Rationale: Assimilating Ozone in MERRA-2 Reanalysis ozone should be recognized as a useful tool for scientific studies

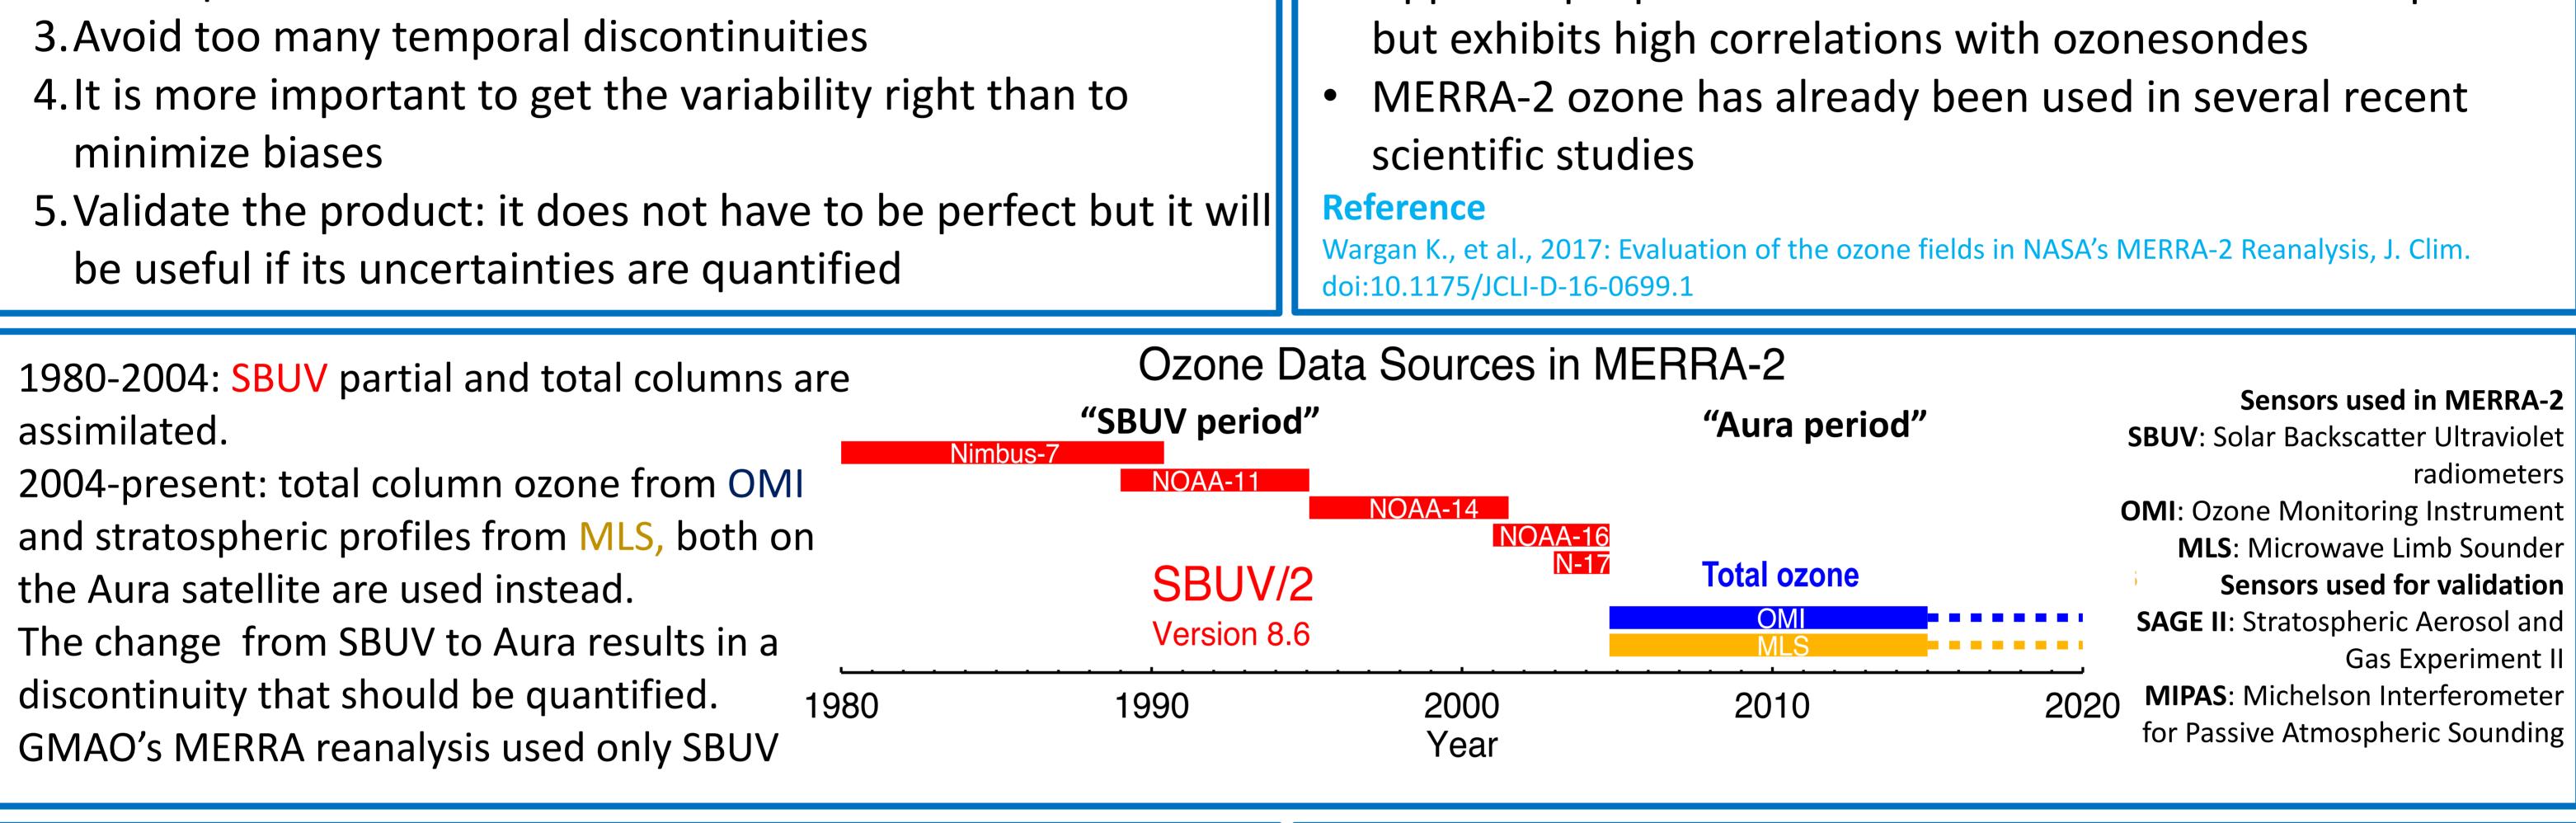

Guiding principles

1. Achieve a faithful representation of ozone fields, particularly in the Upper Troposphere – Lower Stratosphere 2. When possible use the best data available but...

Summary: Usefulness for Science

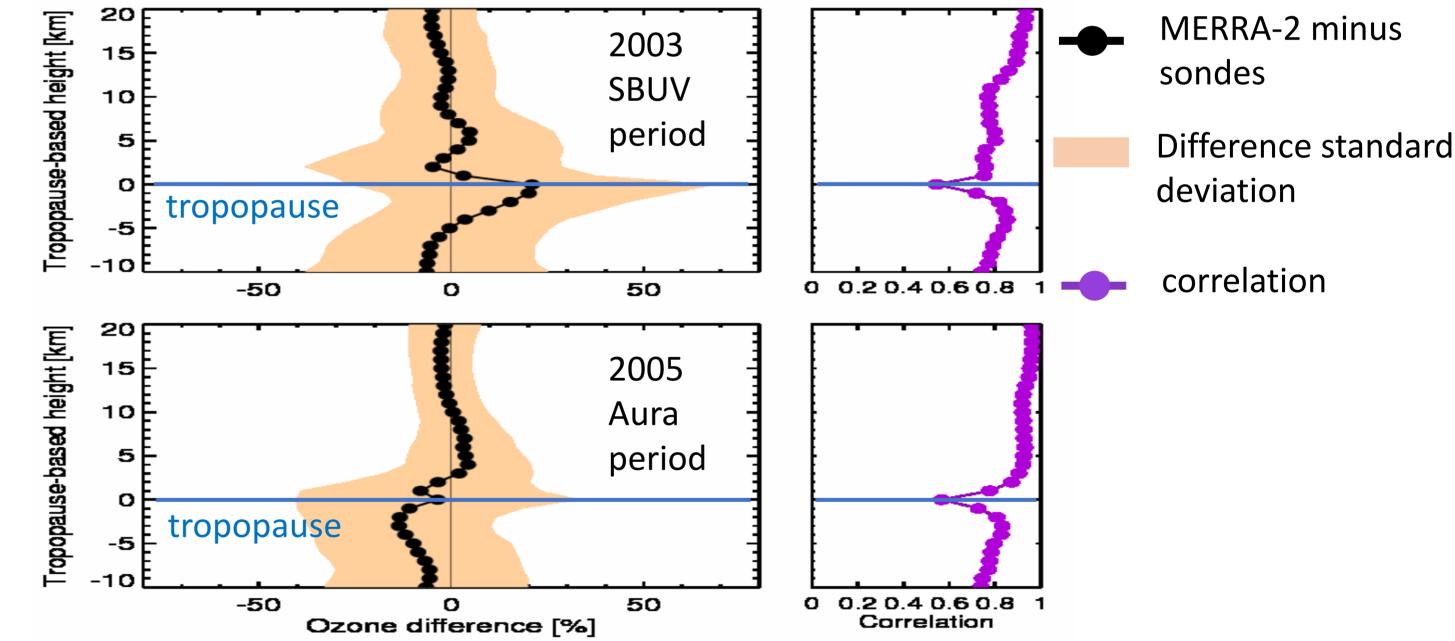

- Comparisons with satellite data: difference standard ${\bullet}$ deviations within 20% above 100 hPa and within 10% in the middle stratosphere
- Ozonesondes: good representation of variability in the lower stratosphere (LS)
- Representation of LS variability improves in the Aura period
- Upper tropospheric ozone has a low bias in the Aura period

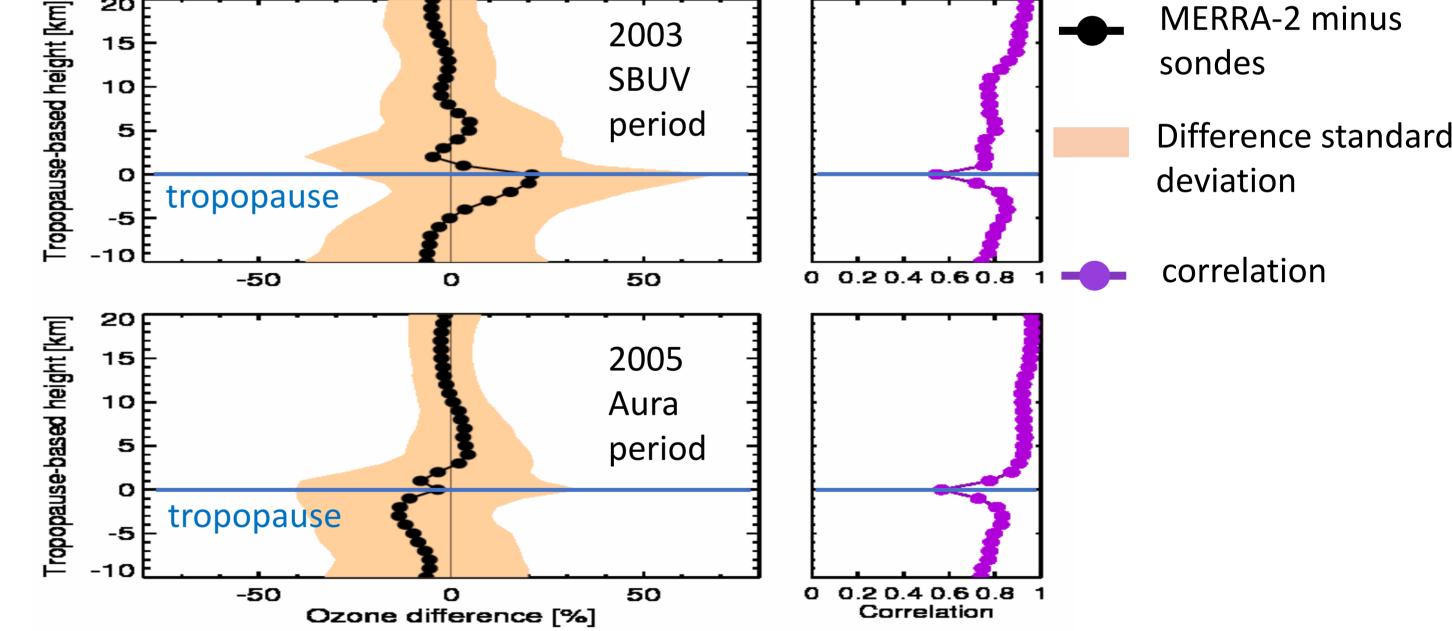

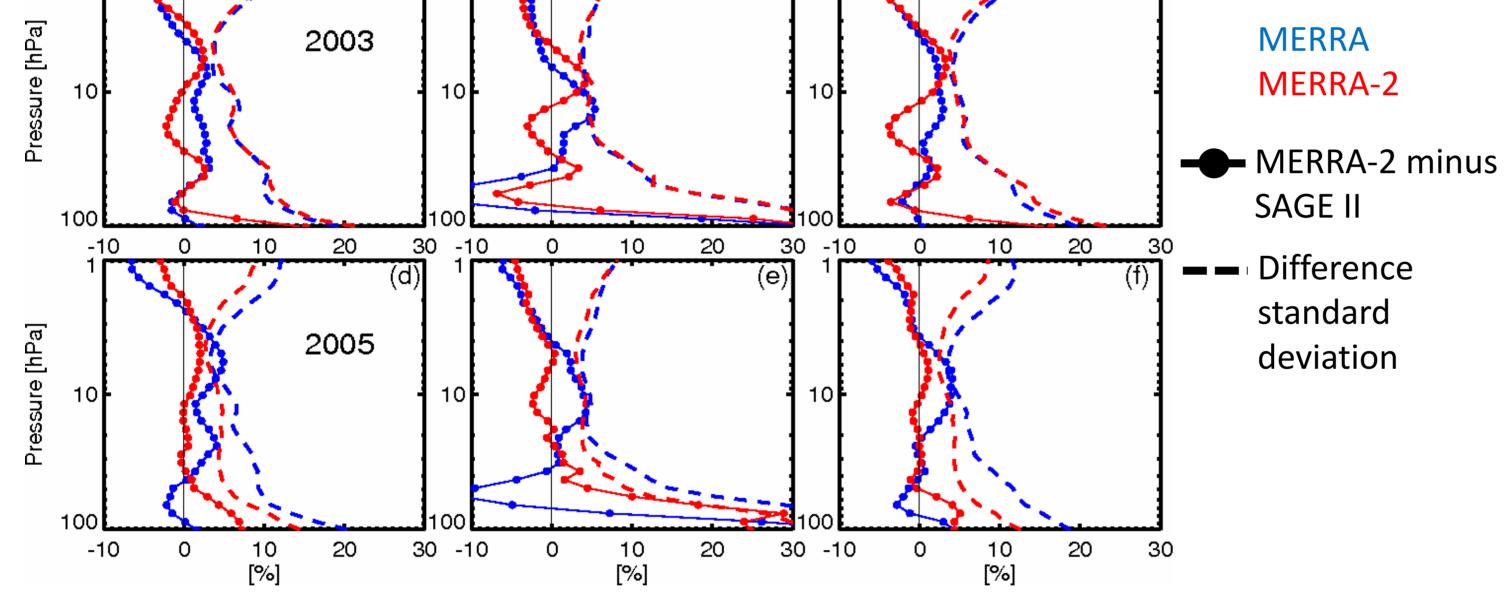

Upper Troposphere – Lower Stratosphere

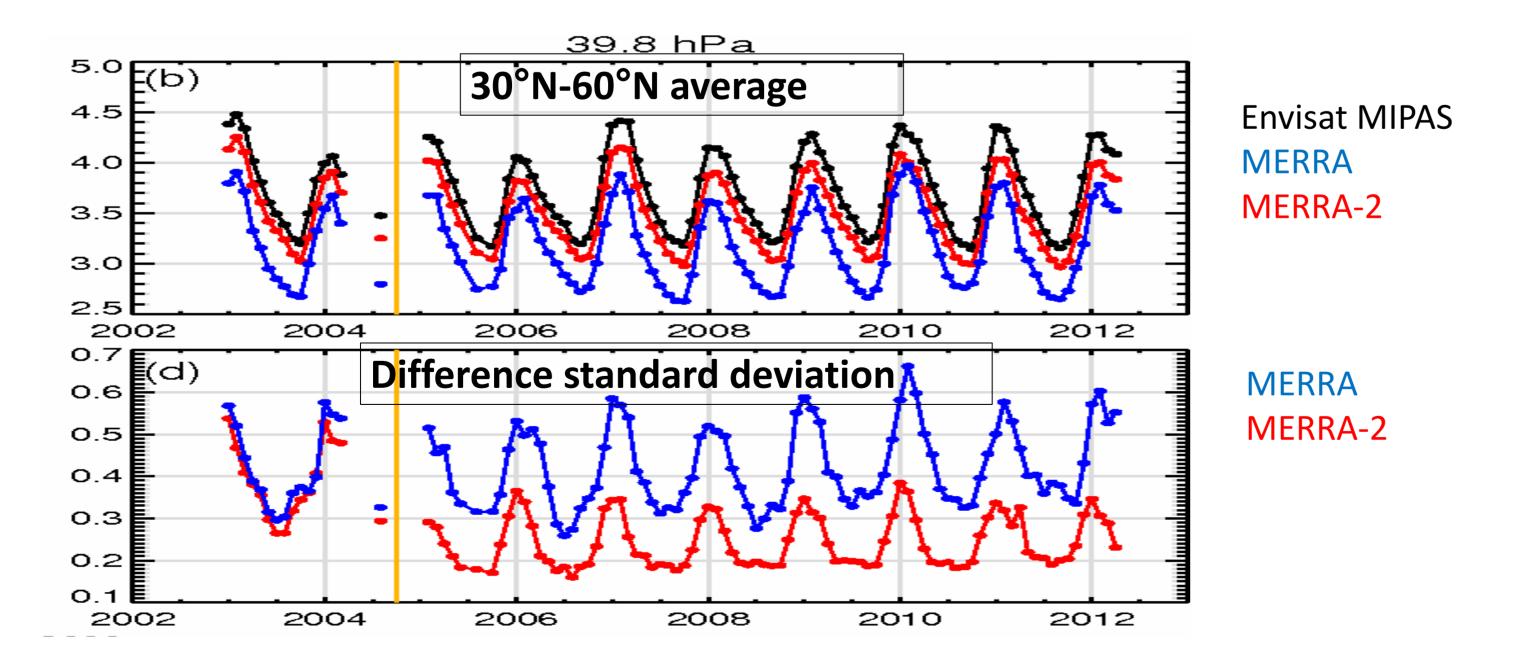

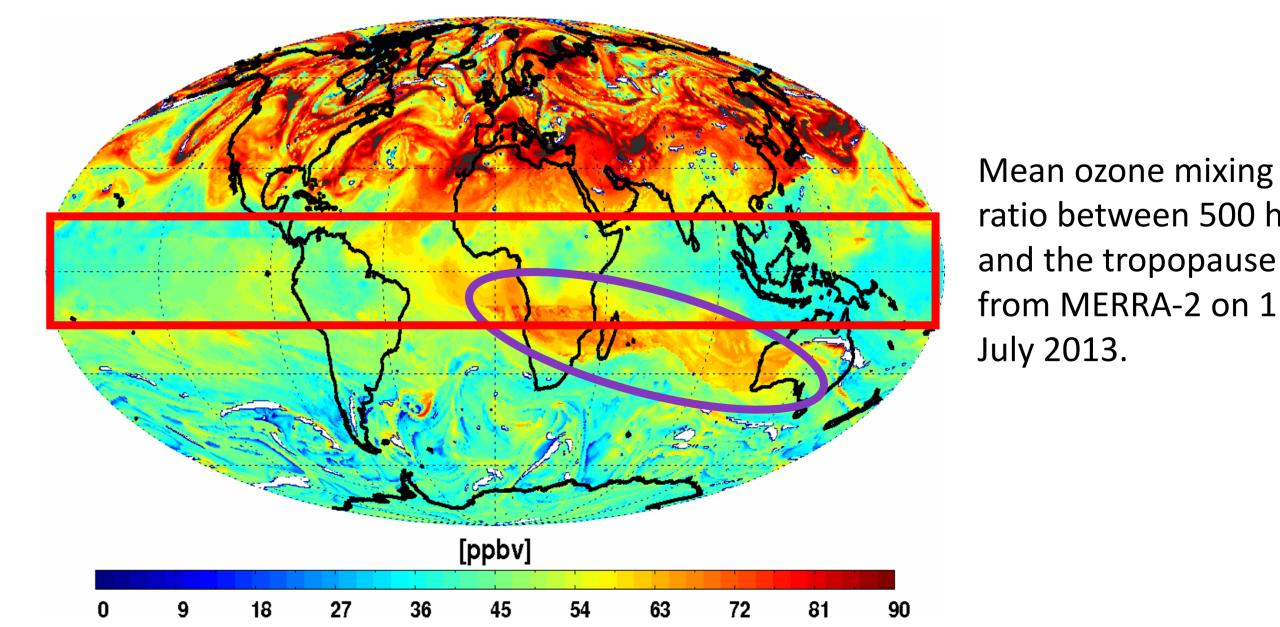

Bias with respect to SAGE II is within ~5% above 50 hPa in both reanalysis in 2003. Difference standard deviation is within ~10% above 50 hPa, up to 20% below.

In 2005 (Aura period) the bias and the difference standard deviation in MERRA-2 are significantly reduced compared to MERRA and to the SBUV period in MERRA-2.

There is a good agreement between MERRA-2 and ozonesondes in the UTLS overall. The Aura period: Smaller difference standard deviations, sharper cross-tropopause gradients and higher correlations but there is a low bias in the upper troposphere.

Mean ozone mixing ratio between 500 hPa and the tropopause

The seasonal cycle is captured by both reanalyses; MERRA-2 has a smaller bias. Difference standard deviations in the SBUV period range from 0.3 to 0.6 ppmv for both reanalyses in the SBUV period and improve by a factor of two in MERRA-2 in the Aura period.

Despite a low bias (as seen above) MERRA-2 produces realistic spatial representation of upper tropospheric ozone. Readily seen are high concentrations in the northern extratropics, the tropical "wave one" and the Southern Hemisphere ozone maximum
