(Received 16 November 2019; revised manuscript received 14 February 2020; accepted 17 April 2020)

For more than 40 years, most astrophysical observations and laboratory studies of two key soft x-ray diagnostic  $2p - 3d$  transitions,  $3C$  and  $3D$ , in Fe XVII ions found oscillator strength ratios  $f(3C)/f(3D)$  disagreeing with theory, but uncertainties had precluded definitive statements on this much studied conundrum. Here, we resonantly excite these lines using synchrotron radiation at PETRA III, and reach, at a millionfold lower photon intensities, a 10 times higher spectral resolution, and 3 times smaller uncertainty than earlier work. Our final result of  $f(3C)/f(3D) = 3.09(8)(6)$  supports many of the earlier clean astrophysical and laboratory observations, while departing by five sigmas from our own newest large-scale *ab initio* calculations, and excluding all proposed explanations, including those invoking nonlinear effects and population transfers.

DOI:

Space x-ray observatories, such as *Chandra* and *XMM-Newton*, resolve  $L$ -shell transitions of iron dominating the spectra of many hot astrophysical objects [1–4]. Some of the brightest lines arise from Fe XVII (Ne-like iron) around 15 Å: the resonance line  $3C$  ( $[(2p^5)_{1/2}3d_{3/2}]_{J=1} \rightarrow [2p^6]_{J=0}$ ) and the intercombination line  $3D$  ( $[(2p^5)_{3/2}3d_{5/2}]_{J=1} \rightarrow [2p^6]_{J=0}$ ). Appearing over a broad range of plasma temperatures and densities, they are crucial for diagnostics of electron temperatures, elemental abundances, ionization

F1:1 FIG. 1. (Top) Experimental setup: an electron beam (orange) aimed at the trap center produces Fe XVII ions, which are then resonantly  
 F1:2 excited by a monochromatic photon beam (red). Subsequent x-ray fluorescence is registered by a silicon drift detector. (Bottom)  
 F1:3 Fluorescence yield and photon energy vs time with three different methods: (1) line scans with open photon shutter; (2,3) by closing it at  
 F1:4 each step (purple areas), we subtract the electron-beam-induced background at (2) each line center and (3) scanning over a one-half-  
 F1:5 width-at-half-maximum range.

52 conditions, velocity turbulences, and opacities [5–15].  
 53 However, for the past four decades, their observed intensity  
 54 ratios persistently disagree with advanced plasma models,  
 55 diminishing the utility of high resolution x-ray observations.  
 56 Several experiments using electron beam ion trap (EBIT) and  
 57 tokamak devices have scrutinized plausible astrophysical  
 58 and plasma physics explanations as well as the underlying  
 59 atomic theory [16–23], but also revealed clear departures  
 60 from predictions while broadly agreeing with astrophysical  
 61 observations [19,20,24]. This has fueled a long-lasting  
 62 controversy on the cause being a lack of understanding of  
 63 astrophysical plasmas, or inaccurate atomic data.

64 A direct probe of these lines using an EBIT at the Linac  
 65 Coherent Light Source (LCLS) x-ray free-electron laser  
 66 (XFEL) found again their oscillator strength ratio  $f(3C)/$   
 67  $f(3D)$  to be lower than predicted, but close to astrophysical  
 68 observations [25]. This highlighted difficulties with oscil-  
 69 lator strength calculations in many-electron systems [24–  
 70 31]. Nonetheless, at the high peak brilliance of the LCLS  
 71 XFEL, nonlinear excitation dynamics [32,33] or nonequi-  
 72 librium time evolution [34] might have affected the result  
 73 of Bernitt *et al.* [25]. An effect of resonance-induced  
 74 population transfer between Fe XVI and Fe XVII  
 75 ions was also postulated [35] since the Fe XVI  
 76 line  $C$  ( $[(2p^5)_{1/2}3s3d_{5/2}]_{J=3/2} \rightarrow [2p^63s]_{J=1/2}$ ) appeared  
 77 blended with the Fe XVII line  $3D$ . A recent semiempirical  
 78 calculation [36] reproduces the LCLS results [25] by fine-  
 79 tuning relativistic couplings and orbital relaxation effects,  
 80 but its validity has been disproved [37].

81 In this Letter, we report on new measurements of  
 82 resonantly excited Fe XVI and Fe XVII with a synchrotron  
 83 source at tenfold improved spectral resolution and

84 millionfold lower peak photon flux than in [25], sup-  
 85 pressing nonlinear dynamical effects [32,34,38] and unde-  
 86 sired ion population transfers [35]. We also carry out  
 87 improved large-scale calculations using three different  
 88 advanced approaches [39–41], all showing a five-sigma  
 89 departure from our experimental results.

90 We used the compact PolarX-EBIT [42], in which a  
 91 monoenergetic electron beam emitted by an off-axis  
 92 cathode (see Fig. 1) is compressed by a magnetic field.  
 93 At the trap center, it collides with a beam of iron-  
 94 pentacarbonyl molecules, dissociating them, and producing  
 95 highly charged Fe ions with a relative abundance of Fe XVI  
 96 to Fe XVII close to unity. These ions stay radially confined  
 97 by the negative space charge of the  $\sim 2$ -mA, 1610-eV ( $\approx 3$   
 98 times the Fe XVI ionization potential) electron beam and  
 99 axially by potentials applied to surrounding electrodes.

100 Monochromatic, circularly polarized photons from the  
 101 P04 beamline [43] at the PETRA III synchrotron photon  
 102 source enter through the electron gun, irradiate the trapped  
 103 ions, and exit through the collector aperture. They can  
 104 resonantly excite x-ray transitions on top of the strong  
 105 electron-induced background due to ionization, recombina-  
 106 tion, and excitation processes. A side-on-mounted energy-  
 107 resolving windowless silicon drift photon detector (SDD)  
 108 equipped with a 500-nm thin aluminum filter registers these  
 109 emissions.

110 By scanning the P04 monochromator between 810 and  
 111 830 eV, we excite the Fe XVII lines  $3C$  and  $3D$ , as  
 112 well as the Fe XVI lines  $B$  ( $[(2p^5)_{1/2}(3s3d_{3/2})]_{J=1/2} \rightarrow$   
 113  $[2p^63s]_{J=1/2}$ ) and  $C$ . They are also nonresonantly excited  
 114 by electron impact as the electron beam energy is well

F2:1 FIG. 2. Fluorescence photon yield and energy vs excitation-photon energy for the Fe XVI *C*, Fe XVII *3C*, and *3D* transitions recorded  
 F2:2 by a silicon-drift detector. Black dots: total fluorescence within a 50-eV region of interest. Red solid lines: Fits to *3C* and *3D*. Red dashed  
 F2:3 line: fit to *C*.

115 above threshold [21,23]. This leads to a strong, nearly  
 116 constant x-ray background at the same energies as the  
 117 photoexcited transitions but independent of the exciting  
 118 photon-beam energy. In our earlier work [25], we rejected  
 119 this background by detecting the fluorescence in time  
 120 coincidence with the sub-picosecond-long LCLS pulses  
 121 of  $\approx 10^{11}$  photons each at 120/s. Because of much longer  
 122 and weaker 50-ps-long pulses ( $\approx 10^3$  photons,  $6 \times 10^6$ /s  
 123 repetition rate) at P04 and the limited time resolution of  
 124 SDD, we could not use the coincidence method and  
 125 reached a signal-to-background ratio of only  $\sim 5\%$ . To  
 126 improve this, we used a shutter to cyclically turn on and off  
 127 the P04 photon beam.

128 Using a 50- $\mu\text{m}$  slit width, we reached a resolving power  
 129 of  $E/\Delta E \approx 10000$ , 10–15 times higher than that of Chandra  
 130 and XMM-Newton grating spectrometers [44,45], and  
 131 tenfold that of our previous experiment [25] (see the  
 132 Supplemental Material [46]). We find a separation of *3C*  
 133 from *3D* of  $\Delta E_{3C-3D} = 13.398(1)$  eV and resolve for the  
 134 first time the Fe XVII *3D* line from the Fe XVI *C* one at  
 135  $\Delta E_{3D-C} = 154.3(1.3)$  meV. This gives us the *3C/3D*  
 136 intensity ratio without having to infer a contribution of  
 137 Fe XVI line *C* (in [25] still unresolved) from the intensity of  
 138 the well-resolved Fe XVI *A* line. Thereby, we largely  
 139 reduce systematic uncertainties and exclude the resonance-  
 140 induced population transfer mechanism [35] that may have  
 141 affected the LCLS result [25].

142 We apply three different methods (Fig. 1) to systemati-  
 143 cally measure the *3C/3D* oscillator strength ratio. In  
 144 *method 1*, we did not operate the photon shutter; instead,  
 145 we repeatedly scanned the lines *C* and *3D* (812.0–  
 146 812.5 eV), as well as *3C* (825.5 – 826.0 eV), in both  
 147 cases using scans of 100 steps with 20-s exposure each (see

Fig. 2). The SDD fluorescence signal was integrated over a  
 50-eV wide photon-energy region of interest (ROI) comprising  
*3C*, *3D*, and *C* and recorded while scanning the incident  
 photon energy. By fitting Gaussians to the scan result,  
 we obtain line positions, widths, and yields, modeling the  
 electron-impact background as a smooth linear function [23].  
 The ratio of *3C* and *3D* areas is then proportional to the  
 oscillator strength ratio [33]. However, given the low 5%  
 signal-to-background ratio and long measurement times,  
 changes in the background cause systematic uncertainties.  
 In *method 2*, we fixed the monochromator energy to the  
 respective centroids of *C*, *3D*, and *3C* found with  
 method 1 and cyclically opened and closed the shutter for  
 equal periods of 20 s to determine the background. The  
 background-corrected fluorescence yields at the line peaks  
 were multiplied with the respective linewidths from method  
 1, to obtain the *3C/3D* ratio. Still, slow monochromator  
 shifts from the selected positions could affect the results.  
 To address this, in *method 3*, we scanned across the  
 FWHM of *C*, *3D*, and *3C* in 33 steps with on-off exposures  
 of 20 s, which reduced the effect of possible monochromator  
 shifts. After background subtraction, we fit Gaussians to  
 the lines of interest fixing their widths to values from  
 method 1.

All three methods share systematic uncertainties caused  
 by energy-dependent filter transmission and detector effi-  
 ciency ( $\sim 1\%$ ) and by the incident photon beam flux  
 variation ( $\sim 2\%$ ). Additionally, for method 1, we estimate  
 systematic uncertainties from background ( $\sim 1.2\%$ ) and  
 ROI selection ( $\sim 2.7\%$ ). In method 2, possible monochromator  
 shifts from (set) line centroids and widths taken from  
 method 1 cause a systematic uncertainty of  $\sim 3.5\%$ .  
 Analogously, for method 3, we estimate a  $\sim 3\%$  uncertainty

F3:1 FIG. 3. Present experimental  $3C/3D$  ratios compared with  
 F3:2 previous predictions and experiments. Red band: combined  
 F3:3 results of the three different methods. Blue open circles: values  
 F3:4 from databases [51–53]. Blue crosses: predictions [29,31,  
 F3:5 32,35,36,54–57]. Note that the validity of theory [36] has been  
 F3:6 disputed [37]. Blue solid circles: present FAC [58], large-scale CI  
 F3:7 [39], MR-MCDHF [40], and AMBiT [41] calculations. Blue  
 F3:8 band: observed line ratios in astrophysical sources [3,4,7,59–61],  
 F3:9 with color shades coding the distribution of values weighted by  
 F3:10 their reported accuracies. Purple band: spread of tokamak results  
 F3:11 [20]. Open green diamonds: previous EBIT results [18,21,25].  
 F3:12 Note that the spread seen in various astrophysical sources and in  
 F3:13 tokamak in part arises from insufficient removal of Fe XVI  $C$  line  
 F3:14 contamination of Fe XVII  $3D$  line, at varying Fe XVI/Fe XVII  
 F3:15 abundance ratios [6,20]; nonlinear dynamical effects [32,34,38]  
 F3:16 (see main text) may have reduced the LCLS ratio [25].

181 due to the use of linewidth constraints from method 1.  
 182 The weighted average of all three methods is  $f(3C)/$   
 183  $f(3D) = 3.09(8)_{\text{sys}}(6)_{\text{stat}}$ ; see Fig. 3 (see the Supplemental  
 184 Material [46] for individual ratio and uncertainties). Note  
 185 that the circular polarization of the photon beam does not  
 186 affect these results, since  $3C$  and  $3D$  (both  $\Delta J = 1$ ) share  
 187 the same angular emission characteristics [47–50].

188 Calculations using a density-matrix approach by  
 189 Oreshkina *et al.* [32,33], and the time-dependent collisional-radiative model of Loch *et al.* [34], pointed to a  
 190 possible nonlinear response of the excited upper state  
 191 populations in [25], reducing the observed oscillator  
 192 strength ratio [38], which would depend on photon pulse  
 193 parameters, like intensity, duration, and spectral distribu-  
 194 tion. It has been estimated that peak intensities above  
 195  $10^{12}$  W/cm<sup>2</sup> would give rise to nonlinear effects [32,38].  
 196 Fluctuations of the self-amplified spontaneous emission  
 197 process at LCLS can conceivably generate some pulses  
 198 above that threshold. At P04, we estimate a peak intensity  
 199 of  $\approx 10^5$  W/cm<sup>2</sup>, more than 6 orders of magnitude below  
 200 that threshold (see the Supplemental Material [46]). This  
 201 could explain why the  $3C/3D$  ratio in Bernitt *et al.* [25] is  
 202 in slight disagreement with the present result. Nonetheless,  
 203 our experiment validates the main conclusion of that work  
 204 with reduced uncertainty. Our work implies that future  
 205

206 experiments at ultrabright light sources should take  
 207 possible nonlinear effects into account.

208 In the present work, we also carried out relativistic  
 209 calculations using a very-large-scale configuration inter-  
 210 action (CI) method, correlating all ten electrons, including  
 211 Breit and quantum electrodynamical [62] corrections. We  
 212 implemented a message passing interface (MPI) version of  
 213 the CI code from [39] to increase the number of configura-  
 214 tions to over 230 000, saturating the computation in all  
 215 possible numerical parameters. Basis sets of increasing size  
 216 are used to check for convergence, with all orbitals up to  
 217  $12sp17dfg$  included in the largest version (the contribu-  
 218 tions of  $n > 12sp$  orbitals are negligible). We start with all  
 219 possible single and double excitations from the  $2s^22p^6$ ,  
 220  $2s^22p^53p$  even and  $2s^22p^53s$ ,  $2s^22p^53d$ ,  $2s2p^63p$ ,  
 221  $2s^22p^54d$ ,  $2s^22p^55d$  odd configurations, correlating eight  
 222 electrons. We separately calculate triple excitations and  
 223 fully correlate the  $1s^2$  shell, and also included dominant  
 224 quadruple ones, finding them negligible. The line strengths  
 225  $S$  and  $3C/3D$  oscillator strength ratio after several compu-  
 226 tation stages are summarized in the Supplemental Material  
 227 [46] to illustrate the small effect of all corrections.  
 228 Theoretical uncertainties are estimated based on the vari-  
 229 ance of results from the smallest to largest runs, size of the  
 230 various effects, and small variances in the basis set  
 231 construction. We verified that the energies of all 18 states  
 232 considered, counted from the ground state, agree with the  
 233 National Institute for Standards and Technology [51]  
 234 database well within the experimental uncertainty of  
 235 0.05%. The theoretical  $3C-3D$  energy difference of  
 236 13.44 eV is in agreement with the experiment to 0.3%.

237 We also carried out entirely independent large-scale  
 238 calculations using the multireference multiconfiguration  
 239 Dirac-Hartree-Fock (MR-MCDHF) approach [40] with up  
 240 to 1.2 million configurations. First, the  $2s^22p^53s$ ,  $2s^22p^53d$ ,  
 241 and  $2s2p^63p$   $J = 1$  levels were used as reference states to  
 242 generate the list of configuration state functions with single  
 243 and double exchanges from all occupied orbitals up to  
 244  $12spdfghi$ . Virtual orbitals were added in a layer-by-layer  
 245 manner. Subsequently, the role of triple excitations was  
 246 studied by the CI method. In a second step, the multi-  
 247 reference list was extended to include all  $J = 1$  odd parity  
 248 states, generated from the Ne-like ground state by single and  
 249 double electron exchanges. Monitoring the convergence of  
 250 the results for the addition of layers of virtual orbits, we  
 251 arrive at an oscillator strength ratio of 3.55(5) and to a  
 252  $3C-3D$  energy splitting of 13.44(5) eV. Another full-scale CI  
 253 calculation with more than a million configurations was  
 254 carried out in the particle-hole formalism using AMBiT [41],  
 255 agreeing well with the other theoretical results. Full details of  
 256 all calculations can be found in the Supplemental  
 257 Material [46].

258 We emphasize that there are no other known quantum  
 259 mechanical effects or numerical uncertainties to consider  
 260 within the CI and MCDHF approaches. With modern

261 computational facilities and MPI codes, we have shown  
 262 that all other contributions are negligible at the level  
 263 of the quoted theoretical uncertainties. The significant  
 264 improvements in experimental and theoretical precision  
 265 reported here have only further deepened this long-standing  
 266 problem. This work on the possibly so far most intensively  
 267 studied many-electron ion in experiment and theory, finally  
 268 demonstrates convergence of the dedicated atomic calcu-  
 269 lations on all possible parameters, excluding an incomplete  
 270 inclusion of the correlation effects as potential explanation  
 271 of this puzzle.

272 Our result is the presently most accurate on the  $3C/3D$   
 273 oscillator strength ratio. Its excellent resolution suggests pro-  
 274 mising direct determinations of the natural linewidth. They  
 275 depend on the Einstein  $A$  coefficients, hence, on the oscillator  
 276 strengths [63]. Thus, future accurate measurements of indi-  
 277 vidual natural linewidths of  $3C$  and  $3D$  not only would test  
 278 theory more stringently than their oscillator strength ratio  
 279 does, but also deliver accurate oscillator strengths.

280 Moreover,  $3C$  and  $3D$  with their, among many transi-  
 281 tions, strong absorption and emission rates can also  
 282 dominate the Planck and Rosseland mean opacity of hot  
 283 plasmas [64–66]. Therefore, an accurate determination of  
 284 their oscillator strengths may help elucidating the iron  
 285 opacity issue [12,14,67], if, e.g., Rosseland mean opacity  
 286 models [68,69] were found to use predicted oscillator  
 287 strengths also in departure from experiments. Our result  
 288 exposes in simplest dipole-allowed transitions of Fe XVII a  
 289 far greater issue, namely, the persistent problems in the best  
 290 approximations in use, and calls for renewed efforts in  
 291 further developing the theory of many-electron systems.

292 Shortcomings of low-precision atomic theory for  $L$ -shell  
 293 ions had already emerged in the analysis of high resolution  
 294 Chandra and XMM-Newton data [13,19,20,24,70]. Similar  
 295 inconsistencies were recently found in the high resolution  
 296  $K$ -shell x-ray spectra of the Perseus cluster recorded with  
 297 the *Hitomi* microcalorimeter [71,72]. Moreover, recent  
 298 opacity measurements [12,14] have highlighted serious  
 299 inconsistencies in the opacity models used to describe the  
 300 interiors of stars, which have to rely on calculated oscillator  
 301 strengths.

302 All this shows that the actual accuracy and reliability of  
 303 the opacity and turbulence velocity diagnostics are still  
 304 uncertain, and with them, the modeling of hot astrophysical  
 305 and high-energy density plasmas. The upcoming x-ray  
 306 observatory missions *XRISM* [73] and *Athena* [74] will  
 307 require improved and quantitatively validated modeling  
 308 tools for maximizing their scientific harvest. Thus, bench-  
 309 marking atomic theory in the laboratory is vital. As for the  
 310 long-standing Fe XVII oscillator strength problem, our  
 311 results may be immediately used to semiempirically correct  
 312 spectral models of astrophysical observations.

 University of Delaware, specifically the high-performance 329  
 Caviness computing cluster. The work of C. C. and M. S. S. 330  
 was supported by USA NSF Grant No. PHY-1620687. 331  
 Work by U.N.I.S.T. was supported by the National 332  
 Research Foundation of Korea (Grant No. NRF- 333  
 2016R1A5A1013277). J. C. B. acknowledges support from 334  
 the Alexander von Humboldt Foundation. We acknowledge 335  
 DESY (Hamburg, Germany), a member of the Helmholtz 336  
 Association HGF, for the provision of experimental facili- 337  
 ties. Parts of this research were carried out at PETRA III. 338

S. K. and C. S. contributed equally to this work. 339
