Pixel-Based Model For High Latitude Dust Detection

G. Priftis¹, B. Freitag², M. Ramasubramanian³, I. Gurung², M. Maskey⁴, R. Ramachandran⁴ - ATS¹, ESSC², CS³, NASA⁴

Introduction
Dust has implications on the energy budget, ocean biodiversity, and economy at regional and global scales. Dust detection relies on spectral sensitivity at visible (RGB) and infrared wavelengths. Radiative properties of high latitude dust and the background surface albedo in these regions (>40°N, >40°S) complicate current dust detection methods. Leveraging supervised machine learning (ML) methods, we propose a new method accounting for regional differences of dust occurrence.

Methodology
- Model input: Aqua- and Terra-MODIS true color imagery
- Images for classification are split for training (80%) and validation (20%)

Results

Performance metrics
- Precision: 0.91
- Recall: 0.41
- Accuracy: 0.7

Strengths
- Detection of dust over the ocean
- Ability to distinguish between clouds and dust
- The detection efficiency doesn’t degrade over different areas

Weaknesses
- Sedimentation near the coast leads to false detection
- Over land detection efficiency decreases
- RGB bands alone might not provide enough spectral discrimination

Conclusions
Machine learning methods facilitate the detection of high latitude dust events over different regions using a variety of training samples. The pixel-based model is able to detect dust, however false detections are present in complicated scenes.

Acknowledgements
This work would not have been possible without funding and computational resources provided by the NASA-IMPACT program. We also acknowledge NASA’s Earth Observing System Data and Information System (EOSDIS) for providing the capability to interactively retrieve MODIS imagery.
