ABSTRACT

Described herein are methods and apparatus for detecting stones by ultrasound, in which the ultrasound reflections from a stone are preferentially selected and accentuated relative to the ultrasound reflections from blood or tissue. Also described herein are methods and apparatus for applying pushing ultrasound to in vivo stones or other objects, to facilitate the removal of such in vivo objects.

RELATED APPLICATIONS

This application claims priority from U.S. Provisional patent application 61/326,904 filed Apr. 22, 2010, and from U.S. Provisional patent application 61/474,002 filed Apr. 11, 2011, which are incorporated herein by reference in their entireties.

GOVERNMENT RIGHTS

This invention was made with government support under grant numbers DK43881 and DK086371 awarded by National Institutes of Health (NIH) and grant number SMST01601 awarded by National Space Biomedical Research Institute (NSBRI) through NASA NCC 9-58. The government has certain rights in the invention.

BACKGROUND

Residual stone fragments such as kidney stones often remain after current methods for stone treatment, such as extracorporeal shockwave lithotripsy, ureteroscopic lithotripsy, and percutaneous nephrolithotomy. In some cases such fragments remain in the lower pole of the kidney. New stones may grow from these fragments, and such fragments have been reported to contribute to a 50% recurrence of kidney stones within 5 years. Thus, improved methods for detecting stones and for facilitating stone clearance from the body are needed.

SUMMARY

It is thus one object of the invention to provide an ultrasound detection method and system for stones in a mammal in which ultrasound reflections from stones are selected and displayed preferentially relative to ultrasound reflections from blood or other tissue.

It is another object of the invention to provide an ultrasound detection method and system for stones in a mammal in which ultrasound reflections from stones are selected and displayed preferentially relative to ultrasound reflections from blood or other tissue, wherein the applied ultrasound used for stone detection is B-mode ultrasound.

It is another object of the invention to provide an ultrasound detection method and system for stones in a mammal in which ultrasound reflections from stones are selected and displayed preferentially relative to ultrasound reflections from blood or other tissue, wherein the applied ultrasound used for stone detection is Doppler ultrasound.

It is another object of the invention to provide an ultrasound detection method and system for stones in a mammal in which ultrasound reflections from stones are selected and displayed preferentially relative to ultrasound reflections from blood or other tissue, wherein the applied ultrasound used for stone detection is Doppler ultrasound, and the preferentially selected reflections are those associated with the Doppler ultrasound twinkling artifact.

It is another object of the present invention to apply an ultrasonic pushing force to a stone to facilitate clearance while using detection of the stone.

It is another object of the present invention to apply an ultrasonic pushing force to a stone to facilitate clearance while using ultrasonic detection of the stone.

In accordance with one aspect of the present invention, ultrasound is used to apply a pushing force to a stone in vivo to facilitate clearance, without causing undue damage to the surrounding tissue. The applied pushing ultrasound can be of lower pressure amplitude than ultrasound used in shock wave lithotripsy ("swl"). It also can have a higher duty cycle to create a sustained force that can reposition a stone.

In another aspect of the present invention, the pushing ultrasound is applied in conjunction with detection ultrasound, to allow for detection of the stone such as by visualization on an ultrasound display monitor, or by aural detection. In one embodiment, the detection ultrasound may be a variant of Doppler ultrasound; in another embodiment the detection ultrasound may be a variant of Doppler ultrasound. In a preferred embodiment of the invention, the ultrasound reflections from the stones are selected and displayed preferentially relative to ultrasound reflections from blood and tissue. Where Doppler ultrasound is used, in one embodiment of the invention the twinkling artifact can be used to facilitate detection of the stone. In one aspect of the invention, such detection ultrasound is used to locate a stone prior to the application of the pushing ultrasound. In another aspect of the invention, the detection ultrasound is used in real time to monitor the movement of the stone during the application of the pushing ultrasound.

In one embodiment of any aspect of the present invention, the pushing ultrasound is applied as a focused beam directed along a propagation axis directed to one or more stones or fragments. In another embodiment of any aspect of the invention the pushing ultrasound is applied in an unfocused or weakly focused mode to a general region of anatomy where stones are likely to occur. For example, such unfocused or weakly focused ultrasound energy could be applied generally to a region of a kidney such as the lower pole region to stir up any fragments that might be located therein, thereby facilitating clearance.

In one embodiment of the invention the methods and systems are used to facilitate the removal of stones, such as stones ranging from about 1 to about 10 mm in diameter. In another embodiment, the in vivo stone is fragmented before applying the pushing ultrasound. Such fragmenting can be carried out by any suitable technique, including but not limited to extracorporeal shockwave lithotripsy, ureteroscopic lithotripsy, and percutaneous nephrolithotomy. In another embodiment of any aspect of the invention, the in vivo stone is fragmented after applying the pushing ultrasound, wherein the in vivo stone can be first pushed toward an exit, so that once fragmented, the fragments are more likely to be easily cleared. In another embodiment of the invention, pushing ultrasound is used to induce displacement of stones that may be larger than 10 mm in diameter. For example, displacement of larger stones at the entrance to the ureteropelvic junction (UPJ) would have considerable clinical benefit in relieving pain.

In an exemplary embodiment of the invention for facilitating removal of in vivo stones, detection ultrasound is used to locate the in vivo stone, and pushing ultrasound is used to cause the located in vivo stone to move toward an exit, which exit can be either naturally occurring or provided surgically.

In a further embodiment, the step of using pushing ultrasound to cause the in vivo stone to move is implemented using a quantity of pushing ultrasound sufficient to cause the in vivo stone to move at a rate of at least about one centimeter per second.
In another embodiment, the pushing ultrasound has a pulse duration of about one hundred times that of the detection ultrasound.

In another aspect of the invention the amount of pushing ultrasound used is calculated based on a numerical simulation program, such that ultrasound exposures can be determined for each unique stone and anatomical situation. In such calculations the radiation force on the stone is found using elasticity equations based on the predicted in situ parameters of ultrasound field and expected mechanical properties of the stone, such as density, shear and compressional moduli.

In a further aspect, the present invention provides non-transitory computer readable storage media, for automatically carrying out the methods of the invention on a device, such as an ultrasound device or system according to the invention.

In a further aspect, the system of the present invention displays the stone as it is pushed in real time and tracks the stone motion, continually refocusing the pushing force on the moving stone.

This Summary has been provided to introduce a few concepts in a simplified form that are further described in detail below in the Detailed Description of the Invention. However, this Summary is not intended to limit key or essential features of the claimed subject matter.

**DRAWINGS**

Various aspects and attendant advantages of one or more exemplary embodiments and modifications thereto will become more readily appreciated as the same becomes better understood by reference to the following detailed description, when taken in conjunction with the accompanying drawings, wherein:

FIG. 1 schematically illustrates a first exemplary embodiment employing the concepts disclosed herein, wherein detection ultrasound is used to locate an in vivo object, and pushing ultrasound is used to move the in vivo object in a desired direction while detecting the movement of the object;

FIG. 2 schematically illustrates an exemplary system employed to visualize an in vivo object using detection ultrasound, and to move the in vivo object, using pushing ultrasound;

FIG. 3 is a flow chart of exemplary steps employed to visualize an in vivo object using detection ultrasound, and to move the in vivo object, using pushing ultrasound;

FIG. 4 schematically illustrates an empirical system employed to verify that pushing ultrasound can be used to move an in vivo object, and that such motion can be visualized in real-time;

FIG. 5A illustrates the basic components of a system for practicing the invention;

FIG. 5B is a schematic illustration of ultrasound radiation emanating from and being reflected back toward a transducer;

FIG. 5C is a flowchart of a system for B-mode ultrasound imaging in accordance with the prior art;

FIG. 6 is a flowchart of one embodiment of the present invention using B-mode ultrasound to preferentially identify and display an image of a stone relative to blood or tissue in which the reflected signals of greatest amplitude or intensity are selected and labeled with color on the display;

FIG. 7 is a flowchart of one embodiment of the present invention using B-mode ultrasound to preferentially identify and display an image of a stone relative to blood or tissue using the shadow created when B-mode ultrasound encounters a stone;

FIG. 8 is a flowchart of one embodiment of the present invention using B-mode ultrasound to preferentially identify and display an image of a stone relative to blood or tissue and using a spatial derivative of the data collected to determine the presence of a stone;

FIG. 9 is a flowchart of a system for Doppler ultrasound imaging in accordance with the prior art;

FIG. 10 is a flowchart of one embodiment of the present invention using Doppler ultrasound to preferentially identify and display an image of a stone relative to blood or tissue and wherein one or more units of pulses, frames or volumes in the ensemble is multiplied by a selected factor;

FIG. 11 is a flowchart of one embodiment of the present invention using Doppler ultrasound to preferentially identify and display an image of a stone relative to blood or tissue and relating to detection of large changes in amplitude among units of pulses, frames or volumes of an ensemble;

FIG. 12 is a flowchart of one embodiment of the present invention using Doppler ultrasound to preferentially identify and display an image of a stone relative to blood or tissue and relating to calculation of the variance of the signal;

FIG. 13 is a flowchart of one embodiment of the present invention using Doppler ultrasound to preferentially identify and display an image of a stone relative to blood or tissue and relating to detection of the strength of the noise and not the signal from the autocorrelation, optionally with a wall filter;

FIG. 14 is an illustration of a device used in the embodiment of Example 2 of this application;

FIG. 15 is a representative image of ultrasonic propulsion of a stone in accordance with Example 2 of this application;

FIG. 16 is a representative histology slide from a control, and exposure to 325 W/cm² and exposure to 1900 W/cm² of the sample of Example 2 of this application.

**DETAILED DESCRIPTION OF THE INVENTION**

Exemplary embodiments are illustrated in referenced Figures of the drawings. It is intended that the embodiments and Figures disclosed herein are to be considered illustrative rather than restrictive. No limitation on the scope of the technology and of the claims that follow is to be imparted to the examples shown in the drawings and discussed herein. Further, it should be understood that any feature of an embodiment or aspect disclosed herein can be combined with one or more features of any other embodiment or aspect that is disclosed, unless otherwise indicated.

The following additional definitions shall apply in this application:

"Stone"—any piece of calculus material such as may be found, for example, in an organ, duct or vessel of a mammal; and including stones, stone fragments, and stone dust that may result from the application of shock waves or other therapeutic procedures; and equivalent embedded objects for which movement or displacement is desired.

Pressure amplitude—the maximum displacement of the acoustic pressure from ambient.

Duty cycle (also referred to as duty factor)—pulse duration divided by pulse repetition frequency times 100%.

Power—Energy per time, for both electric and acoustic power. Electric power excites the transducer element as a source; acoustic power is in the acoustic wave generated by the transducer element.

Intensity—power transmitted through a cross-sectional area. Cross sectional area can be determined as the beamwidth of the acoustic beam; or as applied to a stone cross sectional area can be the cross section of the stone.
Pulse—an acoustic wave of a certain duration. A single pulse encompasses one or several cycles of pressure oscillation at the center frequency. The excitation of one or more elements in the transducer generates a pulse. Pulses in B-mode tend to be 1-2 cycles and pulses in Doppler tend to be 3-7 cycles. The pulse created by a shock wave lithotripter tends to be 1 cycle.

Doppler Ultrasound—a mode or several modes of ultrasound imaging used to detect blood flow. B-mode ultrasound—a mode of ultrasound used to create an image of anatomical structures. Ultrasound waves can be characterized by any one or more of the following intensity parameters:

- **Temporal peak, $I_{TP}$**: The highest instantaneous intensity in the beam.
- **Average intensity over the pulse repetition period, $I_{A}$**: The time averaged intensity over the pulse repetition period.
- **Spatial peak, $I_{SP}$**: The highest intensity spatially in the beam.
- **Average intensity over the beam area, $I_{SA}$**: The average intensity over the beam area.
- **Spatial average-temporal average intensity, $I_{SPTA}$**: The acoustic power contained in the beam in watts averaged over at least one pulse repetition period, and divided by the beam area.
- **Spatial average-pulse average intensity, $I_{SPPA}$**: The acoustic power contained in the beam in watts averaged over at least one pulse repetition period, and divided by the beam area.

**Pulse and Duty Cycle**

Pulse an acoustic wave of a certain duration. A single pulse encompasses one or several cycles of pressure oscillation at the center frequency. The excitation of one or more elements in the transducer generates a pulse. Pulses in B-mode tend to be 1-2 cycles and pulses in Doppler tend to be 3-7 cycles. The pulse created by a shock wave lithotripter tends to be 1 cycle.

Doppler Ultrasound—a mode or several modes of ultrasound imaging used to detect blood flow. B-mode ultrasound—a mode of ultrasound used to create an image of anatomical structures. Ultrasound waves can be characterized by any one or more of the following intensity parameters:

- **Temporal peak, $I_{TP}$**: The highest instantaneous intensity in the beam.
- **Average intensity over the pulse repetition period, $I_{A}$**: The time averaged intensity over the pulse repetition period.
- **Spatial peak, $I_{SP}$**: The highest intensity spatially in the beam.
- **Average intensity over the beam area, $I_{SA}$**: The average intensity over the beam area.
- **Spatial average-temporal average intensity, $I_{SPTA}$**: The acoustic power contained in the beam in watts averaged over at least one pulse repetition period, and divided by the beam area.
- **Spatial average-pulse average intensity, $I_{SPPA}$**: The acoustic power contained in the beam in watts averaged over at least one pulse repetition period, and divided by the beam area.

**Pushing Ultrasound**

Acoustic radiation force results from the transfer of acoustic wave momentum to an absorbing or reflecting object. In the context of the present invention, acoustic radiation of selected pressure amplitude, duration, frequency, and duty cycle is applied to a stone which absorbs the momentum to facilitate non-invasive repositioning of the stone, to allow removal, passage, or further treatment. Such acoustic radiation is referred to herein as pushing ultrasound.

The pushing ultrasound of the system of the present invention will operate at $I_{SPPA} > 3 \text{ W/cm}^2$ in situ. In one preferred embodiment, the pushing ultrasound of the present invention has a time averaged spatial peak intensity of $I_{SPTA} > 4 \text{ W/cm}^2$. A higher pressure can allow for a shorter pulse time or a longer time between pulses. In some embodiments of the invention, the longer time between pulses can be used to real-time imaging between pushing pulses. This is in comparison to diagnostic ultrasound approved for use in the US which must operate at $I_{SPTA} < 720 \text{ mW/cm}^2$ (and $M<1.5$) and $I_{SPTA} > 190 \text{ W/cm}^2$, and shock wave lithotripsy and physical therapy ultrasound which operate at $I_{SPTA} < 5 \text{ W/cm}^2$.

Further in accordance with the present invention, pushing ultrasound waves have pressure amplitudes in the range of between about 5 MPa and about 30 MPa, preferably between about 10 MPa and 20 MPa, and most preferably between about 13 MPa and 18 MPa. As is known in the art, detection ultrasound waves generally have a pressure amplitude in the range of about 5 MPa or less, while, ultrasound waves used in shock wave lithotripsy ("SWL") as approved for use in the United States have amplitudes of at least about 30 MPa as measured in water. The high pressures of lithotripsy are necessary to break the stones.

The pushing ultrasound waves used in the present invention also are distinguished from other ultrasound waves by the number of cycles per pulse, and by the duty cycle. B-mode ultrasound for detection and shock wave ultrasound for lithotripsy each use a single pulse per cycle; while pushing ultrasound waves used in the present invention use more than one pulse per cycle, typically more than about 5-10 pulses per cycle. Pushing ultrasound waves for use in the present invention can have a duty cycle of greater than 1%. For example, in one embodiment the pushing ultrasound waves pulse for 100 microseconds every three milliseconds. By comparison, lithotripsy ultrasound may run, for example, for a 5 microsecond pulse, with a 250 millisecond duration between pulses, for a duty cycle of <1%.

In a preferred embodiment of the invention, the pushing ultrasound will have a pulse duration of about 100 μs; an average frequency of between 2.3 MHz, a pressure amplitude of about 15 MPa in situ; with bursts repeated every 3 ms, and the total duration of each push sequence being about 1s. In one embodiment of the invention, imaging pulses can be interleaved within the pushing pulses for real-time imaging.

The pushing ultrasound facilitates movement of a stone; in one embodiment such movement can be toward an exit location. The exit can be a natural exit of a duct, vessel, or organ, or created surgically. The pushing ultrasound can be more focused when directed to a particular stone, or either weakly focused or unfocused if directed toward a general region of the body such as a kidney pole. For example, a kidney pole area may be suspected of containing very small stone fragments or stone dust which may be difficult to image. Such weakly focused or unfocused pushing ultrasound can be used to stir up the small fragments or dust and facilitate their removal from the pole of the kidney, without the risk of tissue injury that might be caused by shock wave lithotripsy.

In some aspects of the invention, an imaging system can be used to locate the stones for the application of pushing ultrasound. In one embodiment of the invention, such imaging can be accomplished by known imaging techniques such as fluoroscopy. In other embodiments of the invention, such imaging can be accomplished by the application of any of various modes of detection ultrasound, as discussed in greater detail below.

Detection Ultrasound

As noted above, in one aspect the inventive system and method disclosed herein employ detection ultrasound to locate stones within an organ, duct, or vessel such as the kidney, wherein the ultrasound waves reflected from a stone are preferentially selected and displayed relative to ultrasound waves reflected off blood or tissue. The detection ultrasound used in connection with the present invention can be based on B-mode ultrasound or Doppler ultrasound, or both.

Doppler ultrasound is a form of ultrasound that can detect and measure blood flow. There are several types of Doppler ultrasound. Color Doppler is a technique that estimates the average velocity of flow within a vessel by color coding the information. The direction of blood flow is assigned the color red or blue, indicating flow toward or away from the ultrasound transducer. Color Doppler can overlay color on a B-mode image. Pulses Doppler allows a sampling volume or "gate" to be positioned in a vessel visualized on the gray-scale image, and displays a graph of the full range of blood velocities within the gate versus time. The amplitude of the signal is approximately proportional to the number of red blood cells and is indicated, not in color, but simply as a shade of gray. Power Doppler depicts the amplitude, or power, of Doppler signals rather than the velocity. This allows detection of a larger range of velocities and thus better visualization of small vessels, but at the expense of directional and velocity information.
B-mode ultrasound is based on two-dimensional diagnostic ultrasound presentation of echo-producing interfaces in a single plane. B-mode ultrasound is based on brightness modulation, in which bright dots on a screen represent echoes, and the intensity of the brightness indicates the strength of the echo. As is known in the art, the Doppler ultrasound can be overlaid on an image created by B-mode ultrasound, such as to show blood vessels which may appear as red or blue on the ultrasound display.

Standard Doppler detection such as for detecting blood flow is based on small signals that change over time, that are coherent, and have a pattern. At some point in the Doppler image processing, the signals from blood encompass a relatively narrow band of higher frequency and lower amplitude, while ultrasound reflections from tissue such as vessel walls and organ tissue encompass a relatively narrow band of lower frequency and higher amplitude. When using Doppler ultrasound to detect motion of blood, it is known in the art to use an optional "wall filter" which electronically filters from the reflected ultrasound signal the lower frequency, higher amplitude waves reflecting from the vessel walls. When using Doppler ultrasound to evaluate blood flow, it is known in the art to autocorrelate data from an ensemble of Doppler pulses, frames, or volumes, in which patterns of coherent data with relatively small changes from pulse to pulse are retained and converted into an image signal, while pulse data that is not part of the coherent pattern is deleted from the signal as unwanted "noise."

Stones are strong scatterers and therefore reflect strong signals. A signal reflected from stone can change on the next pulse more than a similarly strong signal reflected from tissue. While the cause of the difference in ultrasound reflective properties is not completely understood, it is believed that this difference may be caused by the abruptness of the transition from soft tissue to hard stone, by motion of the stone, or by internal waves in the stone not present in softer tissue. Rather than deleting these signals as unwanted electronic noise as in ultrasound systems of the prior art, in the method and system of the present invention the reflected ultrasound signals are processed such that these strong signals are preferentially retained relative to the narrow bands of coherent signals reflected from blood and tissue, and the retained signals are converted into an image on a display. Thus in contrast to the prior art, the present invention detects stones as strong signals that change over time, with significant change in amplitude that randomly appears in some frames but not others. In some embodiments of the invention these acoustic differences can be exacerbated by nonlinear responses of the front end electronics of the imager.

This feature of the invention in which reflections from stones are preferentially selected and retained in an image display relative to reflections from blood or tissue can be used both with B-mode detection ultrasound and with Doppler detection ultrasound. Where the applied detection ultrasound is Doppler ultrasound, the strong signals that are preferentially selected and displayed as an image can be those reflected waves related to the "twinkling" artifact of ultrasound in which the object being scanned appears brighter or with different colors on the image display monitor.

In those embodiments of the invention in which the pushing ultrasound is used in conjunction with Doppler detection ultrasound, then it is a feature of one embodiment of the present invention that this twinkling artifact can be used to enhance visualization of the stone during the application of pushing ultrasound, thereby allowing for greater control and accuracy in directing the pushing ultrasound toward the stone to be moved. In one embodiment of the invention, an ultrasound system recognizes the twinkling artifact on an ultrasound display and redirects subsequent pulses of pushing ultrasound waves to more efficiently facilitate motion of the stone in a desired direction.

In a further aspect, the present invention provides non-transitory computer readable storage media, for automatically carrying out the methods of the invention on a device, such as an ultrasound device or system according to the invention. As used herein the term "computer readable medium" includes magnetic disks, optical disks, organic memory, and any other volatile (e.g., Random Access Memory ("RAM")) or non-volatile (e.g., Read-Only Memory ("ROM")) mass storage system readable by a Central Processing Unit ("CPU"). The computer readable medium includes cooperating or interconnected computer readable medium, which exist exclusively on the processing system or be distributed among multiple interconnected processing systems that may be local or remote to the processing system.

Unless the context clearly dictates otherwise, embodiments in one aspect of the invention may be used in other aspects of the invention, and can be combined with each other.

FIG. 1 illustrates an exemplary use of pushing ultrasound applied to move a kidney stone in accordance with the concepts disclosed herein. In a pushing ultrasound therapy probe 10, an acoustic coupling 16 is attached to a therapy transducer 14 that is mounted to a handle 12. A lead 18 couples the transducer 14 to a power supply (not shown). In FIG. 1, probe 10 is being used to apply pushing ultrasound to a kidney 24 through a dermal layer 20 of a patient (not otherwise shown).

Probes capable of producing and receiving both detection ultrasound and pushing ultrasound and suitable for use in the present invention include the C4-2 and P4-2 HDI scanheads commercially available from Philips/ATL, although the scope of the invention is not so limited.

While many different acoustic transducers are suitable for pushing ultrasound applications, many ultrasound transducers exhibit a generally conical-shaped beam 26. When probe 10 is positioned so that beam 26 passes through the kidney, acoustic pressure moves a kidney stone from a first position 30a to a second position 30b, closer to an exit 32 which can be either naturally present or artificially introduced such as by surgery. By properly positioning probe 10, the user can control the direction the kidney stone will move. It should be understood that in the context of an artificial exit, the concepts disclosed herein can be used to reposition stones closer to artificially placed tubes/catheters during surgery, such that the method and system disclosed herein can be used intraoperatively.

Acoustic transducer 14 can have a fixed focal length, or a variable focal length. Variable focal length transducers are generally more useful. In applications where a fixed focal length acoustic transducer is used for application of pushing ultrasound, acoustic coupling 16 can be used to control the position of focal region of beam 26 relative to the patient. If a relatively thicker acoustic coupling 16 is employed, the focal region will be disposed closer to dermal layer 20, while if a relatively thinner acoustic coupling 16 is employed, the focal region will penetrate further below the dermal layer and deeper into the subcutaneous target. Thus, the thickness of acoustic coupling 16 can be used to control the position of the focal region relative to a patient's tissue. The transducer may also be a linear, curvilinear, or phased array and be able to steer the beam to push the stone off the axis of the transducer.

In FIG. 1, an ultrasound imaging probe 22 generates an image plane 28. Focal beam 26 and the kidney stone at positions 30a and 30b lie within image plane 28, so that the
movement of the kidney stone can be visualized in an ultrasound image provided by ultrasound imaging probe 22 during therapy. In other embodiments of the invention, the source of imaging ultrasound and the source of pushing ultrasound for moving the stone can be contained within a single probe housing. In still other embodiments of the invention, one transducer having one or a plurality of elements can be used to detect and push the stone. Suitable transducers include the P4-2 or C4-2 HDI transducer from ATL/Philips. These are standard curvilinear and phased array probes for imaging.

FIG. 2 is a functional block diagram of a system for detecting and pushing in vivo objects such as kidney stones and kidney stone fragments. System 40 includes a detection ultrasound component 42, a pushing ultrasound component 44, a control and processing component 46, a user interface 48, and a display 50. In other embodiments, a single unit can provide both ultrasonic detection and ultrasound treatment. Where the detection ultrasound component 42 is a Doppler ultrasound component, then detection of the stone in vivo can use the twinkling artifact in Doppler imaging. Processing and control component 46 can include the power supplies required to energize the ultrasound transducers in detection ultrasound component 42 and pushing ultrasound component 44, or such components can be implemented separately.

In one aspect of the invention the user can interact with user interface 48 to choose an area on the display on which the pushing ultrasound is to be focused. Thus the user can guide the repeated application of pushing ultrasound in real time to urge the stone toward an exit. In one aspect of the invention, the ultrasound system detects the motion of the stone and then sends a new pushing pulse to the new location, to continuously follow the stone on its movement toward an exit. User interface 48 can include a mouse or touch screen as are known in the computer and medical technology arts.

If desired, a separate processing and control component can be employed for each of detection ultrasound component 42 and pushing ultrasound component 44. Displays are sometimes incorporated into conventional detection ultrasound components, and if desired such a display can be used in place of display 50. User interface 48 is employed at least to control the pushing ultrasound component 44, enabling the operator to energize that component as required to achieve the desired movement of the in vivo object. With respect to the operation of pushing ultrasound component 42, if desired, control and processing component 46 can override a command to trigger the pushing ultrasound component if the control and processing component 46 determines that delivery of additional pushing ultrasound could undesirably damage tissue, such as may occur due to thermal or mechanical effects. The processing and control component can be implemented using a custom circuit (i.e., a hardware implementation, such as an application specific integrated circuit) or a processor executing machine instructions stored in a memory (i.e., a software implementation, where the software is executed by a computing device, such as a desktop or laptop computer). Such processing and control components are known to those of ordinary skill in the art.

FIG. 3 is a flowchart of exemplary steps for implementing the concepts disclosed herein. In representative block 50, detection ultrasound is used to visualize an in vivo object such as a kidney stone or kidney stone fragment. As discussed above, in an exemplary but not limiting embodiment, the twinkling artifact in Doppler ultrasound is used to visualize the in vivo object. In a block 52, pushing ultrasound is used to move the in vivo object in a desired direction. In general, the desired direction will cause the in vivo object to move to a desired location. In one aspect of the invention, the user can interact with user interface 48 to choose an area on the display on which the pushing ultrasound is to be focused. Thus the user can guide the repeated application of pushing ultrasound in real time to urge the stone toward an exit. In one aspect of the invention, the ultrasound system detects the motion of the stone and then sends a new pushing pulse to the new location, to continuously follow the stone on its movement toward an exit. User interface 48 can include a mouse or touch screen as are known in the computer and medical technology arts.

EXAMPLE 1

In an empirical study to test the concepts disclosed herein, a pushing ultrasound device was used to move a kidney stone fragment, with the goal of facilitating passage. In one study, natural and artificial stones about 1-8 mm in length were surgically placed in the urine space in pig kidneys. A new system was assembled and programmed to both image stones and push stones. The system had the general design of FIG. 5A where the pulser/receiver and analog to digital converter box was a Versanetics Ultrasound Engine (Versanetics, Bothell Wash.). The transducer was either a P4-2, P4-1, or C4-2 HDI transducer from ATL/Philips, Bothell Wash.).

FIG. 4 schematically illustrates the setup in the empirical study. A tissue phantom 68 (or live porcine kidney) with an embedded object was provided. A pushing ultrasound component 66 was coupled to the phantom using a coupler 70. A detection ultrasound component 64 (a distal end 64a of which can be seen in the Figure), coaxially aligned with the pushing ultrasound component, was used to acquire images of the embedded object as it was moved in the tissue phantom/kidney by the pushing ultrasound. A processing and control component 60 was used to control the ultrasound components, and the ultrasound image was presented to the user on a display 62.

In the empirical studies, a research ultrasound device designed for other medical therapies was used, which combines a commercial ultrasound imaging system with a research pushing ultrasound therapy system. The imaging probe is placed within, looking down the axis of, the therapy probe. In the empirical study, longer bursts of higher amplitude focused ultrasound were applied than are generally employed in diagnostic ultrasound (30-ms, 10-MPa bursts repeated at 10 Hz). The force applied to stone fragments and motion of the fluid around the stone caused stone motion. Motion of natural and artificial stones was observed visually in a kidney phantom of transparent tissue mimicking gel surrounding a water-filled space, and with diagnostic ultrasound and fluoroscopy in live and excised pig kidneys.

Stone velocities were on the order of 1 cm/s and stones quickly moved out of the ultrasound focus. Operators could generally control the direction of stone movement.

In the empirical study, a sonographer using Doppler ultrasound and what is known as “twinkling artifact” visualized stones as small as 1 mm in the kidney of a porcine animal model. When pushing ultrasound was applied, these stones were seen on the real-time ultrasound display to jump up at ~1 cm/s. While in some embodiments pushing ultrasound exposure might result in thermal damage to tissue, no such damage was noted in the empirical study. The empirical study indicated that pushing ultrasound can be used to move stones within a collecting system in order to optimize rates of stone clearance.

It should be noted that while the present novel approach of moving kidney stones (or fragments thereof) using focused ultrasound represents an exemplary embodiment, the concepts disclosed herein can also be used to move other embed-
ded objects, including, but not limited to, stones, fragments and dust located in any of the gall bladder, the salivary tract, and the biliary tract of a human or other mammal.

The following Figures illustrate various modes of detection of stones in accordance with the invention, in which like reference numerals indicate like components. These various modes of detection can be used either alone or in combination with each other and a voting algorithm or with the use of pushing ultrasound to facilitate stone clearance, as discussed above.

FIG. 5A is a schematic representation of a system suitable for use in the present invention comprising a CPU 72, a combined ultrasound pulser/receiver and analog to digital converter 73 operatively connected to a transducer 74, a monitor display 75, and various means for operator input and control such as keyboard 76, mouse 77, and monitor touch screen 79, each of which are conventionally known in the computerized diagnostic arts. Transducer 74 can be used to apply and/or push ultrasound to a patient and to receive reflected ultrasound signals and transmit them back to CPU 72 for further processing as described more fully below, and as shown schematically in FIG. 5B.

FIG. 5C is a flowchart of a method and system 80 of the prior art using B-mode imaging ultrasound. Reflected ultrasound waves are received by the transducer elements 81, and are converted to electrical signals. The electrical signals pass through one or more attenuators and/or amplifiers, collectively indicated at 82, and the amplified and/or attenuated signals are then transmitted to analog-to-digital converter 83. From converter 83 the digitized signals pass to beam former 84, and then to converter 85 where the signals are converted to either amplitude or intensity. The converted are then transmitted to compression means 86, where their values which range over a large scale (e.g., 1-100000) are remapped to a smaller scale (e.g., 1-256) according to some defined algorithm. The compressed data are then displayed at display means 88.

FIG. 6 is a flowchart of an embodiment of the invention using B-mode ultrasound and in which the more intense ultrasound signals reflected from a stone, especially in contrast to less intense signals from regions immediately adjacent to the stone, are preferentially selected or enhanced relative to the less intense ultrasound reflections from blood and tissue. This embodiment is based on the fact that stones normally appear brighter than tissue or blood on a B-mode ultrasound image.

FIG. 7 is a flowchart of an alternative embodiment of the invention using B-mode ultrasound and in which the more intense ultrasound signals reflected from a stone, especially in contrast to less intense signals from regions immediately adjacent to the stone, are preferentially selected or enhanced relative to the less intense ultrasound reflections from blood and tissue. This embodiment relies on the ultrasound "shadows" generated when ultrasound is reflected from a stone, such that the bright spot of the reflection is immediately proximal to the darker spot which represents the shadow on the distal side of the stone. The data is analyzed for this shadow artifact at data analyzer 94, wherein the stone is identified by the adjacency of the bright and dark spots. In a preferred embodiment, the B-mode ultrasound is reapplied at different exposure angles to confirm the presence of the shadow and therefore the presence of the stone. In addition, the ultrasound beam can be modified as is known in the art in other ultrasound applications, for example to a broad plane wave, called in the art a flash, to quickly image the whole field and enhance a shadow that can be obscured in a more focused imaging beam. Once identification of the stone is confirmed the information is optionally stored in data storage means 96 and the generated image of the stone is labeled or otherwise enhanced at display means 88 to indicate the presence of a stone to the operator.

FIG. 8 is a flowchart of an alternative embodiment of the invention using B-mode ultrasound and in which the more intense ultrasound signals reflected from a stone, especially in contrast to less intense signals from regions immediately adjacent to the stone, are preferentially selected or enhanced relative to the less intense ultrasound reflections from blood and tissue in which an image is created from the spatial derivative of the intensity map, such that the highest derivatives indicate the location of the stone. Data from or before compression means 86 is processed at data analyzer 98 to take the spatial derivative, such that the abrupt change in brightness (high derivative) indicates the edge of a stone. These data are then merged with the compressed data to generate an image displayed at display means 88.

FIG. 9 is a flowchart illustrating standard prior art methods of Doppler ultrasound. Doppler ultrasound is applied to the subject, the reflected waves are amplified or attenuated and digitized, and the information is stored at storage means 89. This step may be repeated n-1 times to generate an ensemble of data at data collection means 102. The ensemble of data is beam-formed at 84. The data in beam form are then demodulated into phase and amplitude components at 104. As is known in the art, ultrasound that reflects off tissues such as vessel walls will have a higher amplitude than ultrasound that reflects off of blood. Also the tissue either is not moving or is moving very slowly compared to blood, so at this point in the processing the signals from tissue are lower frequency and the signals from blood are higher frequency. Therefore wall filter 106 removes the low frequency data from tissue, leaving only the data relating to the presence of blood. The filtered data are then processed by autocorrelation at 108 to optimize the indication of blood in the image at a predetermined threshold amplitude. A B-mode image which shows other pertinent features (i.e., anatomical structures) can be either generated from the demodulated data at 110 or obtained from a separate data source at 112. This B-mode image is then merged at 114 with the autocorrelated data from 108, such that a display is provided at 88 comprising both the B-mode image of the surrounding anatomy and the Doppler image of the blood.

In the prior art methods of processing Doppler data, the data are processed to eliminate signals having higher amplitudes, large discontinuities, outliers, and broad band twin-
blood flow. In the alternate mode of operation, no wall filter is
processed by a wall filter to remove data relating to reflections
by those skilled in the art of statistical data analysis. For
pixel. This can be done in several ways that will be recognized
broadband frequency or noise compared to the low frequency
retained in the present invention but are accentuated relative
to tissue. The data is then subjected to a first or higher order
analysis aspects of the invention, or with or without the use of
pushing ultrasound to move a stone. The detection methods
disclosed herein can be used either to display an image of a
stone, or to provide an aural or other indication of the pres-
ence and/or location of a stone.

The system was operated with the following parameters:

FIG. 10 is a flowchart of a modification of the method of
FIG. 9 with the additional steps at 166 of multiplying one or
more of the data sets, also known as frames, in an ensemble by
a selected factor. In one exemplary embodiment, raw data of
fourteen frames is collected in an ensemble and one or more
of the individual frames is multiplied by a factor of about
1.05-1.1, such that the amplitude of the data in that frame is
amplified by about 5-10%. The reflections from the stones
within each frame vary more greatly and in a more random
way from frame to frame than do the reflections from tissue or
blood. This manifests at a point in the Doppler processing as
broadband frequency or noise compared to the low frequency
from tissue and the narrow-band relatively high frequency
from blood. The broadband frequency or high random vari-
ability from stones causes the twinkling artifact. The 5-10%
amplification to one frame amplifies the variability among or
between frames to further draw out the high variability sig-
nals from stones so as to be readily identified at display means
88, thereby providing a more sensitive means for detecting
stones.

FIG. 11 is another alternative embodiment of the stone
detection method of the invention using Doppler radiation and
with the additional step of detecting relatively large changes
particularly in amplitude, i.e., "outliers," within frames in the ensemble. In one aspect of this embodiment of the
invention, in place of a standard wall filter and autocor-
relation the stone detection method is based on relatively
large jumps of a single IQ pair in the Doppler ensemble for a
pixel. This can be done in several ways that will be recognized
by those skilled in the art of statistical data analysis. For
example, in one embodiment, at each pixel the maximum
amplitude is determined as max(signal IQ)-mean(signal IQ).
In another mode, the z-score will be used to evaluate the data
distribution, and the twinkling reflections are determined as
outliers based on the number of standard deviations outside
the expected range.

The selected values are normalized within the region of
interest at step 120; these values are then merged with a
B-mode image and displayed at display means 88.

FIG. 12 is a modification of the method of FIG. 11 wherein
instead of a determination of outliers there is at 122 a stat-
tical determination of the variance of the data, where variance
according to its mathematical definition is determined as the
amount of deviation left in the data after the mean is sub-
tracted out. This statistical method retains signals such as
 twinkling artifacts that are not close to the mean of the data,
such that these signals are accentuated at display means 88.

FIG. 13 is a modification of the algorithm of FIG. 10 but in
which an autoregression analysis is used rather than an auto-
correlation of the Doppler data. This embodiment can be
operated in two different modes. In one mode of operation of
this embodiment, the demodulated data from step 104 is
processed by a wall filter to remove data relating to reflections
from tissue. The data is then subjected to a first or higher order
autoregression analysis to identify coherent signals from
blood flow. In the alternate mode of operation, no wall filter is
used, but the data undergoes a second or higher order autore-
gression analysis at 126 to identify coherent signals from
radiation pressure, as opposed to streaming, caused the
in the narrow focus region. The region over which the pres-
were excited by the synchronized outputs of 8 signals from an
ultrasound, other imaging modalities could be employed.
Such imaging modalities include, without limitation, fluoros-
, 500, and 1000 W/cm².
All animal studies were acute, and animal research proce-
diences were approved by the University of Washington
in the six anesthetized pigs. A longer coupling cone was added
the cone. The abdomen was filled with saline to ensure coupling,
and the cone was placed in direct contact with the kidney. Five
regions on each kidney were targeted, and the surface location
marked with ink. Control regions of the kidney received no
ultrasound exposure. Other regions received two minute total
exposure at 50% duty cycle at time averaged intensities 325
and 1900 W/cm². The pigs were sacrificed, and the kidneys
were harvested. Both kidneys were freshly sectioned for
histological analysis. Microscopic examination was performed using
serial sections stained with hematoxylin and eosin (H&E) and
tissues were 250, 500, and 1000 W/cm².

Detection of the fragment was achieved using the imaging
described above, B-mode ultrasound, and the twinkling arti-
act produced by the stones/fragments in Doppler mode ultra-
sound. In this empirical study, the same elements in the trans-
ducer were used for both imaging and pushing. Ultrasound
and fluoroscopy showed the stones moving in real-time under
the influence of the pushing ultrasound. Stones moved on the
order of 1 cm/s away from the source, and several stones
moved several centimeters down the ureter. It appeared that
such movement was only induced when the stones/fragments
were directly in the path of the focal beam, indicating that
radiation pressure, as opposed to streaming, caused the
motion. While ultrasound imaging and fluoroscopy were used
independently in this study to track the initial position and
motion of the stone/fragments being moved by the pushing ultrasound, other imaging modalities could be employed.
Such imaging modalities include, without limitation, fluoros-
copy, computed tomography (CT), low-dose stone protocol
CT, B-mode ultrasound, magnetic resonance imaging (MRI),
and Doppler ultrasound. When Doppler ultrasound is used the
twinkling artifact may make the stones appear brightly colored in the image display. The methods and systems disclosed
herein can be adapted to use the twinkling artifact to facilitate visualization of the stones for diagnosis and treatment.

EXAMPLE 2

The system used in the Examples is shown in FIG. 14 in
which (a) is a diagram and (b) is a photograph of the ultra-
sound system. It consisted of a 6 cm dia., 2 MHz, eight
element annular array curved to a natural focus of 6 cm (Sonic
Concepts model H-106, Bothell, Wash.). The eight elements
were excited by the synchronized outputs of 8 signals from an
SC-200 radiofrequency synthesizer (Sonic Concepts, Both-
ell, Wash.) and amplified by eight 100 W amplifiers (Icom
IC-706MKIIIG, Bellevue, Wash.). A laptop computer con-
trolled the timing of the excitation of each element, which
allowed the focal depth to be varied from 4.5-8.5 cm. The
computer also collected the image from the ultrasound imag-
ing system (HDI-5000, Philips/ATL, Bothell, Wash.) and
overlaid on the image the user selected focusing depth so the
user could visually align the stone at the focus. The probe of
the imager (P4-2) looked through the aperture of the therapy
array and was within a water-filled coupling head much like a
shock wave lithotripter but smaller and held in the hand of the
user. The electronics and probe with the longer coupling cone
are shown in the photograph. The ultrasound imager is not
shown. A footswitch switch turned the focused ultrasound
such that it was on for about 50 ms and off for about 50 ms
while the switch was closed. Interference obscured the imag-
ing while the focused ultrasound was on but properly syn-
crhonized pulsing permitted the half of the image containing the
stone to remain obscured. Total exposure in a burst of pulses was 1-4 s, and no more than 10 bursts were used to
move one stone. The acoustic beam is shaped as an hourglass
with the greatest energy concentration and highest pressures
in the narrow focus region. The region over which the pres-
sures are within half of the peak pressure is only 1 cm long and
about 1 mm wide. Time-averaged acoustic intensities, mea-
sured in water and derated to the 6.5 cm penetration depth in
tissue were 250, 500, and 1000 W/cm².

FIG. 15 shows super-imposed frames of a fluoroscopic
movie tracking the ultrasonic expulsion of a bead. The fluo-
roscopic image shows the 5-mm bead moved roughly 3 cm in
1.3 s traveling from the lower pole through the UPJ into the
ureter. A single ultrasound burst pushed the 5-mm bead from
the lower pole to the UPJ where it is bounced and fell into the
canalized ureter. The beads are denser and much more radio-
opaque and therefore easier to observe in the fluoroscopic
images than the human kidney stones that were used. The
bead moved several centimeters in 1.1 s. The duration of the
ultrasound burst was only 1 s and more importantly the ultra-
sound energy is concentrated into a region only 1 cm long.

Most of the effort was visualizing the stone at an appropri-
ate angle to push it into a fluid space toward the UPJ. Angles
of focus that were parallel to the axis of the infundibulum
resulted in larger displacement of the stone. Stone motion was
not observed at all angles of focused ultrasound delivery, but
often if stones were pushed toward a tissue interface the stone
ricocheted in a direction along the interface. Larger fluid
spaces made propulsion easier. Stones were repositioned at
all acoustic intensities used; previous in vitro experiments were not successful with lower intensities. It was not observed that a stone was suddenly made to move simply by increasing the power or that stones moved faster with more power. We concluded that the difficulty in moving these stones was primarily due to alignment of the narrow focus on the stone at an appropriate angle.

Fig. 16 shows a representative histology slide from a control, and exposure to 325 W/cm² and exposure to 1900 W/cm². Specifically, the views are hematoxylin and eosin and nicotinamide adenine dinucleotide stained sections of porcine kidney (a) not exposed to ultrasound (b) exposed to levels used in the ultrasonic propulsion of stones, and (c) exposed to levels above those used for stone propulsion. Thermal injury is shown in image (c). The bar represents 100 µm. Control and the sample from the 325 W/cm² exposure are similar and show no apparent injury. The sample from the 1900 W/cm² exposure contains damaged regions consistent with thermal coagulation, as evidenced by shrinkage of the cells and increased intensity of cosinophilic staining. The NADH-stained serial section confirmed thermal damage in the 1900 W/cm² exposure sample as indicated by the lack of staining. None of the three control samples or five samples from the 325 W/cm² exposure showed any evidence of injury thermal or otherwise. Six of the seven samples from the 1900 W/cm² exposure showed thermal injury, but the lesion created was localized to within 1 cm in its longest dimension. Thus, a threshold for injury exists, but it appears to be above the level required to move stones.

Although the concepts disclosed herein have been described in connection with the preferred form of practicing them and modifications thereto, those of ordinary skill in the art will understand that many other modifications can be made thereto. Accordingly, it is not intended that the scope of these concepts in any way be limited by the above description.

We claim:

1. A method for applying an in vivo force to a stone in a body, the method comprising applying pushing ultrasound prior to lithotripsy of said stone to non-invasively push said stone in vivo without fragmenting said stone, said pushing ultrasound inducing displacement of said stone, said pushing ultrasound applied while pushing said stone, and said pushing ultrasound having an IP_{PTA}>3 W/cm².

2. The method of claim 1 wherein said pushing ultrasound has an IP_{PTA}>4 W/cm².

3. The method of claim 1 wherein said pushing ultrasound has a pressure amplitude in the range of about 5 MPa to about 30 MPa.

4. The method of claim 3 wherein said pushing ultrasound has a pressure amplitude in the range of about 10 MPa to about 20 MPa.

5. The method of claim 4 wherein said pushing ultrasound has a pressure amplitude in the range of about 13 MPa to about 18 MPa.

6. The method of claim 1 wherein said pushing ultrasound operates at a rate of about 5-10 pulses per cycle.

7. The method of claim 6 wherein said pushing ultrasound pulses have a duration of about 100 µs or greater.

8. The method of claim 1 wherein a frequency of said pushing ultrasound is in the range of about 0.25-5 MHz.

9. The method of claim 8 wherein said frequency of said pushing ultrasound is in the range of about 1-4 MHz.

10. The method of claim 9 wherein said frequency of said pushing ultrasound is in the range of about 1-3 MHz.

11. The method of claim 1 wherein a duty cycle of pushing ultrasound pulses is greater than 1% over a period of about 1 s.

12. The method of claim 1 wherein a spatial peak pulse average intensity of said pushing ultrasound is greater than 190 W/cm².

13. The method of claim 1 wherein a spatial peak time average intensity of said pushing ultrasound is greater than 720 mW/cm².

14. The method of claim 1 wherein an intensity and duration of the pushing ultrasound does not cause thermal coagulation of tissue.

15. The method of claim 1 wherein said displacement is at a rate of about at least one centimeter per second.

16. The method of claim 1 wherein said force is applied to urge said stone toward an exit location.

17. The method of claim 16 wherein one or more stones are located in a kidney, and said exit location is an exit from the kidney.

18. The method of claim 1 comprising the further step of fragmenting the stone by lithotripsy after applying the pushing ultrasound.

19. The method of claim 1 comprising the further step of detecting said stone before an application of displacing ultrasound.

20. The method of claim 19 wherein said stone is detected through imaging.

21. The method of claim 20 wherein said imaging is accomplished by one or more of fluoroscopy, computer tomography, low-dose stone protocol computer tomography, B-mode ultrasound, Doppler ultrasound, and MRI.

22. The method of claim 21 wherein said imaging is accomplished with Doppler ultrasound.

23. The method of claim 22 wherein locating the stone comprises use of a twinkling artifact of Doppler ultrasound.

24. The method of claim 21 wherein said imaging is accomplished with B-mode ultrasound.

25. The method of claim 21 wherein the imaging comprises real-time imaging.

26. The method of claim 21 wherein said imaging is accomplished with Doppler ultrasound or B-mode wherein a frequency of said imaging ultrasound is in the range of about 1-5 MHz.

27. The method of claim 26 wherein said frequency of said imaging ultrasound is in the range of about 2-4 MHz.

28. The method of claim 27 wherein said frequency of said imaging ultrasound is in the range of about 2-3 MHz.

29. A system for applying an in vivo force to a stone in a body, the system comprising:

a. a computer processing unit (CPU);

b. an ultrasound transducer;

c. a user interface.

wherein each of said ultrasound transducer and user interface are operatively connected through said central processing unit, said ultrasound transducer being operable to apply pushing ultrasound waves having an IP_{PTA}>3 W/cm² prior to lithotripsy of said stone to non-invasively displace said stone in vivo without fragmenting said stone, said pushing ultrasound applied while pushing said stone.

30. The system of claim 29 further comprising an imaging apparatus and a pushing ultrasound apparatus.

31. The system of claim 30 wherein said imaging apparatus is operable to use Doppler ultrasound or B-mode ultrasound.

32. The system of claim 31 wherein said imaging ultrasound is operable to produce a frequency in the range of about 1-5 MHz.

33. The system of claim 31 wherein said Doppler ultrasound is operable to produce a twinkling artifact which is used to facilitate locating said stone.
34. The system of claim 30 wherein said imaging apparatus and said pushing ultrasound apparatus are operable simultaneously to allow the use of real time imaging of one or more stones during application of force thereto.

35. The system of claim 30 wherein said pushing ultrasound apparatus comprises a handle, a transducer mounted on said handle, and an acoustic coupling operatively engaged with said transducer.

36. The system of claim 35 wherein said transducer has a fixed focal length.

37. The transducer of claim 35 wherein said transducer has a variable focal length.

38. The system of claim 29 wherein said transducer is operable to apply Doppler ultrasound to an anatomical region, such that said Doppler ultrasound detects a stone and laminar blood flow, and wherein said central processing unit is operable to optimize an image of said stone in twinkling format relative to said laminar blood flow, whereby said stone is more apparent on said image.

39. The system of claim 38 wherein said central processing unit is operable to suppress detection of said laminar blood flow.

40. The system of claim 39 wherein said system is operable to select a point on a displayed image to indicate an anatomical site at which to apply focused ultrasound waves to said stone thereby to cause displacement of said one or more stones.

41. The system of claim 40 wherein said system is operable to detect movement of said stone, and said system is operable to automatically refocus on a new location and transmit focused ultrasound to said new location.

42. The system of claim 38 wherein said central processing unit is operable to enhance said image of said stone in a display.

43. The system of claim 38 wherein said central processing unit is operable to display said stone in color on said image.

44. The system of claim 38 wherein said transducer is operable to apply B-mode ultrasound to confirm detection of said stone.

45. The system of claim 38 wherein said transducer is operable to apply B-mode ultrasound to the stone at a plurality of angles.
