Episodes of particle ejection from the surface of the active asteroid (101955) Bennu

D. S. Lauretta*† and C. W. Hergenrother**† et al.

INTRODUCTION: Active asteroids are small bodies in the Solar System that show ongoing mass loss, such as the ejection of dust, which may be caused by large impacts, volatile release, or rotational acceleration. Studying them informs our understanding of the evolution and destruction of asteroids and the origin of volatile materials such as water on Earth.

The OSIRIS-REx (Origins, Spectral Interpretation, Resource Identification, and Security–Regolith Explorer) spacecraft has rendezvoused with the near-Earth asteroid (101955) Bennu. The selection of Bennu as the OSIRIS-REx target was partially based on its spectral similarity to some active asteroids. Observations designed to detect mass loss at Bennu were conducted from Earth and during the spacecraft’s approach, but no signs of asteroid activity were found. However, when the spacecraft entered orbit in January 2019, we serendipitously observed particles in the vicinity of Bennu that had apparently been ejected from its surface.

RATIONALE: We analyzed the properties and behavior of particles ejected from Bennu to determine the possible mechanisms of ejection and provide understanding of the broader population of active asteroids. Images obtained by the spacecraft indicate multiple discrete ejection events with a range of energies and resultant particle trajectories. We characterized three large ejection events that respectively occurred on 6 January, 19 January, and 11 February 2019. Tracking of individual particles across multiple images by means of optical navigation techniques provided the initial conditions for orbit determination modeling. By combining these approaches, we estimated the locations and times of ejection events and determined initial velocity vectors of particles. We estimated the particle sizes and the minimum energies of the ejection events using a particle albedo and density consistent with observations of Bennu.

RESULTS: Particles with diameters from <1 to ~10 cm were ejected from Bennu at speeds ranging from ~0.05 to >3 m s⁻¹. Estimated energies ranged from 270 mJ for the 6 January event to 8 mJ for the 11 February event. The three events arose from widely separated sites, which do not show any obvious geological distinction from the rest of Bennu’s surface. However, these events all occurred in the late afternoon, between about 15:00 and 18:00 local solar time.

In addition to discrete ejection events, we detected a persistent background of particles in the Bennu environment. Some of these background particles have been observed to persist on temporary orbits that last several days—in one case, with a semimajor axis >1 km. The orbital characteristics of these gravitationally bound objects make it possible to determine the ratio of their cross-sectional area to their mass. Combined with their photometric phase functions, this information constrains the parameter space of the particles’ diameters, densities, and albedos.

CONCLUSION: Plausible mechanisms for the large ejection events include thermal fracturing, volatile release through dehydration of phyllosilicates, and meteoroid impacts. The late-afternoon timing of the events is consistent with any of these mechanisms. Bennu’s boulder geology indicates that thermal fracturing, perhaps enhanced by volatile release, could occur on the asteroid surface. Smaller events, especially those that occur on the night side of Bennu, could be attributable to reimpacting particles.

Our observations classify Bennu as an active asteroid. Active asteroids are commonly identified by major mass loss events observable with telescopes, on scales much greater than we observed at Bennu. Our findings indicate that there is a continuum of mass loss event magnitudes among active asteroids.

Episodes of particle ejection from the surface of the active asteroid (101955) Bennu

Active asteroids are those that show evidence of ongoing mass loss. We report repeated instances of particle ejection from the surface of (101955) Bennu, demonstrating that it is an active asteroid. The ejection events were imaged by the OSIRIS-REx (Origins, Spectral Interpretation, Resource Identification, and Security–Regolith Explorer) spacecraft. For the three largest observed events, we estimated the ejected particle velocities and sizes, event times, source regions, and energies. We also determined the trajectories and photometric properties of several gravitationally bound particles that orbited temporarily in the Bennu environment. We consider multiple hypotheses for the mechanisms that lead to particle ejection for the largest events, including rotational disruption, electrostatic lofting, ice sublimation, phyllosilicate dehydration, meteoroid impacts, thermal stress fracturing, and secondary impacts.

A
tive asteroids are small bodies that have typical asteroidal orbits but show some level of mass-loss activity, such as ejection of dust or the development of a coma or tail (1). Several objects in the main asteroid belt or the near-Earth asteroid population have been observed to show varying levels of mass loss, such as the active asteroid 133P/Elst-Pizarro (2). Some of these objects behave as comets and eject dust over long periods of time, from days to months, or during multiple perihelion passages (including 133P/Elst-Pizarro (3)). Other active asteroids eject dust over short time scales in one or a series of impulsive events, such as in the case of (6478) Gault (4). Still others have been observed to split into multiple objects or, in the case of P/2016 G1 (PANSTARRS), completely disintegrate (5). Near-Earth asteroid (3200) Phaethon has exhibited low levels of mass loss during multiple orbits when less than 0.15 astronomical units (AU) from the Sun (6, 7). Multiple ejection mechanisms have been suggested to explain asteroid activity, including collisions, water-ice sublimation, rotational destabilization, thermal fracturing, and dehydration (8).

The OSIRIS-REx (Origins, Spectral Interpretation, Resource Identification, and Security–Regolith Explorer) spacecraft arrived at the ~500-m-diameter B-type near-Earth asteroid (101955) Bennu in December 2018. Bennu was selected as the mission target partly because of its spectral similarity to some active asteroids (9). Here, we describe and analyze OSIRIS-REx observations of activity originating from Bennu’s surface. We initially detected this phenomenon in navigational images from 6 January 2019, 1 week after the spacecraft entered orbit and 4 days before Bennu peri-
later shows objects in common with the earlier image that have moved away from Bennu, implying the movement of discrete particles (Fig. 1B). This observation triggered an immediate risk assessment of whether it was safe for the spacecraft to remain in orbit, which was concluded affirmatively, and led to an observational campaign to detect and characterize Bennu’s apparent activity.

We increased the imaging cadence in response to the initial event to better characterize the frequency of particle ejections and any persistent particle population (table S1). Starting on 11 January, NavCam 1 began collecting image pairs of each field every 30 min. On 28 January, we again increased the cadence, collecting image pairs of each field every 20 min. This imaging frequency continued until 18 February. During this time period, we detected two additional ejection events of a similar scale, on 19 January (Fig. 1, C and D, and fig. S3) and 11 February (fig. S4). The distance from the spacecraft to Bennu’s center of mass was 1.66 km for 6 January, 1.99 km for 19 January, and 1.64 km for 11 February. We used the imaging dataset to characterize these three events, which were the largest observed (they had the highest number of detected particles). We also observed several smaller events, in which fewer than 20 particles were detected (Fig. 2). There is also a persistent background level of particles in the Bennu environment; we detected a few particles per day during Orbital A, with observed increases immediately after the 19 January and 11 February events (Fig. 2).
Characterization of the largest observed events

For the 6 January, 19 January, and 11 February events, a particle distribution pattern near the limb of Bennu in the first image of each event is also apparent in the image collected ~7 min later, farther from the limb and dispersed (Fig. 1, B and D), and also appears in subsequent images for the 19 January and 11 February events. Using OpNav techniques developed for spacecraft navigation, we associated individual particle detections from this pattern and determined the trajectory and velocity of each particle (12). Fast-moving particles cross multiple pixels in a single exposure and appear as trails, providing position and velocity information within one image. For each event, OpNav analysis constrains two possible locations (a near and far radiant) on Bennu’s surface from which the particles originated (Fig. 3, Table 1, and table S2) (12).

The 6 January event is the least constrained (particles detected in only two images) of the three largest events. We determined that the event originated at a high southern latitude (between about 57°S and 75°S) (Table 1 and Fig. 3A) (12), with an ejection time between 15:22 and 16:35 local solar time (LST). However, the event location relative to the spacecraft and the limited dataset make estimating the precise latitude and ejection time difficult. For this event, we determined speeds for 117 of the 200 observed particles, ranging from 0.07 to 3.3 m s\(^{-1}\). Fifty-two particles were moving more slowly than Bennu’s escape velocity [20 cm s\(^{-1}\) for the volume-averaged Bennu radius (12, 16)] (fig. S5).

Because of the increased imaging cadence, there is a more extensive dataset for the 19 January and 11 February events. We used the output of the OpNav characterization to provide initial conditions for higher-fidelity orbit determination (OD) modeling. In these models, we assumed that the particles from a given event left Bennu’s surface at the same location on a trajectory influenced by point-mass gravity (12). We performed this analysis on 24 particles from the 19 January event (Movie 1) and 25 particles from the 11 February event. For these two events, with individual particles identified in more than three images, this analysis allows us to estimate a single location for the particle source location (Fig. 3, B and C) as well as ejection timing and initial velocity vectors (Table 1).

We determined the ejection epoch (moment in time) by extrapolating the OD solutions backward to the point where they intersect Bennu’s surface. This analysis shows that the event on 19 January occurred at 00:53:41 ± 4 s (3σ) UTC from a location on Bennu at latitude 20°N, longitude 335°. The epoch corresponds to 16:38 LST at that location. Surface ejection velocity magnitudes ranged from 0.06 to 1.3 m s\(^{-1}\). The 19 January timing data show a bimodal distribution, with a small peak occurring 6 min before the main epoch (fig. S6), suggesting that some of the particles may have ejected in a smaller event before the large release. The event on 11 February occurred at 23:27:28 ± 6 s (3σ) UTC from latitude 20°N, longitude 60°, corresponding to 18:05 LST, with observed velocity magnitudes ranging from 0.07 to 0.21 m s\(^{-1}\). All particles from this event appear to have left the surface nearly simultaneously (fig. S6).

Many of the characterized particles are on ballistic trajectories that reimpact the surface on the night side of Bennu, whereas high-velocity particles escape on hyperbolic trajectories (Movie 1).

Images of the particle source locations on Bennu (Fig. 3, A to C) show no obvious geological distinction from other locations on the surface of Bennu. The event radiant locations contain abundant rocks that are diverse in size and surface texture, as well as small circular depressions that may be impact craters. However, similar features are globally distributed on Bennu (17, 18). We analyzed the normal albedo distribution of the two better constrained source regions (19 January and 11 February) and found that they are similar to the global distribution for Bennu (19), averaging 0.042 ± 0.003 (3σ) (Fig. 3, D and E) (22). The lack of obvious morphologic or albedo variation may be due to the very low energies associated with the ejection events (Table 1 and table S3).

Characterization of gravitationally bound particles

In addition to particles released in ejection events, we observed a gravitationally bound background population of particles in the Bennu environment (Fig. 2). Among these are a few objects that remain in orbit for several days. From among the 215 tracks (linkages of individual detections of the same particle over a short time), we identified a representative group of six distinct gravitationally bound particles for further analysis. The trajectories around Bennu of these six particles and their altitude histories are shown in Fig. 4. Orbital elements are given in Table S4 and fig. S7. Particles 1 to 4 are on short-lived orbits, persisting for 4 to 17 revolutions, with lifetimes ranging from 2 to 6 days. These orbits show a range of inclinations, from near equatorial to polar. Both prograde and retrograde orbits occur. The semimajor axis of particle 1 is >1 km, compared with 0.4 to 0.5 km for particles 2 to 4. Particles 5 and 6 are suborbital. By extrapolating the orbits back to the time when they intersected Bennu’s surface, we determined that three of the six particles ejected from the night side of Bennu (between 18:00 and 06:00 LST) (Table S5). The six particles were ejected with orbital velocities in the range of 15 to 20 cm s\(^{-1}\). Surface-relative velocities at ejection range from roughly 10 to 25 cm s\(^{-1}\).  

---

Fig. 2. Particle detections during the Orbital A mission phase. (A) Distance of Bennu from the Sun over the same time period as shown in (B). (B) Particle detections associated (purple and orange) and not associated (light blue) with observed ejection events. The changes in the background shading indicate when the observation cadence increased on 11 January and again on 28 January 2019.
**Particle properties**

We constrained the area-to-mass ratios (where area is cross-sectional) of the six bound particles by using the trajectory information and modeling the non-gravitational forces, which primarily arise from radiation pressures (table S5) (12). The particle trajectories also enabled us to calculate the phase and range of each observation to the spacecraft, from which we determined the photometric phase functions for particles 1 to 3, constraining the visible absolute magnitude of each particle (table S5). Combining the area-to-mass ratio and absolute magnitude information, and assuming a spherical shape, defines a distinct curve in density ($\rho$)-albedo ($p_V$) space for each particle (fig. S8). If we further assume particles with densities of 2 g cm\(^{-3}\) [on the basis of Bennu meteorite analogs (20)], then their normal albedos range from 0.05 to 0.3. In that case, the derived albedos are brighter than 96% of the material on Bennu, and the particle diameters range from 0.4 to 4.4 cm. If, on the other hand, the particles have normal albedos of 0.04, which is consistent with the average surface material on Bennu (19), then the densities range from 0.7 ± 0.3 (1σ) to 1.7 ± 0.4 (1σ) g cm\(^{-3}\) (fig. S8). The high end of this range is consistent with meteorite analogs. The lower densities lead to larger particle diameters, ranging from 1.2 to 8.5 cm. Given these uncertainties, we conclude that the particle diameters are in the range of <1 to ~10 cm.

With these constraints on the particle sizes, and the ejection velocities from the OD analysis, we can estimate the energy of the ejection events (Table 1 and table S3) (12). Such estimates should be considered lower limits because we may not have observed all ejected particles. In addition, our calculation assumes that the ejected particles had the average surface albedo of Bennu (0.044) (table S3) and the meteorite analog density of 2 g cm\(^{-3}\). For 6 January, the 124 particles with measured photometry ranged in size from <1 to 8 cm, yielding a minimum event energy of ~270 mJ. For the 19 January event, more than 93 photometrically measured particles with radii between <1 and 7 cm ejected from the surface, giving a minimum event energy of 100 mJ. For 11 February, more than 60 particles with radii between <1 and 7 cm ejected from the surface, with an associated minimum event energy of 8 mJ (uncertainties on the event energies are provided in Table 1).

**Possible ejection mechanisms**

Several constraints apply to the particle ejection mechanism: The three largest observed ejection events occurred in the late afternoon, between 15:22 and 18:05 LST. The largest observed event (6 January) occurred days before Bennu reached perihelion (Fig. 1). The particles left the surface at discrete times. The observed particles ranged in size from <1 to ~10 cm. The ejection locations occurred over a range of latitudes from 75°S to 20°N. Particle velocities ranged from 0.07 to at least 3.3 m s\(^{-1}\). The minimum kinetic energy of the ejected particles ranged from 8 to 270 mJ, assuming that the particles have albedos equivalent to the surface average of Bennu. Smaller events occurred that ejected fewer than 20 observed particles. Individual particles were ejected at a range of local solar times, including at night.

Dust ejection is a common phenomenon in comets and active asteroids. Even for well-studied comets such as 67P/Churyumov-Gerasimenko, substantial uncertainty exists as to the physical mechanism through which particles are released from the surface (21). We consider multiple hypotheses for the particle ejection mechanism, evaluating their respective strengths and weaknesses. These include rotational disruption, electrostatic lofting, comet-like ice sublimation, phyllosilicate dehydration, thermally driven stress fracturing, meteoroid impacts, and secondary impacts.

**Rotational disruption**

Mass shedding or splitting that results from rotational instability has been identified as a
possible explanation for the activity of the smaller active asteroids (22). In this scenario, rapidly rotating asteroids experience centrifugal forces greater than the centripetal forces from self-gravity, leading to particle ejection preferentially from low latitudes. Particles launched from Bennu’s surface would have a maximum velocity equal to the equatorial surface velocity of 10 cm s⁻¹ (on the basis of Bennu’s ~250-m equatorial radius and ~4.3-hour rotation period). This mechanism would preferentially produce particles in equatorial orbits in the rotational direction. It is not capable of launching particles on retrograde or hyperbolic trajectories, as we observed.
Electrostatic lofting

Electrostatic lofting is the phenomenon of dust particles detaching from a surface once the electrostatic force on the particles exceeds those of gravity and cohesion (which bind the particles to the surface). The surface of an airless body (such as the Moon or an asteroid) interacts directly with the solar wind plasma, which charges the particles and produces a near-surface electric field. The electrostatic force is the product of the grain charge and the local electric field. Although electrostatic lofting has been discussed as a possible mechanism of the lunar horizon glow (23), when considering cohesion, there remained a discrepancy between the electrostatic force necessary to loft particles and the charging conditions hypothesized to be present in situ (24). Charge exchange between individual particles may produce very strong, short-scale electric fields that are capable of lofting particles in microgravity environments (25, 26). It is possible to electrostatically loft particles up to millimeters in radius at small asteroids such as Bennu (27), smaller than those we observed. The velocities of electrostatically lofted particles are likely to be less than 1 m s⁻¹, unless additionally accelerated away from the surface by solar radiation pressure (27).

Ice sublimation

Dust release from comets is a major source of interplanetary dust particles. On comets, ice sublimation results in gas drag forces that eject dust particles from the surface (21). The gas-drag forces accelerate the released dust within a few times the radius of the nucleus, until solar radiation pressure takes over. For such sublimation to be the driver of the Bennu events, ice must be present at or near the surface. Several observed ejection events occurred at relatively low latitudes, where temperatures reach ~390 K (17). At these temperatures, major cometary ice species (CO, CO₂, and H₂O) are not stable [for example, (28)]. Additionally, there are no water-ice absorption features at 1.5 or 2.0 μm in spectra of the surface (20). Subsurface ice could be trapped at depths greater than 1 m at some locations for long periods (29). Rapid volatile release from such a reservoir would require exposure by large

![Image of Bennu showing exfoliation textures](Fig. 5. Two distinct types of exfoliation textures on Bennu. In all images, north on Bennu is down. The PolyCam telescopic imager (12) acquired the four frames in (A) and (C) while the spacecraft moved with respect to the surface at a speed of 9 cm s⁻¹ with exposures of (A) 1/300 of a second and (C) 1/200 of a second. These side-by-side stereo images are presented in the stereo “cross-eyed” configuration. A stereoscope-viewing version is available in fig. S10. Each pair of images has been adjusted to match their brightness, contrast, and shadow positions. (A) The parallax angle between these two images is 12°. Phase angle, 44°; pixel scale, 6.6 cm per pixel; (longitude, latitude), (90°, 11°). (B) Annotated version of the image on the right in (A). The large, 5-m white rock on the crater rim displays a flat face, with a well-defined step crossing its center. A white “flake” is present in the upper right. (C) The parallax angle between these two images is 8°. Phase angle, 30°; pixel scale, 4.7 cm per pixel; (longitude, latitude), (44°, –30°). (D) Annotated version of the image on the right in (C). The large black boulder displays exfoliation textures along both the east and west faces, with fractures running parallel to the texture in the rock. The large rock column in the bottom left has a profile that matches that of the step in the boulder, suggesting that this fragment may have been uplifted in an energetic exfoliation event. Even though the rock slab measures 5 by 5 by 1 m, it would only require ~5 J of energy to lift it, assuming a density of 2 g cm⁻³. Other spalled fragments are present around the base of the large boulder.)
impacts or deep thermal cracking at meter scales. We observed no geologic evidence of such processes acting recently at the event locations (Fig. 3). There is also no evidence of a coma or jets associated with volatile release (Fig. 1 and figs. S3 and S4).

**Phyllosilicate dehydration**

Although ice has not been observed on Bennu, the surface is rich in water-bearing minerals. Spectroscopy has shown that the surface is dominated by hydrated phyllosilicates, with the closest spectral match being CM-type carbonaceous chondrite meteorites (20). Evolved gas analysis experiments on Murchison (a CM chondrite) have demonstrated that considerable volatile release can occur when heated from ambient temperature up to 473 K under vacuum [for example, (30–32)]. Although this temperature is ~70 K higher than the peak temperatures on Bennu, such low-temperature water release from Murchison indicates that the thermal dehydration of minerals begins with the loss of weakly bound adsorbed and interlayer water.

Mechanical stresses on Bennu’s surface may generate adsorbed water, such as that released in laboratory experiments. The CM chondrites are dominated by Mg-rich serpentine and crocodite, an Fe-rich phyllosilicate (for example, (33)). In these hydrated phases, particle size reduction through grinding enhances dehydroxylation and yields highly disordered material (34). The dehydroxylation reaction is substantially accelerated owing to the transformation of structural hydroxyls into adsorbed water in the resulting matrix. If mechanical stresses on Bennu result in a similar chemical transformation, the structural OH component of the phyllosilicates that dominate the surface mineralogy may be converted into absorbed water concentrated within an outer layer of the surface rocks. It is possible that the release of this adsorbed water within cracks and pores in boulders could provide a gas pressure leading to disruption of rock faces, such as is thought to occur on near-Earth asteroid (3200) Phaethon (35).

**Meteoroid impacts**

Solid bodies in space are routinely impacted by a steady flux of small meteoroids. Because Bennu is on an Earth-like orbit, we expect the flux of meteoroids at Bennu’s surface to be similar to that on Earth, once corrected for gravitational focusing. A model of the interplanetary dust flux in near-Earth space has been determined by using data from in situ spacecraft measurements and lunar microcrater studies (36) and is widely adopted for meteoroid flux in near-Earth space (37). Lunar meteoroids typically impact at velocities between 13 and 18 km s⁻¹ (38). If we assume an average velocity of 15.5 km s⁻¹ for meteoroids at Bennu, an impact by an interplanetary dust particle with mass 2.5 μg would deposit 300 mJ of energy into the surface, which is consistent with the estimated energy of the largest observed event (6 January). However, Bennu has a cross-sectional area of 1.96 × 10⁶ m²; applying this value to the interplanetary dust flux model (36), we found that Bennu should be hit by a particle of this size on average once every minute, which is much more frequently than the observed ejection cadence. The large ejection events occurred on a roughly 2-week cadence. At that frequency, Bennu should be hit by an average of one meteoroid with a mass ~3000 μg, depositing more than 360,000 mJ of energy into the surface if it impacted at 15.5 km s⁻¹. Thus, only 0.07% of the impact energy from such events would need to be transferred to the particles to produce the largest observed ejection event.

The result of hypervelocity impacts into Bennu’s surface depends substantially on the mass and velocity of the impacting grain and on the strength of the target material. Particle impacts at velocities on the order of 2.5 to 3 km s⁻¹ produce well-developed craters with rims, fracturing, and spallation of a large number of particles (39). At higher speeds, such impact events produce little ejecta; instead, they deposit energy into a small volume of the asteroid surface, causing melting, vaporization, and at the highest energy densities, ionization of the target and impactor material producing plasma (40, 41). It is possible that the observed ejection events are the result of low-velocity meteoroid impacts, which occur much less frequently. Alternatively, the particles may be accelerated by the small fraction of impact energy from more frequent, high-velocity impacts that did not result in plasma production.

**Thermal stress fracturing**

Bennu’s surface experiences extreme temperature variations over its 4.3-hour rotation period. Laboratory studies (42) showed that the CM chondrite Murchison quickly developed cracks and spalled particles from diurnal temperature cycling under near-Earth asteroid surface conditions. At the mid-latitudes, where the 19 January and 11 February events occurred, the surface temperature plunges to 250 K in the predawn hours and reaches a peak of 400 K at ~13:00 LST (12). Because Bennu has a moderate thermal inertia of 350 J m⁻² K⁻¹ s⁻¹/² (17), the maximum temperature at the thermal skin depth (penetration depth of daily thermal conduction) of ~2 cm occurs later in the afternoon, at ~16:00 LST. The amplitude of temperature variation falls by a factor of e at one thermal skin depth. Thus, for a region on Bennu whose maximum surface temperature is 400 K, the peak temperature at a depth of ~2 cm reaches 325 K, inducing a strong thermal gradient over this short distance that cycles every 4.3 hours.

Thermal cycling can drive the growth of cracks in rocks over a range of spatial scales within the thermal skin depth, controlled by the amplitude and frequency of the temperature cycle, mineral composition, constituent grain size, the overall rock shape, and its orientation relative to the Sun. At the bulk scale, stresses associated with temperature gradients and surface cooling are induced in different regions of a boulder at different times throughout the thermal cycle. Stresses that arise in the
shallow interior of large boulders tend to drive surface-parallel crack propagation (43). In the thermal fatigue regime, subcrITICAL crack growth occurs slowly, propagating fractures incrementally over many cycles. Crack propagation velocity increases with crack length, until catastrophic disruption occurs, which may disaggregate material and eject particles from the surface.

In terrestrial settings, thermal fatigue combined with tectonic unloading is known to cause rock dome exfoliation and energetic particle ejection (44). In these studies, rocks show the greatest evidence for stress and microfracturing in the afternoon and evening. Although the tectonic unloading effects, which are not likely to be present on Bennu, are thought to add to the energy in these events, much less energy is needed to eject particles in a microgravity environment. Such energy may be stored as a result of structural deformation related to thermal strain, providing excess energy that leads to particle ejection (35).

Secondary surface impacts
A possible mechanism for the small ejection events is the reimpact of disaggregated material released by larger events. Analysis of particle trajectories in the largest events show that the particles have a substantial velocity component in the direction of asteroid rotation. Because the largest events occur in the afternoon, a large fraction of the particles on suborbital trajectories impact the night side of the asteroid (Movie 1). During impact, these particles may bounce off the surface or collide with other small particles on the surface, resulting in subsequent ejection of a small number of low-velocity particles.

Dynamical calculations show that ejection moving at surface-relative velocities up to 30 cm s⁻¹ (escape velocity of ~20 cm s⁻¹ plus Bennu’s surface rotational velocity of 10 cm s⁻¹) lofted from the surface of Bennu can reimpact the surface days later (Movie 1). Depending on the impact location, reimpacting particles may be relaunched into a suborbital trajectory by bouncing off a hard surface such as a boulder (45) or ricocheting off a fine-grained surface (46, 47). Numerical simulations show that impacts on a fine-grained surface may result in the ejection of smaller surface particles at launch speeds that exceed the escape speed of Bennu (fig. S9). However, we have not directly observed particles ejecting from Bennu that are as large as the impactors in these simulations; in the energy regime that we have observed, particles of that size would not have traveled far enough from the asteroid to be detectable in our images. Our assessment thus leaves three viable candidates for the primary ejection mechanism: phyllosilicate dehydration, meteoroid impacts, and thermal stress fracturing (discussed in Conclusions and broader implications).

Table 1. Characteristics of the three largest observed particle ejection events. The more extensive imaging datasets acquired for the 19 January and 11 February 2019 events, relative to that for the 6 January 2019 event, allowed higher-fidelity OD determination of the event locations and times. More detail is given in (12) and tables S2 and S3.

(16). Particles ejected with higher energies that achieve orbit will preferentially reimpact in the equatorial region within the lobe because of the larger asteroid radius there [(16), figure 5 therein]. After impact (which occurs at low speeds relative to the escape velocity), the particles will not have sufficient energy to escape the Roche lobe and again will be preferentially trapped, leading to a concentration of returning particles in these regions, as opposed to a globally uniform distribution.

Previous observations have indicated a steady increase in Bennu’s rotation rate that will lead to doubling of that rate in ~1.5 million years; this acceleration is consistent with the Yarkovsky–O’Keefe–Radzievskii–Paddack (YORP) effect (10, 49). The angular momentum associated with particles ejected on escaping trajectories could also influence the rotation rate. It is possible to generate the measured rotational acceleration of Bennu by ejecting several particles of diameter ~10 cm once per day in the westward direction from the equator, assuming no concurrent water vapor loss. A random ejection of escaping particles from the surface of a spinning body would produce a spin deceleration (50).

We summed the net angular momentum change from particles launched normal to every facet on the asteroid surface and given a sufficient ejection speed for escape (12, 16). We found that such a flux would always cause Bennu to spin slower (fig. S11), counteracting the YORP effect (50). This implies that the strength of the YORP effect on Bennu due to solar photons could be greater than originally estimated (10, 49). If Bennu were to eject, for example, on the order of 20 10-cm particles per day at a speed of 18 cm s⁻¹ (the speed at which the effect is the greatest) normal to random points on its surface, then on average, its rotational acceleration would be slowed by less than 1% of the measured rotational acceleration. Thus, when averaged over the entire surface, the net effect of particle ejection is negligible relative to the YORP effect.

The linear momentum transfer from the particle ejections is orders of magnitude lower than that of the transverse acceleration because of thermal emission from Bennu, the operative component for the Yarkovsky effect (51). This acceleration peaks at ~10⁻¹⁰ m s⁻² during perihelion (51). Such an acceleration leads to a daily change in velocity ΔV of 10⁻¹⁷ m s⁻¹, which is more than 7000 times the ΔV caused by a single 10-cm particle with a density of 2 g cm⁻³ escaping at 1 m s⁻¹.

**Conclusions and broader implications**

The ejection events on Bennu inform our understanding of active asteroids. There are substantial differences between active asteroids as commonly defined—where major mass loss events occur through processes such as large impacts, volatile release, and rotational acceleration, leading to mass shedding—and relatively small mass loss events as we see on Bennu. It is likely that there is a continuum of event magnitudes and that we have been limited to observing only the largest phenomena.

Mass loss observed during perihelion from the B-type near-Earth asteroid (3200) Phaethon, the parent body of the Geminids meteor shower, apparently consists of smaller particles [1 μm (52)] than observed at Bennu (<1 to ~10 cm). However, particles in the centimeter size range were not observable during studies of Phaethon at perihelion, and sub-centimeter particles would have been difficult to detect in NavCam 1 images. Particles in the millimeter size range are observed as Geminids meteors (53). The mass loss from Bennu between 31 December and 18 February (including the three largest ejection events characterized above) was ~10⁻⁷ g, which is orders of magnitude less than Phaethon’s near-perihelion mass loss (~10⁻⁵ to 10⁻⁶ kg per perihelion passage) (7). The mass loss rate (~10⁻⁷ g s⁻¹) on Bennu is also many orders of magnitude less than the rates observed at other active asteroids (~10 to 10⁴ g s⁻¹) (1). Mass loss as seen at Bennu suggests that Phaethon’s current mass loss rate may include larger particles and be greater than remote observations imply.

Having evaluated multiple hypotheses for the mechanism of particle ejection on Bennu, we found that thermal fracturing, volatile release by dehydration of phyllosilicate rocks, and meteoroid impacts are plausible explanations. Rotational disruption and electrostatic lofting cannot explain the observed particle sizes and ejection velocities. There is no evidence for ice on the surface of Bennu or for recent exposure of a subsurface ice reservoir at the multiple ejection sites. Bennu’s boulder morphology and the event ejection times are consistent with exfoliation as a result of thermal fracturing, phyllosilicate dehydration, or an interplay between these two mechanisms. Because we expect meteoroid flux to be greatest in the leading hemisphere (late afternoon on Bennu because of its retrograde rotation), the ejection event times are also consistent with meteoroid impacts. It is possible that multiple mechanisms operate in combination. Reimpacting particles could play a role in the smaller ejections or contribute to the larger events.

The particles that escape from Bennu on parabolic or hyperbolic orbits will escape onto heliocentric orbits, which we expect to disperse over time into a meteoroid stream. On the basis of the measured ejection velocities, meteoroids released after 1500 CE would not have spread wide enough to bridge the current distance between the orbits of Bennu and Earth, 0.0029 AU, but will do so when that distance decreases later in the 21st century (54). However, if Bennu was active in the past, and the ejected particles survive for thousands of years, planetary perturbations would spread the stream wide enough to cause an annual meteor shower on present-day Earth around 23 September. The shower would radiate from a geocentric radiant at right ascension 5°, declination -34°, and speed 6.0 km s⁻¹ (54), corresponding to an apparent entry speed of 12.7 km s⁻¹ (12). Meteoroids moving this slowly would create meteors of integrated visual magnitude +2 to ~5, assuming a 0.7% luminous efficiency (55). The stream would not easily blend with the sporadic background over thousands of years. No shower is detected in current meteor orbit survey data (56), but those data have poor coverage in the Southern Hemisphere.

The primary objective of OSIRIS-REx is to return samples of centimeter-scale rocks from the surface of Bennu to Earth for analysis (14). We have observed centimeter-scale particles frequently being ejected and impacting the asteroid surface. It is possible that the collected sample will contain some particles that were ejected and returned to Bennu’s surface.

A. B. D., D. J. Scheeres, Y. T., N. J. K., and J. W. M. J.W.M. also supported the photometric modeling efforts. S.R.C. led the team that performed the orbital element analysis of the six short-lived orbiting particles, supported by R.A.J., M.B., A.B.D., D.F., Y.T., W.M.O.K., J.R.S., and J.W.M. D.J.S. also calculated the Bennu Roche lobe and contribution of particle ejections to Bennu’s observed rotational acceleration and Yarkovsky, M.C.M. led the team that performed the OSIRIS-REx and OD analyses. J.M.L. performed the OD analysis for the three largest observed ejection events. J.Y.P. led the OSIRIS-REx characterization of the three largest events, supported by J.F., J.L.C., C.D.A., D.S.N., J.K., and E.M. M.C. is the instrument scientist for OLA and performed the analysis of the off-body lidar returns, supported by M.A.A. and J.A.S. J.B.B. is the lead instrument scientist for NavCam I and performed image calibration and image processing for the navigation images. B.R.I. and C.Y.D.A. are the lead and deputy lead instrument scientists, respectively, for the OSIRIS-REx Camera Suite; they analyzed images of Bennu’s surface for evidence of particle infall and processed the images used for the stereo pairs. D.N.D. is the lead image processing scientist for OSIRIS-REx and prepared the global mosaics used to register the particle source locations, supported by K.J.B., C.A.B., and D.R.G. K.J.B. also developed the NavCam camera model for use in registering NavCam images relative to the Bennu shape model and the background star fields. J.P.E. is the lead thermal analysis scientist for OSIRIS-REx, and B.Ro developed the asteroid thermal model to determine the surface temperatures, skin depths, and thermal gradients at the particle ejection sites and globally across the asteroid. R.-L.B. developed the secondary impact hypothesis with support from P.M. and F.T. W.F.B. provided support on the meteoroid impact hypothesis and evaluated the other hypotheses in the context of the dynamical evolution of Bennu. H.C., J.d.L., and J. provided expertise on other known active asteroids. H.C.C.Jr. provided input on the potential mechanisms for ejection events and on the content of the manuscript. P.D. provided rock count data for testing the re-impacting particle hypothesis. D.P. counted rocks and provided input on EGA studies of meteorites and their low-temperature volatile release. C.M.H. developed the electrostatic coating hypothesis and performed the optical analysis of the particle ejection source regions. G.L. provided input on the relevance of thermal cycling experiments and regolith evolution. C.M. and B.M. identified and processed the stereo pair images. J.L.M. provided input on the feasibility of thermal fracture processes as a mechanism for particle ejection. H.L.R. led the development of the figures. S.H.S. provided software for processing NavCam images and identifying candidate particles. P.T. performed calculations for the statistical assessment of particles lifetime and fallback distribution. D.V. supported the development of the force model for non-gravitational forces for orbiting particles, as well as giving input on the general implications and context of Bennu’s activity. C.W.V.W. contributed substantively to the writing and preparation of the manuscript. Competing interests: H.C.C.Jr. is also affiliated with the Department of Earth and Planetary Science, American Museum of Natural History, New York, NY, USA. J.L.M. is also affiliated as a contractor with the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA. Data and materials availability: NavCam I images from Orbital A and OLA data from Preliminary Survey are available from the Planetary Data System (PDS) at https://pds.nasa.gov/pds/resource/oerx/tags/ams.html and https://smi.ssi.sci/sps/psds/resource/orex/ola.html, respectively. The NavCam I images that we used are listed in data file S1. The parameters of the three largest ejection events are given in tables S2 and S3, and the derived orbital data for the six gravitationally bound particles are in tables S4 and S5 and data file S1.
Episodes of particle ejection from the surface of the active asteroid (101955) Bennu

Bennu ejects material from its surface

Most asteroids appear inert, but remote observations show that a small number experience mass loss from their surfaces. Lauretta and Hergenrother et al. describe close-range observations of mass loss on the near-Earth asteroid Bennu (see the Perspective by Agarwal). Shortly after arriving at Bennu, navigation cameras on the OSIRIS-REx (Origins, Spectral Interpretation, Resource Identification, and Security—Regolith Explorer) spacecraft detected objects 1 to 10 centimeters in diameter moving above the surface. Analysis of the objects’ trajectories showed that they originated in discrete ejection events from otherwise unremarkable locations on Bennu. Some objects remained in orbit for several days, whereas others escaped into interplanetary space. The authors suggest multiple plausible mechanisms that could underlie this activity.
