Multiobjective Multidisciplinary Optimization of Low-Boom Supersonic Transports Using Multifidelity Models

Wu Li* and Karl Geiselhart†

NASA Langley Research Center, Hampton, Virginia 23681, USA

A multidisciplinary optimization (MDO) method has been developed to design a computational fluid dynamics (CFD) based low-boom configuration that can be obtained from a Pareto solution of a low-fidelity multiobjective MDO problem with mission constraints. This paper refines the developed MDO method using multifidelity models for CFD-based multiobjective MDO. The refined MDO method can generate a low-boom configuration that satisfies the mission requirements, has the lowest takeoff gross weight and the longest range for the low-boom mission, trims the low-boom cruise flight with fuel redistributions, and has a reversed equivalent area distribution closely matching a low-boom target with ground noise level below 70 PLdB. The validity of the refined MDO method is demonstrated by a design study of a low-boom supersonic transport that carries 40 passengers, flies a low-boom mission with cruise Mach of 1.7 and range of 3500 nm, and cruises overwater at Mach 1.8 with range of 3882 nm. Moreover, the refined MDO method eliminates the difference between the assumed cruise weight for CFD-based low-boom inverse design optimization and the estimated cruise weight of the optimal inverse design solution with respect to the mission requirements.

Nomenclature

\( A_c \) = any equivalent area including \( A_c, A_{e,LoFi}, A_{e,MuFi}, A_{e,CFD}, \) and \( A_{e,r}, \) ft²

\( A'_e \) = second derivative of \( A_e \) with respect to \( x_e \)

\( A_e(D) \) = \( A_e \) for \( D \), ft²

\( A_e(x_e,D) \) = \( A_e \) value at \( x_e \) for \( D \), ft²

\( A_{e,CFD} \) = \( A_{e,m} \) computed using CFD lift distribution, ft²

\( A_{e,LoFi} \) = \( A_{e,m} \) computed using low-fidelity aero lift distribution, ft²

\( A_{e,MuFi} \) = multifidelity model for approximation of \( A_{e,r} \), ft²

\( A_{e,m} \) = classical equivalent area defined by Mach angle cut method, ft²

\( A_{e,r} \) = reversed equivalent area defined by using reverse propagation of CFD off-body pressure, ft²

\( A_{lift,CFD} \) = lift part of \( A_{e,CFD} \), which equals \( A_{lift,CFD}^{\text{CFD}} + A_{lift,CFD}^{\text{MuFi}} \), ft²

\( A_{lift,MuFi} \) = \( A_e \) due to lift computed using the calibrated lift method, ft²

\( A_{lift,CFD}^{\text{LoFi}} \) = multifidelity model for approximation of \( A_{lift,CFD}^{\text{CFD}} \), ft²

\( A_{target} \) = \( A_{e,r} \) target for \( D \), ft²

\( A_{target,LoFi} \) = \( A_{e,r} \) target for \( D \), ft²

\( A_{volume} \) = volume part of \( A_{e,LoFi} \), which equals \( A_{lift,LoFi} + A_{volume} \), ft²

\( CG_c \) = longitudinal center of gravity, ft

\( CG_{c,aff} \) = most aft CG, at start of overland cruise using fuel redistribution for \( D \), ft

\( C_L(D_{\text{LoW}}) \) = lift coefficient of \( D_{\text{LoW}} \) at start of overland cruise

\( CP_x \) = longitudinal center of pressure, ft

\( CP_{x,CFD} \) = computational fluid dynamics CP, for \( D \), ft

\( D \) = vector of \( d_{egt}, d_{m}, d_{wing}, d_{aft}, d_{TO}, \theta_{tail}, F_x, R_{OL}, \) and \( H_{OL} \)

\( \dot{D} \) = independent copy of \( D \) with \( \theta_{tail} \) and \( d_{aft} \) replaced by \( \theta_{\text{tail}}^{\text{aff}} \) and \( d_{\text{aft}}^{\text{aff}} \), respectively

\( \dot{D}_0 \) = \( D \) for baseline

\( \dot{D}_{\text{aff}} \) = \( \dot{D} \) for solution of CFD-based low-boom aft shaping of \( D_{\text{MaxR}} \)

* Senior Research Engineer, Aeronautics Systems Analysis Branch
† Aerospace Engineer, Aeronautics Systems Analysis Branch
\( \mathbf{d}_{\text{aft}} \) = vector of design variables for locations and incident angles of pylon and nacelle
\( \mathbf{d}_{\text{aft}}^{\text{indep}} \) = independent copy of \( \mathbf{d}_{\text{aft}} \) for \( \mathbf{D} \)
\( \mathbf{d}_{\text{frt}} \) = vector of widths, heights, and locations for fuselage cross sections
\( \mathbf{D}_t \) = \( \mathbf{D} \) for feasible low-boom design
\( \mathbf{D}_d \) = \( \mathbf{D} \) for ideal low-boom design
\( \mathbf{D}_{\text{LOT}} \) = previously documented CFD-based low-boom design
\( \mathbf{D}_{\text{LOW}} \) = \( \mathbf{D} \) for the lowest weight solution on the Pareto frontier of multiobjective MDO, which also has an acceptable matching error for low-boom inverse design (i.e., \( \| \mathbf{A}_{\text{e,MUFI}}(\mathbf{D}) - \mathbf{A}_{\text{a,\scriptsize target}}^\text{target}(\mathbf{D}) \|_{k,l} \leq \varepsilon \))
\( \mathbf{d}_{\text{igt}} \) = vector of 6 auxiliary design variables for landing and takeoff: flap deflection angles, main gear length, and CG offsets for trim at landing and takeoff
\( \mathbf{D}_{\text{MaxR}} \) = \( \mathbf{D} \) for plausible low-boom design with maximum overland range
\( \mathbf{D}_{\text{MaxR}}^{\text{hi}} \) = \( \mathbf{D} \) obtained with replacing \( \theta_{\text{hail}} \) of \( \mathbf{D}_{\text{MaxR}} \) by appropriate \( \theta_{\text{hail}} \)
\( \mathbf{d}_{\text{wing}} \) = vector of 15 wing design variables
\( F_s \) = sea-level static thrust for engine, lb
\( \hat{F}_s \) = independent copy of \( F_s \) as input for the Numerical Propulsion System Simulation, lb
\( F(t) \) = \( F \)-function for \( A_e \)
\( g_i \) = constraint function for mission constraint (II.i) computed using the calibrated lift method
\( H_{\text{OL}} \) = cruise altitude for overland mission or for CFD analysis, ft
\( k \) = positive integer to define integral of matching error for low-boom inverse design optimization
\( l \) = lower-bound vector for \( \mathbf{D} \) or \( \dot{\mathbf{D}} \)
\( L/D \) = lift-to-drag ratio
\( l_e \) = effective length of configuration defined by \( \mathbf{D} \), which is the largest effective distance where Mach angle cut plane intersects the configuration, ft
\( l_{e,0} \) = \( l_e \) for \( \mathbf{D}_0 \), ft
\( M_{\text{OL}} \) = cruise Mach number for overland mission
\( \mathbf{M}_{\text{TGO}} \) = maximum of \( \mathbf{M}_{\text{TGO,OL}} \) and \( \mathbf{M}_{\text{TGO,OW}} \), lb
\( p \) = longitudinal pressure distribution at undertrack location below aircraft, lb/ft²
\( p_{\infty} \) = ambient pressure, lb/ft²
\( \text{PLdB}(A_e) \) = perceived level in decibels of sonic boom ground signature for \( A_e \)
\( r \) = distance from undertrack location to aircraft, ft
\( R_{\text{OL}} \) = range for overland mission, nm
\( S_{\text{ref}}(\mathbf{D}_{\text{LOW}}) \) = wing reference area of \( \mathbf{D}_{\text{LOW}} \) for calculation of lift coefficient, ft²
\( t \) = temporary variable
\( \text{TOGW}_{\text{OL}} \) = takeoff gross weight for overland mission of \( \mathbf{D} \), lb
\( \text{TOGW}_{\text{OW}} \) = takeoff gross weight for overwater mission of \( \mathbf{D} \), lb
\( \mathbf{u} \) = upper-bound vector for \( \mathbf{D} \) or \( \dot{\mathbf{D}} \)
\( U_c \) = freestream velocity at cruise altitude \( H_{\text{OL}}, \text{ft/sec} \)
\( W_{\text{crs}} \) = weight at start of overland cruise for \( \mathbf{D} \), lb
\( x, y, z \) = coordinates of point in space, ft
\( x_e \) = effective distance for \( A_e \), ft
\( \hat{x}_e \) = effective distance computed using piecewise linear transformation of \( x_e \), ft
\( x_{\text{ste}} \) = \( x_e \) location corresponding to tailing edge of wing tip airfoil, ft
\( x_e(\mathbf{D}) \) = a specific \( x_e \) location related to \( \mathbf{D} \) such as \( x_{\text{ste}}(\mathbf{D}) \), ft
\( y_i \) = \( y \) coordinate of span location of wing, ft
\( y_{\text{tl}} \) = calibration parameter for span location to truncate wing for low-fidelity aero analysis, ft
\( \alpha \) = angle of attack at start of overland cruise for \( \mathbf{D} \), deg
\( \alpha_{\text{LoW}} \) = angle of attack at start of overland cruise for \( \mathbf{D}_{\text{LOW}} \), deg
\( \beta \) = Prandtl-Glauert factor \( \sqrt{(M_{\text{OL}})^2 - 1} \)
\( \gamma \) = ratio of specific heats
\( \Delta A_{\text{CFD}}^{\text{ref}} \) = correction term for \( A_{\text{a,CFD}}^{\text{ref}} \), ft²
\( \Delta A_{\text{a,\scriptsize target}} \) = correction term for \( A_{\text{a,\scriptsize target}} \), ft²
\( \delta \) = lower bound for trim ratio \( A_{\text{a,\scriptsize target}}(l_e)/A_{\text{a,\scriptsize target}}(l_{e,0}) \)
\( \varepsilon \) = tolerance of \( 0.007 \cdot A_{\text{a,\scriptsize target}}(l_e) \) for acceptable low-boom inverse design objective value
\( \theta_{\text{hail}} \) = deflection angle of an all-moving horizontal tail at start of overland cruise for \( \mathbf{D} \), deg
\[ \hat{\theta}_{\text{ideal}} = \text{independent copy of } \theta_{\text{ideal}} \text{ for } D, \text{ deg} \]
\[ \theta_{\Delta} = \text{calibration parameter for } \theta_{\text{ideal}} \text{ of } D, \text{ deg} \]
\[ \lambda = l_c \frac{\lambda_0}{l_c}, \text{ upper limit for integration of } A_e \text{ matching error for } D, \text{ ft} \]
\[ \lambda_0 = x_0 \text{ location of the highest point on } \theta_{\text{ideal}}(D), \text{ or } l_c,0, \text{ ft} \]
\[ \mu = \text{ratio } A_{e,\text{target}}(l_c)/A_{e,\text{CFD}}(l_c) \text{ as estimate of } A_{e,\text{ideal}}(l_c)/A_{e,\text{CFD}}(l_c) \text{ for expected low-boom design} \]
\[ \rho_c = \text{ambient density at cruise altitude } H_{\text{OL}}, \text{ lb/ft}^3 \]
\[ \tau_{\text{max}} = \text{design section lift coefficient for NACA 63-series airfoil at span location } y_i \]
\[ \tau_{\text{max}} = \text{design section lift coefficient for NACA 63-series airfoil} \]
\[ \| \cdot \|_k = \| \cdot \|_{k,\lambda}, k\text{-norm of a function on interval } [0, l_c] \]
\[ \| \cdot \|_{k,\lambda} = k\text{-norm of a function } f \text{ on interval } [0, \lambda] \text{ defined by } \| f \|_{k,\lambda}, \text{ which equals } \left( \int_0^{\lambda} |f(t)|^k \, dt \right)^{\frac{1}{k}} \]

I. Introduction

The Shaped Sonic Boom Demonstration (SSBD) program [1] validated via flight testing that the shaping benefits of a modified F-5E aircraft could be maintained through the atmosphere to achieve a flat-top front ground signature as predicted using computational methods [see fig. 26 in Ref. [1]]. The NASA X-59 low-boom flight demonstrator (LBFD) [2] aims to achieve a greatly reduced ground noise level of sonic boom under cruise conditions and paves the way for commercial supersonic overland flight. The LBFD project will help determine future Federal Aviation Administration (FAA) regulations on the acceptable ground noise level for supersonic overland flight and validate sonic boom prediction methods. The current NASA low-boom requirement is based on the perceived level in decibels (PLdB [3]) of the sonic boom ground signature. The NASA N+3 goal [4,5] for the acceptable sonic boom level is below 70 PLdB.

The studies of low-boom configurations start with the George-Seebass-Darden (GSD) boom minimization theory, which treats a supersonic wing-body configuration as a body of revolution [6,7] and generates optimal F-functions [8,9] for shaping the equivalent area \((A_{e,m}) \) distributions of low-boom configurations. The GSD low-boom F-functions are used in most pre-SSBD low-boom design studies. Various extensions of the GSD F-functions have been proposed to accommodate more complex nearfield shock wave patterns of low-boom supersonic configurations [10-13]; and a low-boom F-function for an aft A\(_e\) bump [14] was developed to enable a forward shift of lift distribution and achieve the low-boom cruise trim without control surface deflections. The most advanced boom minimization study [15] based on the body-of-revolution approximation is to match \(A_{e,\text{CFD}}\) with a low-boom \(A_e\) target generated using the F-function form in Ref. [11] for a wing-body configuration. The low-boom shaping based on the body-of-revolution approximation is useful to attain a low-boom front shape of the ground signature such as the flat-top ground signature of the SSBD demonstrator [1]. Interested readers should refer to Ref. [16] for a comprehensive documentation of sonic boom research up until 2013.

The ground signature propagated from \(A_{e,\text{CFD}}\) [the computational fluid dynamics (CFD) body-of-revolution approximation form of a three-dimensional supersonic aircraft] has a very different aft shape when compared to the signature propagated from CFD off-body pressure, even for a wing-body configuration [see fig. 2 in Ref. [17]]. The current state-of-the-art sonic boom analysis [18,19] uses CFD off-body pressure at a location at least three body lengths away from the aircraft and propagates the off-body pressure through the atmosphere using an augmented Burgers equation [20,21] to get the ground signature. For convenience, such a ground signature will be called CFD-based ground signature. The NASA N+3 low-boom goal is to develop a supersonic transport concept that has a CFD-based ground signature with noise level below 70 PLdB. To date, this goal has not been achieved computationally by any supersonic concept. The NASA X-59 LBFD is expected to attain a CFD-based ground signature with noise level about 75 PLdB.

CFD-based low-boom inverse design optimization methods [17,22-25] are capable of generating supersonic configurations with nacelles that have CFD-based ground signatures with noise levels below 79 PLdB. The undertrack ground noise levels for the optimized supersonic configurations are about 78.5 PLdB for mixed-fidelity inverse design optimization of reversed equivalent area \(A_{e,\text{CFD}}\) [17,25] and about 76.3 PLdB for adjoint-based inverse design optimization methods [22-24]. For a wing-body configuration, a CFD-based ground signature with noise level of 78.9 PLdB was attained [26] using inverse design optimization of \(A_{e,\text{CFD}}\).

One undesirable consequence of low-boom inverse design optimization is that the resulting low-boom configuration might have a much lower \(L/D\) value at the start of low-boom cruise than anticipated. As a result, the low-boom configuration might only be able to fly a shorter range than required. This is not a problem for a low-boom flight demonstrator such as the NASA X-59 LBFD, which only requires to fly enough distance for ground measurements of sonic boom signatures and noise levels. However, for a commercial low-boom supersonic aircraft,
a shorter range than required might be unacceptable. Moreover, a commercial low-boom supersonic aircraft must be able to take off, cruise, and land for the intended origin-destination pairs of airports. This requires multiobjective multidisciplinary optimization (MDO) of low-boom supersonic aircraft.

The Quiet Supersonic Platform program [27] initiated the research on multiobjective MDO of low-boom supersonic aircraft. Most low-boom MDO studies simultaneously optimize a sonic boom objective and some performance metrics. The sonic boom objectives include the shock strength [28,29] (i.e., the sum of shock jumps within a short time span such as a few milliseconds at the start of the ground signature), maximum value/magnitude [30-32] or range [33-35] of the overpressure on the ground, and dBA [36] or PLdB [10] of the ground signature. The performance metrics include various drag coefficients [29,30,32-34], lift coefficient [33], L/D [10,31,35], wing structural weight [33-35], maximum takeoff gross weight (MTOGW) [28,36], range [28], and trim for low-boom cruise [34]. A consensus from these studies is that a severe penalty on performance is unavoidable when optimizing a sonic boom objective. See Ref. [37] for a review of MDO applied to sonic boom minimization.

The separation of low-boom inverse design optimization and low-boom MDO is not accidental. An inverse design objective in low-boom MDO could make the resulting optimization problem unsolvable due to the implicit requirement of the inverse design optimization: the optimal inverse design objective value must be close to zero for an acceptable inverse design solution. Drag reduction coupled with an inverse design objective is only used to refine an existing low-boom baseline [38,39]. Two configurations with low-boom front $A_e$ shapes are optimized for drag reduction by modifying the upper side of the fuselage [38]. The result shows that a reduction of the drag coefficient is achieved with a significant deviation of the front $A_e$ shape away from the low-boom target (see fig. 12 in Ref. [38]). Another drag reduction study of a low-boom baseline minimizes a weighted average of the drag and a low-boom inverse design objective [39]. The baseline is the Lockheed Martin N+2 low-boom concept. The drag is reduced by 3%, while $A_e$ deviates at most 2% from the target.

To clarify different fidelities of low-boom concepts for inverse design optimization, three qualifers are introduced. For any design vector $D$, $D$ is called a plausible low-boom design with 70 PLdB if $\|A_{e,n}(D) - A_{e,target}\|_k \leq \varepsilon$ and $\text{PLdB}(A_{e,target}) = 70$; $D$ is called a feasible low-boom design with 70 PLdB if $\|A_{e,r}(D) - A_{e,target}\|_k \leq \varepsilon$ and $\text{PLdB}(A_{e,target}) = 70$; and $D$ is called an ideal low-boom design with 70 PLdB if $\text{PLdB}(A_{e,r}(D)) = 70$. The parameter $\varepsilon = 0.007 A_{e,target}(l_c)$ determines the acceptable error tolerance for inverse design optimization, and it can be replaced by any relatively small number. A plausible low-boom design has a low-boom front shape up to the nacelle location; a feasible low-boom design has an approximately perfect low-boom shape; and an ideal low-boom design has the perfect low-boom shape. The ground signature of $A_{e,r}$ is almost identical to that of the off-body pressure used to compute $A_{e,r}$ and the PLdB values of these two ground signatures are about the same (see fig. 4 in Ref. [17]). So, PLdB($A_{e,r}(D)$) accurately represents the noise level of the CFD-based ground signature of $D$. The NASA N+3 low-boom goal can be restated as an ideal low-boom design with PLdB less than 70, which has not been realized yet. However, it is possible to find a feasible low-boom design with PLdB less than 70 that also satisfies the mission requirements, which is a significant step moving toward the required ideal low-boom design as shown below.

The mathematical theory for a feasible low-boom design as an accurate approximation of an ideal low-boom design is based on an approximation relationship [40] between $A_{e,CFD}$ and $A_{e,r}$.

$$A_{e,CFD}(x_e, D_{fs}) - A_{e,CFD}(x_e, D_{id}) \approx A_{e,r}(x_e, D_{fs}) - A_{e,r}(x_e, D_{id}) \text{ for } 0 \leq x_e \leq l_c$$ (1)

Assume that $D_{fs}$ is a feasible low-boom design and its low-boom target $A_{e,target}$ is perfectly matched by an ideal low-boom design $D_{id}$. Then it follows from Eq. (1) and $A_{e,r}(D_{id}) = A_{e,target}$ that

$$\|A_{e,CFD}(D_{fs}) - A_{e,CFD}(D_{id})\|_k \approx \|A_{e,r}(D_{fs}) - A_{e,r}(D_{id})\|_k = \|A_{e,r}(D_{fs}) - A_{e,r}(D_{id})\|_k \leq \varepsilon$$ (2)

The last inequality in Eq. (2) follows from the definition of $D_{fs}$ as a feasible low-boom design. Equation (2) implies that the ideal low-boom design (if it exists) could be obtained with minor modifications of $A_{e,CFD}(D_{fs})$. That is, an ideal low-boom design could be obtained with minor volume and lift modifications of $D_{fs}$. So, a feasible low-boom design is not too far away from an ideal low-boom design (if it exists). A feasible low-boom design with PLdB less than 70 that also satisfies the mission requirements will bring the NASA N+3 low-boom goal closer to reality.

The first design study moving toward the NASA N+3 low-boom goal for supersonic transports is a plausible low-boom design with 68.4 PLdB that also satisfies the mission requirements [41]. The corresponding multiobjective MDO problem minimizes the inverse design objective $\|A_{e,lofl}(D) - A_{e,target}\|_{k,i}$ and MTOW with the specified mission constraints.
The follow-up study [42] adds a system-level trade method to optimize the cruise Mach, cruise altitude, and range for the low-boom overland mission, and increases the fidelity of the inverse design objective. The resulting multiobjective MDO problem seeks a Pareto solution for minimum $\|\Delta_{\alpha}(D) - \Delta_{\alpha}^{tar}\text{get}\|$, minimum MTOGW, maximum overland cruise Mach, and maximum overland range, while satisfying the mission constraints. The optimal solution is a feasible low-boom design with 69.9 PLdB that is obtained from a plausible low-boom design with minor wing modifications. The plausible low-boom design satisfies the mission requirements. This is very close to the goal of finding a feasible low-boom design with PLdB less than 70 that also satisfies the mission requirements. The minor wing differences between the feasible and plausible low-boom designs are caused by the discrepancies between the CFD analysis for low-boom inverse design optimization and low-fidelity aero analyses for low-fidelity multiobjective MDO.

This paper achieves the goal of obtaining a feasible low-boom design with 69.9 PLdB that also satisfies the mission requirements. The block coordinate optimization (BCO) method in Ref. [42] is refined to eliminate the discrepancies between the low-fidelity aero and CFD analyses using multifidelity models. The system-level trade method in Ref. [42] is improved to optimize the takeoff gross weight and range for the low-boom overland mission. The MTOGW and ranges of this feasible low-boom design are all better than those in Ref. [42], with a compromise of reducing the low-boom cruise Mach from 1.8 to 1.7. See Table 1 for a comparison of these three concepts.

The paper is organized as follows. Section II introduces the CFD-based multiobjective MDO problem for design of low-boom supersonic transports and the refined BCO method. Section III demonstrates that the refined BCO method can generate a feasible low-boom design with 69.9 PLdB that also satisfies the mission requirements. Concluding remarks are given in Sec. IV.

II. Block Coordinate Optimization Using Multifidelity Models

A CFD-based multiobjective MDO problem and its solution method are formulated to find a feasible low-boom design with 70 PLdB that also satisfies the mission requirements. Section II.A includes the baseline geometry and design variables for solving the multiobjective MDO problem. A calibrated lift method for low-boom MDO is developed in Sec. II.B. The calibrated lift method allows the low-fidelity aero analysis code LTSTAR [43] to have excellent correlation with the CFD analysis for calculation of lift at the start of overland cruise. This method uses a truncated and shifted wing geometry and a calibrated tail rotation angle for the LTSTAR analysis. The mission performance metrics can be computed using low-fidelity aero analysis codes applied on the same truncated and shifted wing geometry and the horizontal tail at the calibrated tail rotation angle. These mission performance metrics are used to define the CFD-based multiobjective MDO problem in Sec. II.C. To save computational costs, multifidelity models are constructed in Sec. II.D to solve the CFD-based multiobjective MDO problem. The BCO method in Ref. [42] is refined in Sec. II.E with a better trade method for the maximum overland range and a higher fidelity low-boom MDO solution using the multifidelity models. The implementation details for the refined BCO method are provided in Sec. II.F. The validity of the refined BCO method will be demonstrated using a numerical example in Sec. III.

A. Baseline and Design Variables for BCO

The feasible low-boom solution $\hat{D}_{\text{LoT}}$ with 69.9 PLdB in Ref. [42] is used to test and debug the refined BCO method. After the refined BCO method has been implemented correctly, the resulting configuration $\hat{D}_{\text{ref}}$ is used as the initial baseline $D_0$ (see Fig. 1) for the refined BCO method. The engine thrust of 36,000 lb for $\hat{D}_{\text{LoT}}$ [42] is reduced to
34,000 lb for \( D_0 \). The pylon, horizontal tail, and vertical tail of \( \tilde{D}_{\text{LoT}} \) are inherited by \( D_0 \). The horizontal tail area is 388 \( \text{ft}^2 \) and the vertical tail area is 266 \( \text{ft}^2 \), which are fixed in this paper.

The design vector \( D \) has \( d_{\text{frt}}, d_{\text{wing}}, d_{\text{aft}}, d_{\text{LTO}}, d_{\text{tgt}}, \theta_{\text{htail}}, F_s, R_{\text{OL}}, \) and \( H_{\text{OL}} \) as its components. The partition of \( D \) into weakly coupled blocks of design variables is important for low-boom MDO \cite{41,42}. The subvector \( d_{\text{frt}} \) consists of the design variables of the fuselage to define a low-boom front shape. The subvector \( d_{\text{wing}} \) has the wing design variables, which define the low-boom shape in the midrange of effective distance. The subvector \( d_{\text{aft}} \) has the design variables for the aft components and determines the low-boom aft shape. The subvectors \( D_{\text{LTO}} \) and \( d_{\text{tgt}} \) contain the design variables for landing and takeoff (LTO) performance and low-boom target \( x_{\text{target}} \), respectively. The tail rotation angle \( \theta_{\text{htail}} \) determines the appropriate ratio between the wing lift and horizontal tail lift for a low-boom configuration. The engine thrust \( F_s \) is a design variable to find the most efficient engine to complete the overland and overwater missions. The overland cruise altitude \( H_{\text{OL}} \) is a design variable for an optimal trade between the sonic boom noise level on the ground and the cruise efficiency for the overland mission. The overland cruise Mach \( M_{\text{OL}} \) is not a design variable and its fixed value of 1.7 is empirical.

Fig. 1 Cabin arrangement and main gear packaging for initial baseline.

The design variables for span locations of the wing in Ref. [42] are not used in this paper, while the number of design variables for the fuselage is increased for a more accurate low-boom front shape. The fuselage and wing are reparametrized as follows. The locations, widths, and heights at five cross sections for the front fuselage shape (see the 13 blue variables in Fig. 2) are used as design variables \( (d_{\text{frt}}) \) for BCO. The wing has the same parametric planform as in Ref. [42]. However, the span locations are fixed and only 5 design variables (see the blue variables in Fig. 3) are used to change the planform. A design lift parameter \( \tau_{\text{max}} \) (i.e., the parameter CLI in the computer code to generate NACA 63-series airfoils [44]) is used to parameterize each NACA 63-series airfoil. Four parameters \( \tau_{\text{max}} \) for airfoils at the span locations \( y_i \) \((i=1,2,3,4)\) are used as design variables. Moreover, the twist angles for airfoils at the span locations \( y_4 \) and \( y_5 \) are used as design variables. The inboard wing twist variables are fixed to ensure that the main gear strut can be stored inside the wing. The dihedral angles of the four outboard wing sections are also used as design variables. A total of 10 design variables \( (\tau_{\text{max}} \), twist angles, and dihedral angles) are available to modify the camber surface of a given wing planform. The design vector \( d_{\text{wing}} \) consists of the 15 planform and camber design variables. With the given fuselage and wing parametric shapes, any new design will have enough volume for 40 passengers and storage of the main gear (see Fig. 1).

Fig. 2 Fuselage side/top views and design variables.

Fig. 3 Wing planform and design variables.

The design vector \( d_{\text{aft}} \) for aft components has 4 design variables: the longitudinal locations and incident angles for the nacelle and pylon. During the BCO iterations, independent copies \( \theta_{\text{htail}} \) and \( d_{\text{aft}} \) of \( \theta_{\text{htail}} \) and \( d_{\text{aft}} \), respectively, are
used for CFD-based low-boom aft shaping. A parametric Bezier curve with 8 control points is used to define the low-boom target $A_{\text{target}}$; two control points are used to fix the start and end points of $A_{\text{target}}$, and the remaining 12 control-point coordinates are used as components of $d_{\text{gte}}$. The same six auxiliary design variables as in Ref. [42] are the components of $d_{\text{gte}}$ for LTO constraints: trailing edge flap deflection angles for LTO, CG, offsets for LTO, leading edge flap deflection angle for landing, and main gear length. Flap sizes also affect LTO performance, but they are not used as design variables and change proportionally with wing chords in this paper. The design variables and dimensions of design vectors are listed in Table 2. The independent copy $\hat{D}$ of $D$ is obtained by replacing $\theta_{\text{hail}}$ and $d_{\text{aft}}$ with their independent copies $\tilde{\theta}_{\text{hail}}$ and $\tilde{d}_{\text{aft}}$, respectively.

**B. Calibrated Lift Method**

It has been demonstrated in Ref. [42] that a feasible low-boom design can be obtained with minor wing modifications of a plausible low-boom design. One major source for discrepancy between these two low-boom designs is that the root section of the wing inside the fuselage is used for low-fidelity aero analyses, but the wing inside the fuselage is removed to form the watertight geometry for CFD analysis. So, it is natural to remove some of the wing inside the fuselage for more accurate low-fidelity aero analyses. This idea can be implemented using a parametric Bezier curve with 8 control points is used to define the low-fidelity aero analysis code LTSTAR [43] and the CFD analysis: the total wing lift from LTSTAR applied to the calibrated wing equals the total CFD lift for the watertight geometry up to the end of the wing in the effective distance direction (determined by the blue Mach angle cut plane in Fig. 4).

![Fig. 4](image_url) Illustration of two calibration parameters.

The tail lift is calibrated using a tail rotation angle adjustment parameter $\theta_t$ (see Fig. 4). This parameter determines the calibrated tail rotation angle ($\theta_{\text{hail}}-\theta_t$) for low-fidelity aero analyses of any design with a tail rotation angle of $\theta_{\text{hail}}$. The calibrated tail rotation angle makes the total tail lift from LTSTAR equal the total CFD lift after the wing, which includes the lift generated by the pylon and horizontal tail, as well as the interference lift from the nacelle and fuselage.

Figure 4 illustrates the two calibration parameters $y_n$ and $\theta_t$. The $x$-axis is along the flow direction at the start of overland cruise and the fuselage nose is at the origin. The outer mold line (OML) in Fig. 4 is the CFD geometry after the rotation for $\alpha$. The effective distance location $x_{c,e,tte}$ (indicated by the pink dot in Fig. 4) is determined by the intersection point of the $x$-axis and the Mach angle cut plane (shown by the blue line) passing through the trailing edge of the wing tip airfoil (shown by the orange dot in Fig. 4). Note that $x_{c,e,tte}$ also depends on $\alpha$.

To make the LTSTAR analysis as accurate as the CFD analysis for the predictions of the wing lift and total lift, the calibration parameters $y_n$ and $\theta_t$ for a design vector $D$ are the optimal solutions of the following optimization problem.

$$\min_{y_n, \theta_t} \left| A_{\text{e, MIFI}}(x_{e,tte}, D) - A_{\text{e, CFD}}(x_{e,tte}, D) \right| + \left| A_{\text{e, MIFI}}(l_{e}, D) - A_{\text{e, CFD}}(l_{e}, D) \right|$$

In Eq. (3), $A_{\text{e, MIFI}}(D)$ is computed using $M_{\text{OL}}$ and the angle of attack that matches the CFD total lift with the weight of $D$ at the start of overland cruise. The lift equivalent area $A_{\text{e, MIFI}}(D)$ is generated by LTSTAR using the calibrated wing of $D$ and the horizontal tail of $D$ at the calibrated tail rotation angle of $(\theta_{\text{hail}}-\theta_t)$, where $\theta_{\text{hail}}$ is the tail rotation angle.
of $D$ for the CFD analysis. The same $M_{OL}$ and angle of attack for the CFD analysis are used for calculation of $A_{ix}^{\text{BR}}(D)$ by LTSAT. Equation (3) has an ideal optimal value of zero.

Once the calibration parameters $y_i$ and $\theta_i$ are generated by solving Eq. (3), $y_i$ determines the calibrated wing and $\theta_i$ defines the calibrated tail rotation angle for all low-fidelity aero analyses of $D$ in the entire flight envelope. This method will be called the calibrated lift method, which leads to many multifidelity models for all mission performance metrics (such as $M_{TOGW}$ and range). The calibrated lift method does not have the fidelity of CFD analysis, but it has higher fidelity than the original low-fidelity aero analyses in the sense that LTSTAR, when applied with the calibrated wing and the calibrated tail rotation angle, reproduces the CFD wing lift and total lift at the start of overland cruise.

The calibrated lift method described above is a multifidelity method because the mission analysis for each $D$ is calibrated/tuned by one CFD solution of $D$. Reference [45] reviews multifidelity methods for uncertainty propagation, inference, and optimization. It categorizes multifidelity methods according to three classes of strategies: adaptation, fusion, and filtering. The calibrated lift method can be considered as a multifidelity adaptation method. More specifically, the wing lift and total lift at the start of overland cruise computed using the calibrated lift method with LTSTAR can be considered as tuned low-fidelity models reviewed in Ref. [46].

C. CFD-Based Multiobjective MDO for Low-Boom Supersonic Transports

The following CFD-based multiobjective MDO problem is an improvement of the mixed-fidelity low-boom MDO problem in Ref. [42]. The mission performance metrics in Eq. (4), such as $M_{TOGW}$, $R_{OL}$, $C_{G,aft}$, and $g_i(D)$, are computed using the calibrated lift method in Sec. II.B instead of the original low-fidelity aero analyses in Ref. [42]. The objectives are modified to optimize the low-boom mission performance for a fixed cruise Mach, instead of exploring the boundary of the overland cruise Mach and range for low-boom designs with the lowest MTOGW [42].

$$\min_D \{M_{TOGW}, -R_{OL}\} \text{ subject to } l \leq D \leq u, \ g_i(D) \geq 0 \ (1 \leq i \leq 9),$$

$$C_{G,aft} - C_{P_s,\text{CFD}} \geq 1, \ \|A_{ix}(D) - A_{ix}^{\text{target}}(D)\|_k \leq \varepsilon, \ \text{PLdB}\left(A_{ix}^{\text{target}}(D)\right) \leq 70$$

(4)

The inequalities $g_i(D) \geq 0 \ (1 \leq i \leq 9)$ correspond to the following mission constraints.

(II.1) Center-of-gravity (CG) margin to prevent tip over on the ground $\geq 4$ ft (i.e., the longitudinal CG of the aircraft at empty weight is at least 4 ft before the main gear longitudinal location).

(II.2) Static margin (SM) for overland cruise $\geq 2\%$ of the mean aerodynamic chord of the wing (MAC).

(II.3) LTO SMs $\geq 2\%$ of MAC.

(II.4) Tail rotation angles for trim at LTO $\geq 20^\circ$.

(II.5) LTO field lengths $\geq 8350$ ft.

(II.6) Approach velocity $\leq 150$ kt at altitude of 1000 ft.

(II.7) $D$ has storage space for main gear and carries 40 passengers for both overland and overwater missions.

(II.8) $D$ has an overwater mission with cruise Mach of 1.8, range of 3600 nm, and cruise ceiling of 60,000 ft.

(II.9) $D$ has an overland mission with cruise Mach of $M_{OL}$, range of $R_{OL}$, and cruise altitude of $H_{OL}$.

The objectives in Eq. (4) are for the optimal low-boom mission performance. Note that minimizing MTOGW is mainly to improve the overwater cruise efficiency, when MTOGW $= M_{TOGW}$ for a much longer overwater range than the overland range. The overwater mission does not have any low-boom requirement and the cruise altitude is determined by the Flight Optimization System (FLOPS) [47] to be optimal for fuel burn. In contrast, the overland cruise efficiency has a low-boom penalty, because the overland cruise flight must be at the specified cruise altitude $H_{OL}$ to satisfy the imposed low-boom constraints for $A_{ix}$ in Eq. (4). To attain a low-boom design with the optimal overland cruise efficiency, $M_{TOGW}$ instead of MTOGW is used as an objective function in Eq. (4).

In Eq. (4), $l \leq D \leq u$ is the standard constraint to define the ranges of design variables. Even though the constraints (II.1)-(II.9) (represented by $g_i(D) \geq 0$) appear to be the same as those in Ref. [42], their calculations use the calibrated lift method in Sec. II.B. See Ref. [42] for a detailed explanation of the constraints (II.1)-(II.9) and why they can be written mathematically as $g_i(D) \geq 0 \ (1 \leq i \leq 9)$. The upper bound for the LTO field lengths is increased from 8300 ft in Ref. [42] to 8350 ft in this paper. This means an insignificant reduction of the margin of 1700 ft for LTO field lengths in Ref. [42] by 50 ft. The constraint $C_{G,aft} - C_{P_s,\text{CFD}} \geq 1$ is for trim at the start of overland cruise with fuel redistribution. The fuel volume is assumed to be the sum of fixed fractions of the longitudinal wing and fuselage volume distributions. This allows defining a preliminary CG, location vs weight diagram when combined with the component weight and CG, estimates from FLOPS [47,48]. With a large fuselage volume before the cockpit of a low-boom supersonic transport, it is easy to shift the fuel CG forward. So, the trim at the start of low-boom cruise (i.e., $C_{G} = C_{P_s,\text{CFD}}$) can be achieved with a redistribution of fuel if $C_{G,aft} - C_{P_s,\text{CFD}} \geq 1$. Here the trim margin of 1 ft is empirical. The constraints for $A_{ix}$ in Eq. (4) define a feasible low-boom design with PLdB $\leq 70$. 

8
D. Multifidelity Models for Low-Boom MDO

Note that the calibrated lift method in Sec. II.B requires one CFD solution for the mission analysis of each design. So, Eq. (4) is a CFD-based multiobjective MDO problem. To save the computational cost, multifidelity models for all \( D \) based on one CFD solution will be used to solve Eq. (4).

For a given feasible low-boom design \( \mathbf{D}_{\text{bo}} \), let \( \theta_n \) and \( \theta_h \) be determined by solving Eq. (3) for \( D = \mathbf{D}_{\text{bo}} \). In this case, \( A_{\text{e,CFD}}^{\text{lift}}(\mathbf{D}_{\text{bo}}) \) and \( A_{\text{e,Mf}}^{\text{lift}}(\mathbf{D}_{\text{bo}}) \) are computed using CFD and LTSATR, respectively, for \( M_{\text{bo}} \) and the CFD angle of attack. Then the mission performance metrics are computed using the low-fidelity aero analysis codes applied on the calibrated wing for the truncation parameter \( \theta_n \) and the horizontal tail at the calibrated tail rotation angle \((\theta_{h\text{ail}} - \theta_h)\) for any design vector \( D \). These mission performance metrics are used as the multifidelity models for the calibrated mission performance metrics in Eq. (4). The multifidelity approximation here is to use one CFD solution for the calibrated low-fidelity aero analyses of all design vectors instead of one design vector.

For multifidelity \( A_e \) models, \( A_{\text{e,Mf}}^{\text{lift}}(D) \) provides the initial approximation of \( A_{\text{e,CFD}}^{\text{lift}}(D) \). Here \( A_{\text{e,Mf}}^{\text{lift}}(D) \) is computed by applying LTSTAR on the calibrated wing of \( D \) for the truncation parameter \( \theta_n \) and the horizontal tail of \( D \) at the calibrated tail rotation angle of \((\theta_{h\text{ail}} - \theta_h)\), while the total lift generated by LTSTAR matches the weight of \( D \) at the start of overland cruise. The multifidelity models for \( A_{\text{e,CFD}}^{\text{lift}} \) and \( A_{\text{e,Mf}}^{\text{lift}} \) require the following two correction terms.

\[
\Delta A_{\text{e,CFD}}^{\text{lift}}(x_e, \mathbf{D}_{\text{aft}}) = A_{\text{e,CFD}}^{\text{lift}}(x_e, \mathbf{D}_{\text{aft}}) - A_{\text{e,Mf}}^{\text{lift}}(x_e, \mathbf{D}_{\text{aft}}) \quad \text{(Lift } A_e \text{ correction term)} \tag{5a}
\]

\[
\Delta A_{\text{e,Mf}}^{\text{lift}}(x_e, \mathbf{D}_{\text{aft}}) = A_{\text{e,Mf}}^{\text{lift}}(x_e, \mathbf{D}_{\text{aft}}) - A_{\text{e,LoFi}}^{\text{volume}}(x_e, \mathbf{D}_{\text{aft}}) - A_{\text{e,CFD}}^{\text{lift}}(x_e, \mathbf{D}_{\text{aft}}) \quad \text{(Total } A_e \text{ correction term)} \tag{5b}
\]

![Fig. 5 Equivalent areas and \( A_e \) correction terms from \( A_e \) calibration analysis.](image)

Figure 5 shows \( A_{\text{e,Mf}}^{\text{lift}}(\mathbf{D}_{\text{aft}}) \), \( A_{\text{e,CFD}}^{\text{lift}}(\mathbf{D}_{\text{aft}}) \), the optimal solution \( A_{\text{e,Mf}}^{\text{lift}}(\mathbf{D}_{\text{aft}}) \) of Eq. (3) with \( D = \mathbf{D}_{\text{aft}} \), and the \( A_e \) correction terms defined by Eqs. (5a-5b). The secondary vertical axis in Fig. 5 is used for a better view of the correction terms. The data in Fig. 5 are generated by the last BCO iteration cycle for the design study in Sec. III. The corresponding calibration parameters \( \theta_n \) and \( \theta_h \) are 1.270 ft and 3.803\(^\circ\), respectively.

Note that \( A_{\text{e,CFD}}^{\text{lift}}(x_e, \mathbf{D}_{\text{aft}}) = A_{\text{e,Mf}}^{\text{lift}}(x_e, \mathbf{D}_{\text{aft}}) = 0 \) because the optimal objective of Eq. (3) is zero. So, adding any multiple of \( A_{\text{e,CFD}}^{\text{lift}}(\mathbf{D}_{\text{aft}}) \) in the interval \([0, x_{e,\text{MCD}}]\) does not change the total lift on the wing and adding any multiple of \( A_{\text{e,Mf}}^{\text{lift}}(\mathbf{D}_{\text{aft}}) \) in the interval \([x_{e,\text{MCD}}, l_e]\) does not change the total lift after the wing. An accurate prediction of \( A_{\text{e,CFD}}^{\text{lift}}(D) \) can be obtained by a linear combination of \( A_{\text{e,Mf}}^{\text{lift}}(D) \) and \( A_{\text{e,CFD}}^{\text{lift}}(\mathbf{D}_{\text{aft}}) \), then \( A_{\text{e,CFD}}^{\text{lift}}(D) \) can be used to recover \( A_{\text{e,Mf}}^{\text{lift}}(D) \). The multifidelity \( A_e \) models \( A_{\text{e,Mf}}^{\text{lift}} \) and \( A_{\text{e,CFD}}^{\text{lift}} \) are defined as follows.

\[
A_{\text{e,CFD}}^{\text{lift}}(x_e, D) = A_{\text{e,Mf}}^{\text{lift}}(x_e, D) + \frac{A_{\text{e,Mf}}^{\text{lift}}(x_{e,\text{MCD}}, \mathbf{D}_{\text{aft}}) - A_{\text{e,CFD}}^{\text{lift}}(x_{e,\text{MCD}}, \mathbf{D}_{\text{aft}})}{A_{\text{e,CFD}}^{\text{lift}}(x_{e,\text{MCD}}, \mathbf{D}_{\text{aft}}) - A_{\text{e,CFD}}^{\text{lift}}(x_{e,\text{MCD}}, \mathbf{D}_{\text{aft}})} A_{\text{e,CFD}}^{\text{lift}}(x_e, \mathbf{D}_{\text{aft}}) \quad \text{for } 0 \leq x_e \leq x_{e,\text{MCD}} \quad \text{(Multifidelity front lift equivalent area)} \tag{6a}
\]
$$A_{\text{e,MuFi}}(x_e, D) = A_{\text{e,MuFi}}^\text{lift}(x_e, D) + \frac{A_{\text{e,CFD}}^\text{lift}(x_e, \hat{D}_{\text{aft}})-A_{\text{e,CFD}}^\text{lift}(x_e, \hat{D}_{\text{tte}})}{A_{\text{e,CFD}}^\text{lift}(x_e, \hat{D}_{\text{aft}})-A_{\text{e,CFD}}^\text{lift}(x_e, \hat{D}_{\text{tte}})} \cdot \Delta A_{\text{e,CFD}}^\text{lift}(x_e, \hat{D}_{\text{aft}})$$

(6b)

for $$x_{e,tte} \leq x_e \leq l_e$$  (Multifidelity aft lift equivalent area)

$$A_{\text{e,MuFi}}(x_e, D) = A_{\text{e,MuFi}}^\text{volume}(x_e, D) + \frac{A_{\text{e,CFD}}^\text{volume}(x_e, \hat{D}_{\text{aft}})-A_{\text{e,CFD}}^\text{volume}(x_e, \hat{D}_{\text{tte}})}{A_{\text{e,CFD}}^\text{volume}(x_e, \hat{D}_{\text{aft}})-A_{\text{e,CFD}}^\text{volume}(x_e, \hat{D}_{\text{tte}})} \cdot \Delta A_{\text{e,CFD}}^\text{volume}(x_e, \hat{D}_{\text{aft}})$$

(6c)

for $$0 \leq x_e \leq l_e$$  (Multifidelity total equivalent area)

Here the modified effective distance $$\hat{x}_e$$ is computed by aligning the corresponding effective distance locations of wings and tails of $$\hat{D}_{\text{aft}}$$ and $$D$$ (illustrated by the blue and black dots in Fig. 6, where x-axis is along the flow direction).

$$\hat{x}_e = \frac{x_{e,\text{rle}}(\hat{D}_{\text{aft}})}{x_{e,\text{rle}}} \cdot x_e$$

(7a) for $$0 \leq x_e \leq x_{e,\text{rle}}$$

(ahead of wing)

$$\hat{x}_e = x_{e,\text{rle}}(\hat{D}_{\text{aft}}) + \frac{x_{e,tte}(\hat{D}_{\text{aft}})-x_{e,\text{rle}}(\hat{D}_{\text{aft}})}{x_{e,tte}-x_{e,\text{rle}}} \cdot (x_e - x_{e,\text{rle}})$$

(7b) for $$x_{e,\text{rle}} \leq x_e \leq x_{e,tte}$$

(wing segment)

$$\hat{x}_e = x_{e,tte}(\hat{D}_{\text{aft}}) + \frac{x_{e,\text{rft}}(\hat{D}_{\text{aft}})-x_{e,tte}(\hat{D}_{\text{aft}})}{x_{e,\text{rft}}-x_{e,tte}} \cdot (x_e - x_{e,tte})$$

(7c) for $$x_{e,tte} \leq x_e \leq x_{e,\text{rft}}$$

(between wing and horizontal tail)

$$\hat{x}_e = x_{e,\text{rft}}(\hat{D}_{\text{aft}}) + \frac{x_{e,\text{aft}}(\hat{D}_{\text{aft}})-x_{e,\text{rft}}(\hat{D}_{\text{aft}})}{x_{e,\text{aft}}-x_{e,\text{rft}}} \cdot (x_e - x_{e,\text{rft}})$$

(7d) for $$x_{e,\text{rft}} \leq x_e \leq x_{e,\text{aft}} = l_e$$

(horizonal tail segment)

Equations (7a-7d) ensure that the lift $$A_e$$ corrections in Eqs. (6a-6b) are performed for the corresponding $$x_e$$ locations of the wings and horizontal tails of $$D$$ and $$\hat{D}_{\text{aft}}$$. For example, the lift $$A_e$$ correction for the wing of $$D$$ starts and ends over the effective distance range of the wing of $$D$$ using the correction term value over the corresponding effective distance range of the wing of $$\hat{D}_{\text{aft}}$$. The scaling factors in Eqs. (6a-6b) make the lift $$A_e$$ correction magnitudes proportional to the lifts generated by the wing and horizontal tail of $$D$$, respectively. The scaling factor in Eq. (6c) makes the correction magnitude proportional to the changes of the cruise weight and altitude. One could verify that $$A_{\text{e,MuFi}}^\text{lift}(D_{\text{aft}}) = A_{\text{e,CFD}}^\text{lift}(D_{\text{aft}})$$ and $$A_{\text{e,MuFi}}^\text{volume}(D_{\text{aft}}) = A_{\text{e,CFD}}^\text{volume}(D_{\text{aft}})$$ using Eqs. (6a-6c). That is, the multifidelity $$A_e$$ models in Eqs. (6a-6c) recover the $$A_{\text{e,CFD}}^\text{lift}$$ and $$A_{\text{e,CFD}}^\text{volume}$$ of $$D_{\text{aft}}$$.

The multifidelity $$A_e$$ models in Eqs. (6a-6c) use both additive and multiplicative correction terms for design variables in $$D$$. Moreover, these multifidelity models are functions of $$x_e$$ and a piecewise linear transformation of $$x_e$$ is defined by Eqs. (7a-7d) to align the correction terms with the low-fidelity equivalent areas. The multifidelity models in Eqs. (6a-6c) are beyond the scope of predicting a finite number of high-fidelity metrics (such as the CFD lift and drag coefficients). They accomplish what reduced order models do—approximations of high-fidelity distribution functions. Reference [49] includes an example of using a reduced order model to approximate the CFD surface pressure distribution in airfoil inverse design optimization.

The multifidelity models for the mission performance metrics and equivalent areas achieve two goals: 1) better predictions of the CFD wing lift and total lift at the start of overland cruise and 2) accurate predictions of $$A_{\text{e,CFD}}^\text{lift}$$ and $$A_{\text{e,CFD}}^\text{volume}$$ over the entire effective distance interval $$[0, l_e]$$. These multifidelity models aim to achieve the high-fidelity accuracies of lift related metrics or functions that are relevant to the sonic boom analysis.

E. Refined BCO Method

The inverse design constraint makes the multiobjective MDO [Eq. (4)] difficult to solve as a numerical optimization problem (see sec. II.A in Ref. [42] for a detailed explanation). The BCO method in Ref. [42] is refined
with a better trade method for the maximum overland range and the multifidelity models in Sec. II.D for higher fidelity solutions of low-boom MDO. The following optimization subproblems for the refined BCO method use the mission performance metrics generated by the multifidelity models for aero data and the low-boom inverse design objective based on the multifidelity A_e models. Equations (8a-8f) implicitly depend on \( \mathbf{\bar{y}}, \mathbf{\bar{\theta}} \).

\[
\min_{\mathbf{d}_{\text{tgt}}} \text{PLdB} \left( A_{e,r,0}^{\text{target}} \right) \quad \text{subject to} \quad A_{e,r,0}^{\text{target}} \left( \frac{l_e}{2} \right) / A_{e,r,0}^{\text{target}} (l_e, 0) \geq \delta, \quad A_{e,r,0}^{\text{target}} (l_e, 0) / A_{\text{MuFi}}^{\text{lift}} (l_e, 0, D_0) = \mu
\]

(Baseline low-boom target optimization) \hspace{1cm} (8a)

\[
\min \mathbf{d}_{\text{fwd,wing,\text{\textbar{\theta}}}} \left\{ \text{TOGW}_{\text{OLe}}, \left\| A_{e,\text{MuFi}} (D) - A_{e,r}^{\text{target}} (D) \right\|_{k,\ell} \right\} \quad \text{subject to} \quad l \leq D \leq u, \ g_l (D) \geq 0 \ (7 \leq i \leq 9)
\]

(Low-boom MDO using multifidelity models) \hspace{1cm} (8b)

\[
\max R_{\text{OL}} \quad \text{subject to} \quad g_b (D) \geq 0, \ g_l (D) \geq 0, \ \text{PLdB} \left( A_{e,r}^{\text{target}} (D) \right) \leq 70, \ \alpha = \alpha_{\text{Low}}
\]

(Range maximization for overland mission) \hspace{1cm} (8c)

\[
\min \mathbf{d}_{\text{fwd,\text{\textbar{\theta}}}} \left( A_{e,\text{CFD}} (l_e, D) - A_{e,r}^{\infty} (l_e, D) \right) \quad \text{subject to} \quad l \leq D \leq u, \ \mathbf{d}_{\text{aft}} = \mathbf{d}_{\text{aft}}
\]

(Engine thrust and mission constraint optimization) \hspace{1cm} (8d)

\[
\min \mathbf{d}_{\text{fwd,\text{\textbar{\theta}}}} \left( A_{e,r} (D) - A_{e,r}^{\text{target}} (D) \right) \quad \text{subject to} \quad l \leq D \leq u
\]

(Adjustment of CFD tail rotation angle for lift matching) \hspace{1cm} (8e)

The low-boom target \( A_{e,r}^{\text{target}} (D) \) in the above formulations is defined by the following scaling formula.

\[
A_{e,r}^{\text{target}} (x_e, D) = \frac{A_{e,r}^{\text{MuFi}} (l_e, D)}{A_{e,r}^{\text{MuFi}} (l_e, 0)} \cdot A_{e,r,0}^{\text{target}} \left( \frac{l_e}{2} \cdot x_e \right) \quad \text{for Eqs. (8b), (8c), and (8f)}
\]

(9)

Equation (9) is the same as the weight scaling formula [eq. (3a)] in Ref. [42] if \( D_0 \) and \( D \) have the same overland cruise altitude. The relationship between \( A_{e,\text{MuFi}} (l_e) \) and \( W_{\text{crs}} \) can be formulated as the following equation.

\[
A_{e,\text{MuFi}} (l_e) = A_{e,\text{MuFi}}^{\infty} (l_e) + A_{e,\text{Low}}^{\text{volume}} (l_e) = A_{e,\text{MuFi}} (l_e) = \frac{\rho}{\rho_{\text{crs}}} \cdot u_{\text{crs}} \cdot W_{\text{crs}}
\]

(10)

The first equality in Eq. (10) follows from \( A_{e,\text{Low}}^{\text{volume}} (l_e) = 0 \), while the second equality is the definition for \( A_{e,\text{crs}} (l_e) \), and the third equality is the relationship between \( A_{e,\text{MuFi}} (l_e) \) and \( W_{\text{crs}} \) [e.g., see eq. (6) in Ref. [15]]. So, the scaling in Eq. (9) is proportional to \( W_{\text{crs}} \) and inversely proportional to the ambient density \( \rho_{\text{crs}} \) at \( H_{\text{OL}} \).

The optimization problems defined by Eqs. (8a-8f) are just iteration steps to get a solution of Eq. (4) and they do not include some of the actual design requirements in Eq. (4). The following post-optimization conditions must be satisfied by a solution pair \( (D, \mathbf{\bar{D}}) \) of Eqs. (8a-8f) to obtain a solution of Eq. (4).

\[
\| A_{e,\text{MuFi}} (D) - A_{e,r}^{\text{target}} (D) \|_{k,\ell} \leq \varepsilon
\]

(11a)

\[
\| A_{e,r} (\mathbf{\bar{D}}) - A_{e,r}^{\text{target}} (D) \|_{k} \leq \varepsilon
\]

(11b)

\[
\text{CG}_{x,aft} - \text{CR}_{x,\text{CFD}} \geq 1
\]

(11c)

Equations (11a-11b) are the implicit requirements for inverse design optimization problems [Eqs. (8b) and (8f)], respectively. Equation (11c) is the CFD trim constraint in Eq. (4), which can only be checked after the optimal solution of Eq. (8e) or (8f) is obtained.

The refined BCO method is represented by the flowchart in Fig. 7. Each optimization problem in Eqs. (8a-8f) is one iteration step of the refined BCO method with Eqs. (11a-11c) as termination criteria for the BCO iterations. The
design vector $D$ and its independent copy $\hat{D}$ are partitioned into six blocks of design variables: $d_{\text{gsl}}$, $(d_{\text{fsl}}, d_{\text{wsl}}, \theta_{\text{total}})$, $(R_{\text{OL}}, H_{\text{OL}})$, $(F_{\text{e}}, d_{\text{LTO}})$, $\theta_{\text{ail}},$ and $(\theta_{\text{ail}}, \hat{d}_{\text{aft}})$, which are different from the block partitions in Ref. [42]. Each of Eqs. (8a-8f) uses one block of design variables. In the BCO iterations, each optimal solution is used as the initial design for the next optimization problem.

Fig. 7 BCO for low-boom MDO using multifidelity models.

The refined BCO method in Fig. 7 starts with a feasible low-boom design $\hat{D}_{\text{aft}}$ and solves Eq. (3) with $D = \hat{D}_{\text{aft}}$ for the calibration parameters $\hat{y}_e$ and $\hat{\theta}_b$. The required feasible low-boom design $\hat{D}_{\text{aft}}$ could be generated by the BCO method in Ref. [42]. The calibration parameters $\hat{y}_e$ and $\hat{\theta}_b$ define the multifidelity models for the mission performance metrics and the multifidelity equivalent areas in Eqs. (8a-8e) (see Sec. II.D). The four parameters $\mu$, $\delta$, $l$, and $u$ are not design variables, but their values have a significant influence on the solution pair of Eqs. (8a-8f). The parameter $\mu$ determines how the baseline low-boom target should be defined a priori for low-boom MDO. The difference $\mu - A_{e,r}(l_e, \hat{D}_{\text{aft}})/A_{e,\text{CFD}}(l_e, \hat{D}_{\text{aft}})$ determines proportionally how much $A_{e,r}(l_e, D)$ will deviate above or below $A_{e,r}^\text{target}(l_e, D)$ for the solution $\hat{D}$ of Eq. (8f). The parameter $\delta$ implicitly enforces the CFD trim constraint [Eq. (11c)]. The initial choice of $\delta$ is always zero. Once a solution of Eq. (11b) violates Eq. (11c), $\delta$ must be set at a value greater than the current value of $A_{e,r}^\text{target}(l_e, D)/A_{e,r}(l_e, D)$. The value of $A_{e,r}^\text{target}(l_e, D)/A_{e,r}(l_e, D)$ will be called the trim ratio for any $A_{e,r}$ target, which is fixed during each iteration cycle of solving Eqs. (8b-8f) [see Eq. (9)]. A target $A_{e,r}^\text{target}$ with a higher trim ratio tends to move $CP_{C_{\text{CFD}}}$ of the corresponding feasible low-boom design forward. So, with a proper trim ratio for $A_{e,r}^\text{target}$, the corresponding feasible low-boom design will satisfy Eq. (11c) (see Sec. III). The design vector bounds $l$ and $u$ are extensively discussed in Ref. [41]. The key idea is to avoid having an optimized geometry design variable close to one of its bounds, while using small design ranges so that Eq. (8b) can be solved effectively. In practice, a trial and error approach is required to get a set of appropriate values for $\delta$, $l$, and $u$. The fifth parameter $\lambda_0$ is usually the $x_e$ location of the highest point on $A_{e,\text{LoR}}(D_0)$. However, as $A_{e,\text{LoR}}$ becomes very accurate in predicting $A_{e,r}$, reset $\lambda_0 = l_{e,0}$ for a better aft matching between $A_{e,\text{LoR}}$ and $A_{e,r}^\text{target}$.

The baseline low-boom target optimization [Eq. (8a)] is solved only when $\mu$ or $\delta$ is changed. Otherwise, the baseline low-boom target is reset to $A_{e,r}^\text{target}(D_{\text{MaxR}})$. The Pareto frontier of the multiobjective optimization problem [Eq. (8b)] usually requires a significant amount (1-2 days using about 15 parallel design evaluations) of wall-clock time to generate. The selected solution $D_{\text{LoW}}$ of Eq. (8b) is the lowest weight solution on the Pareto frontier that also satisfies Eq. (11a).

The overlap range optimization [Eq. (8c)] is completely different from that in Ref. [42]. Because the PLdB requirement is removed from the post-optimization constraint Eq. (11a), PLdB($A_{e,r}^\text{target}(D_{\text{LoW}})$) could be greater than 70. For the previous two BCO methods [41,42], this would be considered as a failed attempt to find a low-boom concept due to the infeasible overlap mission requirement. For the refined BCO method, this becomes the opportunity to discover the appropriate overlap mission requirement. The goal of Eq. (8c) is to get a plausible low-boom design with 70 PLdB when $D_{\text{LoW}}$ satisfies Eq. (11a).

To verify that the maximum range solution $D_{\text{MaxR}}$ of Eq. (8c) is always a plausible low-boom design with 70 PLdB, the following equalities will be proved for any design vector $D$ in Eq. (8c) satisfying $\alpha = \alpha_{\text{LoW}}$. 

\[
C_L(D_{\text{LoW}}) \cdot S_{\text{ref}}(D_{\text{LoW}}) = \frac{2}{\rho_{\infty} u_{\infty}^2} \cdot W_{\text{crs}}
\]

(12a)

\[
A_{\text{target}}(D) = A_{\text{target}}(D_{\text{LoW}}) \cdot A_{e,\text{MuFi}}(D) = A_{e,\text{MuFi}}(D_{\text{LoW}})
\]

(12b)

In Eq. (12a), \(W_{\text{crs}}\) and \(\rho_{\infty}\) are the weight at the start of overland cruise and the ambient density at the cruise altitude of \(D\), respectively.

Note that Eq. (12a) is the standard lift equation when \(W_{\text{crs}}\) and \(\rho_{\infty}\) are the cruise weight and the ambient density for \(D_{\text{LoW}}\), respectively. Because each optimization starts with the optimal solution from the previous optimization subproblem, any design vector \(D\) in Eq. (8c) has the same OML as \(D_{\text{LoW}}\). So, \(D\) and \(D_{\text{LoW}}\) have the same wing reference area. The constraint \(\alpha = \alpha_{\text{LoW}}\) implies that \(D\) has the same lift coefficient as \(D_{\text{LoW}}\). As a result, Eq. (12a) is also the lift equation for any \(D\) in Eq. (8c) satisfying \(\alpha = \alpha_{\text{LoW}}\). This completes the proof of Eq. (12a).

Because the left side of Eq. (12a) is fixed, the right side of Eq. (12a) is the same for all \(D\) satisfying \(\alpha = \alpha_{\text{LoW}}\). It follows from Eqs. (9), (10), and (12a) that \(A_{\text{target}}(D) = A_{\text{target}}(D_{\text{LoW}})\). Because \(D\) and \(D_{\text{LoW}}\) have the same OML and the same angle of attack, 1) the calibrated lift method yields \(A_{\text{target}}^{\text{mid}}(x_{e}D) = A_{\text{target}}^{\text{mid}}(x_{e}D_{\text{LoW}})\), and 2) \(A_{\text{target}}^{\text{volume}}(x_{e}D) = A_{\text{target}}^{\text{volume}}(x_{e}D_{\text{LoW}})\). The multifidelity total equivalent area \(A_{e,\text{MuFi}}\) is uniquely determined by \(A_{\text{target}}^{\text{volume}}(x_{e}D)\), the OML, the angle of attack, and the cruise Mach [see Eqs. (6a-6c)]. So, \(A_{e,\text{MuFi}}(D) = A_{e,\text{MuFi}}(D_{\text{LoW}})\). This completes the proof of Eq. (12b).

An important relationship between \(\text{PLdB}\) and \(H_{\text{OL}}\) is that, for a fixed \(H_{\text{OL}}\) and a fixed \(A_{\text{target}}\), \(\text{PLdB}(A_{\text{target}})\) is a strictly decreasing function of \(H_{\text{OL}}\). That is, the \(\text{PLdB}\) value of the signature of \(A_{\text{target}}\) propagated from \(H_{\text{OL}}\) to the ground is a strictly decreasing function of \(H_{\text{OL}}\). This relationship has no mathematical proof, but it has been verified for \(A_{\text{target}}\) used in this paper. This relationship allows Eq. (8c) to enforce \(\text{PLdB}(A_{\text{target}}(D)) = 70\) using \(R_{\text{OL}}\) and \(H_{\text{OL}}\).

If \(\text{PLdB}(A_{\text{target}}(D_{\text{LoW}})) > 70\), let \(D\) be any design obtained by reducing the overland range of \(D_{\text{LoW}}\). The reduced range decreases the cruise weight \(W_{\text{crs}}\) of \(D\), which implies that the angle of attack \(\alpha\) for \(D\) is smaller than \(\alpha_{\text{LoW}}\) at the cruise altitude of \(D_{\text{LoW}}\). If the overland cruise altitude of \(D\) increases and the cruise weight of \(D\) does not change, the reduced air density at the increased altitude requires a higher lift coefficient to match the same cruise weight, which means that \(\alpha\) for \(D\) increases. Even though the cruise weight actually changes with the cruise altitude, the effect of the cruise weight change on the required lift coefficient is eclipsed by the air density change. As a result, \(\alpha\) for \(D\) increases if the overland cruise altitude of \(D\) increases. There exists an increased altitude for \(\alpha\) such that \(\alpha = \alpha_{\text{LoW}}\). Because \(D_{\text{LoW}}\) satisfies Eq. (11a), Eq. (12b) implies that \(D\) is a plausible low-boom design and \(A_{\text{target}}(D) = A_{\text{target}}(D_{\text{LoW}})\). Because \(D\) has a higher cruise altitude than \(D_{\text{LoW}}\), \(\text{PLdB}(A_{\text{target}}(D)) < \text{PLdB}(A_{\text{target}}(D_{\text{LoW}}))\) follows from the relationship between \(\text{PLdB}\) and \(H_{\text{OL}}\) mentioned above. With an appropriate value of \(R_{\text{OL}}\), there exists an increased altitude \(H_{\text{OL}}\) for \(D\) such that \(D\) is a plausible low-boom design with \(\text{PLdB}(A_{\text{target}}(D)) = 70\). That is, the solution \(D_{\text{LoW}}\) of Eqs. (8b) and (11a) can always be converted into a plausible low-boom design \(D_{\text{MaxR}}\) with 70 \(\text{PLdB}\). The cost is a reduced overland range for \(D_{\text{MaxR}}\) when \(\text{PLdB}(A_{\text{target}}(D_{\text{LoW}})) > 70\). Similarly, if \(\text{PLdB}(A_{\text{target}}(D_{\text{LoW}})) < 70\), the overland range can be increased with the corresponding lower cruise altitude such that \(D_{\text{MaxR}}\) generated by Eq. (8c) is a plausible low-boom design with 70 \(\text{PLdB}\).

The new range maximization formulation [Eq. (8c)] tolerates a wrong choice of the overland mission requirement and avoids solving the multiobjective MDO problem [Eq. (8b)] after a change of the overland mission requirement. This is significantly better than the range maximization formulation [eq. (2f)] in Ref. [42].

The maximum range solution \(D_{\text{MaxR}}\) of Eq. (8c) is updated by the solution of Eq. (8d) to satisfy the LTO constraints with the optimal engine thrust. This is also different from the BCO method in Ref. [42], where the engine thrust optimization is independent of the feasibility optimization for the LTO constraints. There are three reasons to combine these two optimization subproblems: 1) the current engine thrust \(F_s\) is close to be optimal so it does not have to be optimized before solving Eq. (8b), 2) \(F_s\) could have a significant influence on the takeoff field length, and 3) Eq. (8d) is computationally easy to solve if the LTO constraints are feasible. If the LTO constraints cannot be satisfied by modifying \(D_{\text{LTO}}\) and \(F_s\), the horizontal tail and wing flaps might have to be redesigned. In practice, the red iteration step involving redesign of the horizontal tail in Fig. 7 needs to be avoided if possible (e.g., reducing the margin in the LTO field length constraints if needed or increasing the wing flap sizes). A significant change of the horizontal tail could lead to a difficult low-boom aft shaping problem [Eq. (8f)], which might have no solution satisfying Eq. (11b). If the LTO constraints are satisfied after solving Eq. (8d) but the engine thrust is changed, then Eq. (8c) might have to be solved again because the weight change at the start of overland cruise might invalidate Eq. (11a). This leads to the inner iteration loop formed by the blue arrow in Fig. 7, which is easy to solve.

CFD-based low-boom inverse design optimization is only performed for the aft components. In most cases, only one CFD off-body analysis is required to verify whether \(D_{\text{MaxR}}\) is a feasible low-boom design. First, Eq. (8e) is solved using CFD surface solutions to enforce \(A_{e,\text{CFD}}(I_e, D_{\text{MaxR}}) = A_{\text{target}}^{\text{mid}}(I_e, D_{\text{MaxR}})\), which means that the CFD total lift matches
the cruise weight of $D_{MaxR}$ at the start of overland cruise [see Eq. (10)]. If the inverse design optimization criterion [Eq. (11b)], the trim constraint [Eq. (11c)], and $|\bar{\theta}_{tail} - \theta_{tail}| \leq 0.05$ are satisfied for $\bar{D}_{MaxR}$, then $\bar{D}_{MaxR}$ is a solution of Eq. (4) and the refined BCO method terminates. If $\bar{D}_{MaxR}$ does not satisfy Eq. (11b), then Eq. (8f) is solved for $\bar{D}_{lift}$ with a low-boom aft shape and the iteration continues. If $\bar{D}_{MaxR}$ satisfies Eq. (11b) but violates Eq. (11c), then the parameter $\delta$ in Eq. (8a) is reset at a value greater than the current value of $A_{e\theta, target}/(\bar{F}_s/2)/A_{\theta, target}/(\bar{l}_e)$. The baseline low-boom target $A_{e\theta, target}$ is regenerated by solving Eq. (8a) and the iteration continues. The last non-termination condition of $|\bar{\theta}_{tail} - \theta_{tail}| > 0.05$ means that the prediction of the CFD tail rotation angle needs to be improved. In this case, usually one additional iteration cycle of solving Eqs. (8b-8e) after another calibration of the low-fidelity aero analyses terminates the refined BCO iteration.

Using the multifidelity models, the refined BCO method eliminates the minor wing differences between a plausible low-boom design and a feasible low-boom design generated by the BCO method in Ref. [42]. No convergence theory similar to that in Ref. [50] is available for the refined BCO method. But, in practice, the refined BCO method terminates after a finite number of iteration cycles of solving Eqs. (8a-8f) (see the design study in Sec. III).

F. Implementation of Refined BCO Method

All functions of $D$ used in Eqs. (8a-8d) are computed using the multidisciplinary feasible (MDF) architecture in Fig. 8 (see Ref. [51] for classifications of MDO architectures). The MDF architecture in Fig. 8 is based on the MDO frameworks documented in Refs. [52,53]. The analysis process is similar to that in Ref. [42] and uses the same analysis codes. The main differences are: 1) the low-fidelity aero analyses are performed on the calibrated wing for the truncation parameter $\hat{\gamma}_r$, 2) $(\bar{\theta}_{tail} - \bar{\theta})$ instead of $\theta_{tail}$ is used as the tail rotation angle for low-fidelity aero analyses, and 3) the multifidelity model $A_{c,LoFi}(D)$ [defined by Eqs. (6a-6c)] instead of $A_{c,LoFi}(D)$ is used to define the low-boom inverse design objective for multiobjective MDO.

Fig. 8 MDF architecture for analyses of supersonic aircraft concept.

An advanced engine model was developed using the Numerical Propulsion System Simulation (NPSS) [54]. This engine model is only scaled by the engine thrust $F_s$ in this paper. Equation (8d) can be solved by any derivative-free optimization method (such as the Design Explorer in ModelCenter [55]) if the LTO constraints are feasible. To avoid expensive NPSS runs, an independent copy $\hat{F}_s$ of $F_s$ for NPSS is fixed at the initial value of $F_s$ for a baseline configuration and a surrogate model is used during the optimization iterations. The engine size, weight, and performance data are linearly scaled by the surrogate model for any $F_s$. The optimized engine thrust $\hat{F}_s$ is reanalyzed using NPSS to validate the scaling after the optimization. This can be done simply by setting $\hat{F}_s = \hat{F}_s$ (of $D$) in Fig. 8, which forces NPSS to regenerate the size, weight, and performance data when the value of $\hat{F}_s$ is changed.

The constraints $g_8(D) \geq 0$ and $g_9(D) \geq 0$ [i.e., the range constraints (II.8) and (II.9)] are automatically satisfied with a coupled weight and fixed-range dual-mission analysis method (see the highlighted iteration loop in Fig. 8 and more details in Ref. [41]) using FLOPS [43,44]. The coupled weight and mission analysis generates MTOW and the weight at the start of overland cruise, along with the component weight and CG data. The mission analysis follows the relevant FAA rules for the fuel reserve: 30 min hold at 1500 ft, 5% of total trip fuel, and fuel for 200 nm to
alternative airport. Each mission has the following segments: 1) taxi out (9 min), 2) takeoff to 35 ft, 3) climb max 250 kt CAS below 10,000 ft, 4) climb and accelerate to cruise altitude using minimum fuel, 5) cruise at fixed Mach number and optimal altitude (60,000 ft ceiling for overwater mission or $H_{\text{OL}}$ for overland mission) for specified range, 6) descend at optimal $L/D$, 7) approach and land (4 min), and 8) taxi in (5 min). This mission profile is based on the one used by Boeing [see fig. 5.2 in Ref. [5]]. Linear aerodynamics codes WINGDES and AERO2S [56] are used to generate aero data for mission, cruise, and LTO analyses. These aerodynamic analysis codes are applied on the calibrated wing for the truncation parameter $y_{\text{f}}$ and the horizontal tail at the calibrated tail rotation angle of $(\theta_{\text{hail}}-\hat{\theta}_{\text{hail}})$. In addition to drag due to lift from WINGDES, skin friction and wave drag coefficients are estimated using the methods in Refs. [57,58], respectively. The SMs are based on the WINGDES/AERO2S centers of pressure and the most aft CG, values for cruise and LTO weights. For approach velocity and LTO field lengths, the landing weight is 70% of MTOGW and all relevant Part 25 requirements of Federal Aviation Regulations are met [59].

Any equivalent area $A_{e}$ (including $A_{e,\text{MaFi}}$, $A_{e,\text{CFD}}$, $A_{e,\text{LoW}}$, $A_{e,\text{target}}^{\text{LoW}}$, and $A_{e,\text{target}}^{\text{OL}}$) can be converted to an F-function using the following formula [6,7], where $A_{e}(t)$ denotes the second derivative of $A_{e}(t)$.

$$F(x_{e}) = \frac{1}{2\pi} \int_{0}^{x_{e}} A_{e}(t) \left( \frac{1}{\sqrt{x_{e}-t}} \right) dt$$

Then the F-function is converted to a pressure distribution $p(x)$ with $r = 50$ ft using the following equation [8].

$$\frac{p(x_{e}+r,\beta)-p_{\infty}}{p_{\infty}} = \frac{\gamma \rho_{\infty} \alpha_{\text{target}}^{\text{LoW}}^{2}}{(2r \beta)^{2}} \cdot F(x_{e})$$

Finally, the solver for an augmented Burgers equation [21] is used to compute the ground signature for $A_{e}$ by propagating the corresponding $p$ through the standard atmosphere [60] from the altitude ($H_{\text{OL}}-50$) to the ground. The method in Ref. [3] is used to compute PLDB of the ground signature.

All CFD results for Eqs. (8e) and (8f) are generated using the Cart3D solver [61] based on three-dimensional Euler equations. The engine shown in Fig. 1 is modeled using a flow-through nacelle for CFD analysis. A volume mesh of about 32 million cells [62] is used for calculation of CFD off-body pressure at 3 body lengths below the aircraft, as well as CPs. The Mach, altitude, and angle of attack for CFD analysis are $M_{\text{OL}}$, $H_{\text{OL}}$, and $\alpha$ of the maximum range solution $D_{\text{MaxR}}$ of Eq. (8c). The CFD off-body pressure is used for calculation of $A_{e}$ [17].

The positive integer $k = 8$ for the inverse design objective functions in Eqs. (8b) and (8f) provides a good balance for minimizing both maximum and average matching errors. Equations (8a), (8d), (8e), and (8f) are solved using the Design Explorer in ModelCenter [55]. The multiobjective MDO [Eq. (8b)] is solved using the Non-Dominated Sorting Genetic Algorithm II (NSGA II) in ModelCenter. The overland range optimization [Eq. (8c)] is solved only when $|\text{PLDB}(A_{e,\text{target}}^{\text{LoW}}(D_{\text{LoW}}))| < 0.001^\circ$. Equation (8c) is solved with a nested iteration loop: 1) start with $D = D_{\text{LoW}}$, 2) for a given $R_{\text{OL}}$, change $H_{\text{OL}}$ such that the equality constraint for the angle of attack is satisfied (with a tolerance of $0.001^\circ$ for $D$); 3) reduce $R_{\text{OL}}$, if $|\text{PLDB}(A_{e,\text{target}}^{\text{LoW}}(D))| < 0.001^\circ$ and increase $R_{\text{OL}}$, if $|\text{PLDB}(A_{e,\text{target}}^{\text{LoW}}(D))| > 0.001^\circ$. Repeat the previous two steps until $|\text{PLDB}(A_{e,\text{target}}^{\text{LoW}}(D))| < 0.001^\circ$.

For an operational computing environment of Windows servers with 40 cores of Intel Xeon CPUs at 2.4 GHz and Linux servers with 96 cores of Intel Xeon CPUs at 2.2 GHz, the average wall-clock time of one iteration cycle for solving Eqs. (8a-8f) is about 2-5 days. It takes about 1-2 days for solving Eq. (8b), 4 hours for solving Eq. (8e) and verifying whether Eqs. (11b-11c) hold, and 1-2 days for solving Eq. (8f) if a feasible low-boom design exists. The refined BCO method usually terminates after a few iteration cycles of solving Eqs. (8a-8f) if no exception occurs. The exceptions include that the horizontal tail has to be resized for the LTO constraints or Eq. (8f) cannot be solved using the simplistic set of the design variables in this paper.

### III. Design Study of Low-Boom Supersonic Transports

For the design study in this paper, the baseline in Sec. II.A is used as the initial $D_{\text{aft}}$ for the refined BCO method in Fig. 7. Except for the last iteration cycle, $D_{0}$ is the $x_{e}$ location of the highest point on $A_{e,\text{LoW}}(D_{0})$. The engine thrust $F_{e}$ of 34,000 lb is never changed during the refined BCO iterations. Six iteration cycles of the refined BCO method in Fig. 7 without any LTO constraint violation are performed to get a converged solution $D_{\text{MaxR}} \approx D_{\text{MaxR}}$. The solutions $D_{\text{MaxR}}$ and $D_{\text{MaxR}}$ differ only by a tail rotation angle difference of $(\theta_{\text{hail}}-\hat{\theta}_{\text{hail}}) = 0.04^\circ$.

Optimization results for an intermediate low-boom aft shaping solution $D_{\text{aft}}$ of Eq. (8f) are shown in Fig. 9. The calibration parameters $\hat{y}_{\text{f}}$ and $\hat{\theta}_{\text{h}}$ are 1.145 ft and 4.166$^\circ$, respectively, for the multifidelity models in Sec. II.D. The parameters for the baseline low-boom target are $\mu = 1.227$ and $\delta = 0.438$. The maximum range solution $D_{\text{MaxR}}$ has
MTOGW of 148,724 lb. The maximum overland range is 3595 nm with $H_{OL}$ of 52,106 ft and the maximum overwater range is 3928 nm (after setting TOGW = MTOGW). The angle of attack and the tail rotation angle at the start of overland cruise are 1.92° and 5.04°, respectively. The solution $D_{\text{MaxR}}$ of Eq. (8e) has a tail rotation angle of 4.92° to match the CFD lift with the weight of $D_{\text{MaxR}}$ at the start of overland cruise. The design of $D_{\text{MaxR}}$ is considered to be too far away from the low-boom target (see Fig. 9a). So, Eq. (8f) is solved to get a feasible low-boom design $D_{\text{aft}}$. In this case, $D_{\text{aft}}$ can be obtained from $D_{\text{MaxR}}$ by a change of the incident angle of the pylon with respect to the fuselage from $-0.5°$ to $0.5°$. Figure 9a compares the equivalent areas of $D_{\text{MaxR}}$, $D_{\text{MaxR}}$, and $D_{\text{aft}}$. While Fig. 9b compares the aft pressure contours of $D_{\text{MaxR}}$ and $D_{\text{aft}}$. Note that $A_{e,MuFi}(D_{\text{MaxR}})$ is an accurate prediction of $A_{e,r}(D_{\text{MaxR}})$ except some noticeable differences in the aft region.

**Fig. 9** Optimization results for intermediate low-boom aft shaping solution.

**Fig. 10** Low-boom targets for different trim ratios.

**Fig. 11** Pareto frontier and equivalent areas for $D_{\text{LoW}}$. 
For the last iteration cycle of the refined BCO method, the calibration parameters $\gamma_{\text{rt}}$ and $\theta_{\Delta}$ are 1.270 ft and 3.803°, respectively. The CFD correction terms for the multifidelity $A_e$ models are plotted in Fig. 5. The optimal $R_{\text{OL}}$ and $H_{\text{OL}}$ from the previous iteration cycle are 3695 nm and 51,321 ft, respectively, which define the overland range constraint $g_D(D) \geq 0$ for Eq. (8b). The baseline low-boom target is generated using $\mu = 1.215$ and $\delta = 0.448$. Figure 10 compares the baseline low-boom targets for $\delta = 0, 0.432$ (used for $D_{\text{LoT}}$ in Ref. [42]), and 0.448 when $H_{\text{OL}} = 51,321$ ft, $l_c = 249$ ft, and $A_{\text{e,target}}(l_c/2) = 250$ ft$^2$. Note that the trim ratio $A_{\text{e,target}}(l_c/2)/A_{\text{e,target}}(l_c)$ equals $\delta$ if $\delta$ is large enough to make the midpoint constraint in Eq. (8a) active. A total of 13,300 designs are generated by NSGA II in ModelCenter with a population size of 100 for each generation. The fixed-range dual mission analysis failed for 238 designs. For each failed case, high objective and infeasible constraint values (see the red box in Fig. 8) are used to steer the optimizer away from the design with failed mission analysis. The Pareto frontier for Eq. (8b) and the $A_e$ analysis results for $D_{\text{LoW}}$ are shown in Fig. 11. Note that $D_{\text{LoW}}$ is a plausible low-boom design with 70.1 PLdB, which is higher than 70 PLdB.

When using Eq. (8c) to get a plausible low-boom design $D_{\text{MaxR}}$ with 69.9 PLdB from $D_{\text{Low}}$, $R_{\text{OL}}$ is reduced from 3695 nm to 3500 nm and $H_{\text{OL}}$ is increased from 51,321 ft to 52,240 ft. The angle of attack and the tail rotation angle at the start of overland cruise for $D_{\text{MaxR}}$ are 2.30° and 4.61°, respectively, which are the same as those for $D_{\text{Low}}$. The solution $D_{\text{MaxR}}$ has MTOGW of 144,251 lb. After setting TOGW$_{\text{OW}} = $ MTOGW, the maximum overwater range of $D_{\text{MaxR}}$ is increased from 3600 nm to 3882 nm. It is worth noting that the calibrated lift method usually leads to a higher drag at the start of cruise than that from the original low-fidelity aero analysis. For $D_{\text{MaxR}}$, the total of wave drag and induced drag using the calibrated wing is 0.00792, higher than 0.00764 for using the original wing, at the start of low-boom cruise.
the low-boom target closely. The feasible low-boom design $D_{\text{MaxR}}$ has a shaped ground signature oscillating along the low-boom target signature (see Fig. 12b). Moreover, $D_{\text{MaxR}}$ has a trim margin of $CG_{\text{af}} - CP_{\text{CfD}} = 169.5 - 167.6 = 1.9$ ft and satisfies Eq. (11c). So, the refined BCO method terminates with $|\theta_{\text{hail}} - \theta_{\text{hail}}| = 4.61 - 4.57 = 0.04 < 0.05$. The following mission constraint values for $D_{\text{MaxR}}$ satisfy the constraints (II.1)-(II.6).

(III.1) CG margin to prevent tip over on the ground is 12.6 ft.
(III.2) SM for overland cruise = 6.5% of MAC.
(III.3) LTO SMs are 4.8% and 2% of MAC, respectively.
(III.4) Tail rotation angles for trim at LTO are $-15.2^\circ$ and $-14.9^\circ$, respectively.
(III.5) LTO field lengths are 6742 ft and 8320 ft, respectively.
(III.6) Approach velocity = 136 kt at altitude of 1000 ft.

The fuselage and wing shapes of $D_{\text{MaxR}}$ are compared with those of $D_{\text{LoT}}$ in Ref. [42] (see Fig. 13). The widths of front fuselage of $D_{\text{LoT}}$ are increased and the wing of $D_{\text{LoT}}$ is extended forward for $D_{\text{MaxR}}$ to match $A_{\text{euler}}(D_{\text{MaxR}})$. The surface pressure contour of $D_{\text{MaxR}}$ is shown in Fig. 14, which is visually similar to that of $D_{\text{LoT}}$ (see fig. 16 in Ref. [42]), and the Euler $L/D$ at the start of overland cruise for $D_{\text{MaxR}}$ is 10.1, about 13.5% higher than the Euler $L/D$ of 8.9 for $D_{\text{LoT}}$.

IV. Conclusions

A CFD-based multiobjective MDO problem is formulated for development of low-boom supersonic transports. For every design, the mission analysis is calibrated using one CFD analysis so that the wing lift and total lift generated by the low-fidelity aero analysis code are nearly identical to the CFD wing lift and total lift at the start of overland cruise. The multifidelity mission analysis eliminates the inconsistency between CFD analysis for low-boom inverse design optimization and low-fidelity aero analyses for multiobjective MDO with the mission constraints.

Multifidelity models for the mission performance metrics and CFD equivalent areas are constructed to solve the CFD-based multiobjective MDO problem. The previous block coordinate optimization (BCO) method is refined to improve the low-boom cruise efficiency and increase the fidelity of MDO solutions. For a given low-boom cruise Mach, the refined BCO method can generate a low-boom supersonic transport that has a reversed equivalent area matching a low-boom target with ground noise level of 69.9 PLdB, trims the low-boom cruise flight with fuel redistributions (instead of control surface deflections), satisfies the specified mission requirements, and attains the maximum range for the low-boom mission.

The generated low-boom supersonic transport carries 40 passengers at seat pitch of 48 in, flies a low-boom overland mission with cruise Mach of 1.7 and range of 3500 nm, cruises overwater at Mach 1.8 with range of 3882 nm, satisfies the LTO constraints, and has an Euler CFD trim margin of 1.9 ft and $L/D$ of 10.1 at the start of low-boom cruise. This concept demonstrates that the NASA N+3 low-boom goal for a supersonic transport with ground noise level below 70 PLdB might be achievable.
