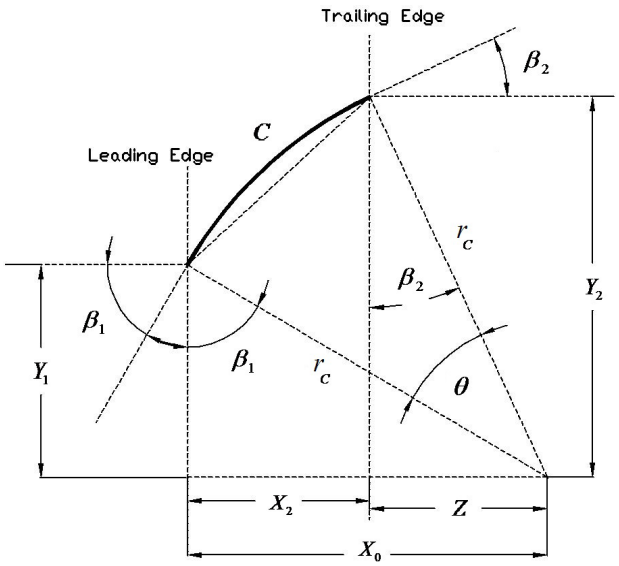

Figure 5: Compressor airfoil camber line geometry creation in COMDES. A s*imple circular arc camber line with radius r_c is generated in the compressor code based on input values of tip solidity of the rotor and stator, and angles at the leading (β_1) and trailing (β_2) edges.*

The following equations are used to solve for the coordinates of the airfoil leading and trailing edges and the coordinates of the center of the circular arc (X_O, Y_O) which defines the arc radius r_c at the blade mid-chord.

$$r_C{}^2 = X_O{}^2 + Y_O{}^2 \tag{13}$$

$$r_C{}^2 = \left(X_2 - X_O{}^2\right)^2 + Y_2{}^2 \tag{14}$$

$$Sin\beta_1 = \frac{X_O}{r_C} \tag{15}$$

$$Cos\beta_2 = \frac{Y_2}{r_C} \tag{16}$$

The airfoil section coordinates shown in Figure 5 are determined using the above equations for a circular arc. Both the rotor blades as well as the stator vanes are generated with a single circular arc.

Energy Balance between Ice Particle and the Air

As the ice passes through the inlet, fan, and LPC blade rows, it is continuously absorbing heat from the warmer air through the compressor blades. The amount of energy that the ice particle absorbs from the air while it experiences sublimation, melting, and evaporation will be described in the subsequent section named "Ice Particle Melting and Evaporation." The transfer of energy between the air and the ice particle can be expressed as a change in enthalpy. The enthalpy increase of the ice particle is equal to the enthalpy decrease of the air, which results in a decrease of the total temperature of the air. The energy balance between the ice particle and the air is determined iteratively with the results from the compressor code and the particle melt code exchanging boundary conditions of static temperature, static pressure and change in enthalpy until convergence. The change in total temperature of the air through the rotor is a function of the enthalpy rise due to the work input by the rotor, and the enthalpy that the ice particle removes from the air, as determined from the particle melt code. To account for effects of the energy exchange between the ice particle and the air through the compressor rotor, the Euler equation energy balance in the

compressor code has been modified to account for the enthalpy exchange between the particle and the air, and is represented by the following equation, where the subscripts 1 and 2 represent the conditions at the rotor leading edge (station 1) and trailing edge (station 2) respectively (see Figure 4).

$$J\ c_{p_{wet}}\ g_c\ (T_2 - T_1) = (U_2\ C_{U2} - U_1\ C_{U1}) - \Delta H_{melt(2-1)} \tag{17}$$

The solution of flow conditions at the rotor exit is obtained by executing the compressor code and the particle melt code iteratively, by passing boundary conditions of static temperature and velocity from the compressor code to the MELT code, where the enthalpy change (ΔH_{melt}) of the ice particle is calculated, and returned to the compressor code where the change in air temperature due to the change in enthalpy is calculated. A similar iterative process is utilized to calculate the change in air temperature due to enthalpy exchange between the air and the ice particles through the gaps between the rotor and stator, and through the stator vanes, where the subscripts 1 and 2 represent the inlet and outlet of the gap, and subscripts 3 and 4 represent the conditions at the stator leading edge and trailing edge respectively (see Figure 4). Note that when calculating the air temperature in the gap, the subscripts 3 and 4 are replaced with subscripts 2 and 3, respectively, in the following equation.

$$J\ c_{p_{wet}}\ g_c\ (T_4 - T_3) = \Delta H_{melt(4-3)} \tag{18}$$

Wet-Bulb Temperature

In this study, the wet-bulb temperature parameter is utilized as one of the key indicators of whether there is a risk of ice accretion within one of the compressor blade rows. A mathematical derivation of a wet-bulb temperature (T_{WB}) for application in analysis of mixed-phase icing tests has been derived and implemented into the mean line compressor flow analysis code, thus enabling the multistage code to compute the local wet-bulb temperature at each rotor and stator leading and trailing edge and at the stator throat. In this derivation T_{WB} is the temperature of an evaporating wet adiabatic surface and is a function of the surrounding air temperature (dry-bulb), air pressure, and moisture content. The T_{WB} is obtained by equating the rate of heat transfer to a surface to the heat loss by evaporation. During this process, it is assumed that the surface remains wet and any water added to replace that lost by evaporation is at T_{WB}. The analysis is an adaptation of heat and mass transfer principles described in Incropera & DeWitt[12] and thermodynamic concepts presented in Çengel and Boles[13]. It is assumed that the process is steady state, with adiabatic boundaries, except at the edge of the boundary layer. The surface (and water layer) is maintained at T_{WB}. The surface always remains wet (either evaporation is negligible from a mass loss perspective or water is replaced at T_S via some process). The static pressure remains constant, and the partial pressure of water vapor at the surface is assumed to be the saturation value at the surface temperature. Figure 6 illustrates the conceptual representation of the control volume for the thermodynamic balance model that is utilized to derive the wet-bulb temperature.

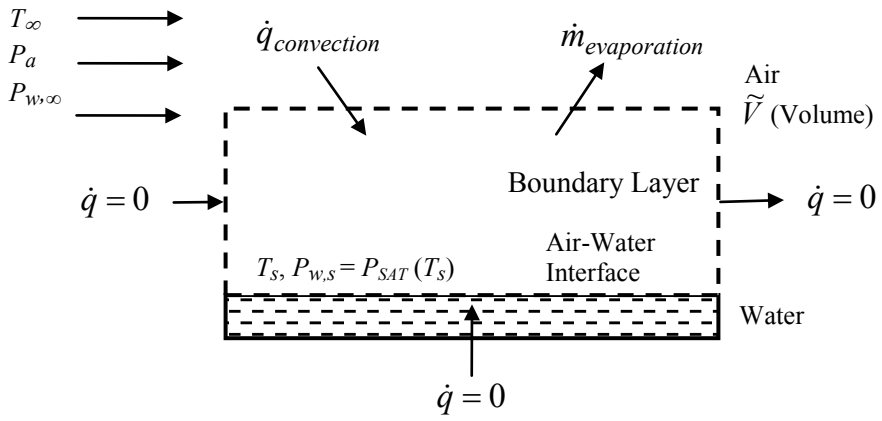

Figure 6: The control volume for the thermodynamic balance model.

An energy balance performed on the above control volume with the given assumptions is shown in Eq. (19).

$$\rho_a \ \widetilde{V} \ c_{p_a} \frac{dT_M}{dt} = h \ A \ (T_\infty - T_s) - \dot{m}_w \ L_v \tag{19}$$

Assuming a steady state process, the above equation can be rearranged to solve for the surface temperature as shown in Eq. (20).

$$T_s = T_\infty - \frac{\dot{m}_w \ L_v}{h \ A} \tag{20}$$

Examination of the above equation shows that T_{WB} will be less than the T_∞ when there is evaporation from the surface given the assumptions stated above.

To determine the amount of mass evaporated leaving the top of the boundary layer, it is assumed that the process is steady (i.e., no accumulation in the control volume). The evaporated water leaving the control volume is resupplied to the surface at T_{WB} via some unspecified process. It is also assumed that saturated conditions exist at the water and interface. Under these assumptions, the mass flux leaving the control volume is shown in Eq. (21):

$$\dot{m}_w = h_m \ A \ \rho_a \left(w_s - w_\infty \right) \tag{21}$$

Combining the mass flux leaving the control volume, Eq. (21), with the energy balance, Eq. (20), provides another expression for the surface temperature, as shown in Eq. (22):

$$T_s = T_\infty - \frac{h_m}{h} L_v \ \rho_a \left(w_s - w_\infty \right) \tag{22}$$

Invoking the analogy of heat and mass transfer yields another expression for the surface temperature, equation. This analogy is valid for both local and bulk transfer coefficients as well as laminar or turbulent conditions. The properties values are evaluated at the average of the free-stream and the surface temperature. A more detailed derivation of this expression is presented in Reference 14.

$$T_s = T_\infty - \frac{L_v}{c_{p_a} \ Le^{2/3}} \left(\frac{M_w}{M_a} \right) \frac{T_M}{P_a} \left[\frac{P_{w,s}}{T_s} - \frac{P_{w,\infty}}{T_\infty} \right] \tag{23}$$

Eq. (23) can be solved iteratively. The surface temperature, *Ts*, is the wet-bulb temperature, based on the above assumptions.

The partial pressure of water vapor at the surface is assumed to be the saturation value at the surface temperature, Eq. (24). The partial pressure of water vapor outside the boundary layer can be defined based on the ambient relative humidity, ϕ, as shown in Eq. (25).

$$P_{w,s} = \phi_s \ P_{sat,s} \ ; \text{ evaluated at } T_{WB} \quad (\phi_s = 1.0, \ \text{ fully saturated}) \tag{24}$$

$$P_{w,\infty} = \phi_\infty \ P_{sat,\infty} \ ; \text{ evaluated at } T_\infty \tag{25}$$

For this work, total conditions were used for T_∞ and P_∞ to calculate wet-bulb temperature to represent conditions at a stagnation point.

Ice Particle Melting and Evaporation

The capability to model ice particle and evaporation has been added to the COMDES compressor analysis code. The appropriate equations were taken from the LEWICE2D code and were implemented into the compressor code in the subroutine named MELT. This enables the code to calculate the change of phase of an ice particle which sublimates, melts, and evaporates, as it passes through the fan and low pressure compressor blades and stator vanes. The ice particle residence times through the compressor of existing engines are estimated based on the velocities at the leading and trailing edge of each blade row, and the blade chords and the axial spacing of the gap between the rotors and stators. This provides a reasonable estimate of the actual residence times of the ice crystals through each blade passage and gap, resulting in an accurate estimate of the sublimation, melting, and evaporation physics. The inlet specific humidity and the ice particle concentration (grams per cubic meter) and size distributions are specified at the inlet to the engine. For this study, values for ice particle size and concentrations in the atmosphere are varied parametrically, as there is limited data currently available on the ice crystal content of high altitude convective clouds.

After the flow conditions through the blade rows have been calculated by the compressor code, the static temperatures, pressures, and velocities are passed to the ice melting subroutine to determine the rate of melting and evaporation, and thus, the local melt ratio in each blade row. The ice particle sublimation, melting, and evaporation equations are shown below. The calculations for sublimation, melting, and evaporation take into consideration the local temperatures, pressures and residence times as they traverse the blade passages and gaps between blades at their mid span location. Conservation of mass on each particle results in the following equation for the ice particle size as a function of position, where w_s is the mass fraction of water vapor at the surface and w_∞ is the mass fraction of the water vapor in the free-stream.

$$d^2 = d_o^2 - \frac{4Sh\ \rho_a\ D_v}{\rho_i\ V_\infty}(x - x_o)(w_s - w_\infty) \tag{26}$$

Similarly, the rise in specific humidity is related to the amount of mass lost by the particle and is given by the equation below.

$$\omega = \omega_o + \frac{IWC}{\rho_a}\left(1 - \left(\frac{d}{d_o}\right)^3\right) \tag{27}$$

Equating the heat absorbed by the particles to a decrease in enthalpy in the airstream provides the decrease in air temperature.

$$T_a = T_{a,o} - \frac{L_s}{c_{p_a}}\frac{IWC}{\rho_a}\left(1 - \left(\frac{d}{d_o}\right)^3\right) \tag{28}$$

The enthalpy increase of the particle through the compressor is equal to the heat absorbed from conduction plus the energy provided by evaporation, resulting in the following equation for the change in particle temperature prior to melt

$$\frac{dT_i}{dx} = \frac{Nu}{\tau_T\ V_\infty}(T_a - T_i) + \frac{L_s\ Sh}{\tau_T\ c_{pa}\ V_\infty}\frac{\mathrm{Pr}}{Sc}(w_\infty - w_s) \tag{29}$$

The mass fractions of water vapor in the above equation are given by the equations below.

$$w_\infty = \phi_\infty \frac{M_w}{M_a}\frac{P_{w,\infty}}{P_a} \tag{30}$$

$$w_s = \phi_s \frac{M_w}{M_a}\frac{P_{w,s}}{P_a} \qquad (\phi_s = 1.0, \text{ fully saturated}) \tag{31}$$

The non-dimensionalization of the energy equation above results in the following term for the thermal response time

$$\tau_T = \frac{c_{p_i}\ \rho_i\ d^2}{6k_a} \tag{32}$$

The Nusselt number, Sherwood number, and the Prandtl number in these equations are provided by assuming spherical particles. If other particle geometries are of interest, the correlations can be easily modified for those cases.

$$\mathrm{Pr} = \left(\frac{c_p\ \mu}{k} \right)_a \tag{33}$$

$$Nu = \frac{h\ d}{k_a} \tag{34}$$

$$Nu = 2 + 0.6\,\mathrm{Re}^{1/2}\ \ \mathrm{Pr}^{1/3} \tag{35}$$

The Schmidt number is defined by the following equation.

$$Sc = \frac{\mu_a}{\rho_a\ D_v} \tag{36}$$

The Sherwood number is defined by the following equation.

$$Sh = \frac{h_m\ d}{D_v} \tag{37}$$

$$Sh = 2 + 0.6\,\mathrm{Re}^{1/2}\ Sc^{1/3} \tag{38}$$

The Reynolds number in the above equation is based on the particle size and the relative velocity of the particle to the velocity of the air stream

$$\mathrm{Re} = \frac{\rho_a |V_\infty - V_d| d}{\mu_a} \tag{39}$$

where the particle/drop velocity, V_d, is obtained by integrating the equation of motion

$$\frac{dV_d}{dt} = \frac{3}{4} C_d\,\mathrm{Re}^2\,\frac{\mu_a^2}{\rho_a \rho_i d^3} \tag{40}$$

Once the particle starts to melt, its temperature no longer changes. In this case, the energy equation above can be written as a change in the enthalpy or a change in the melt fraction[8] as shown below.

$$\frac{dn_{melt}}{dx} = \frac{c_{p_i}}{L_f}\frac{Nu}{\tau_T\ V_\infty}\left(T_a - T_i\right) + \frac{c_{p_i}}{L_f}\frac{L_s\ Sh}{\tau_T\ c_{p_a}\ V_\infty}\frac{\mathrm{Pr}}{Sc}\left(w_\infty - w_s\right) \tag{41}$$

The local fluid conditions of temperature and pressure are used in the above equations to determine the rate of sublimation, ice melting, and evaporation. The distance the ice particle traverses through the compressor rotors and stators is determined from the length of the engine inlet, and the geometry of the rotor blades, stator vanes, and the axial gaps between the rotors and stators. The distance through the fan and LPC blade rows is estimated from the true blade chord of the rotors and stators at the mid span, and the axial distance through the gaps between the blades, as illustrated in Figure 7. Note that each stage is analyzed at the blade edges as shown in Figure 4. In this study, the

simple circular arc blade camber line shapes are utilized and provide a means of easily estimating the geometry of the compressor blades and vanes. This facilitates estimating the distance traveled by the water/ice particle. The COMDES and MELT codes exchange boundary conditions of pressure, temperature and velocity, to estimate the residence time of the particle through each blade row, as well as to determine the rate of ice sublimation, melting, and evaporation.

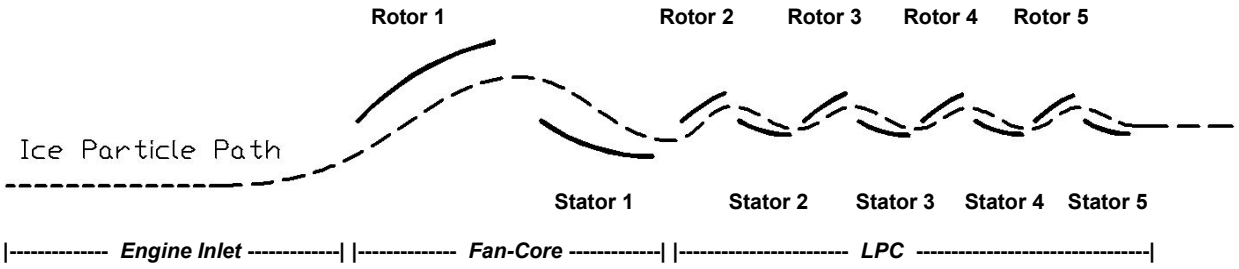

Figure 7: Ice particle path through the fan-core and low pressure compressor stages. *Rotor and stator blade mean camber line chord at the mid-span section is used to estimate the distance traveled and residence time of the ice particles.*

Figure 7 illustrates the ice particle path through the rotor blades in the relative frame of reference, while the path through the stator vanes is in the absolute frame of reference. The calculations of ice sublimation, melt, and evaporation are performed in increments from the leading to the trailing edge of each rotor and stator, as well as through the axial gap between the blades. As the engine is flown through the flight trajectory, the ice particle sublimation, melting, and evaporation is calculated in each rotor and stator blade row. The amount of water due to sublimation and evaporation is added to the local value of specific humidity, thus having an effect on the local relative humidity, and likewise on the local wet-bulb temperature calculation in the compressor code. The MELT code is also used to evaluate the particle conditions through the engine inlet which is then provided as ice particle initial conditions at the leading edge of the fan-core.

Identifying the Risk of Ice Accretion

When the wet-bulb temperature and melt ratio parameters indicate a risk of ice accretion at a particular location in the compressor, an additional blockage can be applied, which will result in a change in the performance of the compressor and engine. Though not implemented in the current study, the capability to simulate turbofan engine performance with additional blockage due to accretion has been previously demonstrated in References 4, 5. In that study, the blockage due to accretion was varied parametrically. The approach was to add blockage as a function of empirically derived ice growth rate, and time spent at that operating condition. However, the main focus of this paper was to determine the risk of ice accretion and its location, with an estimate of ice particle melt ratio, and the wet-bulb temperature calculation with no additional blockage due to ice accretion.

Using data from laboratory testing,[10] Figure 8 shows the normalized ice accretion growth rate as a function of measured liquid water content (LWC_m) to injected total water content (TWC_{inj}). In this figure, the measured ice growth rates (G) are normalized by the theoretical maximum ice growth rate, G_{max}, as shown in Eq. (42). The data from this experiment suggest that some liquid water needs to be present for accretion to occur. A non-zero growth rate, G/G_{max}, was first observed when the ratio of LWC to TWC increased to 14% (Figure 8). Only the portion of the data with wet-bulb temperatures below freezing is represented in Figure 8. However, data for wet-bulb temperatures marginally above freezing have also resulted in ice accretion with shedding, as reported in Reference 14. The ice accretion growth rate as a function of the ratio of LWC to TWC data shown in Figure 8 is included in Appendix A.

In this study it is assumed that ice accretion can only occur at values of T_{WB} that are below the temperature of 499 R (~ 4°C). This assumption is based on observations[10] that showed significant growth rates and buildup of ice at values of T_{WB} below 499 R. However, at values just above freezing (between 492 R and 499 R), the ice was slushy, and had a tendency to shed before a large buildup of ice could occur, but at values below freezing, the accreted ice did not shed and continued to grow as a function of time, provided that there was a positive melt ratio. Note that the effects

of ice shedding have not been modeled in this study. However, the detrimental effects of shedding on engine performance cannot be ruled out. Therefore, in this study the upper limit of 499 R is used as the maximum wet-bulb temperature ice accretion risk indicator. The criteria for the risk of ice accretion therefore are the wet-bulb temperature being less than 499R (i.e., slightly above freezing or below), and when the ratio of *LWC* to *TWC* exceeded 10%, which includes some margin in comparison to the 14% ratio that was observed in the experiment to have significant growth rate. In this study, the ratio of *LWC* to *TWC* is an approximation to the melt ratio used elsewhere in this document.

It is important to note that the data in Figure 8 is preliminary as the values LWC_m and TWC_{inj} require corrections which are not yet well understood. The subscripts *m*, referring to the *LWC*, denotes a measured value using a hot-wire probe which has not yet been characterized in mixed-phase flow. The value used for *LWC* in Figure 8 is the uncorrected value. The subscript *inj*, referring to the *IWC*, denotes a bulk injected value using bulk water or ice flow rate data assuming a uniform cloud. The corrections to the *LWC* and *IWC* are topics of current research efforts. In addition, as higher fidelity, multi-disciplinary computational tools become available with accretion, erosion, particle breakup, and shedding models, they can result in more accurate predictive capability for the growth rate.

$$G_{\max} = \left(\frac{TWC_{inj}}{\rho_i} \right) V_\infty \tag{42}$$

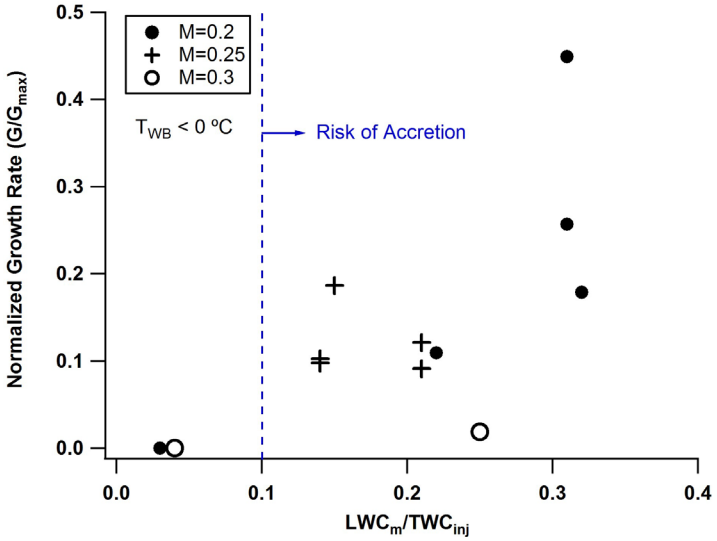

Figure 8: Ice accretion growth rate as a function of the liquid-water-to-total water content ratio (i.e., melt ratio) when the wet-bulb temperature was below freezing[10]. *A finite rate of ice growth was observed when the melt ratio was above 10%.*

For completeness, an outline of how the additional blockage due to high growth rate of ice accretion can be utilized in the compressor flow analysis code. The amount of blockage due to ice accretion on the blades can be estimated from the maximum growth rates of ice accretion that have been observed during laboratory testing at the NRCC laboratory.[10] The size of the ice growth is a function of time (*t*) spent at that operating condition and the ice growth rate is specified in terms of length per time. Although this growth rate is measured at a single point (i.e., the leading edge) of a blade, it is used here to generate a first order estimate of the blockage within a compressor.

The amount of ice blockage in a blade row is estimated in the compressor code from the measured growth rate (*G*) and the blade spacing parameter (*S*). The ice accretion on the compressor vanes is illustrated in Figure 9, and shows how the blade spacing is reduced due to the estimated accretion.

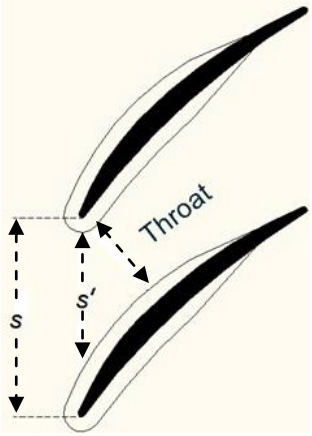

Figure 9: Estimating the blockage due to ice accretion in the stator blade row. *The ice accretion can be modeled in the compressor code as an additional blockage at the stator leading edge and throat.*

The blockage from ice accretion can be modeled in the compressor code as an additional blockage and added to the nominal value of aerodynamic blockage. The reduction in the circumferential blade spacing (S') is estimated by Eq. (43), from the empirical value of ice growth rate (G), the time spent at that operating condition (t), and the nominal blade spacing (S). The reduced blade spacing results in a reduced annular area at the stator inlet and exit, and also a reduced throat area.

$$S' = S - 2tG \tag{43}$$

The blockage due to ice accretion is estimated from the reduction in blade spacing. The performance of the compressor and the engine system, computed with the additional blockage added parametrically (not as a function of time and growth rate) at a specific location in the compressor, has been demonstrated in References 4, 5.

III. Analysis of Turbine Engine Performance in an Ice Crystal Environment

A. Fan and Low Pressure Compressor Conceptual Design

In order to perform the engine icing study, it was necessary to have the geometry of the low pressure compressor (LPC) in adequate detail such that the flow conditions between each blade row can be computed with the mean line compressor flow code. The conceptual design task was performed for a notional turbofan engine in the 40000 lb thrust class having a bypass ratio of 5.8 with the mean line compressor flow analysis code. The rotor and stator blade shapes were approximated with simple circular arcs. The conceptual design effort of the notional fan-core and LPC determined the key dimensions that define the blade and flow path geometry. Figure 10 illustrates the notional fan and low pressure compressor that was used in this study. The fan-core and LPC design point aerodynamic performance is included in Appendix B as output from the compressor code analysis.

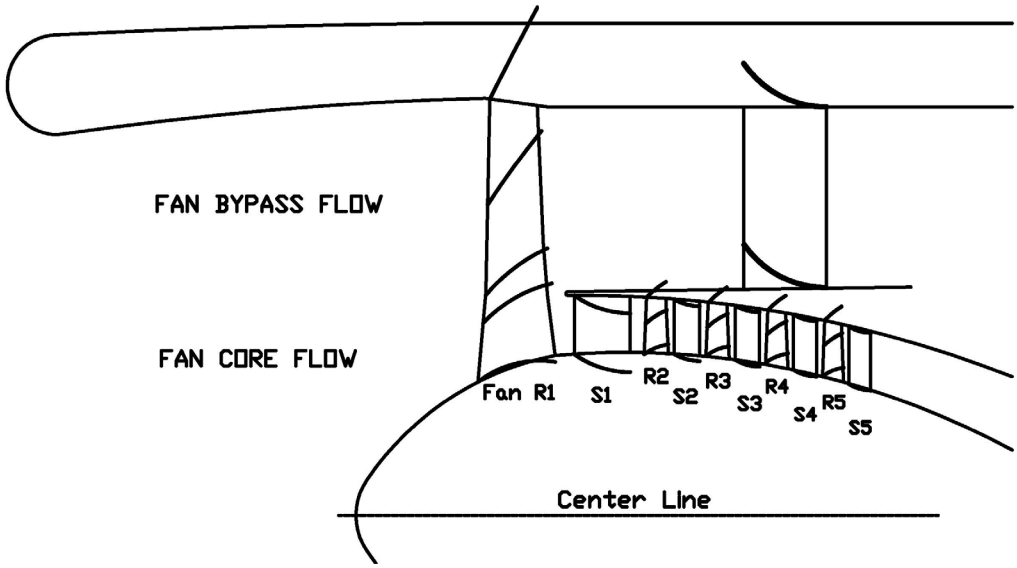

Figure 10: Fan and low pressure compressor of the notional high bypass ratio turbofan engine.

A compressor flow model with the COMDES code represents the fan-core and LPC in the NPSS engine system model. The radial view of the blade centerline sections are superimposed onto the flow path in Figure 10. Table I lists key aerodynamic and geometric design parameters at the root-mean-square (RMS) radius of each blade row and stator vane. The fan-core is considered the first stage in this study, followed by a four stage LPC.

B. The Performance of the Notional Turbine Engine System Model through a Typical Commercial Aircraft Flight Trajectory

In order to perform the engine icing study, the NPSS-COMDES engine model was executed at numerous operating conditions through a flight trajectory. The inlet conditions of ice crystal concentrations in grams per cubic meter, particle size, and the elevated ISA (International Standard Atmosphere) temperature were varied parametrically at ISA +0 R, +18 R, +27 R, and +36 R, since that is in the range of where ice accretion has been reported, as was illustrated in Figure 1. The detailed analysis of the fan-core and low pressure compressor with the COMDES code was obtained at each operating condition. The engine analyses were performed with the fully coupled computer models described in the above sections. The system model was utilized to determine the performance of the notional 40000 lb_f thrust class engine through a typical flight trajectory of a commercial aircraft (Figure 11).

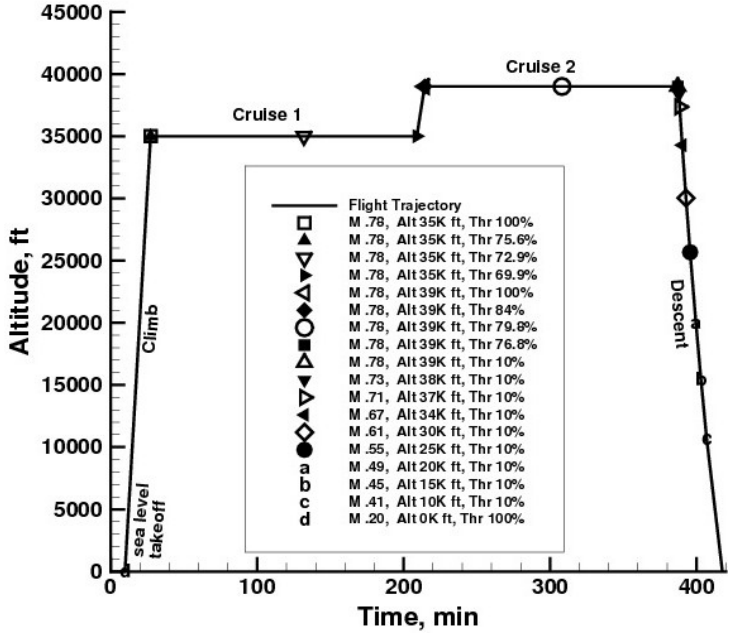

Figure 11: Flight trajectory for a typical commercial aircraft. *The notional 40000 lb thrust engine is "flown" through the vehicle flight trajectory to determine the blade row where conditions for ice accretion may be possible.*

The notional flight trajectory[4, 5, 15] used in this study includes takeoff, climb, two cruise altitudes, and one descent profile. The detailed output listing of the flight trajectory is included in Appendix C. The first cruise altitude is at 35000 feet, where the engine thrust is reduced from 100% down to 69.9% of maximum thrust at the end of the cruise. The aircraft then proceeds to 39000 feet where again the thrust reduces from 100% down to 76.8% maximum thrust at that altitude. The engine is then spooled back to 10% maximum thrust at 39000 feet as it prepares to descend in altitude. The engine is maintained at 10% maximum thrust as it descends to 10000 feet, which was the lowest altitude that was analyzed in this study.

Figures 12 and 13 illustrate the baseline pressure ratio and efficiency characteristic maps of the fan-core and LPC and the superimposed operating points through the flight trajectory. The baseline maps have no additional blockage due to ice accretion. These maps were generated by the compressor code executed in the stand-alone mode (independent of the NPSS system modeling code); however, the operating points along the map were obtained by running the fully coupled engine system model, the compressor flow analysis, and the melt codes as illustrated in Figure 3. The plot file of the overall compressor maps shown in Figures 12 and 13 are listed in Appendix D. The plot file of the fan-core and LPC performance along the engine operating line is listed in Appendix E. The complete output listing of the mean line compressor flow analysis code, along the entire baseline performance map and the flight trajectory, are listed in Appendices D and E of Reference 5 respectively.

The risk of ice accretion on a stator is a function of where in the flight trajectory the engine is operating and the atmospheric conditions of temperature and pressure, as well as the ice particle concentration and size. As will be illustrated in a later section of this paper, at high altitudes, the rear stages of the LPC may be at risk for accretion, while at lower altitudes, the risk of accretion may be in the front stages.

Even though no additional blockage is added at any location to the compressor, the compressor analysis code was utilized in this study to determine which stage had a risk of ice accretion, based on the wet-bulb temperature and melt ratio criteria. This could not have been determined from an LPC compressor map showing overall performance alone.

In the previous study[4] that included compressor flow analysis with parametric blockage, the LPC performance with ice accretion could not be represented by traditional compressor performance maps, since the amount of blockage due to ice, and the stage where there is blockage, was different along each speed line, and depended on the altitude and thrust level it is operating at in the flight trajectory. The solution that was chosen was to fully couple the NPSS and the COMDES codes, thus the compressor performance was passed to the system model for each unique point of operation, which included the unique amount of blockage due to ice accretion at a specific blade row.

In this study the performance of the engine with blockage is not addressed; as this was addressed in an earlier publication. The focus here is to more accurately predict the locations in the low pressure compression system where there is a risk of ice accretion, as well as the atmospheric conditions that could support it, along a flight trajectory. The fully coupled NPSS_COMDES_MELT code has been executed through the flight trajectory, and the results of the icing risk analyses, in each stage of the LPC, are shown graphically in the following figures.

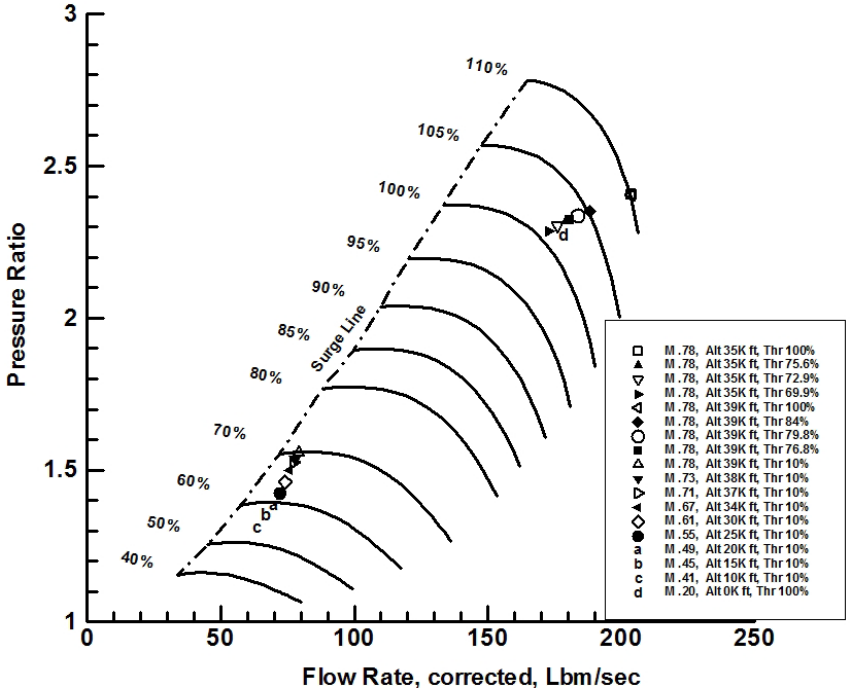

Figure 12: Fan-core and LPC pressure ratio showing the baseline performance. *Operating points of the fan-core and LPC throughout the flight trajectory are superimposed onto the baseline pressure ratio map.*

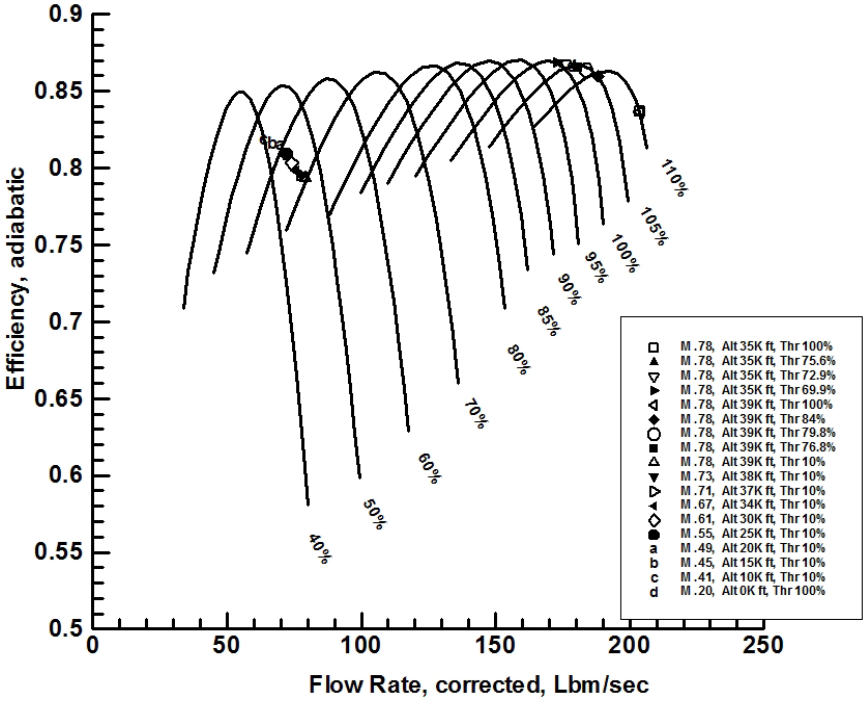

Figure 13: Fan-core and LPC performance showing the baseline efficiency map. *Operating points of the fan-core and LPC throughout the flight trajectory are superimposed onto the baseline efficiency maps.*

A range of ice particle concentrations, and particle diameters were analyzed with the icing code, at various ambient temperatures above the ISA standard. The local values of wet-bulb temperature and melt ratio at each LPC blade and stator inlet and outlet, were computed for the engine operating conditions through the vehicle flight trajectory. The performance of the fan and LPC stages were analyzed.

Ice Particle vs. Ambient Temperature

In this study we assumed that ice crystals cannot form at temperatures above freezing. As illustrated in Figure 1, the range of temperatures where engine icing events occurred was between the ISA temperature and 36 R above the ISA temperature. The altitude at which freezing occurs is a function of ISA offset temperature, as illustrated in Figure 14. For example, at an ISA offset temperature of 0 R, the minimum altitude where ice crystals can form in the atmosphere is 7500 ft, while with an offset of +36 R, the minimum altitude is 17400 ft. In the study the ISA offset temperatures of +18, +27, +36 R were considered through a wide range of altitudes along the flight trajectory. However, at conditions below the 492 R line in Figure 14, the assumption is that the particle is all liquid water; therefore the melt ratio even before entering the engine is equal to 1.0. Likewise, the calculated wet-bulb temperature at these conditions is above the range where ice accretion is a risk, based on the analysis. Therefore, no conditions exist that would support ice accretion at operating points below the 492 R line shown in Figure 14.

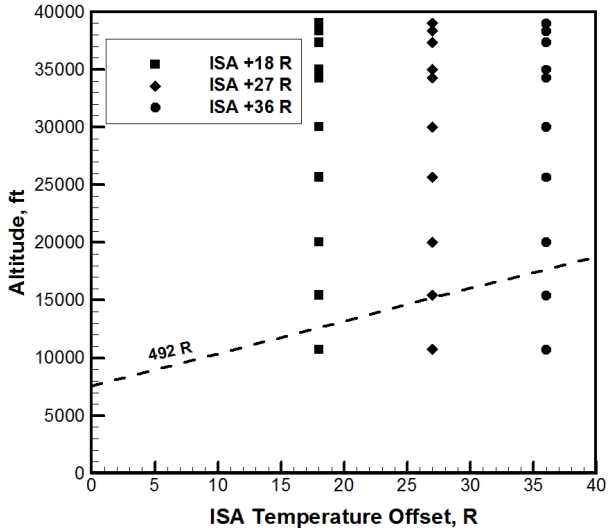

Figure 14: Altitude vs. ISA offset temperature indicating the assumed minimum altitude where ice crystals can form. *Note that ice crystals are not expected to form at conditions below the 492 R line.*

Ice/Water Particle vs. Air Temperature through the Engine Inlet

In the NPSS code, there is a model to estimate the aerodynamic performance of the engine inlet, from the entrance region through the plane of the fan face, based on the area ratio and length. The change in total temperature due to the forward velocity of the vehicle is estimated, and the static temperature is calculated from the entrance of the engine to the plane of the fan leading edge. At the entrance, the temperature of an ice crystal is equal to the ambient temperature. However, because the aircraft is flying at a moderately high Mach number, the total temperature of the air is increased above the ambient, and the change in temperature is calculated based on the Mach numbers at the entrance and at the fan face. As the air is diffused through the subsonic inlet, the static temperature of the air rises even before reaching the fan leading edge. At high altitude operating points, for example during the descent mode at an altitude of 38334 ft. and vehicle Mach .73 in Figure 11, the temperature of the ice particles in the engine inlet is typically well below freezing, until the particles are inside the fan-core and LPC, as illustrated in Figure 15. Through the inlet and most of the fan-core and LPC, the ice particle temperature rises and also sublimates. Note that throughout the flow path the enthalpy exchange between the ice particle and the air is iteratively computed.

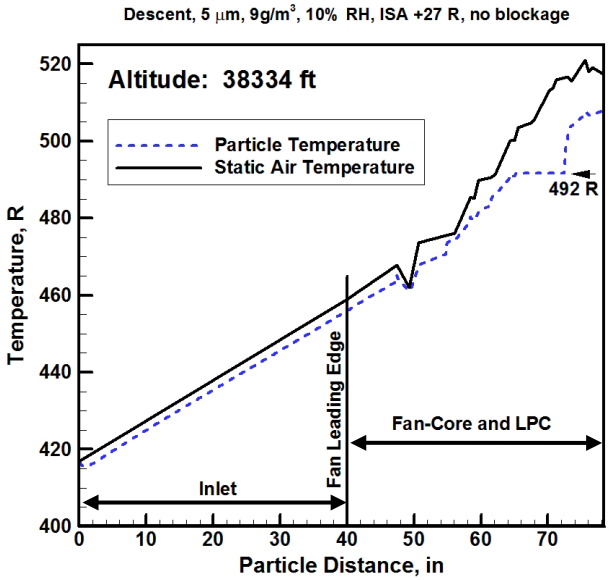

Figure 15: The temperature of the ice crystal particles lags the static temperature of the air through the engine inlet, the fan-core and the LPC at 38K ft during the descent mode, with particle travel distance.

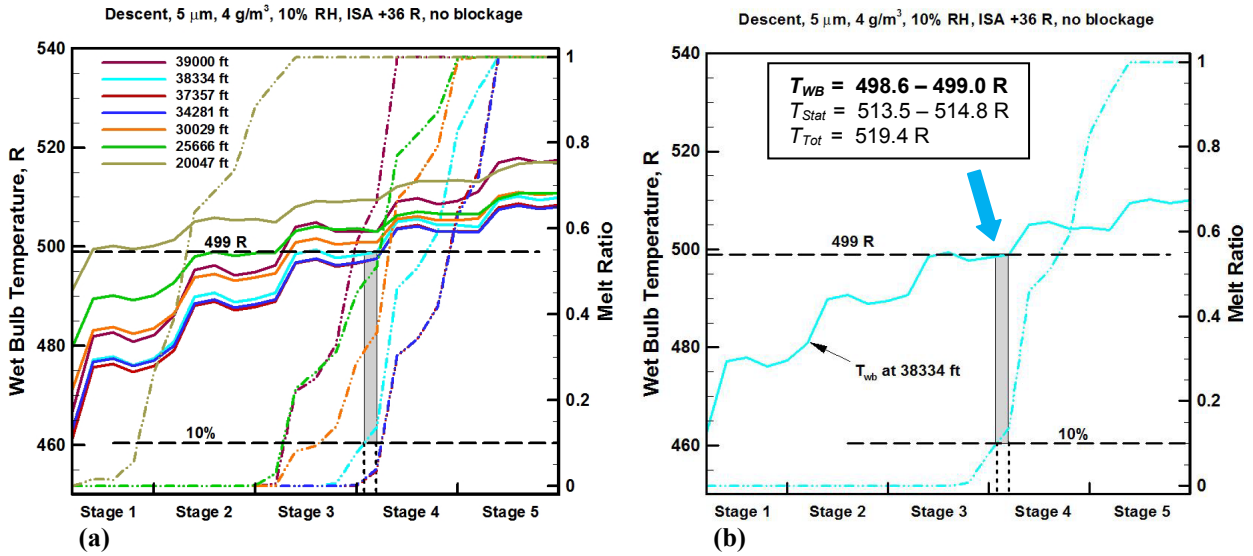
At a distance traveled of 64 inches, the particle reaches the freezing temperature of water (492 R) and begins the melting and evaporation process. The ice-water particle remains at 492 degrees until it is fully melted at 72 inches of distance traveled. At 72 inches the particle is fully melted (melt ratio = 1.0). Beyond 72 inches the fully melted particle continues to rise in temperature while continuing to evaporate. Although the computer code models the air flow and ice crystal physics through the inlet portion of the engine, the subsequent figures will illustrate the flow conditions of wet-bulb temperature and melt ratio only through the fan-core and LPC, since those are the areas where there can be risk of accretion due to ice crystals. Details of ice crystal temperature and static temperature of the air as a function of temperature data are provided in Appendix F.

Methodology to Determine Ice Risk

The methodology to determine whether there is a potential risk of ice accretion throughout the flight trajectory in the low pressure compression system involved tracking the wet-bulb temperature and the melt ratio through the flow path. The figures below illustrate how varying the ice particle size and temperature above ISA through the descent affected the local wet-bulb temperature and the melt ratio through each blade row in the fan-core and LPC. To illustrate this methodology Figure 16(a, b) is provided as an example. Figure 16(a) shows the seven descent mode altitudes that were analyzed, from 39000 to 20047 feet. In this and similar figures, the solid lines show the calculated wet-bulb temperature while the hatched lines show the melt ratio.



Figures 16(a, b): Wet-bulb temperature and melt ratio both indicate that there is a risk of ice accretion between stage-3 and stage-4 during descent. (a) All altitudes. (b) Risk of ice accretion at 38334 feet.

With an ice particle size of 5 μm, an IWC of 4 g/m^3, and the inlet temperature of +36 R offset from the ISA, it was found that at 38334 feet altitude, the wet-bulb temperature and the melt ratio criteria are both met at the same location, as indicated by the gray shaded area of Figure 16(a). Figure 16(b) shows the results at the 38334 feet extracted from Figure 16(a). This indicates that there is a risk of ice accretion in the stator gap of stage-3, specifically just past the stator trailing edge. The wet-bulb temperature in the stage-3 stator gap is 498.6 R. The range of static temperature is 513.5-514.8 R, while the total temperature is 519.4 R. This methodology was used in the parametric icing risk analysis that follows, where particle size, IWC, and ISA offset temperature were varied through the flight trajectory (Figure 11), which includes two cruise altitudes and a descent mode.

Parametric Icing Risk Analysis

The parametric study of the engine performance was carried out by varying the specified inlet conditions of ice particle size, concentration, and ambient temperature offset above the ISA. This study extends the work from an earlier paper[16] with updated COMDES and MELT analysis codes, as well as a broader range of IWC. Furthermore the complete analysis results are included in the Appendices. Each cruise altitude was studied at four separate operating points, representing different thrust settings, as shown in Figure 11. In Figures 18-23, the ice particle size studied were 5, 10, 25, 50, and 100 μm; the ISA temperature increase was varied from +18 R to +36 R. The cruise conditions studied were at a range of engine thrust settings from 100% to 69.9% of maximum thrust for the given

altitude. In the descent mode, the thrust was set at 10% of maximum thrust at each altitude analyzed. The ice concentrations in this study were 2, 4, and 9 g/m^3. The results shown in the following figures indicate whether there is a risk of ice accretion at the specific altitude operating condition, ice crystal concentration, size, and temperature above ISA. The scale in Figures 18-23 indicates the wet-bulb temperature variation through the blade rows and axial gaps in the fan-core and low pressure compressor. The melt ratio is also plotted on a scale from 0.0 – 1.0, where 0.0 indicate no melting, and 1.0 indicates an ice particle that is 100% melted. Note that the inlet relative humidity was kept at 10%, since it was noticed early in the analysis that it did not have a strong effect on the results. It was observed that even if the ambient relative humidity at the fan face was 80%, the rise in temperature through the rotor blades quickly reduced the local relative humidity in each stage to significantly lower levels, as illustrated in Figure 17. The rate at which the relative humidity is reduced through the stages is also a function of engine thrust level, as shown in Figure 17. The local value of relative humidity has a direct effect on the local wet-bulb temperature determination, as calculated by the equations (23, 24, and 25).

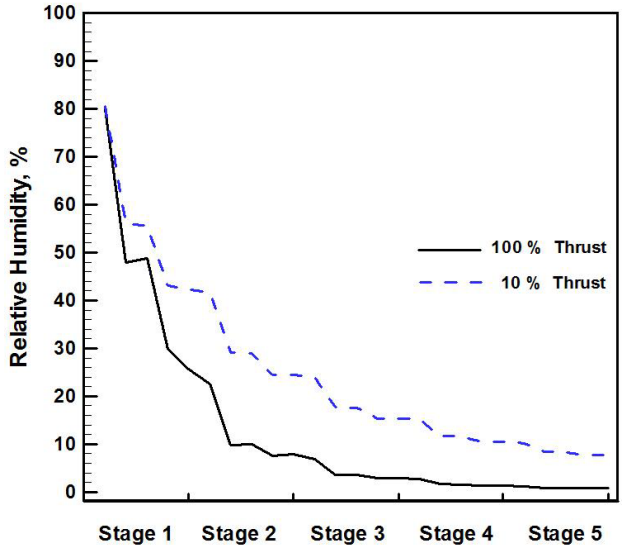


Figure 17: Change in relative humidity through the five stage fan-core and low pressure compressor, at 100% and 10% engine thrust levels. Note that the relative humidity is quickly reduced in each subsequent stage.

Cruise at 35000 feet:

The analysis was conducted at the altitude cruise condition of 35000 feet using the methodology described above. The engine thrust level was varied between 100% and 69.9% of max thrust at this cruise altitude. The particle size was varied from 5 µm to 100 µm, and the IWC was varied between 2 and 9 g/m^3, but only the results for the 2 g/m^3 are presented below as representative at this cruise altitude.

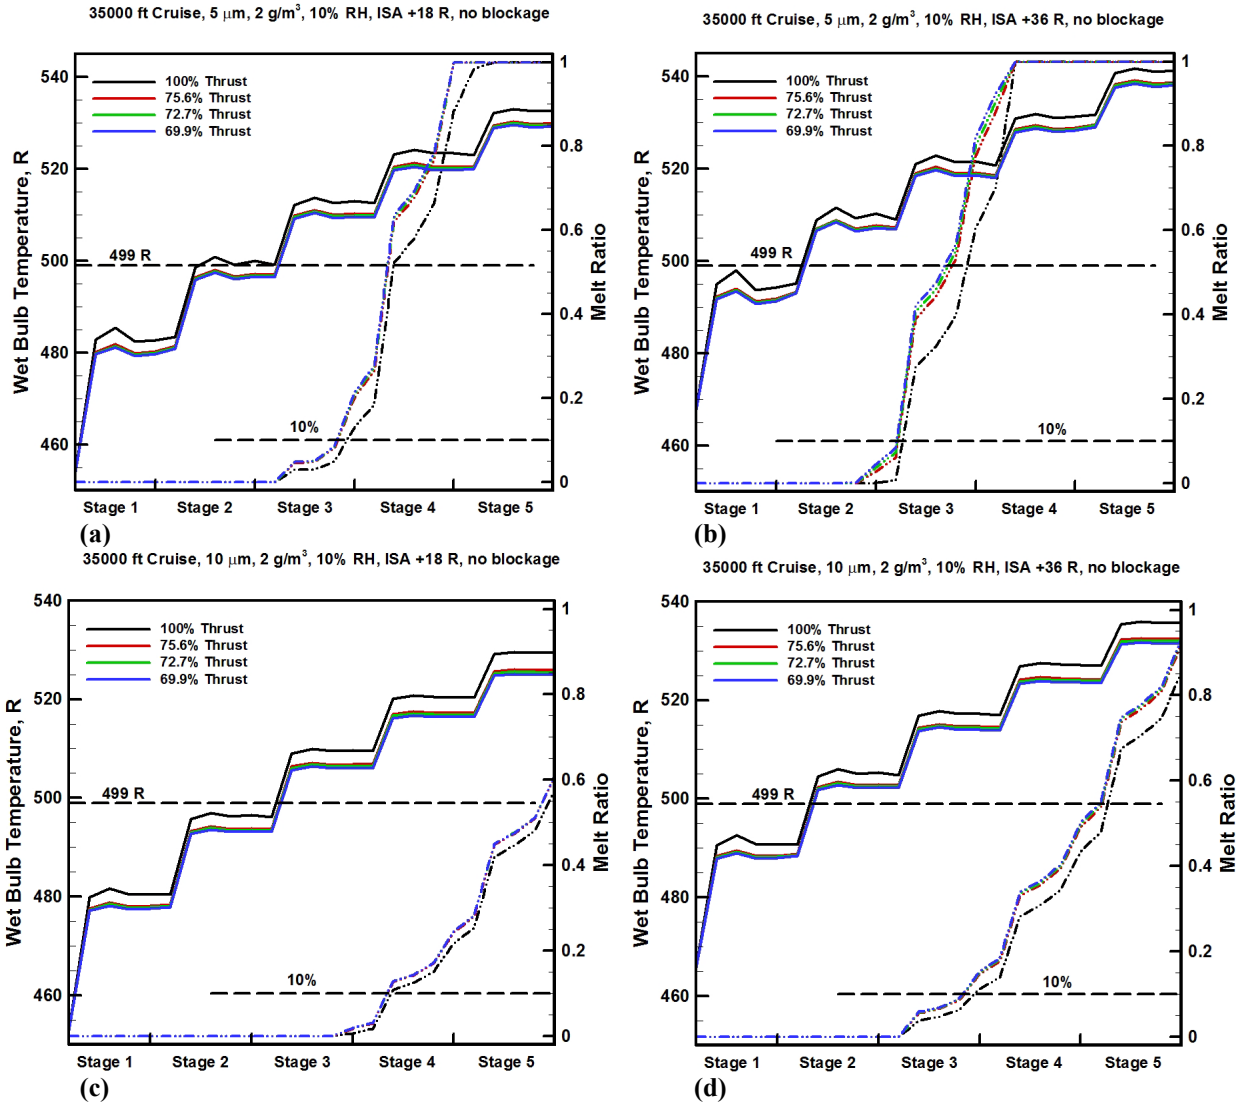

Figure 18(a-d): Cruise condition at 35000 feet altitude, with particle sizes of 5 µm (a, b) and 10 µm (c, d) and ISA temperatures of +18R (a, c) and +36R (b, d).

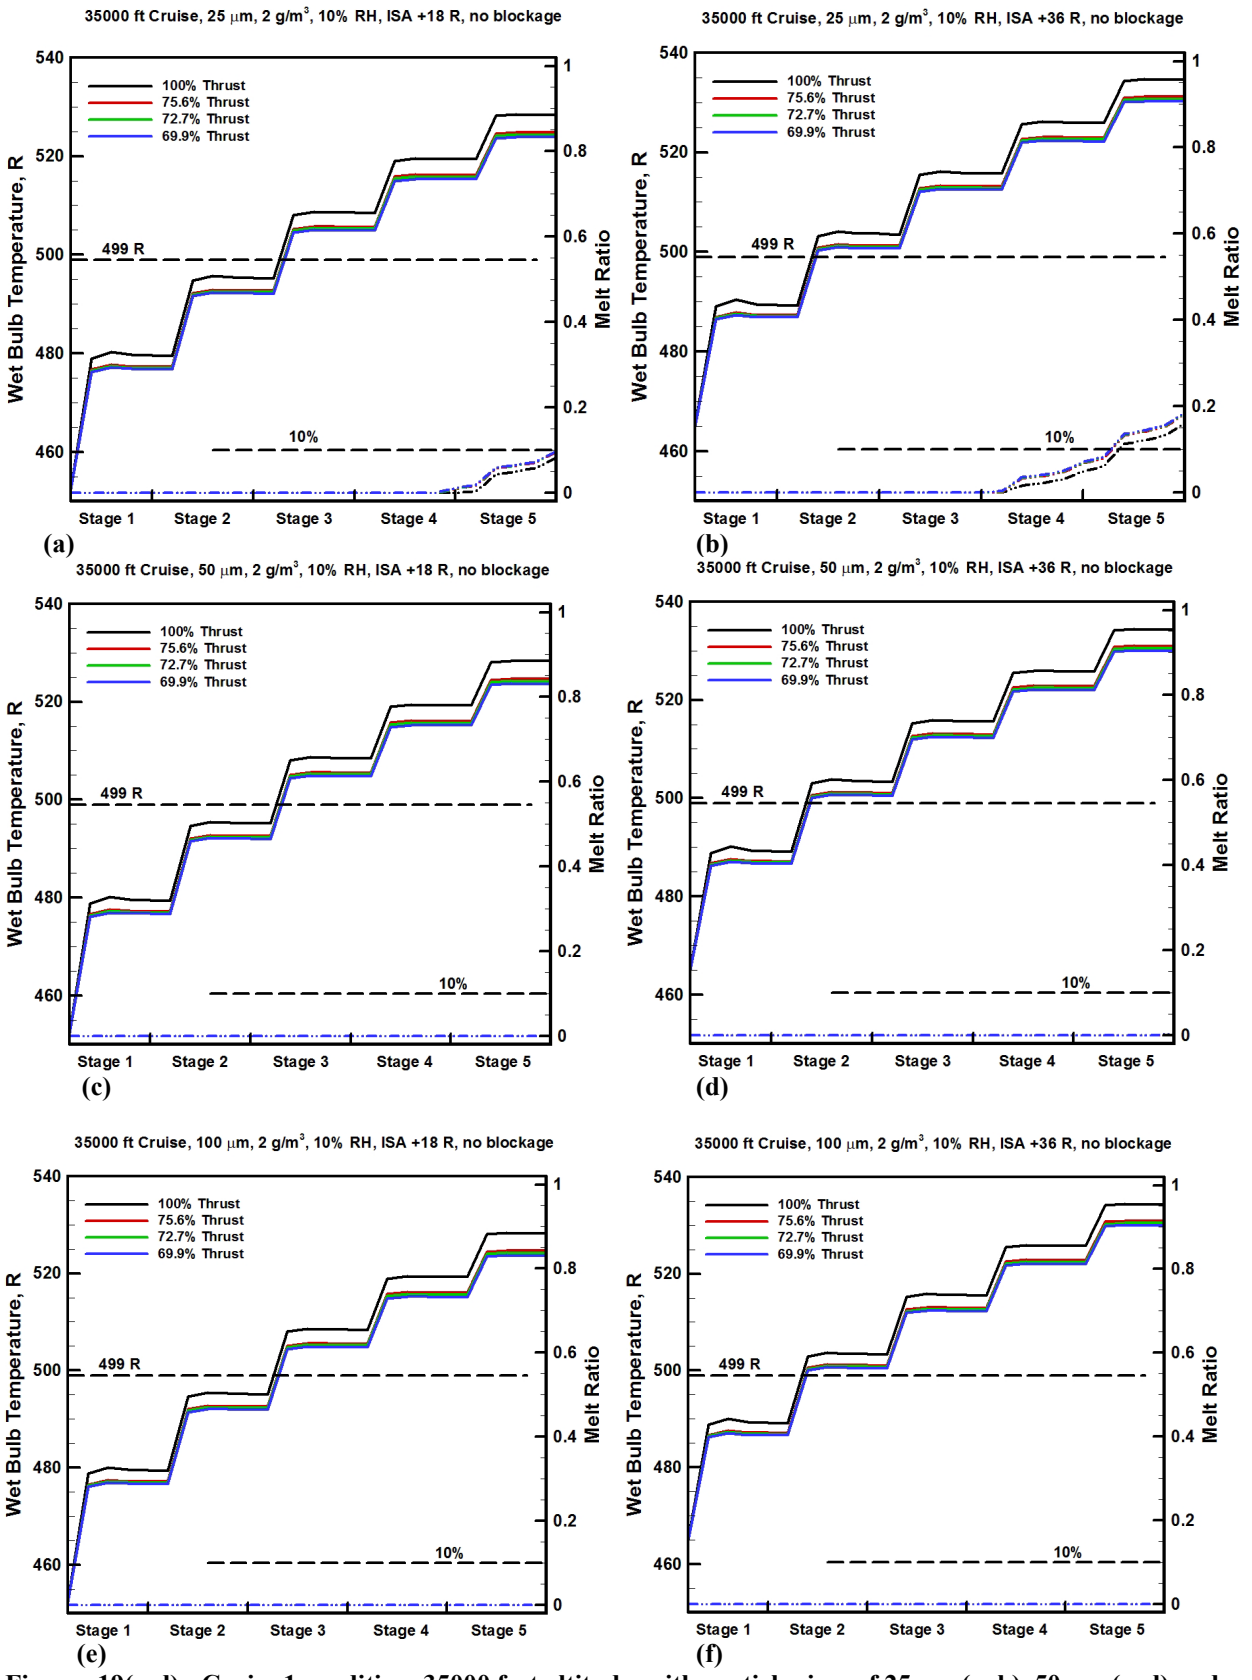
The results illustrated in Figure 18(a-d) show no risk of ice accretion is possible at this cruise condition with these particle sizes (5 and 10 µm), since the wet-bulb temperatures are excessively high in the compressor stages where the 10% melt ratio condition is met. For example, the 10% melt ratio criterion is reached in stage-3 as shown in Figure 18(a), but the wet-bulb temperature there is 512 R, and is well above the 499 R temperature limit. The effects of ice particle size and elevated ISA temperature can be seen in the location within the LPC where the minimum melt ratio criterion of 10% is reached. At all of these conditions, even though the melt ratio of 10% is achieved in the LPC, the wet-bulb temperature is well above the 499 R limit, at that location. Therefore, there is no expected risk of ice accretion at these operating conditions.

The ice crystal particle size was further increased at this cruise altitude to determine the risk of ice accretion, as shown in Figure 19(a-f). The particle sizes were 25, 50, and 100 µm, with the same increment of temperatures (+18 R and +36 R) above ISA. The range of engine thrust settings varied from 100% to 69.9% of maximum thrust.

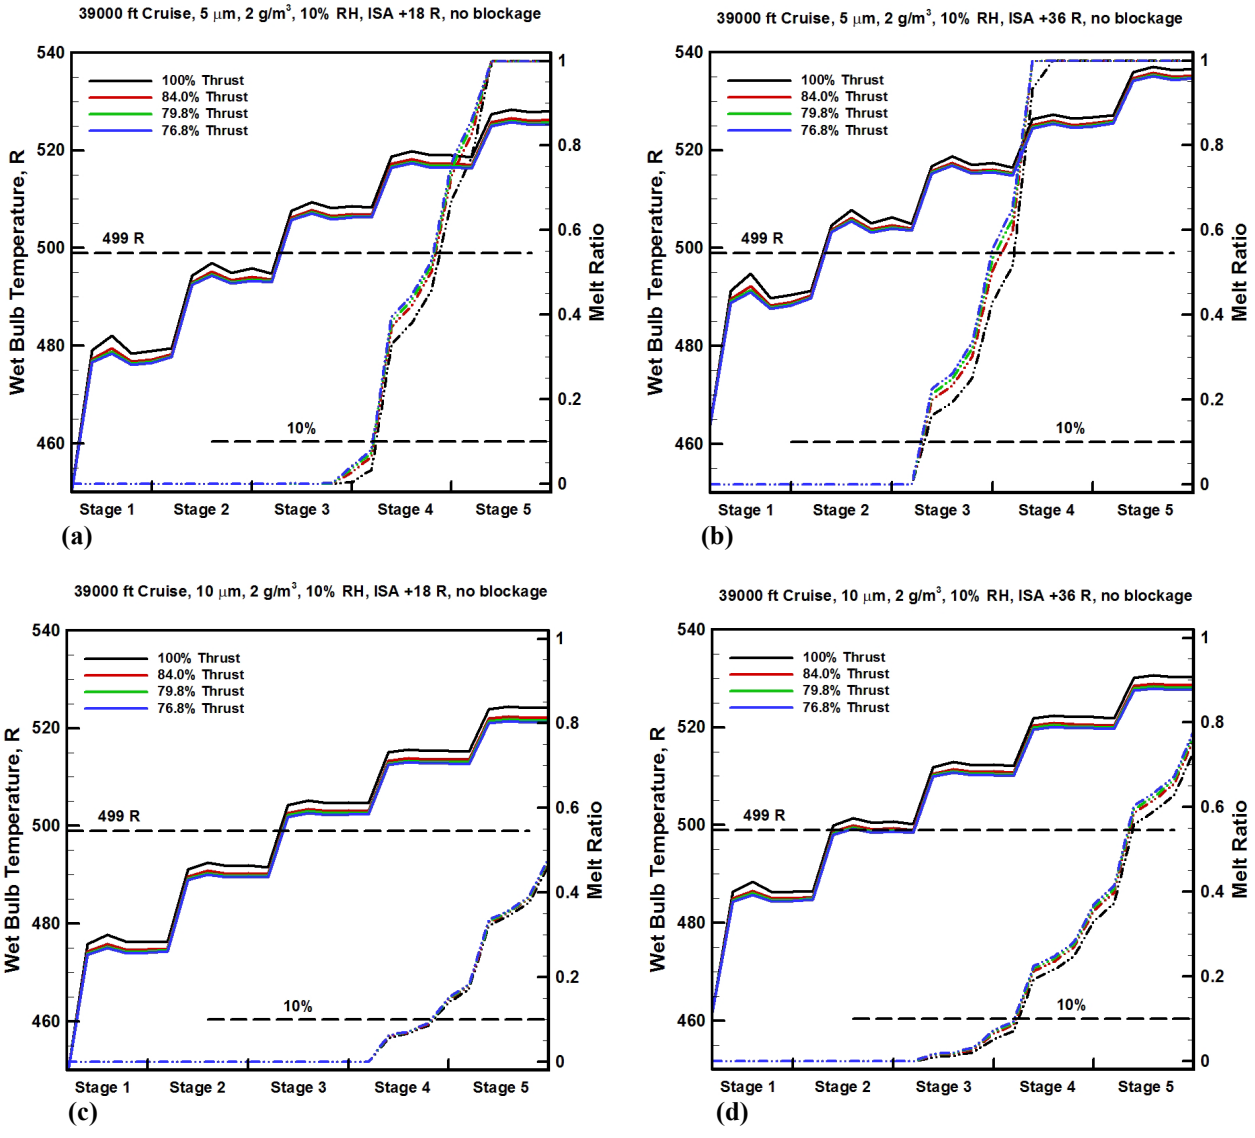


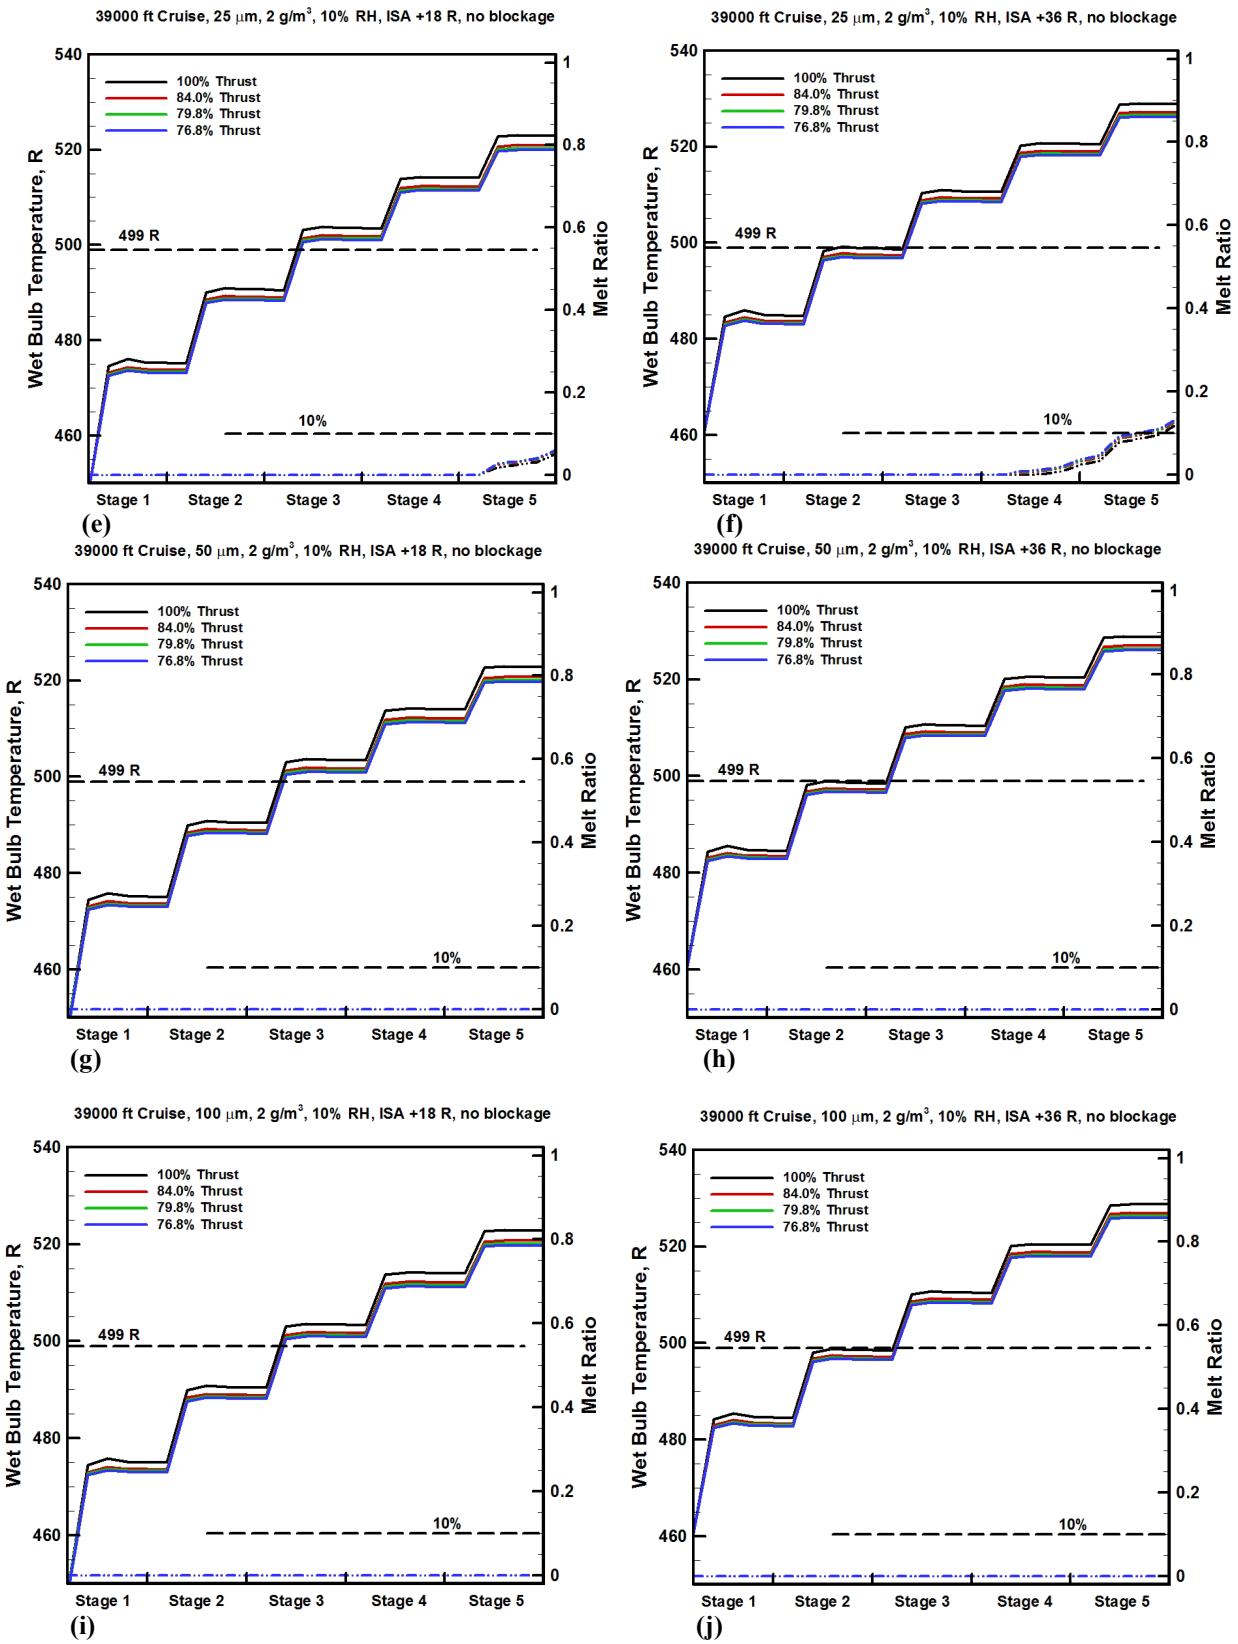
Figures 19(a-d): Cruise 1 condition, 35000 feet altitude, with particle sizes of 25 µm (a, b), 50 µm (c, d) and 100 µm (e, f) and ISA temperatures offsets of +18 R (a, c, e) and +36 R (b, d, f).

The results illustrated in Figure 19(a-b) show that the 10% melt ratio limit is reached only in stage-5 with the 25 µm particle. However, the wet-bulb temperature in stage-5 is well above the 499 R temperature limit. In Figure 19(c-f) the 50 and 100 µm particles do not melt through the entire fan-core LPC, and the melt ratio remains zero. Therefore, there is no risk of ice accretion at any of the conditions illustrated in Figures 19(a-f). Note that even though the ice particle may not have melted, there was some degree of sublimation, adding to the specific humidity of the air and is accounted for in the flow analyses. Appendix G is a listing of the NPSS cycle analysis and Appendix H is the corresponding output listing of the compressor analysis code for the altitude cruise conditions at 35000 feet.

Cruise at 39000 feet:

The next points in the flight trajectory analyzed were at the cruise altitude of 39000 feet. The ice crystal particle size was varied from 5 µm to 100 µm in diameter, with the temperature offset at +18 R and +36 R above ISA. The results are illustrated in Figures 20(a-j). The range of engine thrust settings at this cruise condition was varied from 100% to 76.8% of maximum thrust.



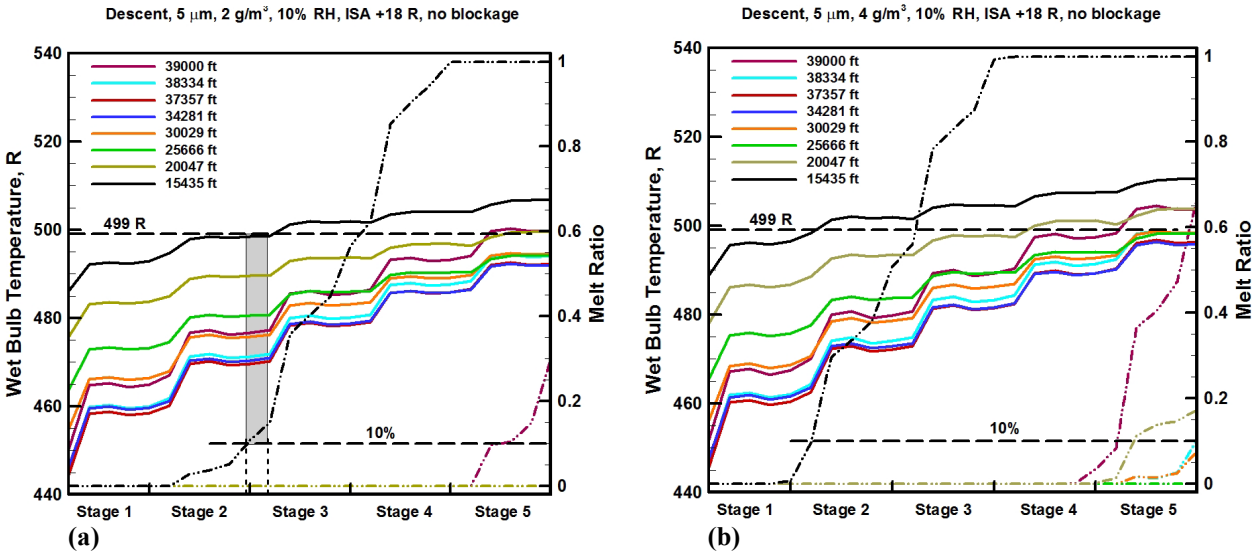


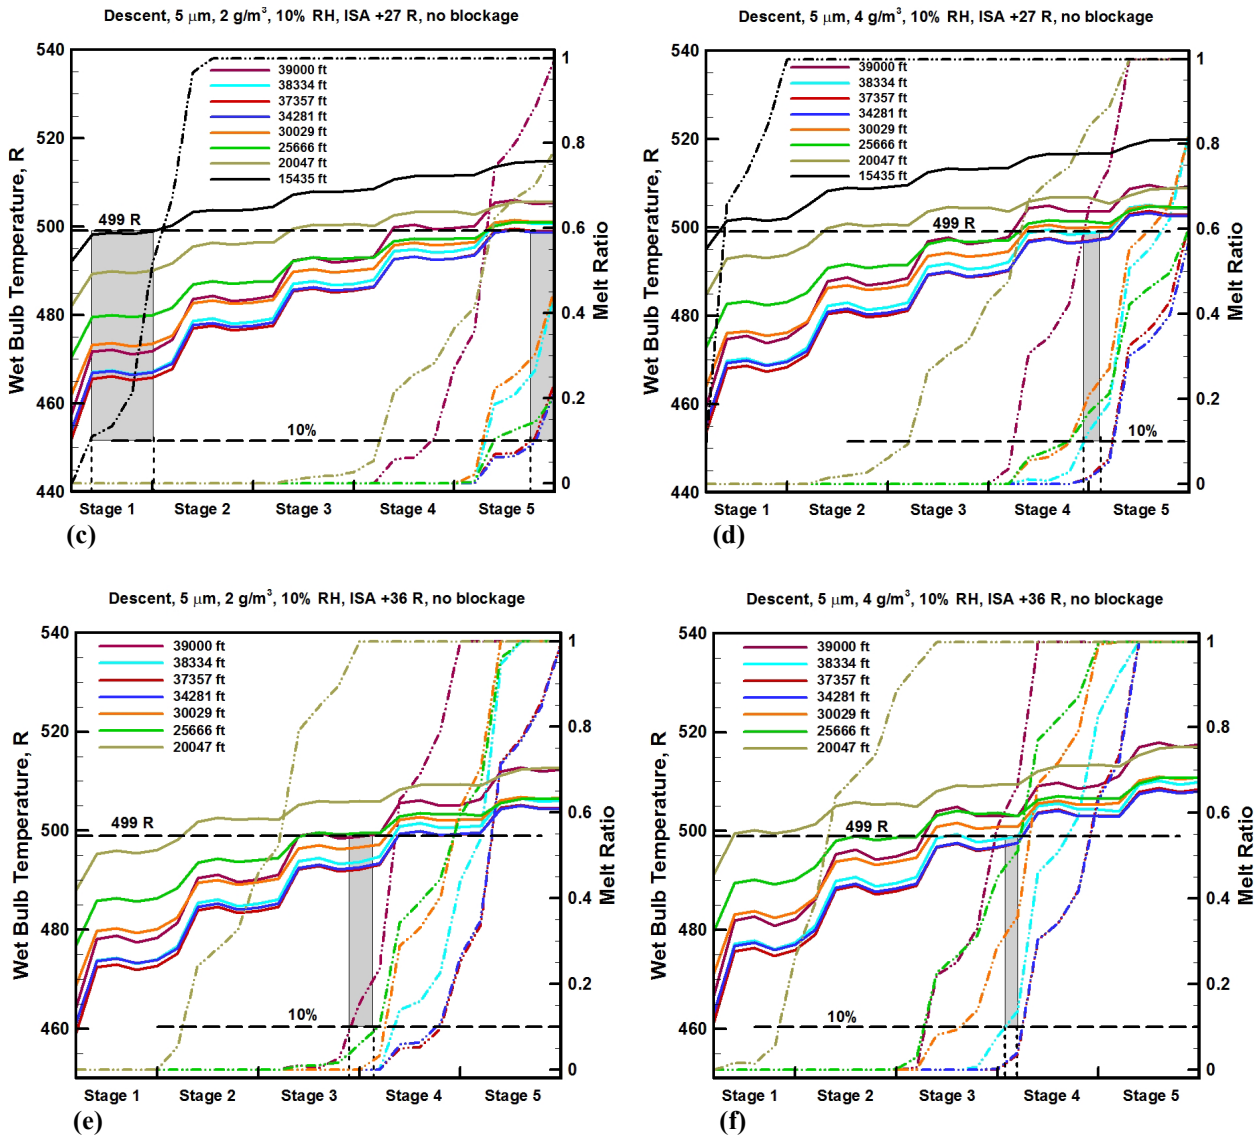
Figures 20 (a-j): The cruise condition at 39000 feet altitude, with particle sizes of 5 μm (a, b) and 10 μm (c, d) 25 μm (e, f), 50 μm (g, h), and 100 μm (i, j) and ISA temperatures offsets of +18 R (a, c, e, g, i) and +36 R (b, d, f, h, j).

The results illustrated in Figure 20(a) show that the 10% melt ratio limit is reached in the axial gap at the leading edge of the rotor between stages 3 and 4 with the 5 μm particle and ISA temperature offset of +18 R. However, the wet-bulb temperature exceeds the maximum limit of 499 R for accretion to occur. In Figure 20(b), at the engine inlet temperature of ISA +36 R, the minimum melt ratio of above 10% is achieved in the stator of stage-3, while the wet-bulb temperature exceeded the limit that would support ice accretion. In both of these cases, the melt ratio reaches the value of 1.0, indicating that the ice particle has completely melted before exiting the LPC. In Figure 20(c) with the 10 μm particle and +18 R ISA offset, the results indicate that the minimum melt ratio is achieved in the stator of stage-4. At the elevated ISA temperature of +36 R, Figure 20(d), the minimum melt ratio is reached at the leading edge of the stage-4 rotor. In both cases the wet-bulb temperature is too high to support ice accretion. In Figures 20(e) the minimum melt ratio is not reached at the lower temperature of ISA +18 R, but is reached at ISA + 36 R near the trailing edge of the stage-5 stator, as shown in Figure 20(f). However, the wet-bulb temperature is well above the limit that would support ice accretion. The results with the 50 and 100 μm ice particle sizes as illustrated in Figures 20(g, h, and i, j) show that the minimum melt ratio limit is not reached at any stage within the fan-core and LPC. Furthermore, the wet-bulb temperature at the end of the LPC is well above the maximum limit for accretion. Appendix I is a listing of the NPSS cycle analysis and Appendix J is the corresponding output listing of the compressor analysis code for the altitude cruise conditions at 39000 feet.

Descent:

The next operating points in the flight trajectory that were analyzed were computed during the descent mode from the 39000 feet cruise altitude, as shown in Figure 11. These consisted of eight altitudes starting at 39000 feet and descending to 15435 feet, at +18 R, +27 R and +36 R ISA offset temperatures at reduced engine thrust level of 10% of maximum thrust at the given altitude. As before, the ice crystal particle sizes modeled were 5, 10, 25, 50, and 100 μms in diameter. Due to the ice particle formation limits that are illustrated in Figure 14, there were seven altitudes that were analyzed at the +36 R offset temperature between 39000 feet and 20047 feet. In a more refined parametric study, it is suggested that smaller increments of altitude, particle size, ice particle concentration, relative humidity, and elevated ISA temperatures should be used. The calculated results of wet-bulb temperature and melt ratio at each computing station within the fan-core and LPC stages are illustrated in Figures 21(a-f) with an initial ice crystal particle diameter of 5 μm and IWC of 2 and 4 grams per cubic meter. Note that the analysis also included 9 g/m^3, but the results indicated no risk of ice accretion at any altitude, or ISA offset temperature.





Figures 21(a-f): Descent mode. The ice particle size used in the analyses was 5 μm. The inlet temperature specified were ISA +18R (a, b), ISA +27R (c, d), and ISA +36 R (e, f).

The results illustrated in Figure 21(a) show that the 10% melt ratio limit is reached in the stator and gap after stage-2 with the 5 μm particle and ISA +18 R at an altitude of 15435 feet. In addition, the maximum wet-bulb temperature limit criterion of 499 R is also satisfied at this location. This would indicate that there is a potential risk for ice accretion. With the same values for particle size and ISA offset temperature, the IWC is increased to 4 g/m^3. However, in this case, the melt ratio criterion is not met where the wet-bulb temperature criterion is satisfied at any of the selected operating conditions in the descent flight trajectory, as shown in Figure 21(b). As the IWC is increased, the amount water vapor in the air due to sublimation and evaporation rises resulting in an increase in relative humidity as well as the wet-bulb temperature. Therefore there is no risk of ice accretion predicted for this case. In Figure 21(c), at the engine inlet temperature of ISA +27 R, there are three altitudes where there is a risk of ice accretion during descent. The first occurs at an altitude of 37357 feet near the trailing edge section of the stage-5 stator and in the following gap. Similarly, at an altitude of 34281 feet the ice accretion risk coincides with that at 37357 feet. The altitude of 15435 feet there is an ice accretion risk predicted in the broad region of the stage-1 rotor-stator gap and through the stage-1 stator, likewise illustrated in Figure 21(c). When the IWC is increased from 2 to 4 g/m^3 the region where there is a predicted risk of ice accretion shifts to the stage-4 stator trailing edge and stator-rotor gap as illustrated in Figure 21(d). At an ISA temperature offset of +36 R and the IWC of 2 g/m^3, there is a risk of ice accretion in the stage-3 stator trailing edge and stator-rotor gap in the descent from the cruise at an altitude of

39000 feet, as shown in Figure 21(e). When the IWC is increased to 4 g/m^3, the icing region of risk is at the altitude of 38334 feet and is located in the gap between the stage-3 stator and the stage-4 rotor, as illustrated in Figure 21(f). The NPSS listings along with the corresponding compressor analysis for the descent conditions shown in Figure 21 (a-f) are provided in Appendices K and L, respectively.

As mentioned previously, the parametric study also included analyzing an ice particle size of 10 µm with IWC of 2, 4, and 9 g/m^3 at the same range of ISA offset temperatures as in the previous descent analyses. For this particle size, a risk of ice accretion during descent was found only at an altitude of 15435 feet with an IWC of 9 g/m^3 and an ISA temperature offset of +27 R. The accretion risk was located in the region of the stage-1 stator trailing edge and a portion of the gap prior to rotor-2, as illustrated in Figure 22 (details of NPSS and compressor analysis output are provided in Appendix M).

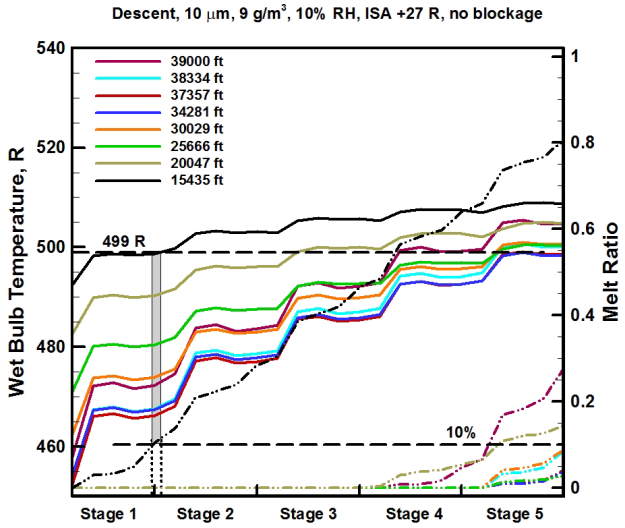


Figure 22: Descent condition, from 39000 feet to 15435 feet altitude. There is a risk of icing with an ice particle size of 10 µm and a temperature offset of ISA +27 R.

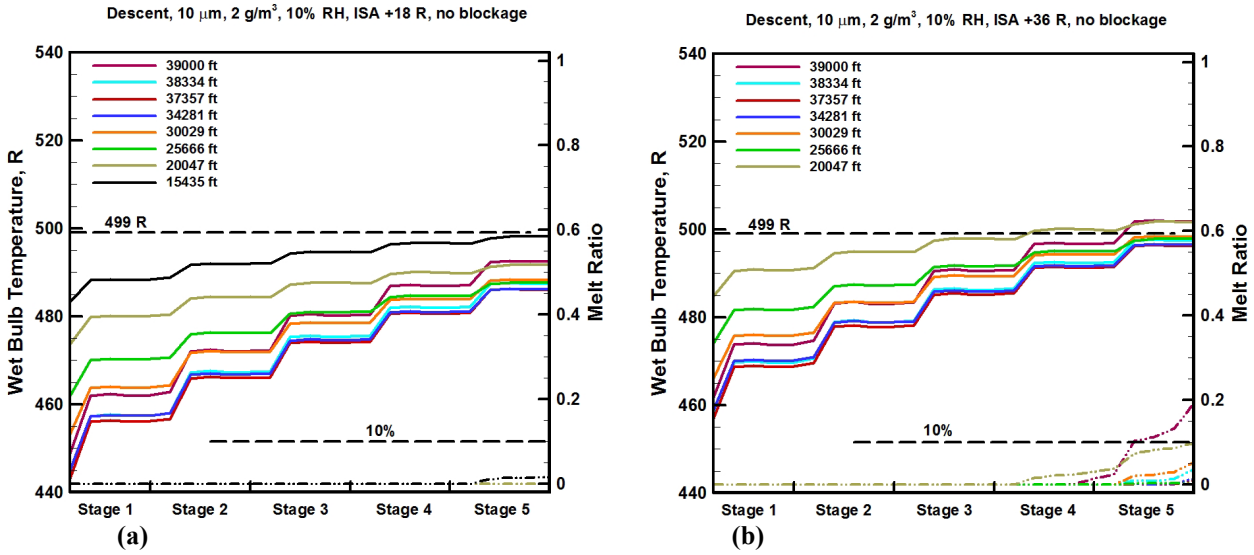
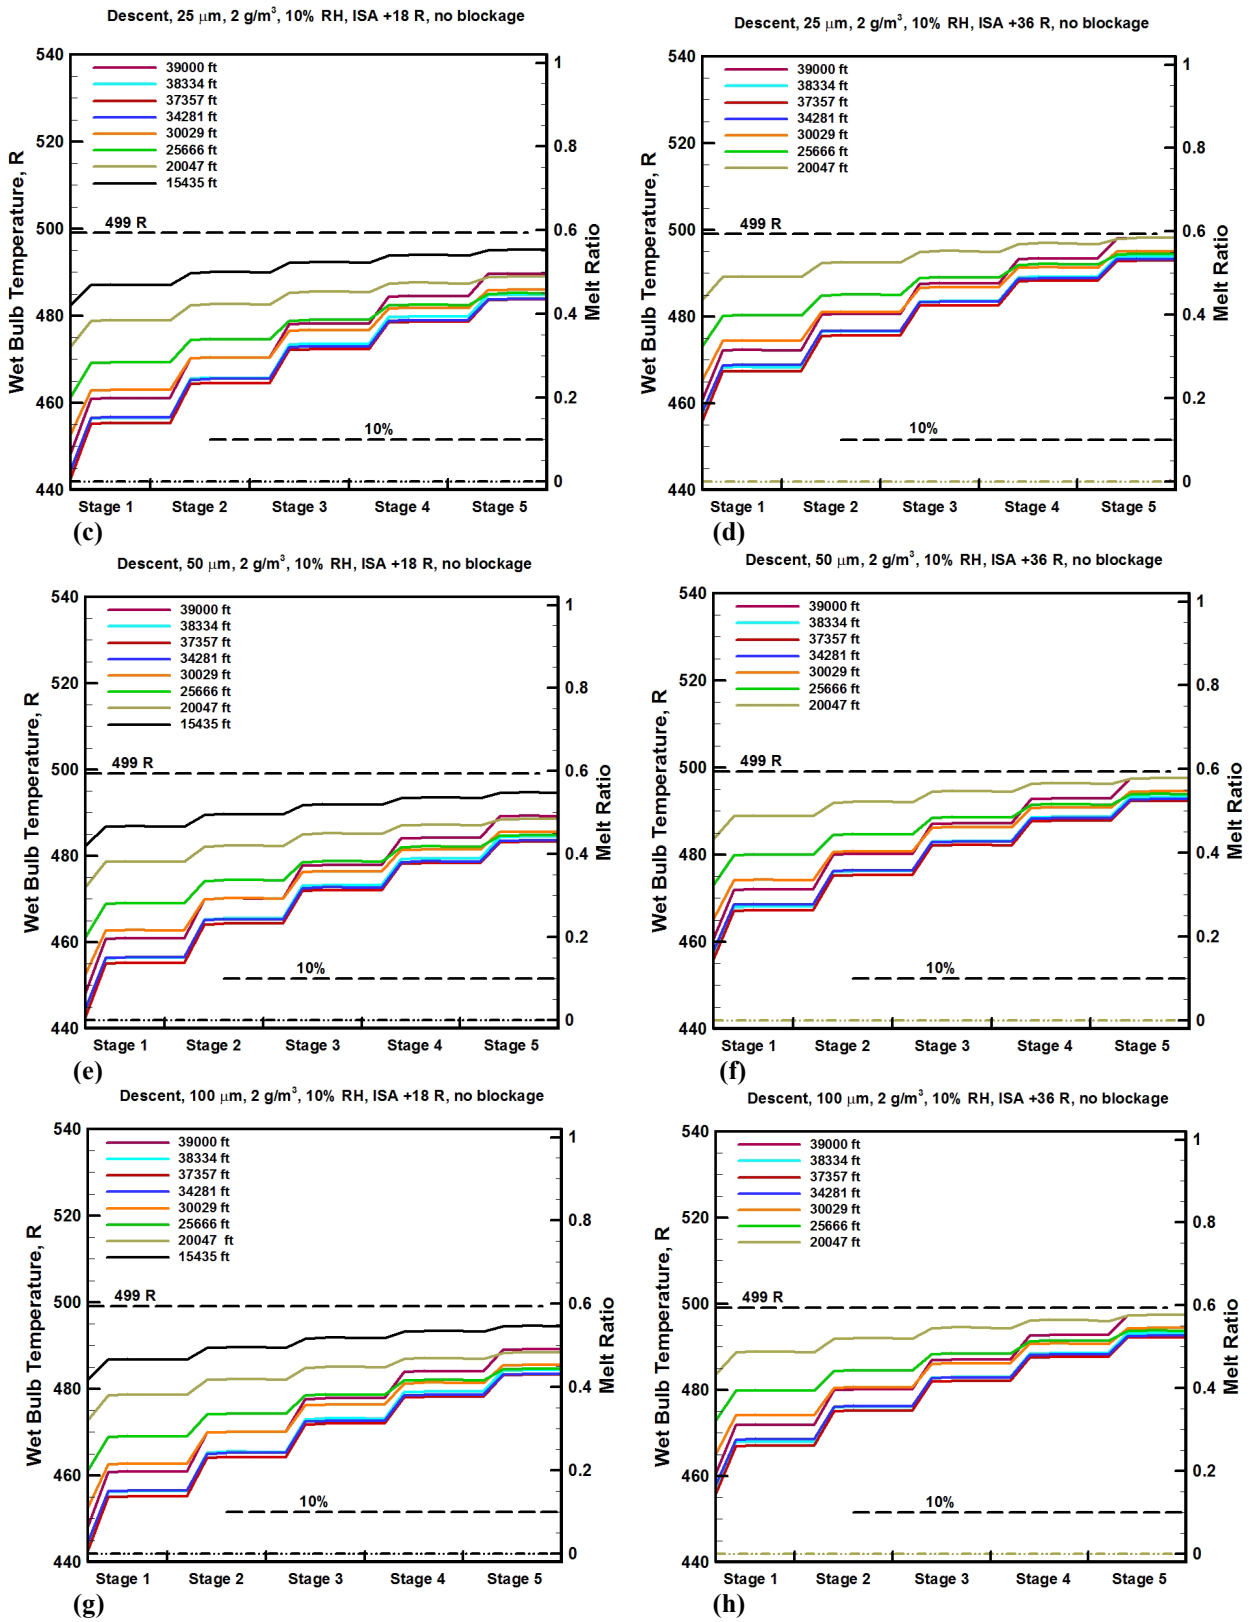
The parametric analysis of the descent mode was continued by further studying the effects of even larger particle sizes at a fixed IWC of 2 g/m^3 and at ISA offset temperatures of +18 R and +36 R. As during the cruise conditions, the particles sizes utilized to analyze the descent portion of the flight trajectory were 10, 25, 50 and 100 µm, and the results are presented in Figure 23(a-h).





Figures 23(a-h): Descent mode, from 39000 feet to 15435 feet altitude (a, c, e, g) and 39000 feet to 20047 feet altitude (b, d, f, h). The ice particle sizes used in the analyses were: 10 μm (a, b), 25 μm (c, d), 50 μm (e, f), and 100 μm (g, h). The inlet temperature offset specified were ISA +18R (a, c, e, g) and ISA +36 R (b, d, f, h).

In Figures 23(a, c, e, g) with particle sizes of 10, 25, 50, and 100 μm, respectively, and an inlet temperature offset from ISA of +18 R, and an IWC of 2 g/m^3, the melt ratio was well below the criterion limit minimum of 10%. Similarly, in Figure 23(d, f, h) with the equivalent particle size and an inlet offset temperature of ISA +36 R, the melt ratio was well below the criterion limit of 10% minimum. Therefore, no risk of ice accretion was expected at these conditions. The only case where the minimum melt ratio criterion was met is the 10 μm and +36 R ISA temperature offset at the altitude of 39000 feet, in the stage-5 stator as shown in Figure 23(b). However the wet-bulb temperature there was almost 3 R above the specified maximum criterion. Therefore there was no risk of ice accretion. The NPSS listings for the descent conditions shown in Figure 23 (a-h) are provided in Appendix N with the corresponding compressor analysis detailed in Appendix O.

Summary of Engine Icing Risk Analysis:

Figures 24(a) and Table II illustrate where the risk of ice accretion was identified along the flight trajectory. Figure 24(b) shows where this notional engine may have a risk of ice accretion in comparison with the events that have been reported in the open literature. The engine events predicted in this study are also summarized in Table II. There were other conditions analyzed parametrically in this study, and the cases shown are a sample of the results to illustrate the method used to determine the icing risk based on the wet-bulb temperature and melt ratio criteria.

IV.Assumptions and Recommendations for Future Research

This study is ongoing research and is intended to be a status report on the current state of the engine icing modeling tool development effort at NASA Glenn Research Center utilizing the NPSS-COMDES-MELT analysis tool. Simple empirical models have been used that were derived from test data to determine the aero-thermodynamic conditions within the fan and low pressure compressor that identified the risk of ice accretion. Two key parameters were identified to predict whether there is a risk of ice accretion within any turbofan engine. Numerous other simplifying assumptions were made that enabled studying the very complex physics involved in engine icing due to ice crystal ingestion. The actual IWC ice crystal concentration (grams of ice per cubic meter of air) in ice clouds is currently unknown. Likewise, the actual particle size existing in the atmosphere is also unknown, and is likely larger than was assumed in this study, before entering the fan and LPC, but may be broken up into much smaller particles upon impact with the high speed rotor blades and stator vanes of the compression system. Also, there may be a particle size distribution after impact, as opposed to a particle of a single size, as was assumed in this study. There is currently research in these areas that will attempt to quantify the ice particle impact dynamics, as well as the particle size distribution after impact. Therefore in this study it was assumed that the ice particles entering the engine have already been broken up into small particles due to impact with engine components. In addition it is assumed that the small particles are evenly distributed through the bypass duct and the engine core, as well as evenly distributed in the radial direction.

The low fidelity approach was selected for this study primarily to provide a fast capability to screen engines for potential icing risk in an ice crystal environment. It would be computationally expensive to model the three phase flow through the fan and low pressure compressor with a multidisciplinary, time-dependent code that simulates the aerodynamics, thermodynamics, ice particle physics, accretion, and heat transfer analyses through the blades and end walls. Additionally finer increments of altitude, ISA offset temperatures, and ice particle size can be considered for a more refined parametric study. Ranges of particle concentrations at altitude obtained from future flight tests may reduce the need to parametrically vary IWC.

Ice accretion is not addressed in the current study, but should be considered in the future. Likewise there is no radial distribution of blockage currently available in the low fidelity approach used in this study. However, a bulk value of blockage at a specific location in the compressor is available in the code and has been previously demonstrated. Further research is necessary to model the effects of shape and roughness of the accreted ice on the surfaces of the flow path walls and stator vanes. Unusual ice shapes that accrete on the compressor stators and walls will likely have a detrimental effect on the pressure recovery and losses and the cumulative effects on the downstream compressor stages, as well as the overall power balance of the engine system. Erosion of ice due to impact of incoming ice particles on the accreted ice was likewise not considered in this study, but is a topic for future research. Another area of research may be to study the dependence of accretion on the local Mach number and particle concentration. High fidelity compressor flow simulations in the future should consider these effects. There is no data available on the accreted ice shapes in turbomachinery, as the ice shapes may likely be influenced by the unsteady air flow fluctuations between the rotors and stators. Experiments that quantify the accreted ice shapes in rotating turbomachinery need to be conducted to determine the unsteady effects on ice accretion for high fidelity flow

analysis and ice accretion code validation and calibration. These results can also be incorporated in the low fidelity modeling to improve its current capabilities.

The current study does not have an ice shedding model. Based on observed accretion behavior, the assumption in this study is that if the wet-bulb temperature is below freezing, then the ice that accretes is firm, and does not shed, but continues to grow as a function of time. Although laboratory testing has shown that there is some level of ice buildup at conditions that were at wet-bulb temperatures approximately 499 R, the ice accretion at these conditions was not firm, but was loose "slushy ice" that quickly shed before a substantial amount of ice could accrete. The current analysis was limited for this reason to wet-bulb temperatures less than or equal to 499 R. Even though this was not modeled, it is thought that the shedding of loose ice may cause a problem in the compressor by choking the downstream compressor stages due to the instantaneous addition of mass flow, thus it could possibly force the fan or other upstream stages to surge. Further research is needed in this area to study its effect on the compressor and engine system performance.

V.Conclusion

The purpose of this effort was to develop a system of codes to provide a first order predictive capability to estimate the risk of the occurrence of engine ice accretion during flight through high altitude convective ice crystal clouds. A first generation computational tool has been developed for estimating the susceptibility of engines to icing. The tool consists of an engine thermodynamic cycle model, a compressor mean line flow analysis model that calculates the aerodynamic performance of each blade row, and an ice particle sublimation, melting, and evaporation model that tracks the state of the ice/water particle through the compressor blade rows. Using this fully integrated capability, a notional turbofan engine was studied to predict the risk of ice accretion in the low pressure compressor, operating in a gas turbine engine system environment through a flight trajectory of a typical commercial aircraft. Two aero-thermodynamic parameters were identified as the criteria for determining whether there is a risk of ice accretion when flying in a high altitude ice crystal environment: the local wet-bulb temperature and the ice melt ratio. A parametric approach was utilized to determine the risk of accretion in the low pressure compressor over a range of atmospheric conditions while varying ice crystal size, ice water content, and ambient temperature. With the assumptions that were made in this study, it was determined that the notional engine would experience a risk of ice accretion at multiple operating conditions during the descent mode of the flight trajectory, with ice particle sizes on the order of 5 μm and ambient temperature offset from the ISA were in the range of +18 R to +36 R. The results of this study indicate that the risk of ice accretion on this engine occurs between 39000 – 34000 feet, and near 15000 feet. At the higher altitude near 39000 feet, the risk of accretion occurred in the rear LPC stages, while at the lower altitude near 15000 feet, the risk of accretion occurred in the front stages. All of the predicted icing risk operating points identified for this notional engine were within the envelope of the known icing events of commercial aircraft engines that have been reported in the literature.

APPENDICES

The following appendixes can be accessed from the hyperlinks below or from the bookmarks panel located on the left-hand side of this document.

A. Normalized Growth Rate as a function of LWC_m/TWC_{inj}, Figure 8.

B. Design Point Performance; compressor code output listing for the Fan-Core and LPC.

Nomenclature; Variable Description of COMDES Compressor Code Output

Area1	Rotor leading edge annular area, in^2
A1/A*	Ratio of annular area at the rotor leading edge to the choke area
A*	Choke area of rotor, in^2
AeroBl	Aerodynamic blockage (e.g., 0.98 = 2% blockage)
AthrRotor	Throat area of rotor, in^2
Alfa	Absolute flow angle at stator exit, degrees
Abs MACH	Absolute Mach number
Beta BLADE	Blade angle, degrees
B2 axial	Rotor exit height in axial direction, in.
BetaFlo	Relative flow angle, degrees
BetaBlade	Rotor blade angle, degrees
Beta FLO	Relative flow angle, degrees
C	Absolute velocity, ft/s
ChokeMargin	Choke margin of rotor
Cu	Tangential component of absolute velocity at rotor leading edge, ft/s
Cm	Meridional component of velocity at rotor leading edge, ft/s
C_p	Specific heat at constant pressure
CFM	Volumetric flow rate, ft^3/min
DelRCu	Angular momentum change through blade
Del Enthalpy	Enthalpy rise
Del_H/U^2	Head coefficient (Enthalpy rise / tip speed squared)

Del T	Total temperature rise, R
Deviat	Flow deviation angle from blade trailing edge, degrees
Diff Fct	Diffusion factor
DIFF LOSS	Diffuser, or stator loss coefficient
Efficiency	Efficiency, adiabatic
EffAVG	Rotor average efficiency, adiabatic
GAMMA	Ratio of specific heats (C_p / C_v).
GHP	Horsepower
Incid	Rotor leading edge incidence angle, degrees
NBLAD	Number of rotor blades
Ns	Specific speed
Ns nondim	Specific speed, non-dimensional
OPR	Overall Pressure ratio, total-to-total
PR	Stage pressure ratio, total-to-total
Pdisch	Discharge pressure, psia
Pt	Inlet total pressure, psia
Ps	Static pressure, lbf / ft^2
POTH	Potential ratio hub, absolute axial velocity at hub / axial velocity at mean radius radius (typical value can be 0.9, or 10% lower velocity at hub)
POTS	Potential ratio shroud, absolute axial velocity at tip / axial velocity at mean radius (typical value can be 1.1, or 10% higher velocity at tip)
RPM cor	Shaft rotational speed, corrected to standard temperature conditions of 518.7 R
Rel Mach	Relative Mach number
THK	Rotor blade thickness, in
R	Radius from centerline at rotor leading edge, in
R_g	Gas constant, Universal gas constant / mole weight, for air R_g = 53.35 ft-lbf / R
RPM act	Shaft rotational speed, rotations per minute
Reynolds#	Reynolds number
Slip F	Slip factor
Solidity	Solidity
SCFM	Volumetric flow rate, standard cubic feet per minute (14.7 psia, 518.7 R)
Stator	Setting angle at stator, or inlet guide vane exit, degrees
THK	Blade normal thickness, in
Tt	Inlet total temperature, degrees, R
Ts	Static temperature, R
TR	Temperature ratio, total-to-total
Texit	Total temperature at last stage exit, R
U	Blade peripheral velocity at rotor leading edge, ft/sec
U1 corrected	Rotor peripheral tip speed corrected to standard inlet temperature
W act	Mass flow rate, lb_m/s
W cor	Mass flow rate corrected to standard pressure and temperature conditions (14.7 psia, 518.7 R)
Ws1/W2	Inlet tip relative velocity / exit relative velocity
W	Relative velocity, ft/s
