18  
19 **S1. Theoretical Methodology**

20 To determine the radiant energy budget for a planet or a moon, we have to measure the  
21 absorbed solar energy and the emitted thermal energy (Conrath et al., 1989). We have estimated  
22 Titan’s emitted thermal energy with the observations recorded by the Cassini Composite Infrared  
23 Spectrometer (Creecy et al., 2019). In this study, we focus on measuring Titan’s absorbed solar  
24 energy with the observations obtained by the Cassini Imaging Science Sub-system and Visual and  
25 Infrared Mapping Spectrometer. The methodology of computing the absorbed solar energy is  
26 provided in some previous studies (Conrath et al., 1989), and discussed in detail in one of our  
27 previous studies (Li et al., 2018). Here, we briefly introduce the main idea of the methodology.  
28 Generally, we measure the reflected solar energy and then subtract the reflected solar energy from  
29 the total solar energy to get the absorbed solar energy. The key parameter of computing the

30 reflected solar energy is the Bond albedo  $A$ . The Bond albedo at each wavelength is called the  
31 monochromatic Bond albedo ( $A_m$ ). It is defined as  $A_m = A_0 q$ , where  $A_0$  and  $q$  are the  
32 monochromatic geometric albedo and the monochromatic phase integral, respectively. The  
33 monochromatic geometric albedo  $A_0$  is defined as the full-disk albedo at  $0^\circ$  phase angle for a  
34 given wavelength. The phase integral  $q$  is the integral of the reflected solar irradiance over phase  
35 angle (Li et al., 2018). Once the monochromatic Bond albedo  $A_m$  at each wavelength is measured,  
36 we can compute the Bond albedo  $A$  for a planet or a moon by weighting the monochromatic Bond  
37 albedo with the solar spectral irradiance (see sections as below).

38

## 39 **S2. Summary of Observational Data Sets**

40 Based on the methodology we discussed in “Methods”, we know the monochromatic Bond  
41 albedo ( $A_m$ ) is computed by the product of the monochromatic geometric albedo ( $A_0$ ) and the  
42 monochromatic phase integral ( $q$ ). Both qualities are related to the ratios between the reflected  
43 solar irradiance and the incoming solar irradiance at each wavelength. Therefore, the incoming  
44 solar irradiance at each wavelength, which is also named as the solar spectral irradiance (SSI),  
45 provides the reference for computing the monochromatic Bond albedo. In this study, we also  
46 investigate the temporal variations of Titan’s Bond albedo and the radiant energy budget during  
47 the Cassini epoch (2004-2017). So the first data set is the time-varying SSI for the Cassini epoch.  
48 To compute the total reflected solar irradiance, we need integrate the reflected solar irradiance  
49 over the phase angle from  $0^\circ$  to  $180^\circ$  (i.e., phase function or phase integral). The observations of  
50 phase function and the reflected spectra are mainly provided by the Cassini Imaging Science  
51 Subsystem (ISS) (14) and the Visual and Infrared Mapping Spectrometer (VIMS) (15). The Cassini  
52 ISS and VIMS do not cover the complete wavelength range from 0 nm to 6000 nm, so we need  
53 observations of the reflected spectra at these wavelengths outside the Cassini wavelengths. These  
54 observations not only help fill the observational gaps in wavelength but also help validate the  
55 Cassini ISS and VIMS observations. The observations of the reflected spectra, which come from  
56 the Cassini ISS and VIMS observations and the other observations, are defined as the spectral  
57 observations. The albedo spectra in the wavelength range 150-190 nm come from the Cassini  
58 Ultraviolet Imaging Spectrograph (UVIS) observations (Esposito et al., 2004; Ajello et al., 2008).  
59 The Faint Object Spectrograph (FOS) of the Hubble Space Telescope (HST) and the European  
60 Southern Observatory (ESO) also provide albedo spectra of Titan (Karkoschka, 1994, 1998;  
61 McGrath et al., 1998).

62 For the phase function of Titan’s albedo, the Imaging Photopolarimeter (IPP) on the  
63 spacecraft Pioneer 11 conducted the first observations (Tomasko and Smith, 1982). The coverage  
64 of phase angle is better for the Cassini ISS/VIMS observations than for Pioneer 11 observations,  
65 but the latter can help validate the Cassini observations. Table S1 in the Supporting Information  
66 summarizes the data sets for the SSI, the phase integral, and the spectral observations. These data  
67 sets are discussed in detail in following sections.

68

## 69 **S3. Solar Spectral Irradiance Data**

70 The Solar Spectral Irradiance (SSI) provides a base for computing Titan’s albedo and hence  
71 the reflected/absorbed solar power at each wavelength. The SSI from 0 to 6000 nm contributes to  
72  $\sim 99.7\%$  of the total solar power, so we construct the SSI in the wavelength range 0-6000 nm. The  
73 SEE, SORCE, and ASTM are three data sets used for the solar spectral irradiance (SSI). They are  
74 the Solar EUV Experiment (SEE) ([http://lasp.colorado.edu/lisird/data/timed\\_see\\_ssi\\_13a/](http://lasp.colorado.edu/lisird/data/timed_see_ssi_13a/)), the

75 Solar Radiation and Climate Experiment (SORCE)  
76 ([http://lasp.colorado.edu/lisird/data/sorce\\_ssi\\_l3/](http://lasp.colorado.edu/lisird/data/sorce_ssi_l3/)), and the American Society for Testing and  
77 Materials (ASTM) (<https://www.nrel.gov/grid/solar-resource/spectra-am1.5.html>), respectively.  
78 We do not find trustable data sets for the SSI in the wavelength range 4000-6000 nm, so we  
79 compute it by assuming the blackbody spectra for the Sun with a temperature 5778 K.

80 It should be mentioned that the longest wavelength of VIMS is 5131 nm, so our analyses of  
81 Titan's albedo is mainly in the wavelength range 0-5131 nm, which contains more than 99.5% of  
82 the total solar power. The total solar power varies  $\sim 0.1\%$  on the time scale of decades (Willson  
83 and Mordvinov, 2003; Lean and Rind, 2009) (also see Fig. S1), but the SSI at some wavelengths  
84 can vary with much larger magnitudes. Therefore, it is better to resolve the temporal variations of  
85 the SSI. We construct the SSI in the wavelength range 0-6000 nm for the Cassini epoch (2004-  
86 2017) from different data sets (see Table S1) listed in Fig. S1. Figure S1 shows both the SSI (panel  
87 A) and the total solar power at Earth (i.e., solar constant) (panel B) by integrating the SSI over  
88 wavelength.

89 Based on the constructed SSI at Earth (Fig. S1), we can compute the SSI at Titan (panel A  
90 of Fig. S2) with the distance between the Sun and Titan (panel B of Fig. S2). The distance between  
91 the Sun and Titan during the period of 2004-2017 (panel B) comes from the NASA/JPL solar  
92 system dynamics – the Horizons Web-interface (<https://ssd.jpl.nasa.gov/horizons.cgi>). In addition,  
93 the total solar power at Titan (i.e., solar flux), which is computed by integrating the SSI (panel A)  
94 over wavelength, is shown in panel C. The SSI at Titan is used for the computation of Titan's  
95 albedo.

96

#### 97 **S4. Supplementary Observations and Data**

98 As shown in Table S1, there are observations different from the Cassini ISS and VIMS  
99 observations (i.e., Supplementary Observations), which can help to validate the Cassini ISS and  
100 VIMS measurements and fill the observational gaps in wavelengths. There are many observations  
101 of Titan's albedo spectra in different wavelengths and times. Here, we select the best available  
102 observations. The first observations come from the ESO (Karkoschka, 1994, 1998), one of the best  
103 observations of Titan's albedo spectra cover the wavelengths from  $\sim 305$  nm to 1050 nm with a  
104 very high spectral resolution ( $\sim 0.4$  nm). Two data sets from the ESO are used: one is the albedo  
105 spectra at a phase angle  $2.7^\circ$  in 1993 and the other is the albedo spectra at a phase  $5.7^\circ$  in 1995.  
106 The two spectra are shown in Fig. S3.

107 The shortest effective wavelength of the ESO observations is about 305 nm, so we also  
108 searched for albedo spectra with wavelengths less than 305 nm. Two data sets are used: one comes  
109 from the Cassini UVIS (Esposito et al., 2004) and the other comes from HST/FOS (McGrath et  
110 al., 1998). Based on the observations from the Cassini UVIS and the HST/FOS, the studies by  
111 Ajello et al. (2008) and McGrath et al. (1998) provide the albedo spectra in the wavelength ranges  
112 of 150-190 nm and 190-305 nm, respectively. We are unable to locate good data sets for the albedo  
113 spectra in the wavelength range 0-150 nm, so we assume that the albedo spectra in this wavelength  
114 range are the same as that at 150 nm.

115 There are very limited observations for the phase function of Titan's albedo mainly because  
116 the Earth-based observations cover a very narrow range of phase angle. To the best of our  
117 knowledge, the only good measurements of the phase function of Titan's albedo aside from Cassini  
118 were conducted by the IPP on Pioneer 11 (Tomasko and Smith, 1982). Compared to the Cassini  
119 observations, the coverage of phase angle by the Pioneer 11 observations are quite limited, but  
120 they are the best observations for the phase function of Titan's albedo before the Cassini epoch.

121 The IPP on the spacecraft Pioneer 11 conducted measurements of Titan’s albedo in two  
122 wavelengths (452 nm (blue) and 648 (red)) with phase angles varying from  $21.9^\circ$  to  $95.9^\circ$ . The  
123 Pioneer 11/IPP measurements, which have been described in a previous study (Tomasko and  
124 Smith, 1982), are shown in Fig. S5.

125

## 126 **S5. Cassini ISS/VIMS Data and Data Processing**

127 The Cassini spacecraft conducted on-orbit observations of the Saturn system from October  
128 2004 to September 2017. During this period, there are many observations of Titan with multiple  
129 flybys. In this study, we mainly analyze the observations of Titan’s reflected solar irradiance from  
130 two Cassini instruments: ISS and VIMS. The observations recorded by the Cassini ISS and VIMS  
131 have many improvements than the previous observations, which have been discussed in our  
132 previous studies (Li et al., 2010, 2011, 2018; Creedy et al., 2019). Therefore, our analyses of  
133 Titan’s Bond albedo, which are based on the Cassini observations, represent the best existing  
134 measurements of Titan’s Bond albedo. The measurements of Titan’s Bond albedo are combined  
135 with our previous measurements of Titan’s emitted power (Creedy et al., 2019) with the  
136 observations from the Cassini Composite Infrared Spectrometer (CIRS) (Flasar et al., 2004) to  
137 provide the first precise measurements of Titan’s global radiant energy budget. More importantly,  
138 the long-term Cassini observations from 2004 to 2017 make it possible to investigate the temporal  
139 variations of Titan’s radiant energy budget and examine the possible energy imbalance for the first  
140 time.

141 Here, we briefly introduce the two Cassini instruments (i.e., ISS and VIMS), which are used  
142 to measure Titan’s Bond albedo for the Cassini epoch. As the imaging system of the Cassini  
143 spacecraft, the ISS is a Charged-Coupled Device with two cameras (one is the narrow-angle  
144 camera and the other is the wide-angle camera) (Porco et al., 2004). The characteristics of the ISS  
145 instrument and the related data processing (e.g., calibrating and navigating) are described in  
146 previous studies (Porco et al., 2004; Li et al., 2018). The ISS has multiple filters (i.e., wavelengths)  
147 ranging from the ultraviolet to the near infrared. Here we mainly use the 12 filters with a  
148 wavelength range from 264 nm to 939 nm, which were summarized in our previous study of  
149 Jupiter’s radiant energy budget and internal heat (Li et al., 2018), to compute the full-disk albedo  
150 of Titan. The basic characteristics of 12 filters (three ultraviolet filters “UV1”, “UV2”, and “UV3”;  
151 three methane-absorption filters “MT1”, “MT2”, and “MT3”; the three continuum filters “CB1”,  
152 “CB2”, and “CB3”; and the three color filters “BL1”, “GRN”, and “RED”) are introduced in the  
153 ISS introductory paper (Porco et al., 2004) and summarized in our previous study of Jupiter (Li et  
154 al., 2018).

155 To compute Titan’s full-disk albedo, we searched for the global images of Titan from the  
156 complete ISS data set (<https://pds-imaging.jpl.nasa.gov/volumes/iss.html>). We selected the ISS  
157 global images with spatial resolutions from  $\sim 6$  km/pixel to  $\sim 200$  km/pixel, which resolve Titan  
158 well, to conduct the measurements. The corresponding phase angles vary from  $\sim 0^\circ$  to  $\sim 167^\circ$ ,  
159 which are the best among all available observations. There are observational gaps in phase angle  
160 even with the Cassini ISS observations, so the least-squares method is used to fill the observational  
161 gaps in phase angle (see section “Filling Observational Gaps in Phase Angle”).

162 After collecting the raw ISS global images, we calibrated the recorded digital number of  
163 brightness to radiance using the latest version of the Cassini ISS CALibration software ([https://pds-  
164 imaging.jpl.nasa.gov/data/cassini/cassini\\_orbiter/coiss\\_0011\\_v4.3/](https://pds-imaging.jpl.nasa.gov/data/cassini/cassini_orbiter/coiss_0011_v4.3/)), which was developed by the  
165 ISS team (West et al., 2010; Knowles et al., 2020). An example of such calibration is presented in  
166 Fig. S6. The radiance at each pixel of the global images is multiplied by the area of the pixel, and

167 summed over all pixels in Titan's disk with an effective radius (see section "Effective Radii of  
168 Titan's Atmosphere") to get the observed full-disk reflected solar irradiance. At the same time, the  
169 reference SSI (Fig S2) is multiplied by the total area of Titan's disk with the effective radius to get  
170 the reference full-disk solar irradiance. Then the ratio between the observed full-disk solar  
171 irradiance and the reference full-disk solar irradiance is taken as the full-disk albedo (i.e., I/F).

172 The Cassini ISS observations have the best coverage of phase angle, but they focus on limited  
173 wavelengths only. On the other hand, the Cassini VIMS instrument is a spectral camera that takes  
174 images in 352 wavelengths between ~350 nm and ~5130 nm with varying spectral resolutions  
175 from ~ 4 nm to ~ 25 nm (Brown et al., 2004). The VIMS observations can help extend the spectral  
176 coverage of the ISS observations. The raw global VIMS images, which are available on the PDS  
177 system (<https://pds-imaging.jpl.nasa.gov/volumes/vims.html>), are well calibrated by the VIMS  
178 Operations Team (Brown et al., 2004; McCord et al., 2004; Filacchione et al., 2007; Buratti et al.,  
179 2010; Pitman et al., 2010).

180 For the wavelengths covered by the Cassini ISS observations (~ 264-939 nm), the reflected  
181 solar irradiance is dominant over the emitted thermal radiance in the recorded radiance, so the  
182 emitted thermal radiance from Titan can be neglected in the ISS recorded radiance. When the  
183 wavelength increases, the emitted thermal radiance becomes stronger, even though it is still much  
184 smaller than the reflected solar irradiance (even at the longest VIMS wavelength 5131 nm).  
185 However, it is more accurate to consider the emitted thermal radiance when computing Titan's  
186 albedo in the relatively long infrared wavelengths covered by the VIMS observations. Based on  
187 the incident solar angle, we divide each VIMS global image into the day-side and night-side parts  
188 (see examples in Fig. S7). The radiance recorded by the night-side part is mainly from the thermal  
189 emission, and the radiance recorded by the day-side part includes both the reflected solar irradiance  
190 and the thermal emission. In order to precisely measure the reflected solar irradiance and hence  
191 full-disk albedo, we subtract the night-side thermal emission from the day-side radiance to get the  
192 reflected solar irradiance.

193 The spatial resolutions are generally much lower for the VIMS images than for the ISS  
194 images. Here, we select the VIMS global images with spatial resolutions better than 210 km/pixel.  
195 The coverage of phase angle is also much more sparse for the VIMS observations than for the ISS  
196 observations. We searched the complete data set of the VIMS observations and found high-quality  
197 global observations at ~11 phase angles only (see section "Filling Observational Gaps in Phase  
198 Angle" and Fig. S23). The selected VIMS observations are used to address the phase functions of  
199 Titan's albedo in the wavelength range 350-5131 nm. But these VIMS observations are distributed  
200 in different years of the Cassini era, so they cannot resolve temporal variations of the phase  
201 function of Titan's albedo. The temporal variations of the phase function observed at the ISS  
202 wavelengths were extrapolated to these VIMS wavelengths outside of the ISS wavelengths (936-  
203 5131 nm) (see section "Filling Observational Gaps in Wavelength and Time").

204 The Cassini spacecraft has one more instrument observing the reflected solar irradiance of  
205 Titan - the UVIS (39). The UVIS was used to observe Titan at the wavelengths (56 - 190 nm),  
206 which are shorter than the wavelengths covered by the ISS and VIMS. The UVIS team has already  
207 generated Titan's full-disk geometric albedo in the wavelength range 150-190 nm (Ajello et al.,  
208 2008), which is used in this study (see Fig. S4 in the Supplementary Information 4). There are  
209 some difficulties in retrieving Titan's albedo in the wavelength range 56-150 nm with the UVIS  
210 observations (Ajello et al., 2008). In addition, the SSI in the wavelength range 56-150 nm occupies  
211 only ~ 0.006% of the total solar irradiance. So the UVIS-retrieved albedo in the wavelength range  
212 56-150 nm are not analyzed in this study. Instead, we simply assume that Titan's albedo in the

213 wavelength range 0-150 nm is the same as that at 150 nm (see section “Filling Observational Gaps  
214 in Wavelength and Time”).

215

## 216 **S6. Effective Radii of Titan’s Atmosphere**

217 Titan’s thick atmosphere extends to a few hundred kilometers, which is not negligible  
218 compared to its solid body radius  $\sim 2575$  km (Zebker et al., 2009). Therefore, Titan’s optical radius  
219 in which the solar irradiance is effectively absorbed and reflected (i.e., effective radius) is generally  
220 larger than its solid radius. In this section, we discuss the effective radius, which varies with  
221 wavelength. We follow the method from a previous study (Smith, 1980), in which the edge of the  
222 optical disk corresponds to the maximal radiance contrast. We therefore compute the gradient of  
223 the calibrated radiance around the boundary of Titan’s optical disk and search for the maximal and  
224 minimal radiance gradients. The pixel positions with the maximal and minimal radiance gradients  
225 are used to locate the left and right edges of the optical disk, respectively.

226 We first test this idea with Cassini observations of Enceladus. For Enceladus, its effective  
227 radius should be equal to its solid surface because this moon does not have a visible atmosphere.  
228 We first select two lines around the boundaries of the optical disk (i.e., two horizontal solid lines  
229 in panel A of Fig. S8), which are along the equator of Enceladus. The calibrated radiances for the  
230 pixels in the two lines are plotted in panel B of Fig. S8. The gradients of the radiance along the  
231 two solid lines are presented in panel C. Then we can determine the pixel location of the maximal  
232 gradient of the line around the left boundary (i.e., the location of the left edge of the optical disk)  
233 and the pixel location of the minimal gradient of the line around the right boundary (i.e., the  
234 location of the right edge of the optical disk). The left and right edges are shown by the two vertical  
235 dashed lines respectively in panel A of Fig. S8. The distance between the two edges (i.e., the  
236 product of the pixel number between the two edges and the spatial resolution) is used to determine  
237 the diameter of the optical disk, and half of the diameter is the effective radius.

238 For the estimate of the error bar in determining the effective radius by the radiant gradient,  
239 we simply assume there is one-pixel uncertainty in such a method. So we can use the size  
240 corresponding to one pixel (i.e., spatial resolution) to estimate the error bar of the effective radius.  
241 Based on the analysis shown in Fig. S8, we have the effective radius of Enceladus is  $253.8 \pm 2.6$   
242 km, which is consistent with the solid radius of Enceladus  $252.1 \pm 0.2$  km (Thomas, 2010). This test  
243 validates the method of the maximal/minimal radiance gradient works for determining the  
244 effective radius of moons.

245 After the validation, we apply the method to the global images recorded by the ISS 12  
246 filters. We try the global ISS images at both low and high phase angles. The inter-comparison of  
247 the comparisons between the low and high phase angles can be used to double check the results.  
248 Examples of determining the effective radius are demonstrated with ISS images recorded by the  
249 red filter. The analyses of the observations at the low and high phase angles are shown in Fig. S9  
250 and Fig. S10, respectively. The analyses based on the observations at a low phase angle (Fig. S9) generate an  
251 effective radius  $2849.0 \pm 10.8$  km, which is basically consistent with the effective radius  
252  $2857.9 \pm 12.4$  km from the analyses from the observations at a high phase angle (Fig. S10).

253 We also test the temporal variations of the effective radius. Among the global images  
254 recorded by the ISS 12 filters, the largest number of images were recorded by the CB3 filter.  
255 Therefore we searched for the highest-quality global images of Titan recorded by the CB3 filter in  
256 different years to examine the temporal variations of its effective radius. Panels A, B, and C in Fig.  
257 S11 show the global images recorded by the CB3 filter in 2004, 2009, and 2016, respectively. The

258 effective radii in the three years are displayed in panel D of Fig. S11. We can see the effective  
259 radius at the CB3 wavelength is basically constant with time.

260 Titan's effective radii at the wavelengths covered by the ISS 12 filters are shown in Fig.  
261 S12. Panel A shows that the differences of effective radius between the low and high phase angles  
262 are smaller than the error bars, which suggests that the results based on the low and high phase  
263 angles are consistent. The analyses at both low and high phase angles show that the effective radius  
264 decreases with wavelength except for small oscillations at some wavelengths. The effective radii  
265 averaged over the analyses at the low and high phase angles are shown in panel B of Fig. S12.

266 We also validate the effective radii measured from the Cassini/ISS observations with some  
267 previous studies. Based on the Pioneer observations, Smith (1980) measured Titan's effective radii  
268 at the blue (440 nm) and red (640 nm) wavelengths. There are also some theoretical investigations  
269 of Titan's effective radii (55-57). With a model study, Toon et al. (1992) suggested a formula to  
270 estimate the effective radii at visible wavelengths. In panel A of Fig. S13, we compare the Cassini  
271 results with the two previous studies. First, the Cassini ISS results are basically consistent with the  
272 Pioneer IPP results (i.e., the differences between them are smaller than the error bars of  
273 measurements). The trend of decreasing effective radius with wavelength, which is shown by the  
274 ISS observations, is also consistent with the results from the model study (Toon et al., 1992). In  
275 panel B of Fig. S13, we further compute the ratio of the difference between the ISS results and the  
276 previous results over the ISS results. We find that the ratio is smaller than 3%, which also suggests  
277 that the Cassini ISS results are approximately consistent with the previous results.

278 The Cassini ISS multi-filter observations cover limited wavelengths only, so we have to  
279 use the VIMS observations to determine Titan's effective radii in more wavelengths. Generally,  
280 the spatial resolution in the radial direction is much better for the VIMS solar-occultation  
281 observations (Maltagliati et al., 2015; Cours et al., 2020) than for the VIMS direct observations of  
282 Titan at low and high phase angles. The glow of Titan's atmosphere in some wavelengths (e.g.,  
283 3200-3500 nm) can reach  $\sim 700$  km in the VIMS images of Titan (Baines et al., 2005), which  
284 makes the method of determining the effective radius by the radiance gradient based on the VIMS  
285 images of Titan at low and high phase angles does not work. Therefore, the VIMS solar-occultation  
286 observations are used to determine the effective radii in the longer wavelengths.

287 The solar-occultation observations were performed by the infrared part of the VIMS  
288 instrument ( $\sim 884$ -5000 nm) only, so there are no data acquired in the visible wavelengths during  
289 the solar-occultation observations. The solar-occultation can help us determine the cross section  
290 of Titan's atmospheric extinction (Maltagliati et al., 2015; Cours et al., 2020), and the cross section  
291 is used to determine the effective radius. Four solar-occultation observations are used in our  
292 measurements of the effective radii in the infrared wavelengths, and we average the four  
293 measurements to get the effective radii in the VIMS infrared wavelengths (see Fig. S14). In the  
294 radial direction, the spatial resolutions change from 7 km to 15 km for the four solar-occultation  
295 observations (Maltagliati et al., 2015). Such spatial resolutions are comparable to the standard  
296 deviation of the four measurements of effective radius ( $\sim 5$ -20 km). We combine the spatial  
297 resolution of observations and the standard deviation of measurements to represent the  
298 uncertainties of the VIMS measurements of effective radii. It should be mentioned that the standard  
299 deviation of the VIMS measurements of Titan's effective radius is probably related to the spatio-  
300 temporal variations of Titan's atmospheric processes (e.g., haze) (West et al., 2018, Seignovert et  
301 al., 2021). The uncertainties of the VIMS measurements of Titan's effective radius, which includes  
302 the possible spatio-temporal variations, are accounted in the analysis of Titan's Bond albedo and  
303 hence the absorbed solar energy. Figure S15 further compares the effective radii between the ISS

304 and VIMS measurements. The differences between the ISS and VIMS measurements are smaller  
305 than the error bars of the VIMS measurements, which suggests that they are basically consistent.  
306

### 307 **S7. Validation of Cassini ISS and VIMS Results**

308 After determining Titan's effective radii by the ISS and VIMS observations (Figs S12 and  
309 S14), we can calculate Titan's full-disk albedo by integrating the calibrated radiance over the disks  
310 with the effective radii in these wavelengths covered by the ISS and VIMS (see section "Cassini  
311 ISS/VIMS Data and Data Processing"). To validate the full-disk albedo computed from the ISS  
312 and VIMS observations, we first made an inter-comparison between the ISS and VIMS results.  
313 Then we compared the ISS and VIMS results with other studies.

314 Figure S16 shows the comparison of Titan's full-disk albedo between the ISS and VIMS  
315 observations. Only 10 ISS filters are displayed in this figure because the wavelengths of the UV1  
316 and UV2 filters are outside of the VIMS wavelength range. The VIMS observations dispersed in  
317 different years of the Cassini epoch, and it is difficult to find a simultaneous ISS observation for  
318 each VIMS observation. Titan's full albedo, based on all available ISS and VIMS observations  
319 during the Cassini epoch, is displayed in Fig. S16. Both the ISS and VIMS observations show that  
320 Titan's albedo decreases from phase angle  $0^\circ$  to  $\sim 100\text{-}140^\circ$  then increases from phase angle  $\sim$   
321  $100\text{-}140^\circ$  to  $\sim 160^\circ$ . The increase of albedo at the high phase angles is due to the efficient forward  
322 scattering of sunlight by Titan's thick atmosphere (Garcia Munoz et al., 2017). Figure S16  
323 demonstrates that the ISS and VIMS measurements of Titan's full-disk albedo are consistent.

324 The spacecraft Pioneer 11 conducted observations of Titan's full-disk at the blue (440 nm)  
325 and red wavelengths with phase angle varying from  $21.9^\circ$  to  $95.9^\circ$ . The range of phase angle from  
326 the Pioneer 11 observations are less than that of the Cassini ISS observations ( $0\text{-}167^\circ$ ), but the  
327 Pioneer 11 observations are the best in coverage of phase angle before the Cassini epoch. Here,  
328 we compare the Pioneer 11 observations at blue and red wavelengths<sup>46</sup> with the Cassini ISS and  
329 VIMS observations at the corresponding wavelengths (Fig. S17). The Cassini blue (459 nm) and  
330 red (648 nm) filters have slightly different wavelengths from the blue and red wavelengths of the  
331 Pioneer 11. Figure S17 shows that the differences between the Cassini and Pioneer measurements  
332 are smaller than the uncertainties in the Pioneer measurements, which suggests that the Cassini  
333 measurements are consistent with the Pioneer measurements.

334 The Pioneer observations have the best coverage of phase angle among the observations  
335 before the Cassini epoch, but the Pioneer observations are limited to two wavelengths (blue and  
336 red). The Earth-based ESO provide high-spectral-resolution ( $\sim 0.4$  nm) measurements of Titan's  
337 full-disk albedo in a relatively wide wavelength range (305-1050 nm) (Karkoschka, 1994, 1998).  
338 The geometry of Earth-Sun-Titan makes the phase angles of the Earth-based observations vary in  
339 a very narrow range. For the measurements conducted in 1993 and 1995 (Karkoschka, 1994, 1998),  
340 the phase angles are  $2.7^\circ$  and  $5.7^\circ$ , respectively. Here we use the ESO observations in 1995  
341 (Karkoschka, 1998) because the observational time is closer to the Cassini epoch. The ISS UV1  
342 filter ( $\sim 264$  nm) has the wavelength shorter than the low limit the ESO wavelength range ( $\sim 305$   
343 nm). To validate the ISS UV1 measurements, the observations recorded by the FOS on the HST,  
344 which cover the wavelength 264 nm, are used. As shown in Fig. S18, the comparisons between  
345 the Cassini ISS measurements and the other measurements suggest that they are basically  
346 consistent.

347 The Cassini ISS observations cover limited wavelengths, but the Cassini VIMS  
348 observations have much better coverage of wavelength. So we also compare the spectral lines  
349 between the VIMS observations and the ESO observations. The VIMS observations do not have

350 high-quality global images at phase angle less than  $11.7^\circ$ . Here, we compare the ESO observations  
 351 with the VIMS observations at a phase angle  $11.7^\circ$ , which is the closest to the phase angle  $5.7^\circ$  for  
 352 the ESO observations in 1995. Figure S19 shows the two spectra, which suggests that the ESO  
 353 spectra and the VIMS spectra have the same spectral structures. However, there are significant  
 354 differences between the two spectra, which can be explained by the different phase angles between  
 355 them ( $5.7^\circ$  for the ESO spectra and  $11.7^\circ$  for the VIMS spectra). In addition, the spectral resolution  
 356 is much worse in the VIMS observations ( $\sim 4\text{-}25$  nm) than in the ESO observations ( $\sim 0.4$  nm).  
 357 Therefore, the VIMS observations cannot resolve some fine spectral structures, which are revealed  
 358 by the ESO high-spectral-resolution observations.

359

### 360 **S8. Filling Observational Gaps in Phase Angle**

361 In this study, we want to examine the temporal variations of Titan's Bond albedo and hence  
 362 the reflected/absorbed solar power during the Cassini epoch. Such examinations are further  
 363 combined with our previous measurements of the temporal variations of Titan's emitted power  
 364 (Creedy et al., 2019) to determine the temporal variations of Titan's radiant energy budget. We  
 365 first organize the ISS observations by time. In addition, the computation of Bond albedo requires  
 366 the observations at different phase angles (Li et al., 2018). Therefore, the computed full-disk albedo  
 367 is organized over time and phase angle. Figure S20 displays the organized full-disk albedo from  
 368 the ISS observations in the two-dimensional domain of time and phase angle.

369 Figure S20 suggests that there are observational gaps in phase angle and such observational  
 370 gaps vary from year to year. We use the least-squares fitting (Bevington and Robinson, 2003) to  
 371 fill the observational gaps in phase angle. In our study of Jupiter's Bond albedo, we tried different  
 372 functions (Li et al., 2018) to fit the phase function of Jupiter's full-disk albedo and we concluded  
 373 that the polynomial functions of phase angle work well for fitting the phase function. Here, we try  
 374 different polynomial functions to fit Titan's data, and we find a six-order polynomial function  
 375  $P(\hat{f}) = c_1 \hat{f}^6 + c_2 \hat{f}^5 + c_3 \hat{f}^4 + c_4 \hat{f}^3 + c_5 \hat{f}^2 + c_6 \hat{f} + c_7$  (where  $\hat{f}$  is phase angle and the parameters  $c_1$ ,  
 376  $c_2, c_3, \dots, c_7$  are fitting coefficients to match the observations with least-squares method) has the  
 377 smallest fitting residual. An example of such fitting is shown in Fig. S21. For comparison, a  
 378 physically-based function (i.e., the double Henyey-Greenstein (H-G) function) is also included in  
 379 Fig. S21. The double H-G function (Henyey & Greenstein 1941; Hapke, 2002) is defined as  
 380  $P(A_{HG}, g_1, g_2, f, \hat{f}) = A_{HG} \cdot (f P_{HG}(g_1, \hat{f}) + (1-f) P_{HG}(g_2, \hat{f}))$ , where  $A_{HG}$  is the coefficient to match  
 381 the amplitude of the observed phase function. The term  $P_{HG}(g, \hat{f})$  represents both forward (with a  
 382 factor  $g_1$  and  $g_1 \hat{f} \in [0,1]$ ) and backward (with a factor  $g_2$  and  $g_2 \hat{f} \in [-1,0]$ ) scattering lobes,  
 383 respectively. The factor  $f$  ( $f \hat{f} \in [0,1]$ ) stands for the fraction of the forward versus backward  
 384 scattering. The term  $P_{HG}(g, \hat{f})$  ( $g$  can be  $g_1$  or  $g_2$  and  $\hat{f}$  is phase angle) has a form as  
 385  $P_{HG}(g, \hat{f}) = (1 - g^2) / (1 + g^2 + 2g \cdot \cos \hat{f})^{3/2}$ . Figure S21 shows the polynomial-function fitting is  
 386 better than the double H-G fitting. In addition, the double H-G fitting is smaller than the  
 387 polynomial-function fitting at the highest phase angles ( $165\text{-}180^\circ$ ). Therefore, our following  
 388 estimate of the fitting uncertainty at the highest phase angles by assuming the uncertainty can reach  
 389 the fitted values of the polynomial-function fitting (see B.2 in section S11. Analyses of the  
 390 uncertainties in determining Titan's radiant energy budget) is good enough. Note that Titan's  
 391 albedo is larger at very high phase angles (i.e.,  $> 170^\circ$ ) than at  $0^\circ$  phase angle, which is caused by  
 392 Titan's thick atmosphere and efficient forward scattering of sunlight (Garcia Munoz et al., 2017).

393 Then the six-order polynomial functions from the least-squares technique are used to fit  
394 the phase functions and fill the observational gaps in phase angle for the ISS-derived albedo in the  
395 12 filters during the Cassini epoch. Note that the direct fitting does not work for the data in some  
396 years with very poor coverage of phase angle. For these years, we increase the coverage of phase  
397 angle by linear interpolation/extrapolation in time from the neighboring years before doing the  
398 fitting. The fitting results for the ISS-derived albedo during the Cassini epoch are presented in Fig.  
399 S22.

400 The fitting residuals, which are the differences between the fitted results (Fig. S22) and the  
401 data (Fig. S20), are used to evaluate how well the fitting preforms. The ratios between the fitting  
402 residuals and the raw data are shown in Fig. S23. Most of the ratios are less than 5% and a few  
403 ratios are larger than 5% but smaller than 10%. Generally, the six-order polynomial functions work  
404 well in fitting the ISS full-disk albedo and hence filling the observational gaps in phase angle.

405 There are relatively few high-quality global images from the VIMS observations, so we  
406 only find 10 VIMS observations with the phase angle varying from  $11.7^\circ$  to  $159.1^\circ$ . The 10  
407 observations disperse in different years of the Cassini epoch, so the VIMS observations themselves  
408 cannot resolve the temporal variations of the phase function of Titan's full-disk albedo. The  
409 temporal variations retrieved from the ISS observations are extrapolated to the VIMS wavelength  
410 range to address the temporal variations of the phase functions of Titan's Bond albedo in that range  
411 (see section "Filling Observational Gaps in Wavelength and Time").

412 The available VIMS high-quality spectra are displayed in Fig. S24. The 10 VIMS  
413 observations do not cover the complete range of phase angle, so we have to fill the observational  
414 gaps in phase angle. We first try the six-order polynomial function for the VIMS data. The  
415 comparison of fitting in the overlap wavelengths between the ISS and VIMS suggests that the six-  
416 order polynomial function works well for the range of phase angle for the VIMS observations  
417 ( $11.7^\circ$ - $159.1^\circ$ ), but it does not work well for fitting the VIMS data in the ranges of low and high  
418 phase angles ( $< 11.7^\circ$  and  $> 159.1^\circ$ ) because the VIMS observations are lacking in these ranges.  
419 The ISS observations have better coverage than that of the VIMS observations, especially in the  
420 range of the low and high phase angles. So we first use the ISS observations in low and high phase  
421 angles to fill the VIMS observational gaps. Then we use the six-order polynomial function to fit  
422 the data, and such a fitting works well for filling the VIMS observations gaps.

423 The wavelength range of the VIMS observations is larger than the wavelength range of the  
424 ISS observations. For the VIMS wavelengths covered by the ISS 12 filters, we follow the method  
425 discussed above to do the fitting and then fill the observational gaps. For the VIMS wavelengths  
426 not covered by the ISS filters, we interpolate/extrapolate the ISS observations from the ISS  
427 wavelengths to the VIMS wavelengths to fill the VIMS observational gaps at the low and high  
428 phase angle first. Then we apply the six-order polynomial function to fit the VIMS data and then  
429 fill the observational gaps. After filling the VIMS observational gaps in phase angle, we have the  
430 full-disk albedo in the two-dimensional domain of wavelength and phase angle for the VIMS  
431 wavelength range (350-5131 nm), which is shown in Fig. S25.

432 Figure S26 displays the ratio between the fitting residual (i.e., fitting results – observational  
433 results) and the observational results for these phase angles where the VIMS observations exist.  
434 Most of the fittings have ratios less than 10%, but there are fittings with residual ratios larger than  
435 10% or even 20%. We further examine these fittings with the large residual ratios. We find that  
436 the residual ratios generally get bigger with longer wavelengths (especially in these wavelengths  
437 longer than 2000 nm). The observational data (i.e., full-disk albedo) are extremely small when

438 wavelengths longer than 2000 nm, so even the small fitting residuals can make the residual ratios  
439 pretty large.

440 These fittings with large residual ratios are mainly in the wavelengths longer than 2000 nm.  
441 In these longer wavelengths, solar spectral irradiance contributes a very small fraction (< 6%) to  
442 the total solar power. So the uncertainties in these wavelengths do not significantly affect our  
443 measurements of Titan's Bond albedo and hence the reflected/absorbed solar power. However, the  
444 uncertainty related to such fitting residuals is considered in our analyses of the measurement  
445 uncertainties (see section "Analyses of the Measurement Uncertainties").

446

### 447 **S9. Filling Observational Gaps in Wavelength and Time**

448 The Cassini observations of Titan's full-disk albedo have observational gaps in not only  
449 phase angle but also wavelength. After filling the observational gaps in phase angle, which is  
450 discussed in the previous section, we work on the observational gaps in wavelength. Both the ISS  
451 and VIMS data have observational gaps in wavelength. The ISS 12 filters record Titan's albedo in  
452 separated and limited wavelengths from ultraviolet (~ 264 nm) to near infrared (~ 939 nm) and the  
453 VIMS observations do not cover the wavelengths shorter than 350 nm. In order to compute Titan's  
454 full-disk albedo, we need measurements of Titan's albedo in the wavelength range of 0-5131 nm.  
455 The SSI in this wavelength range contributes to more than 99.5% of the total solar power.

456 We first fill the observational gaps in wavelength for the Cassini ISS observations. The  
457 ground-based observations (see Fig. S3) and the Cassini VIMS observations both suggest that the  
458 magnitude of Titan's albedo spectra change with phase angle but the spectral structure and shape  
459 basically stay constant. It means that the phase functions are correlated among different  
460 wavelengths. With the least-squares fitting, we have derived Titan's full-disk albedo over the  
461 whole range of phase angle for these wavelengths covered by the Cassini ISS 12 filters (see Fig.  
462 S22). Please note that the ISS UV1/2 observations do not cover all years during the Cassini epoch  
463 (see Fig. S20), and we use interpolation and extrapolation to fill the observations gaps in time for  
464 the UV1/2 results. Then, we use the complete phase functions (i.e., distribution over phase angles  
465 0-180°) at the Cassini ISS 12 wavelengths to derive the phase functions at all wavelengths from  
466 264 nm (i.e., the shortest wavelength of the ISS observations) to 939 nm (i.e., the longest  
467 wavelength of the ISS observations) by referring to the spectral shape at the phase angle 5.7° which  
468 is from the high-spectral-resolution measurements (see Fig. S3). Figure S27 displays examples of  
469 the ISS-derived albedo in the two-dimensional domain of wavelength and phase angle for these  
470 years during the Cassini epoch.

471 To validate the ISS-derived albedo in the two-dimensional domain of wavelength and  
472 phase angle, we compare the derived results between the ISS and VIMS observations. We first  
473 average the ISS-derived two-dimensional albedo over the Cassini epoch. Then we compare the  
474 time-mean ISS-derived albedo with the VIMS-derived albedo in the overlap wavelengths (350-  
475 939 nm). Figure S28 shows that the results are basically consistent between ISS (panel A) and  
476 VIMS (panel B) results. Figure S29 further provides the differences and differences ratio between  
477 the ISS-derived and the VIMS-derived results. Panel A shows that large differences are mainly  
478 concentrated in the low and high phase angles. However, the difference ratios suggest that the  
479 values are less than 15% even for these large differences in the low and high phase angles.

480 To address the temporal variations of Titan's Bond albedo and hence the reflected/absorbed  
481 solar power during the Cassini epoch, we require the time series of Titan's full-disk albedo in the  
482 two-dimensional domain of wavelength and phase angle with the complete coverage of phase  
483 angle (0-180°) and wavelength (0-5131 nm). The above ISS-derived albedos (Fig. S27) with the

484 complete coverage of phase angle are used for the wavelength range 264-939 nm. It should be  
485 mentioned that we get Titan's albedo in the two-dimensional domain from both the ISS  
486 observations (Fig. S27) and the VIMS observations (Fig. S25) for the overlap wavelengths (i.e.,  
487 350-939 nm) between the ISS and VIMS observations. In this study, we use the ISS-derived results  
488 for the overlap wavelengths (i.e., 350-939 nm) because: (1) the ISS observations resolved the  
489 temporal variations of the phase functions for Titan's full-disk albedos; (2) the coverage of phase  
490 angle is much better for the ISS observations than for the VIMS observations so that the fitted  
491 phase functions are more precise for the ISS observations than for the VIMS observations; and (3)  
492 the spectra from the Earth-based observations<sup>42</sup>, which are used to derive the ISS albedo (Fig.  
493 S27), have a very high spectra resolution  $\sim 0.4$  nm. Such a spectral resolution is much better than  
494 the spectral resolution of the VIMS observations ( $\sim 4-24$  nm), so that some fine spectral structures  
495 can be better resolved.

496 The low and high limits of the wavelengths for the ISS observations are 264 nm (UV1) and  
497 939 nm (CB3), respectively. For the temporal variations of Titan's full-disk albedo in the  
498 wavelengths shorter than 264 nm (i.e., 0-264 nm), we refer to the ISS measurements at the UV1  
499 filter (264 nm). We first interpolate and extrapolate the UV1 phase functions in 2009 and 2015  
500 (Fig. S22) to the whole Cassini epoch (2004-2017). We then extrapolate the available geometric  
501 albedo spectra from the Cassini UVIS (150-190 nm) and the HST/FOS (190-305 nm) (Fig. S4) to  
502 the wavelength range 0-150 nm to get the geometric albedo spectra in the wavelength range of 0-  
503 264 nm. Finally, the extrapolated phase function in each wavelength of the wavelength range 0-  
504 264 nm is combined with the available albedo at the same wavelength to derive Titan's albedo  
505 over the complete range of phase angle. For each year of the Cassini epoch, we build the albedo  
506 in the two-dimensional domain of wavelength and phase angle for the wavelength range 0-264  
507 nm.

508 For the temporal variations of Titan's albedo at wavelengths longer than 939 nm (i.e., 939-  
509 5131 nm), we combine the ISS and VIMS observations together. The basic idea is that we  
510 extrapolate the temporal variations at 939 nm, which are based on the ISS CB3 observations, to  
511 the wavelength range 939-5131 nm. The albedos in the wavelength range 939-5131 nm (Fig. S25),  
512 which are derived from the VIMS observations, are assumed to be the time-mean albedo. During  
513 the process of extrapolating the temporal variations of the ISS observations to the VIMS  
514 wavelengths 939-5131 nm, the time-mean two-dimensional albedos (Fig. S25) are used as a  
515 reference.

516 After addressing the temporal variations of Titan's albedo in the wavelengths outside of the  
517 ISS coverage (i.e., 0-264 nm and 939-5131 nm), we have the two-dimensional albedo in the  
518 complete coverage of phase angle (0-180°) and wavelength (0-5131 nm) for each year during the  
519 Cassini epoch (2004-2017). Some examples of such two-dimensional albedo are shown in Fig.  
520 S30.

521

## 522 **S10. Computing Titan's Bond Albedo and the Related Qualities**

523 Based on Titan's full-disk albedo in the complete domain of wavelength and phase angle for  
524 each year of the Cassini epoch (Fig. S30), we can compute Titan's monochromatic Bond albedo  
525 and the related qualities at each wavelength for each year of the Cassini epoch. The monochromatic  
526 geometric albedo, which is defined as the albedo at phase angle 0°, is automatically found from  
527 Fig. S30. The phase integral, which is the integral of phase function of Titan's albedo, can be  
528 computed from the distribution of Titan's albedo with phase angle at each wavelength. Finally, we  
529 can derive the monochromatic Bond albedo from the product of the monochromatic geometric

530 albedo and monochromatic phase integral (see section “Method of Computing the Bond Albedo”).

531 Figure S31 displays the monochromic geometric albedo, phase integral, and Bond albedo  
532 in the two-dimensional domain of time (2004-05 – 2017) and wavelength (0 – 5131 nm). For the  
533 distribution with wavelength, the geometric albedo has roughly the same spectral structures as  
534 those shown in the Earth-based observations (Fig. S3) and the VIMS observations (Fig. S24) at  
535 high phase angles. The phase integral largely increases with wavelength. In the visible part (300-  
536 800 nm), the phase integral has the smallest values ~1.6-2.3. In some infrared parts (e.g., 3900-  
537 4500 nm), the phase integral can reach the largest values ~5-5.5. In the direction of wavelength,  
538 Panel E shows that the Bond albedo has similar distributions as those of the geometric albedo. The  
539 Bond albedo reaches maxima (~ 0.4-0.5) around the visible wavelengths between 600 nm and 800  
540 nm, and it becomes very small (< 0.2) at wavelengths longer than 2200 nm. The large Bond albedo  
541 between 600 nm and 800 nm is mainly due to the large geometric albedo in the same wavelengths.  
542 The small monochromatic Bond albedo at wavelengths longer than 2200 nm is because the small  
543 geometric albedo is dominant over the large phase integral at these wavelengths. The anomalies  
544 (i.e., difference from time-mean) suggest that the temporal variations of the geometrical albedo  
545 (panel B of Fig. S31) and Bond albedo (panel F of Fig. S31) are mainly concentrated in the  
546 wavelength range 400-1000 nm. The anomaly of the phase integral (panel D of Fig. S31) displays  
547 the temporal variations basically in all wavelengths.

548 Based on the distribution of the monochromatic Bond albedo (Panel E of Fig. S31), we can  
549 compute the wavelength-average Bond albedo (i.e. Titan’s Bond albedo) by weighting the  
550 monochromatic Bond albedo with the SSI (Fig. S2), as we did in our study of measuring Jupiter’s  
551 Bond albedo (Li et al., 2018). Titan’s Bond albedo during the Cassini epoch is displayed in Fig. 1  
552 in the main text.

553 The product between the SSI at Titan (panel A of Fig. S2) and the monochromatic Bond  
554 albedo (panel E of Fig. S31) generates the reflected SSI. Subtracting the reflected SSI from the  
555 SSI at Titan, we have the absorbed SSI at Titan. Multiplying the SSI, the reflected SSI, and the  
556 absorbed SSI by the effective radius at each wavelength, we have the total SSI, the total reflected  
557 SSI, and the total absorbed SSI over Titan’s optical disk at each wavelength. Integrating the total  
558 SSI, the total reflected SSI, and the total absorbed SSI at each wavelength over the complete  
559 wavelength range 0-5131 nm, we have the total solar power, the total reflected solar power, and  
560 the total absorbed solar power at Titan. Their temporal variations during the Cassini epoch are  
561 presented in Fig. 2 in the main text.

562

## 563 **S11. Analyses of the uncertainties in determining Titan’s radiant energy budget**

564 In this section, we discuss the uncertainties in computing Titan’s radiant energy budget.  
565 Titan’s radiant energy budget is determined by the emitted thermal energy and the absorbed solar  
566 energy of Titan. Therefore, we mainly discuss the uncertainties in the measurements of Titan’s  
567 emitted power and absorbed power. In addition, other possible energy sources (e.g., emission from  
568 Saturn and Titan’s internal heat), which possibly affect the radiant energy budget, are also  
569 discussed.

### 570 ***A. Uncertainties in the measurements of Titan’s emitted thermal power***

571 We first discuss the uncertainties in computing Titan’s emitted power with the  
572 Cassini/CIRS observations. Such uncertainties were briefly discussed in our previous studies of  
573 Titan’s emitted power (Li et al., 2011; Creecy et al., 2019), which are based on the methodology  
574 we developed in our investigation of Saturn’s emitted power (Li et al., 2010). Here, we provide  
575 more discussions on the uncertainty in computing Titan’s emitted power. There are two dominant

576 uncertainty sources in computing Titan’s emitted power with the Cassini/CIRS observations: (1)  
 577 the uncertainty related to the CIRS data calibration; and (2) the uncertainty related to filling the  
 578 observational gaps of the CIRS data.

### 579 **A.1. Uncertainty in the CIRS data calibration**

580 The basic approach for calibrating the CIRS measurements to radiance of targets (e.g.,  
 581 Titan) was introduced in the introductory CIRS paper (Flasar et al., 2004) and discussed in our  
 582 previous study of Saturn’s emitted power (Li et al., 2010). The main process of the CIRS  
 583 calibration is to remove the radiance of the background (i.e., the instrument itself) from the  
 584 radiance of targets. To estimate the background radiance, the CIRS routinely viewed deep space  
 585 (i.e., zero radiance from target) and recorded the spectra of the deep space. Generally, the spectra  
 586 of deep space are much smaller than the spectra of targets. Figure S32 displays the comparison  
 587 between the spectra of Titan and the typical spectra of deep space, which were recorded by the  
 588 three focal planes (FP1, FP3, and FP4) of the CIRS. Figure S32 suggests that calibration  
 589 uncertainty mainly comes from the FP1, which is dominant among the three focal planes. So we  
 590 focus on the FP1 data in the following discussion.

591 The absolute radiometric calibration of the FP1 was operated at 170 K instrument  
 592 temperature. The radiance from deep space is the main error source for the CIRS calibration.  
 593 Figure S33 shows the temporal variations of the FP1 spectra of deep space, which suggests a good  
 594 stability. The uncertainty related to the background noise in the FP1 spectra is estimated as follows:  
 595 we randomly choose ~ 100,000 spectra of deep space for each year of 2004–2017. These spectra  
 596 are first integrated in wavenumber because Titan’s spectra are integrated when calculating the  
 597 emitted power. The mean value and standard deviation of the 100,000 wavenumber-integrated  
 598 spectra are used as an estimator for the uncertainty due to the background radiance in each year.  
 599 The mean values and the standard deviations of some years were presented in one of our previous  
 600 studies (Li et al., 2010). We add the absolute mean value to the standard deviation to estimate the  
 601 absolute calibration uncertainty of Titan’s emitted power for each Earth year.

602 It should be mentioned that the thermal control of the CIRS instrument possibly affects the  
 603 data calibration. The entire FP1 interferometer and detector were operated at the 170 K instrument  
 604 temperature. The sensors were calibrated before flight and didn't show any evidence of drift during  
 605 the Cassini observational period. The temperature control was about 0.1 K, so an absolute accuracy  
 606 of 0.2 K overall is a good estimate for the upper limit. Panel A of Fig. 34 shows the blackbody  
 607 spectra of the CIRS instrument at 170 K. In contrast, we also plot the blackbody spectra at 170.2  
 608 K by adding the temperature control (0.2 K) to the designed temperature of the CIRS instrument  
 609 (170 K). Panel B shows the difference between the two spectra shown in panel A, which is used  
 610 to estimate the spectral noise related to the temperature control of the CIRS instrument. Panel C is  
 611 the comparison between the spectral noise and typical spectra of deep space, which suggests that  
 612 the spectral noise related to the temperature control is much smaller than the spectra of deep space.  
 613 Therefore, we only consider the spectra of deep space for the CIRS data calibration.

### 614 **A.2. Uncertainty related to filling CIRS observational gaps**

615 The other uncertainty of computing Titan’s emitted power is related to filling observational  
 616 gaps of the CIRS data in emission angle. Based on the uncertainty analysis in our study of Saturn’s  
 617 emitted power (Li, et al., 2010), we have the sum of unknown radiance in the observational gaps  
 618 along a single latitude ( $P_{emit}(N)$ ) as

$$619 \quad P_{emit}(N) = 2\rho \sum_{k=1}^N I(d_k) \cos d_k \sin d_k D d = \sum_{k=1}^N c_k I_k \quad (1)$$

620 where  $N$  the number of the radiance at the unknown emission angles and  $I(d_k)$  is the radiance at  
 621 the unknown emission angles ( $d_k$ ). In the above equation, we also simplify the equation with a  
 622 coefficient  $c_k$ , which is represented by  $c_k = 2\rho \cos d_k \sin d_k D d$ . Then the total difference between  
 623 the fitted radiance and the real radiance for all observational gaps along the latitude ( $P_{emit}(N)^{\zeta}$ )  
 624 can be expressed as

$$625 \quad P_{emit}(N)^{\zeta} = \sum_{k=1}^N c_k I_k^{\zeta} \quad (2)$$

626 where  $I_k^{\zeta}$  is the radiance difference between the fitted value and the real value at unknown emission  
 627 angles.

628 The variance of  $P_{emit}(N)^{\zeta}$  is used to estimate the uncertainty of emitted power related to  
 629 filling the observational gaps. The variance of the sum of multiple variables can be determined by  
 630 the following equation (23)

$$631 \quad S^2_{\zeta} P_{emit}(N)^{\zeta} = \sum_{k=1}^N c_k^2 S_k^2 + 2 \sum_{i=2}^N \sum_{j=1}^{i-1} c_i c_j S_{ij}^2 \quad (3)$$

632 where  $S_k^2$  is the variance of the radiance difference  $I_k^{\zeta}$  and  $S_{ij}^2$  is the covariance of the radiance  
 633 difference at two different unknown emission angles with the two corresponding coefficients  $c_i$   
 634 and  $c_j$ . Our previous analyses (19, 20) show that least-squares fitting does a good job in fitting the  
 635 recorded radiance. Figure S35 shows an example of the fitting and the fitting residual. The fitting  
 636 residual is used to estimate the variance of the radiance difference  $d_k^{\zeta}$  at the observational gaps.  
 637 The covariance  $d_{ij}^{\zeta}$  will disappear if we assume that the radiances at different unknown points are  
 638 independent from each other. Then Eq. (3) can be used to compute the uncertainty related to filling  
 639 the observational gaps.

### 640 **A.3. Total uncertainty of emitted power**

641 With the analysis in the above section, we have the uncertainty related to filling the  
 642 observational gaps at each latitude. In addition, we assume that the calibration uncertainty is  
 643 constant with latitude. As an example, the meridional distribution of calibration uncertainty and  
 644 filling uncertainty in 2009 are shown in Fig. S36. It suggests that the fitting uncertainty is larger  
 645 than the calibration uncertainty by roughly one order of magnitude.

646 We combine the two uncertainties as the total uncertainty of emitted power by

647  $S_{all} = \sqrt{S_{calibration}^2 + S_{fitting}^2}$ . Now, we discuss the uncertainty of the global-average emitted power.

648 The global-average emitted power can be written as (Li et al., 2010)

$$649 \quad \bar{P} = \frac{1}{2(1-2e/3)} \sum_{i=1}^N (1-2e \sin^2 f_i) P(f_i) \cos f_i D f = \sum_{i=1}^N c_i P(f_i) \quad (4)$$

650 where  $e$  is the oblateness of Titan ( $\sim(2574.91-2574.34)/2574.91 \sim 0.00022$ ),  $f_i$  is latitude, and  
 651  $P(f_i)$  is the emitted power at the latitude  $f_i$ . The index  $N$  is the number of latitude bands from  
 652 pole to pole. The coefficient  $c_i$  is represented by  $c_i = \left[ (1-2e \sin^2 f_i) \cos f_i D f \right] / \left[ 2(1-2e/3) \right]$ . With

653 the coefficient, the global-average emitted power is the sum of multiple variables. Again, we can  
 654 use the analysis of the variance of the sum of multiple variables (Bevington and Robinson, 2003)  
 655 to estimate the uncertainty of the global-average emitted power.

656 Using the uncertainty of emitted power at each latitude ( $S^2(P_i)$ ) (Fig. S36) and assuming  
 657 the emitted power is independent at different latitudes, we have the uncertainty of the global-  
 658 average emitted power as

$$659 \quad S^2(\bar{P}) = \sum_{i=1}^N c_i^2 S^2(P_i) \quad (5)$$

660 Based on eq. (5), we can compute the uncertainty of global-average emitted power in each Earth  
 661 year during the Cassini time period of 2004–2017. Figure S37 shows the time series of different  
 662 uncertainties for Titan’s emitted power. Panel B of Fig. S37 suggests that the ratios between the  
 663 total uncertain and Titan’s emitted power are about 0.3 percent for the Cassini/CIRS  
 664 measurements. Such ratios are much smaller than the ratios in the meridional direction (Fig. S36),  
 665 because averaging uncertainties over all latitudes smoothens the uncertainties into a much smaller  
 666 value, as Eq. (5) suggests.

667 The effective radius is different between Titan’s emitted thermal emission and absorbed  
 668 solar irradiance, so we integrate the uncertainty over the effective radius of Titan’s thermal  
 669 emission (i.e., 2575+500 km) (Li et al., 2011) to get the uncertainty of Titan’s sphere-integrated  
 670 emitted power (Fig. S38). Such uncertainty is used in the comparison between the sphere-  
 671 integrated emitted thermal power and the disk-integrated absorbed solar power (Fig. 3 in the main  
 672 text), which helps to determine if Titan’s global radiant energy budget is balanced.

### 673 ***B. Uncertainties in the measurements of Titan’s absorbed solar power***

674 The absorbed solar power is determined by Titan’s Bond albedo with known solar flux at  
 675 Titan (Fig. S2). Therefore, the uncertainties in the absorbed solar energy mainly come from the  
 676 uncertainties in computing Titan’s Bond albedo with the Cassini observations. At each  
 677 wavelength, the monochromatic Bond albedo ( $A_l$ ) can be expressed as below (Li et al., 2018)

$$678 \quad A_l = \frac{2}{S/D^2} \sum_{f_i=0}^{f_i=180^\circ} I_l(f_i) \sin f_i D f \quad (6)$$

679 where  $l$  is wavelength,  $\rho S$  is the solar constant at Earth,  $D$  is the distance of the planet from the  
 680 Sun in astronomical units (1 AU = 149.6×10<sup>9</sup> m), and  $I_l(f_i)$  is the reflected solar irradiance at  
 681 phase angle  $f_i$ .

682 We organize the uncertainty sources in the measurements of monochromatic Bond albedo  
 683 in three categories: (1) the uncertainty in calibrating the Cassini ISS and VIMS images; (2) the  
 684 uncertainty related to filling observational gaps with the least-squares fitting; and (3) other  
 685 uncertainties.

#### 686 ***B.1. Uncertainty in the ISS and VIMS data calibration***

687 We first discuss the uncertainty in the calibration of the ISS and VIMS data. For the ISS  
 688 images, we use the latest version of the Cassini ISS CALibration software (Knowles et al., 2020),  
 689 to calibrate the data. The calibrated ISS images are generated with a unit of radiance, as shown in  
 690 Fig. S39. In Fig. S39, the domain outside Titan’s disk corresponds to deep space. It should be  
 691 mentioned the calibrated radiance in the domain of deep space, which is used to estimate the  
 692 absolute calibration of the CIRS spectra, cannot be used to estimate the absolute calibration  
 693 uncertainty of the ISS images. In the ISS images, the domain of deep space contains light from

694 Titan’s disk spreading out by the point spread function, plus stray light from scattering of Titan  
695 light off the structures in the telescope (West et al., 2010; Knowles et al., 2020).

696 In the ISS calibration papers (West et al., 2010; Knowles et al., 2020) and the Cassini  
697 calibration manual ([https://pds-rings.seti.org/viewmaster/volumes/COISS\\_0xxx/COISS\\_0011/](https://pds-rings.seti.org/viewmaster/volumes/COISS_0xxx/COISS_0011/)),  
698 the calibration uncertainties, which include many error sources (e.g., uneven bit-weighting, 2-Hz  
699 noise, dark current in the ISS cameras, bright/dark pixel pair artifacts from anti-blooming mode,  
700 flat-field artifacts), are discussed in detail. Most of the calibration uncertainty sources vary with  
701 filter, viewing geometry, and observing object. But the combined effect of these uncertainty  
702 sources typically results to ~ a few percent of the calibrated radiance (2-6%) (Knowles et al., 2020).  
703 Here, we assume that the total calibration uncertainty is 5% for the absolute calibrated radiance of  
704 Titan’s images. It should be emphasized that the 5% calibration uncertainty is not systematic and  
705 it is a random error (Knowles et al., 2020). In other words, it overestimates the real radiance at  
706 some wavelengths & phase angles but underestimates the radiance at other wavelengths and phase  
707 angles (Knowles et al., 2020). When we integrate the recorded radiance over wavelength and phase  
708 angle for computing the Bond albedo, the calibration uncertainties at different wavelengths and  
709 phase angles cancel each other so that its effect on the Bond albedo becomes very small (<1%). It  
710 should be mentioned that there is a systematic uncertainty related to the ISS instrumental  
711 effect. For the ISS images in which Titan occupies almost all of the image frames, some of Titan’s  
712 reflected flux can be outside of the ISS image frames. This effect systematically underestimates  
713 the real radiance. Fortunately, such images are relatively few (< 10% of the total global images  
714 used in our analysis). The tests by the ISS calibration team suggest that such a systematic bias is  
715 ~ 0.5% of the total scattered flux from Titan, which is accounted in our computation of Titan’s  
716 Bond albedo.

717 For Cassini VIMS observations, the calibration has already been discussed in a few  
718 previous studies (15, 50-53). Work described by McCord et al. (2004) and Filacchione et al. (2007)  
719 conducted the basic calibration processes (e.g., correcting flat-field artifacts, subtracting the noise  
720 from the radiation of Cassini’s power generators, and removing cosmic rays). The calibration of  
721 the VIMS data of satellites of Saturn (Pitman et al., 2010) suggests that the calibration uncertainty  
722 is on the order of 5% of the calibrated radiance. Based on these previous analyses, the calibration  
723 uncertainty for the VIMS data is 5%. Such an estimate is the same as that of the ISS data even  
724 though the two instruments did independent calibrations. As discussed with respect to the ISS  
725 calibration uncertainty, the VIMS 5% calibration uncertainty is not systematic either. The random  
726 calibration errors at different wavelengths and phase angles cancel each other when integrating  
727 over wavelength and phase angle for Titan’s Bond albedo.

728 The comparison of full-disk albedo between the ISS and VIMS (Fig. S16 in section  
729 “Validation of Cassini ISS and VIMS results”), which are based on the calibrated data from the  
730 two instruments, also suggests that the calibrations from the two instruments are consistent.  
731 Finally, the validation of the Cassini ISS/VIMS data by the other observations (Fig. S17-19 in  
732 section “Validation of Cassini ISS and VIMS results”) also suggests that the Cassini ISS/VIMS  
733 data are calibrated well.

### 734 ***B.2. Uncertainty related to filling ISS/VIMS observational gaps***

735 From the equation of monochromic Bond albedo (Eq. (6)), we know that the Bond albedo  
736 is determined by the reflected solar irradiance at phase angles varying from 0° to 180°. But there  
737 are observational gaps in phase angle for the Cassini ISS/VIMS observations (see Figs. S20 and  
738 S24). In the equation of monochromic Bond albedo, the part for the observational gaps can be  
739 expressed as

740 
$$A'_i = \frac{2}{S/D^2} \sum_{i=1}^N I_i(f_i) \sin f_i D f = \sum_{i=1}^N c_i I_i(f_i) \quad (8)$$

741 where  $N$  is the number of unobserved points in phase angle and the coefficient  $c_i$  is expressed  
 742 as  $c_i = 2D^2 \sin f_i D f / S$ . Then the Bond albedo for the observational gaps can be represented as  
 743 the sum of multiple variables. Likewise, we use the variance of the sum of multiple variables  
 744 (Bevington and Robinson, 2003) to estimate the uncertainty of the Bond albedo from filling the  
 745 observational gaps as below

746 
$$S^2(A'_i) = \sum_{i=1}^N c_i^2 S(I_i(f_i)) \quad (9)$$

747 Now we discuss how to estimate the variance of the reflected radiance at the unobserved  
 748 phase angles. The observational gaps in phase angle are filled by least-squares fitting for the  
 749 Cassini ISS/VIMS observations of Titan's reflected solar irradiance. Figure S40 shows a fitting  
 750 example for the full-disk albedo recorded by the ISS observations, which suggests that the least-  
 751 squares fitting does a good job in fitting the Cassini observations. Panel C of Fig. S39 further  
 752 suggests that most of the residual ratios are less than 3%. The fitting residual is used in the estimate  
 753 of the uncertainty in the CIRS measurements of Titan's emitted power by least-squares fitting.  
 754 Such a method works for the fitting for the ISS/VIMS observational gaps at the relatively s, but it  
 755 does not work for the ISS/VIMS observational gaps at very high phase angles.

756 The smallest phase angles of the ISS observations change from  $\sim 0.5^\circ$  to  $\sim 4.4^\circ$  for most  
 757 filters except for the filters UV1, UV2, and CB1 (see Fig. S20). The smallest phase angles for the  
 758 ISS images recorded by UV1, UV2, and CB3 are between  $\sim 8.4^\circ$  and  $\sim 9.8^\circ$ . The smallest phase  
 759 angle for the high-quality VIMS observations is  $\sim 9.8^\circ$  (see Fig. S24). The Cassini ISS/VIMS  
 760 observations at the s are consistent with other observations at s including  $0^\circ$  phase angle, which  
 761 were recorded by the HST and ESO (see Fig. S18). So we think least-squares fitting works well  
 762 for extrapolating the ISS/VIMS observations at the s including  $0^\circ$  phase angle. Therefore, we use  
 763 the fitting residuals to estimate the variances of the ISS/VIMS observational gaps at the relatively  
 764 s.

765 The estimate of the variances of the ISS/VIMS observational gaps at very high phase angles  
 766 is a different story. In our discussion of the uncertainty in the measurements of Titan's emitted  
 767 power with the Cassini CIRS observations, the fitting residuals are used to estimate the variance  
 768 for these observational gaps at both low and high emission angles. But there is one difference  
 769 between the CIRS observational gaps in emission angle and the ISS/VIMS observational gaps in  
 770 phase angle. For the CIRS observations, we have the data around the lowest and highest emission  
 771 angles ( $0^\circ$  and  $90^\circ$  respectively) for most latitudes (see Fig. S35), so we know the basic distribution  
 772 of emitted radiance along emission angle. But for the ISS/VIMS observations, we have the  
 773 observations around the lowest phase angle ( $0^\circ$ ) but not around the highest phase angle ( $180^\circ$ ), as  
 774 shown in Fig. S20. There are no high-quality ISS/VIMS observations at the phase angles larger  
 775 than  $\sim 165^\circ$  because the solar irradiance comes into the instrument and could damage the Cassini  
 776 detectors if the phase angle is even higher. In addition, the ground-based telescopes and Earth-  
 777 orbiting observatories can conduct observations of Titan with s only ( $< 6.5^\circ$ ) due to the orbit  
 778 geometry of Earth and Titan. The largest phase angle of the Pioneer 11 observations is  $\sim 96^\circ$ .

779 In summary, there are no high-quality observations of Titan at phase angles larger than  
 780  $\sim 165^\circ$ . Lacking observations makes it difficult to estimate the uncertainty in filling the

781 observational gap at the phase angles larger than  $165^\circ$ . Using the fitting residuals at the lower  
782 phase angle probably underestimates the uncertainties at high phase angles larger than  $165^\circ$ . In  
783 this study, we use the fitting residuals at these available points (Fig. S40) to estimate the variance  
784 of the observational gaps with phase angles smaller than  $165^\circ$ . For the observational gaps with  
785 phase angles larger than  $165^\circ$ , we set larger uncertainty and assume that the uncertainty can reach  
786 the fitted values.

### 787 ***B.3. Other uncertainties in the measurements of Titan's Bond albedo***

788 In addition to the uncertainties from the Cassini data calibration and filling the  
789 observational gaps in phase angle, there are other uncertainty sources. The first one is the high-  
790 altitude detached haze. Some haze features have altitudes higher than 500 km, which are beyond  
791 the effective radii of Titan's reflected solar irradiance. Figure S41 shows that the detached high-  
792 altitude haze shows in the ISS images at some filters but not in other filters. Even for the ISS  
793 images including strong-reflection haze (e.g., panel A of Fig. S41), our calculation suggests that  
794 the reflected solar irradiance from the detached haze is  $\sim 0.2\%$  of the total reflected solar irradiance  
795 from the full disk of Titan. Therefore, the high-altitude haze does not significantly contribute to  
796 the uncertainty of the Bond albedo compared to the calibration and filling uncertainties. However,  
797 we include it in the uncertainty analysis.

798 The errors in estimating the effective radii of Titan's reflected solar irradiance also  
799 introduce uncertainty in computing Titan's Bond albedo. Based on the average effective radius ( $\sim$   
800  $2884.9$  km) retrieved from the ISS observations and the corresponding average error ( $\sim 9.7$  km),  
801 we simply estimate the uncertainty as  $((2884.9+9.7)^2-2884.9^2)/2884.9^2 \sim 0.7\%$ .

802 Titan has a thick atmosphere, which is not uniform in latitude and longitude. In addition,  
803 atmospheric processes (e.g., clouds) vary with time. Finally, the solar irradiance can be reflected  
804 from Titan's surface at some wavelengths (e.g., the ISS CB3 filter). The optical characteristics of  
805 Titan's surface vary spatially. The heterogeneous nature of the atmosphere and surface and their  
806 possible temporal variations can introduce more uncertainty in measuring the full-disk albedo of  
807 Titan. Figure S42 shows full-disk images of Titan recorded by the ISS CB3 filter at different times  
808 but with the same phase angle ( $\sim 14^\circ$ ). The CB3 images record both the atmosphere and surface  
809 of Titan, so the CB3 images at different times can be used to address the heterogeneous property  
810 of Titan's atmosphere and surface and their temporal variations. The first two global images are  
811 separated by  $\sim 3$  days, which are shorter than the orbital period of Titan around Saturn ( $\sim 16$  Earth  
812 days). The two images cover different longitudes (panel A mainly covers longitudes  $\sim 200$ - $360^\circ$   
813 and  $0$ - $20^\circ$  and panel B mainly covers longitudes  $\sim 150$ - $330^\circ$ ). So the comparison between panels  
814 A and B can help us to address not only the heterogeneous property but also the diurnal variation  
815 of Titan's atmosphere and surface. However, we find that the full-disk albedo only changes  $\sim 0.4\%$   
816 from  $0.1911$  in the first image to  $0.1903$  in the second image in Fig. S42.

817 We average the observations in each year of the Cassini period (2004-2017) to get yearly  
818 albedo of Titan. So the temporal variations with time scales longer than one Titan day ( $\sim 16$  Earth  
819 days) but shorter than one Earth year are not resolved. Panel C of Fig. S42 shows an image of  
820 Titan recorded  $\sim 2$  Earth months after the second image (panel B). But the two images have the  
821 roughly same latitude/longitudinal coverage. Therefore, the comparison between panel B and  
822 panel C can help us examine the temporal variations of Titan's full-disk albedo at the time scales  
823 longer than one Titan day but shorter than one Earth year. Titan's full-disk albedo changes  $\sim 0.7\%$   
824 from  $0.1903$  in panel B to  $0.1890$  in panel C. Therefore, Titan's heterogeneous property and  
825 temporal variations at the time scales shorter than one Earth year is probably smaller than  $1\%$  and  
826 we assume  $1\%$  for this uncertainty.

827 The cloud bands also develop on Titan sometimes. An example of such cloud bands is  
 828 shown in Fig. S43. Cloud bands are generally composed by very bright clouds aligned in the  
 829 longitudinal direction. Our estimates shows that the cloud bands shown in Fig. S43 increase the  
 830 original albedo by  $\sim 20\%$ . The ratio between the area of the cloud bands and the full-disk area is  
 831  $\sim 2\%$ , so the cloud bands increase the full-disk albedo by  $0.4\%$ . It is hard to examine the whole  
 832 lifetime (i.e., from birth to death) of the cloud bands. But it is probable that the cloud bands have  
 833 lifetimes less than one half of an Earth year. So the cloud bands shown in Fig. S43 increase the  
 834 annual-mean albedo with an upper limit  $0.4\% \times 1/2 = 0.2\%$ .

835 Combining the uncertainties from the high-altitude haze, the error in determining Titan's  
 836 effective radius, the spatio-temporal variability of Titan's atmosphere and surface, and the effects  
 837 of cloud bands, we have the combined uncertainty as  $\sqrt{0.002^2 + 0.007^2 + 0.01^2 + 0.002^2} = 0.012 =$   
 838  $1.3\%$ .

#### 839 **B.4. Total uncertainty of Bond albedo**

840 We combine the calibration, fitting, and other uncertainties into the total uncertainty of Titan's  
 841 monochromic Bond albedo ( $d(A_l)$ ). The total uncertainty can expressed as

$$842 \quad d(A_l) = \sqrt{d_{cal}^2(l) + d_{fit}^2(l) + d_{other}^2(l)} \quad (10)$$

843 where  $d_{cal}(l)$ ,  $d_{fit}(l)$ , and  $d_{other}(l)$  are uncertainties related to data calibration, fitting, and  
 844 other error sources, respectively. Titan's Bond albedo is computed by weighting the monochromic  
 845 Bond albedos over the whole wavelength range (0-6000 nm) by the solar spectral irradiance. But  
 846 the Cassini ISS/VIMS observations do not cover the whole wavelength range, and there are  
 847 observational gaps in wavelength. First, we interpolate/extrapolate the uncertainty in these  
 848 wavelengths recorded by the Cassini ISS/VIMS to other wavelengths in the wavelength range of  
 849 0-6000 nm. Figure S43 shows the spectral distribution of the uncertainties in the measurements of  
 850 monochromic Bond albedo during the Cassini epoch.

851 Figure S44 suggests that the uncertainty related to filling the observational gaps in phase  
 852 angle is dominant in the total uncertainty. This figure also shows that the temporal variations of  
 853 the uncertainties are not very strong. That is because the ISS and VIMS data calibrations and the  
 854 observational gaps do not vary significantly with time. Figure S45 further shows the ratio between  
 855 the total uncertainty and the corresponding monochromic Bond albedo. First, we can see that the  
 856 spectral distribution of the total uncertainty is basically the same as that of the measured Bond  
 857 albedo, which means that the uncertainties of the large Bond albedo are also large. Second, the  
 858 ratio can reach 35% in some wavelengths (panel C of Fig. S45). These large ratios appear in the  
 859 wavelengths longer than 1000 nm. The relatively small monochromic Bond albedos at these  
 860 wavelengths are the main reason why there are large ratios. It should be mentioned that the large  
 861 ratios in these wavelengths do not significantly contribute to Titan's Bond albedo and the  
 862 corresponding uncertainty because the SSI in the wavelengths longer than 1000 nm are relatively  
 863 small compared to the SSI in the short wavelengths.

864 Based on the spectral distribution of the uncertainties in the monochromatic Bond albedo  
 865 (Fig. S44), we can estimate the uncertainties of Titan's Bond albedo. The Bond albedo ( $A$ ) is  
 866 computed by weighting the monochromic Bond albedos with the SSI as below (Li et al., 2018)

$$867 \quad A = \frac{1}{SSI_{sum}} \overset{l=5131nm}{\overset{\circ}{\sum}}_{l=0} SSI_l A_l = \overset{l=5131nm}{\overset{\circ}{\sum}}_{l=0} c_l A_l \quad (11)$$

868 where  $SSI_i$  and  $SSI_{sum}$  are the SSI at different wavelengths and the sum of SSI over wavelength,  
 869 respectively. The coefficient  $c_i$  is defined as  $c_i = SSI_i / SSI_{sum}$ . Eq. (11) suggests that the process  
 870 of computing Bond albedo is like the sum of the monochromatic Bond albedos at different  
 871 wavelengths with weighting factors. Therefore, the uncertainty of Titan's Bond albedo can be  
 872 estimated from the uncertainties of the monochromatic Bond albedo by applying the rule of error  
 873 propagation of addition (Bevington and Robinson, 2003) as below

$$874 \quad S^2(A) = \sum_i c_i^2 S^2(A_i) \quad (12)$$

875 where  $d^2(A)$  and  $d^2(A_i)$  are variances of Titan's Bond albedo and monochromatic Bond albedo,  
 876 respectively. Combining the spectral distribution of the monochromatic Bond albedo (Fig. S44)  
 877 and Eq. (12), we have uncertainty of Titan's Bond albedo shown in Fig. S46. Compared with the  
 878 uncertainties in the monochromic Bond albedo (Fig. S44), the uncertainties in Titan's Bond albedo  
 879 (Fig. S46) are much smaller because the uncertainties of monochromic Bond albedo can cancel  
 880 each other when they are averaged over wavelength.

881 When investigating Titan's radiant energy budget, we need to determine the emitted  
 882 thermal power and the absorbed solar power. Considering that the effective radius is different  
 883 between Titan's emitted thermal emission (Creedy et al., 2019) and absorbed solar irradiance (this  
 884 study), we need to compute the sphere-integrated emitted power and absorbed power. The  
 885 uncertainties in the sphere-integrated emitted thermal power are discussed in previous section.  
 886 Here, we discuss the uncertainty of disk-integrated absorbed solar power, which are related to the  
 887 uncertainties of disk-integrated solar flux and reflected solar power.

888 Titan's disk-integrated solar flux is computed by production of the SSI at Titan (Fig. S2)  
 889 and Titan's disk areas based on the effective radii (Figs. S8-S15). The solar flux at Titan is based  
 890 on the measured solar constant at Earth (Fig. S1), which have negligible uncertainties. So the  
 891 uncertainty in the disk-integrated solar flux is mainly determined by the uncertainty in the  
 892 measurements of effective radii. Because the uncertainty in the measurements of effective radius  
 893 is very small and such small uncertainty becomes even smaller when averaging over wavelength  
 894 (see Eq. (12)). Then the uncertainty in the disk-integrated solar flux can be used to compute the  
 895 uncertainty in the disk-integrated reflected solar power. The disk-integrated reflected solar power  
 896 can be computed by  $P_{reflect} = P_{solar} \cdot A$  (where  $P_{solar}$  and  $P_{reflect}$  are disk-integrated solar flux and the  
 897 reflected solar power respectively). Based on the error propagation, we have the uncertainties of  
 898 disk-integrated reflected solar power as

$$899 \quad \frac{d^2(P_{reflect})}{P_{reflect}^2} = \frac{d^2(P_{solar})}{P_{solar}^2} + \frac{d^2(A)}{A^2} \quad (13)$$

900 where  $d^2(P_{reflect})$  and  $d^2(P_{solar})$  are variances of the disk-integrated solar flux and reflected solar  
 901 power, respectively. The disk-integrated absorbed solar power ( $P_{absorb}$ ) can be computed by  
 902  $P_{absorb} = P_{solar} - P_{reflect}$ . Then the uncertainty in the disk-integrated absorbed solar power ( $d^2(P_{absorb})$ )  
 903 ) can expressed as

$$904 \quad d^2(P_{absorb}) = d^2(P_{solar}) + d^2(P_{reflect}) \quad (14)$$

905 where  $d^2(P_{absorb})$  is the variance of the disk-integrated absorbed solar power. The uncertainties of  
 906 the disk-integrated solar flux, reflected solar power, and absorbed solar power are shown in Fig.  
 907 S47, which are furthered used in Figs. 2 and 3 in the main text.

### 908 **C. Other uncertainties affecting the radiant energy budget of Titan**

909 When investigating the global radiant energy budget of Titan, we take the atmosphere and  
910 surface as a system. For such a system, there are other energy sources, which should be considered.  
911 The first one is the emitted thermal radiance from Saturn. Saturn's emitted power is  $\sim 4.95 \text{ Wm}^{-2}$   
912 in the Cassini epoch (Li et al., 2010). Such a power drops to  $\sim 0.012 \text{ Wm}^{-2}$  at the distance of Titan.  
913 During the Cassini epoch, Titan's average solar constant (Fig. S2) and Bond albedo (Fig. 1 in the  
914 main text) are  $\sim 15.04 \text{ Wm}^{-2}$  and  $\sim 0.26$ , respectively. So the absorbed solar power is  $\sim 15.04 \times (1 -$   
915  $0.26) = 11.13 \text{ Wm}^{-2}$ . Assuming that the albedo for the Saturn's thermal radiance is the same as  
916 Titan's Bond albedo ( $\sim 0.26$ ), we have the absorbed power from Saturn's thermal emission is  $\sim$   
917  $0.012 \times (1 - 0.26) = 0.009 \text{ Wm}^{-2}$ , which is about 0.1% of the absorbed solar power ( $0.009/11.13 \sim$   
918 0.1%).

919 There are two other energy sources: (1) internal energy released from the surface (Sohl et  
920 al., 1995; Tobie et al., 2006); (2) tidal heat (Tobie et al., 2006). Both have values of order  $10^{-3}$   
921  $\text{Wm}^{-2}$ , which is comparable to the thermal radiant power from Saturn's emission. The two powers  
922 are also comparable to the uncertainty in the measurements of Titan's emitted thermal power ( $\sim$   
923  $0.006 \text{ Wm}^{-2}$ ) (see Fig. S37) but are much smaller than the uncertainty in the measurements of  
924 Titan's absorbed solar power. The measurements of Titan's Bond albedo and hence the absorbed  
925 solar power have large uncertainty because there are no observations of reflected solar irradiance  
926 at the highest phase angles. Based on the uncertainty of Titan's Bond albedo ( $\sim 0.0026$ , see Fig.  
927 S45) and the solar constant at Titan ( $\sim 15.04 \text{ Wm}^{-2}$ , see Fig. S2), we have the uncertainty in the  
928 measurements of Titan's absorbed solar power as  $15.04 \times 0.0026 = 0.039 \text{ Wm}^{-2}$ . Such an  
929 uncertainty is much larger the uncertainties from internal energy and tidal heat. Therefore, the  
930 powers from Saturn's thermal emission, internal energy, and tidal heat are not considered in our  
931 discussion of the global radiant energy budget of Titan.

932 In summary, the uncertainty related to filling observational gaps is dominant in the  
933 measurements of Titan's emitted power (see Figs. S36 and S37). For the uncertainty of the  
934 measurements of Titan's Bond albedo and hence absorbed solar power, the large observational  
935 gaps at the highest phase angles ( $\sim 165\text{-}180^\circ$ ) significantly contribute to the uncertainty (see Fig.  
936 S44). The large observational gaps in measuring Titan's Bond albedo also make the uncertainty is  
937 much larger in the measurements of Titan's absorbed solar power ( $\sim 0.039 \text{ Wm}^{-2}$ ) than in the  
938 measurements of Titan's emitted thermal power ( $\sim 0.006 \text{ Wm}^{-2}$ ), as we discussed above.  
939 Considering that the emitted power goes off from the whole sphere and the absorbed solar power  
940 acts on the cross section of Titan, we have that uncertainties of the total power are not that different  
941 between the disk-integrated absorbed power ( $\sim 10 \times 10^{11} \text{ W}$ , see Fig. S47) and the sphere-integrated  
942 emitted power ( $\sim 7 \times 10^{11} \text{ W}$ , see Fig. S38).

### 943 **Extending the Cassini analysis to a complete Titan's year**

944 The Cassini epoch (2004-2017) occupies slightly less than one half of Titan's orbital period  
945 around the Sun (i.e., a Titan year  $\sim 29.4$  years). In order to examine Titan's radiant energy budget  
946 during a complete Titan year, we investigate the possible seasonal cycles of the absorbed solar  
947 power and the emitted power. The temporal variations of the absorbed solar power follow the  
948 seasonal cycle of the solar irradiance (Fig. 2). Earth's global emitted power (Jacobowitz et al.,  
949 1979; Yang et al., 1999) clearly displays a seasonal cycle, so we assume that Titan's emitted power  
950 also has a seasonal cycle (Creedy et al., 2019). We use a sine function with a period of 29.4 years  
951 to fit the observed absorbed power and emitted power (Fig. 3) and estimate their seasonal cycles,

952 which are displayed in Fig. S48. The uncertainty of fitting is estimated by the fitting residuals and  
953 extrapolating the fitting residuals from the Cassini epoch to a complete Titan year.

954 Integrating the fitted functions over a complete Titan year (Fig. 3), we find that the total  
955 absorbed solar energy,  $(2.676 \pm 0.005) \times 10^{23}$  J, and the total emitted thermal energy,  
956  $(2.549 \pm 0.053) \times 10^{23}$  J, have an even bigger energy imbalance of  $(0.127 \pm 0.053) \times 10^{23}$  J for the  
957 complete Titan year. Such an energy imbalance is  $5.0 \pm 2.1\%$  of the total emitted energy for a  
958 complete Titan year. The extrapolated energy imbalance over a complete Titan year is larger than  
959 the energy imbalance during the Cassini epoch because the relatively large energy imbalance  
960 mainly happened in the time period before the Cassini epoch (see Fig. S48).

 1124 Earth's solar power (i.e., solar constant). The solar power is computed by integrating the SSI over  
 1125 wavelength. The time-varying SSI from 2004 to 2017 in the wavelength range 0-200 nm and 200-  
 1126 2400 nm comes from the Solar EUV Experiment (SEE) and the Solar Radiation and Climate  
 1127 Experiment (SORCE), respectively. The climatological SSI in the wavelength range 2400-4000  
 1128 nm comes from American Society for Testing and Materials (ASTM). The SSI in the range 4000-  
 1129 6000 nm is computed by assuming the blackbody spectra with a temperature 5778 K (which  
 1130 matches best the observed SSI over the wavelength range 0-4000 nm), in which the temporal  
 1131 variations of SSI are not considered (see Table S1 for more details).

 1146 **Figure S2.** The SSI, Sun-Titan distance, and solar flux at Titan from 2004 to 2017. (A) The SSI at  
 1147 the distance of Titan. (B) The distance between the Sun and Titan. (C) The solar flux at the distance  
 1148 of Titan. The SSI at the distance of Titan (panel A) is computed by dividing the SSI at Earth (panel  
 1149 A of Fig. S1) by the square of the distance between the Sun and Titan (panel B). The solar flux at  
 1150 Titan is computed by integrating the SSI (panel A) over wavelength.

1172 **Figure S3.** Titan's albedo spectra (305-1050 nm) recorded by the European Southern Observatory  
 1173 (ESO). The two spectra were recorded in 1993 and 1995 with phase angles  $2.7^\circ$  and  $5.7^\circ$   
 1174 respectively. Note that the spectra generated by Karkoschka were derived with the solid radius of  
 1175 Titan  $\sim 2575$  km (see section "Supplementary Observations and Data" in Materials and Methods).  
 1176 Titan's wavelength-dependent effective radii (see section "Effective Radii of Titan's  
 1177 Atmosphere") are considered in the spectra.

**Figure S12.** Titan’s effective radii measured by the Cassini ISS 12 filters. (A) Effective radii at the wavelengths of the ISS 12 filters with low and high phase angles. Note: the CB1 is composed by two sub-filters (CB1a and CB1b). It is hard to differentiate the CB1 observations between CB1a and CB1b. We use the CB1 observations to get the effective radii first. Then we use the slope of effective radii at the neighboring filters (GRN and RED) to interpolate the CB1 results to the wavelengths of CB1a and CB1b. (B) Averaged effective radii at the wavelengths of the ISS 12 filters. We average over the analyses at the low and high phase angles shown in panel A to get the average radii. Vertical lines in the two panels represent the error-bars of the measurements (see section “Effective Radii of Titan’s Atmosphere”).

**Figure S16.** Comparison of Titan's full-disk albedo between the Cassini ISS and VIMS observations. Among the ISS 12 filters, the three violet filters (UV1 ~ 264 nm, UV2 ~306 nm, and UV3 ~ 343 nm) are out of the wavelength range of the VIMS (350-5131 nm). The wavelength of the UV3 filter (343 nm) is close to the low limit of the VIMS wavelength (350 nm), so we keep the ISS UV3 results and compare them with the VIMS measurements at 350 nm (panel A).

**Figure S18.** Comparison of Titan’s full-disk albedo between the Cassini ISS observations and Earth-based observations. The ground-based ESO measurements in 1995 are used (see Fig. S3). Please note that the ESO measurements are based on the observations over Titan’s disk with a solid radius (Fig. S3). We scale the results by the ratio between the ISS measurements with the solid radius and the ISS measurements with the effective radii. The ESO observations were conducted in the effective wavelength range 305-1050 nm with a phase angle  $\sim 5.7^\circ$ , so we use the ISS observations with a phase angle  $5.7^\circ$  for comparison. The ISS UV1 (264 nm) filter is outside of the ESO wavelength range (305-1050 nm). So we use the observations from the HST/FOS (also see Fig. S4). The full-disk albedo from the HST was corrected to zero phase angle, so we use the ISS UV1 measurements at zero phase angle too.

**Figure S24.** Titan’s full-disk albedo observed by the Cassini VIMS. The times (spatial resolutions) for the VIMS observations with phase angles 11.7°, 18.1°, 32.6°, 49.9°, 60.7°, 74.4°, 89.2°, 115.8°, and 144.7° are 2007 (206 km/pixel), 2006 (191 km/pixel), 2007 (147 km/pixel), 2007 (178 km/pixel), 2006 (139 km/pixel), 2008 (147 km/pixel), 2008 (161 km/pixel), 2006 (206 km/pixel), and 2007 (129 km/pixel), respectively. The largest phase angles of the high-quality VIMS observations are 159.1° and 156.1° for the visible part (~350-1046 nm) and the infrared part (~1046-5131 nm), respectively. The observations with the phase angle 159.1° (visible part) were recorded in 2007 with a spatial resolution ~ 151 km/pixel. The observations with the phase angle 156.1° (infrared part) were recorded in 2012 with a spatial resolution ~ 126 km/pixel. We combine the visible spectra at 159.1° and the infrared spectra at 156.1° together (red line).

**Figure S27.** ISS-derived albedo in the two-dimensional domain of phase angle (0-180°) and wavelength (264-939 nm) during the Cassini epoch. The derived albedo is based on the ISS fitted phase functions in Fig. S22 and reference albedo spectra with a high spectral resolution shown in Fig. S3 (40) (see section “Filling Observational Gaps in Wavelength and Time”). Titan’s two-dimensional albedo in each year of the Cassini period of 2004-2017 is derived. Here, only four years (2004-05, 2009, 2013, and 2017) are shown as examples.

**Figure S30.** Titan’s albedo in the complete wavelength range 0-5131 nm during the Cassini epoch. The time-varying albedo in the wavelength range 264-939 nm comes from Fig. S27. The time-varying albedo in the wavelength range 939-5131 nm (outside of the ISS wavelength range but in the VIMS wavelength range) is based on the VIMS fitted results (Fig. S25) and assume the VIMS results have the same temporal variations of those of the ISS CB3 results at 939 nm. The time-varying albedo in the wavelength range 0-264 nm (uncovered by the Cassini ISS & VIMS observations) is based on the albedo spectra from Cassini/UVIS (150-190 nm) the HST/FOS (190-264 nm) and assume that the albedo spectra in the wavelength range 0-150 nm has the same albedo as that at 150 nm. In addition, the phase functions and the corresponding temporal variations from the ISS UV1 (264 nm) observations are used to approximate the phase functions and their temporal variations in the wavelength range 0-264 nm (see section “Filling Observational Gaps in Wavelength and Time”).

**Figure S45.** Ratio between the total uncertainty and the corresponding monochromatic Bond albedo during the Cassini epoch (2004-2017). (A) Total uncertainty. (B) Bond albedo. (C) Ratio between the total uncertainty (panel A) and the corresponding monochromatic Bond albedo (panel B). Panels A and B are the same as panel D of Fig. S43 and panel E of Fig. S31, respectively.

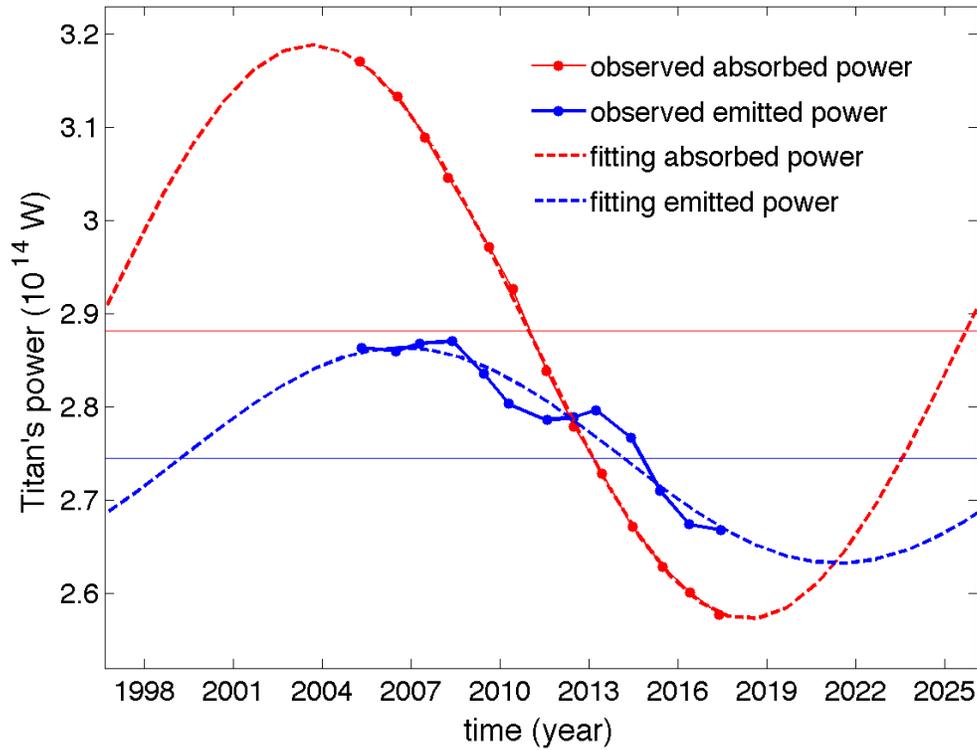

**Figure S46.** Uncertainties in the measurements of Titan’s Bond albedo during the Cassini epoch. (A) Different uncertainties. (B) Uncertainty ratio. The uncertainty ratio is defined as the ratio between the uncertainties shown in panel A and Titan’s Bond albedo (Fig. 1 in main text).

**Figure S48.** Fitted Titan’s absorbed power and emitted power. The observed absorbed power and emitted power are fitted by sine functions with a fixed period – one Titan year (29.424 years). The red and blue horizontal lines represent the annual-mean absorbed power and emitted power, respectively.

**Table S1. Observational Data Sets For Measuring Titan’s Bond Albedo.** The numbers in the parentheses are observational wavelengths and times. The full names of the abbreviations in the table are introduced as below. The ISS, VIMS, and UVIS are three instruments on the Cassini spacecraft. They are Imaging Science Sub-system (ISS), the Visual and Infrared Mapping Spectrometers (VIMS), and Ultraviolet Imaging Spectrograph (UVIS), respectively. The SEE,

2338    SORCE, and ASTM are three data sets for the solar spectral irradiance (SSI). They are the Solar  
 2339    EUV Experiment (SEE), the Solar Radiation and Climate Experiment (SORCE), and the American  
 2340    Society for Testing and Materials (ASTM), respectively. The Pioneer 11/IPP represents the  
 2341    Imaging Photopolarimeter (IPP) on the spacecraft Pioneer 11, whose observations were used to  
 2342    measure the phase function of Titan’s albedo in a previous study. The HST/FOS and ESO stand  
 2343    for the Faint Object Spectrograph (FOS) of the Hubble Space Telescope (HST) and the European  
 2344    Southern Observatory (ESO), respectively. Their observations also provide the albedo spectra of  
 2345    Titan (see sections “Summary of Observational Data Sets” and “Supplementary Observations and  
 2346    Data” for more details and references).  
 2347

<b>Variable</b>	<b>Cassini Observations</b>	<b>Other Observations</b>
solar spectral irradiance (SSI)		SEE (0-200nm, 2004-2017), SORCE (200-2400 nm, 2004-2017), ASTM (2400-4000 nm, climatology), and blackbody spectrum (4000-6000 nm)
phase function	ISS (264-939 nm, 2004-2017) and VIMS (350-5131 nm, 2004-2017)	Pioneer 11/IPP (452 nm (blue) and 648 nm (red), 1979).
spectral observations	ISS (264-939 nm, 2004-2017), VIMS (350-5131 nm, 2004-2017), and UVIS (150-190 nm, 2004).	HST/FOS (190-305 nm, 1991 and 1992) and ESO (305-1050 nm, 1993 and 1995)
