ABSTRACT

This is the second in a series of reports on the use of tracking information from NASA's Syncom II satellite to define the longitude-dependent gravity field of the earth. This tracking information shows that Syncom II drifted freely in the gravity fields of the earth, sun and moon from 25 April to 3 July 1964. In early May, the ascending Equator crossing of the orbit, as determined from radar range and range-rate tracking at the Goddard Space Flight Center, was at 121° West, with a westward drift rate of 0.81 degrees/day. During the following two-month period, this drift rate decreased steadily until late in June when, with the ascending Equator crossing at 161° West, the westward drift rate was 0.75 degrees/day. This decelerating drift rate is entirely consistent with the magnitude and phase angle of the equatorial ellipticity of the earth, as previously determined by this author. These ellipticity constants were responsible for the accelerated drift of this satellite in the longitudes from 55° to 64° West. By utilizing the first (energy) integral of the drift motion of a 24-hour satellite in a second-order longitude-dependent earth gravity field, the drift of Syncom II over the Central Pacific during the two months in question was seen to be sensitive to the following parameters of the earth's equatorial ellipticity.

\[ J_{22} = -(1.71 \pm 0.22) \times 10^{-6} \]

which corresponds to a difference in the major and minor equatorial axes of the earth of \( a_0 - b_0 = 214 \pm 28 \) feet, and

\[ \lambda_{22} = -(17.1 \pm 4.9) \] degrees,

which gives the longitude of the major equatorial axis with respect to Greenwich. These new results confirm the postulate (made in an earlier study) that higher order longitude-dependent earth gravity has small influence on the long term drift of the high-altitude 24-hour satellite. The consistency of the new drift data indicates that the earth's mass inhomogeneities of third order are of smaller magnitude than previously supposed by most geodesists.

C. A. Wagner
Goddard Space Flight Center

INTRODUCTION

This paper is one of a series dealing with the utilization of the Syncom II satellite to gain insight into the exact nature of the earth's gravity field. During long periods between gross orbit change maneuvers initiated by on-board propulsion, this nearly synchronous satellite has remained over limited longitude regions of the earth for a time sufficient for it to accumulate noticeable drift perturbations caused by small longitude mass anomalies within the earth. The first gravity experiment with this satellite (Reference 1) was designed to test the sensitivity of its observed drift to the simplest kind of longitude-dependent gravity; namely, that associated with an earth whose equator is elliptical, not circular. As a result of that experiment the very strong assertion was made that the earth is, in fact, a triaxial ellipsoid whose gross elliptic equatorial "bulge" amounts to between 200 and 250 feet. This new gravity investigation, which essentially confirms the previous result, examines drift data from Syncom II for two months during the period April-June 1964. The mean daily drift rate of the satellite was 0.8 degrees/day during these months, and the nearly figure eight ground track progressively swept over 45° of longitude from 117° West to 163° West.

It was shown in Reference 1 that at a drift rate larger than 0.39 degrees/day a 24-hour satellite with the inclination of Syncom II would circulate completely around the world if left to drift freely. Clearly, Syncom II in April-June 1964 had a period far from "very close to synchronous." The approximate theory of drift as a function of time for such a satellite, used in Reference 1 to analyse Syncom II data from August-February 1963-1964, was not serviceable for this "fast-drift" regime. The essential point is that the "very close to synchronous" theory dealt with long term drift in a limited longitude range. In fact, it assumed that the perturbation force averaged over the orbit referred to a single mean longitude position of the satellite, the longitude at synchronism. For data over a large longitude arc, it has been found most convenient and efficient to use a data reduction theory stemming from the exact expression of drift rate as a function of longitude position for a 24-hour satellite. The important point in the applicability of this theory is that the net longitude drift of the satellite is limited over a single orbit. In the case of Syncom II during
April-June 1964, the small drift of 0.8° per orbit allowed the direct application of the theory to the ascending equator crossing of the satellite. For drift regimes with rates much larger than this, this simple theory for the drift of the ascending equator crossing probably should be modified to apply to the drift of the mean of the longitudes of the ascending equator crossings over a single orbit. Moreover, if the eccentricity of the 24-hour satellite is fairly large, R. R. Allan* suggests that this simple theory for the 24-hour circular orbit satellite would still apply with the longitude position taken as the mean of ascending and descending equator crossings.

At any rate, aside from the use of the first integral of the drift motion instead of the second, the analysis for longitude-dependent earth gravity in this report proceeds with the same basic assumptions as those of the previous report, namely:

1. Only second-order longitude-dependent earth gravity (associated with an earth whose equator is elliptical) was sensed during the long term drift of Syncom II in April-June 1964;
2. All non-gravity perturbations on the orbit of Syncom II during this period were negligible;
3. The earth zonal and sun and moon gravity effects on Syncom II drift can be adequately represented over the span of a few months by a small bias in the reduced results. The bias can be estimated from simulated Syncom II trajectories, numerically integrated, as explained below.

Assumptions 2 and 3 proved good for the previous data analysis. Assumption 1 was not evaluated in that analysis. Calculations of probable higher order earth effects on the bias of recently reported geoids shows (Reference 2) that the Syncom II reduction in Reference 1 for the second-order effect only has a bias of no more than 25% in the reported magnitude of that effect. The major conclusion of this report is that assumption 1 is probably satisfied to a greater degree than this for all the Syncom II drift data thus far available.

The theory of Syncom II drift rate variation in a second order field is presented. The application of this theory to the calculation of the second order field from equator crossing data is then discussed. As shown in Reference 1, this second order drift theory is only strictly exact for a perfectly synchronous satellite, and ignores sun, moon and other earth perturbations. While the errors in the theory due to these sources were proved to be small in the previous Syncom analysis, there is no guarantee that they will be similarly small for the fast drift Syncom II in April-June 1964. Therefore, in order both to verify the theory for this Syncom drift orbit and gain insight into the likely magnitude of these "model errors," the field calculating method stemming from the drift rate theory is tested on simulated Syncom data. This simulated data consists of equator crossings closely paralleling the observed Syncom crossings for this period.

The simulated data is derived by numerical integration of the motion of Syncom II starting from the observed elements in late April 1964. The closely paralleling numerically integrated Syncom trajectory is disturbed by the sun and moon. It is also disturbed by an earth which

*Private communication.
includes, as inputs to the integrating program, two second order longitude gravity constants believed to be close to those for the real earth. The proposed field calculating method, applied to this simulated data, estimates these input constants. The discrepancy between this estimate and the input constants is found to be small. This discrepancy is then taken as a good measure of the model error in the constants derived, in the final section of the report, from the observed Syncom crossing data.

THEORY OF THE REDUCTION

Equation 36 in Reference 1 gives the first integral of the drift motion of a 24-hour satellite in a second-order longitude-dependent earth gravity field as:

\[(\dot{\gamma})^2 = A_{22} \cos 2\gamma + C_1,\]  

(1)

where \(\gamma\) is the geographic longitude of the ascending equator crossing of the 24-hour satellite east of the equatorial minor axis, \(C_1\) is an integration constant for the motion, and \(A_{22}\) is a function of the semimajor axis \((a_s)\) and the inclination \((i_s)\) of the satellite's orbit, the mean radius \((R_0)\) of the earth's equator, and the magnitude \((J_{22})\) of second-order longitude gravity. \(A_{22}\) is given by

\[A_{22} = -72 \pi^2 J_{22} \left(\frac{R_0}{a_s}\right)^2 \left(\frac{\cos^2 i_s + 1}{2}\right).\]  

(2)

Let \(\lambda\) be the geographic longitude of the ascending equator crossing of the 24-hour satellite at a certain time. If \(\lambda_{22}\) is the geographic longitude of the equatorial major axis, then \(\lambda = \gamma - (90^\circ - \lambda_{22})\) from Figure 3 of Reference 2 and Equation 1 can be rewritten as:

\[(\dot{\lambda})^2 = -A_{22} \cos 2(\lambda - \lambda_{22}) + C_1.\]  

(3)

It is evident from Equation 3 that if three sets of simultaneous values of \(\dot{\lambda}\) and \(\lambda\) are available from position and velocity observations on the 24-hour satellite, then a unique set of values of \(A_{22}\), \(\lambda_{22}\) and \(C_1\) can be calculated. These values, together with the known values of \(R_0\), \(a_s\), and \(i_s\), may be used in Equation 2 in order to calculate \(J_{22}\), the magnitude of the second-order longitude gravity effect. To show the form of the "condition equations" for \(A_{22}\) and \(\lambda_{22}\) more explicitly, Equation 3 may be expanded to give

\[(\dot{\lambda})^2 = C_1 + \cos 2\lambda (-A_{22} \cos 2\lambda_{22}) + \sin 2\lambda (-A_{22} \sin 2\lambda_{22}).\]  

(4a)
or

\[(\hat{\lambda})^2 = C_1 + C_2 \cos 2\lambda + C_3 \sin 2\lambda, \]  \hspace{1cm} (4b)

where

\[\lambda_{22} = \frac{1}{2} \tan^{-1} \left( \frac{-C_3}{C_2} \right) \]  \hspace{1cm} (5)

and

\[A_{22} = \left[ C_2^2 + C_3^2 \right]^{1/2}. \hspace{1cm} (6)\]

Thus, three or more sets of \(\hat{\lambda}\) and \(\lambda\) values make it possible to determine a best set of \(C_1, C_2\) and \(C_3\) values from Equation 4; for example, a best set in a "least squares" sense.

From this set "best" values of \(\lambda_{22}\) and \(A_{22}\) can be calculated from Equations 5 and 6. The actual observations on which the reduction from Equation 4 will be based are nine sets of orbital elements for Syncom II calculated at the Goddard Space Flight Center from range and range-rate radar data returned from the satellite during April-June 1964 (see Appendix A). For each of these elements, the longitude of the ascending equator crossing nearest to the epoch of the set plus six hours has been calculated numerically using a zonal gravity field through fourth order and a sun and moon gravity field, both of which are almost identical to the fields used in the orbit determination program for the satellite (Appendix A, Table A-2). This particular ascending equator crossing was chosen as that which fell as close as possible to the center of the observations from which the orbit in question was determined. From these equator crossing longitudes and times, longitude rates were estimated by the ratio of the change in longitude to the time elapsed between successive crossing points. In this way the relatively large daily-periodic effect of the sun and moon on the instantaneous "two-body orbit" drift rate was virtually eliminated from the "basic data" before the actual reduction for the second-order longitude gravity effect began.

The question arises as to what geographic longitude, the longitude rate so calculated, belongs. If there were no acceleration in the longitude drift, it would make no difference where this calculated drift rate was applied. But it is clear that with any small acceleration the correct application point is somewhere near the mean of the two successive longitudes. It is shown in Appendix C that approximating the exact longitude at which this calculated orbit rate should be applied, by the mean of successive longitudes, is sufficiently accurate for the weekly data on Syncom II obtained in April-June 1964.

DATA REDUCTION OF THE SIMULATED SYNCOM II TRAJECTORY OF APRIL-JUNE 1964 FOR THE SECOND-ORDER LONGITUDE GRAVITY EFFECT

This scheme of data reduction based on Equation 4 is now tested for a simulated Syncom II trajectory which begins with the actual orbit elements of epoch 64-04-25-02 U.T. in Appendix A and which closely approximates the actual Syncom II trajectory. In the digital program of this simulation (called "ITEM," Interplanetary Trajectory by an Enke Method, at Goddard Space Flight Center), a basic earth zonal gravity and sun-moon field is used which is identical with that used in the actual Syncom II orbital determination program. In addition, a second-order longitude-dependent earth gravity field with \( J_{22} = -1.68 \times 10^{-6} \) and \( \lambda_{22} = -18^\circ \) is used in the numerical computation of the two-month trajectory. (See Appendix B for the basic data of the simulated trajectory.)

The drift data reduction for this simulated Syncom II trajectory—the reduction for the actual trajectory in the next section follows the same pattern—is described in what follows. Table 1 gives a summary of the reduction.

Column 3 of Table 1 shows the mean longitudes, \( \lambda_i \), upon which the data reduction is made. They are simply the mean longitudes of successive weekly equator crossings listed in column 3 of Table B-2. The corresponding drift rates, \( \dot{\lambda}_i \), (column 4, Table B-2) are the differences in successive longitude crossings divided by the time interval between these crossings. Column 4 of Table 1 is self explanatory as are columns 5, 6 and 7.

As stated in the previous section, the first problem is that of obtaining good values of \( c_1, c_2 \) and \( c_3 \) (in Equation 4) from the data. The general procedure is as follows (this applies to the next section as well). Table 1 gives ten sets of corresponding values of \( \langle \dot{\lambda} \rangle^2 \) and \( \lambda \), but they are inconsistent in the sense that any three sets used in Equation 4 will give values of \( c_1, c_2 \) and \( c_3 \) that in general are not the same as the values obtained for a different set of three. In order to make use of all the data, it is assumed that the \( \lambda \)'s are known exactly but that the values of the \( \langle \dot{\lambda} \rangle^2 \) are subject to slight random error. Then for the \( i \)th set \( \langle \dot{\lambda}_i \rangle^2 = c_1 + c_2 \cos 2\lambda_i + c_3 \sin 2\lambda_i + \epsilon_i \) and the problem is that of establishing a criterion for estimating \( c_1, c_2 \) and \( c_3 \) from the ten equations \( i = 1 \) to 10. The least squares method of estimation (Reference 3) seems most appropriate here, and it requires that those estimates of \( c_1, c_2 \) and \( c_3 \) be chosen which minimize the sum

\[
\sum_{i=1}^{10} \epsilon_i^2
\]

The simple change in notation indicated in the headings of columns 4, 6 and 7 of Table 1 is made in order to conform with the notation used in the statistical literature. When the change in notation is made, the equations take the form
\[ Y_i = X_{1i} c_1 + X_{2i} c_2 + X_{3i} c_3 + \epsilon_i, \quad i = 1, \ldots, 10, \quad X_{1i} = 1 \quad \] (7)

Least squares estimates of \( c_1, c_2 \) and \( c_3 \) (\( \hat{c}_1, \hat{c}_2 \) and \( \hat{c}_3 \)) are found and then the data in column 8, Table 1 is calculated from \( Y_{ei} = X_{1i} \hat{c}_1 + X_{2i} \hat{c}_2 + X_{3i} \hat{c}_3 \). Columns 9 and 10 of Table 1 are self-explanatory.

It is shown in the theory of least squares estimation (Reference 3) that the \( \hat{c}_i \)'s must satisfy the so-called normal equations:

\[ \sum_{i=1}^{N} Y_i X_{1i} = \hat{c}_1 \left[ \sum_{i=1}^{N} X_{1i} X_{1i} \right] + \hat{c}_2 \left[ \sum_{i=1}^{N} X_{1i} X_{2i} \right] + \hat{c}_3 \left[ \sum_{i=1}^{N} X_{1i} X_{3i} \right], \quad (8) \]

\[ \sum_{i=1}^{N} Y_i X_{2i} = \hat{c}_1 \left[ \sum_{i=1}^{N} X_{2i} X_{1i} \right] + \hat{c}_2 \left[ \sum_{i=1}^{N} X_{2i} X_{2i} \right] + \hat{c}_3 \left[ \sum_{i=1}^{N} X_{2i} X_{3i} \right], \quad (9) \]

\[ \sum_{i=1}^{N} Y_i X_{3i} = \hat{c}_1 \left[ \sum_{i=1}^{N} X_{3i} X_{1i} \right] + \hat{c}_2 \left[ \sum_{i=1}^{N} X_{3i} X_{2i} \right] + \hat{c}_3 \left[ \sum_{i=1}^{N} X_{3i} X_{3i} \right]. \quad (10) \]

From Table 1, those mixed-product sums for the simulated drift data which are not calculated at the bottoms of the columns in Table 1 are

\[ \sum_{i=1}^{N} Y_i X_{2i} = 4.06013 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2, \]

\[ \sum_{i=1}^{N} Y_i X_{3i} = 16.97526 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2, \]

\[ \sum_{i=1}^{N} X_{2i} X_{3i} = 1.484560. \]

Equations 8, 9 and 10 for the simulated Syncom drift of Table 1 are therefore:

\[ 19.6626 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 = 10.0000\hat{c}_1 + 2.27791\hat{c}_2 + 8.57387\hat{c}_3 \quad (11) \]
\[ 4.06013 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 = 2.27791 \hat{C}_1 + 2.43213 \hat{C}_2 + 1.48456 \hat{C}_3 \quad (12) \]

\[ 16.97526 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 = 8.57387 \hat{C}_1 + 1.48456 \hat{C}_2 + 7.56780 \hat{C}_3 \quad (13) \]

The solution of Equations 11, 12 and 13 for \( \hat{C} \) may be accomplished by any convenient algorithm. We choose to use the inverse of the right side coefficient matrix for this solution because the elements of the inverse are also statistically valuable (see Equation 34).

The inverse of the matrix of coefficients on the right sides of Equations 11, 12 and 13 is found to be

\[
\begin{bmatrix}
8.305427 & -2.312087 & -8.955996 \\
-2.312087 & 1.110737 & 2.401565 \\
-8.955996 & 2.401565 & 9.807638
\end{bmatrix}
\]

When \((\text{COEFF})^{-1}\) is multiplied by the \(1 \times 3\) matrix of left side constants of Equations 11, 12 and 13, the \(1 \times 3\) matrix

\[
\begin{bmatrix}
\hat{C}_1 \\
\hat{C}_2 \\
\hat{C}_3
\end{bmatrix}
\]

is found to be

\[
\hat{C}(\text{simulated data}) = \begin{bmatrix}
1.88855 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 \\
-0.18471 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 \\
0.13970 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2
\end{bmatrix}
\quad (15)
\]

From Equations 15 and 5 the "best" value of \( \lambda_{22} \) for the drift data in Table 1 is

\[
\hat{\lambda}_{22,\text{sim}} = \frac{1}{2} \tan^{-1} \left( \frac{-\hat{C}_1}{\hat{C}_2} \right) = \frac{1}{2} \tan^{-1} \left( \frac{0.13970}{0.18471} \right) = -18.4^\circ . \quad (15a)
\]
Similarly, Equations 15 and 6 give

\[
\left( \hat{\lambda}_{22} \right)_{\text{simulated}} = \left( \hat{\chi}_{2,\text{sim.}}^2 + \hat{\chi}_{3,\text{sim.}}^2 \right)^{1/2} = 23.15 \times 10^{-6} \left( \frac{\text{rad}}{\text{solar day}} \right)^2
\]

\[
= 23.15 \times 10^{-6} \times \left( \frac{1436.06817}{1440.00000} \right) \left( \text{solar day} \right)^2
\]

\[
= 23.02 \times 10^{-6} \left( \frac{\text{rad}}{\text{solar day}} \right)^2
\]

(16)

Data from Table B-1, Appendix B used in Equation 2 yields

\[
\left( \lambda_{22} \right)_{\text{sim.}} = \left( J_{22} \right)_{\text{sim.}} \left[ -72 \times \pi^2 \times \left( \frac{6378.4}{42230.01} \right)^2 \left( \cos^2 32.6^\circ + \frac{1}{2} \right) \right]
\]

\[
= \left( J_{22} \right)_{\text{sim.}} \left( -13.86 \right) \left( \frac{\text{rad}}{\text{solar day}} \right)^2
\]

(17)

From Equations 16 and 17 the "best" value of \( J_{22} \) for this simulation, according to the drift theory presented in Chapter 2, is

\[
\hat{J}_{22,\text{sim.}} = -\frac{23.02 \times 10^{-6}}{13.86} = -1.66 \times 10^{-6}
\]

(18)

The simulation actually used the following values of \( J_{22} \) and \( \lambda_{22} \):

\[
J_{22,\text{sim.}} = -1.68 \times 10^{-6}
\]

\[
\lambda_{22,\text{sim.}} = -18.0^\circ
\]

(19)

Comparison of Equations 15a and 18 with Equation 19 shows that the "model error" of the drift theory presented in the previous section, which ignored drift rate changes due to sun, moon and earth zonal gravity influences, accumulates a small bias in the results for \( J_{22} \) and \( \lambda_{22} \) calculated according to the simple theory for a two-month simulated Syncom II drift which closely approximates the actual drift in this period (Figure 1). This model bias (ignoring higher order earth longitude gravity effects) in \( J_{22} \) calculated from the theory for this two-month drift is estimated from the above results of the simulated data reduction as

\[
J_{22,\text{sim.}} - \hat{J}_{22,\text{sim.}} = -1.68 \times 10^{-6} + 1.66 \times 10^{-6}
\]

\[
= -0.02 \times 10^{-6}
\]

(20)
The model bias in $\lambda_{22}$ is estimated as

$$
\lambda_{22, \text{sim}} - \lambda_{22, \text{sim}} = -18.0 + 18.4 = +0.4^\circ
$$

**REDUCTION OF NINE SYNCOM II ORBITS IN APRIL-JUNE 1964 TO DETERMINE THE ELLIPTICITY OF THE EARTH'S EQUATOR**

Table A-1 in Appendix A lists nine orbits in April-June 1964 for Syncom II computed at GSFC from range and range-rate information without taking into account the anomalous gravity field due to the ellipticity of the earth's equator. Figure 1 shows the observed steady decrease in the westward drift rate of the mean longitude of the satellite for 45° of drift excursion over the Central Pacific in this period. This rate decrease is closely paralleled by that in the simulated drift of Syncom II using a longitude-dependent gravity field which includes sun, moon and high-order earth zonal components. Other simulated trajectories have shown minor, negligible drift rate changes over a duration of time measured by months if longitude-dependent earth gravity is not used in the simulation. The experience with the simulated Syncom II trajectory (the previous section and Appendix B), which closely agrees with or closely parallels the actual drift, gives us confidence that the simple reduction theory used successfully in the previous section to determine equatorial ellipticity from the simulated data can be applied as successfully to determine equatorial ellipticity from the actual data. The following Table 2 of drift data has been derived from Appendix A using the nine orbits of Syncom II in April-June 1964.

From Table 2, the mixed product sums not calculated at the bottoms of the columns are:

$$
\sum Y_i X_{2i} = 2.87010 \times 10^{-4} \left(\frac{\text{rad}}{\text{day}}\right)^2
$$

$$
\sum Y_i X_{3i} = 13.17124 \times 10^{-4} \left(\frac{\text{rad}}{\text{day}}\right)^2
$$

$$
\sum X_{2i} X_{3i} = 1.19093
$$

*On 30 April 1964.
†On 20 June 1964.
Following the technique of data reduction according to the 24-hour satellite drift theory discussed in the previous section, the normal equations for the "best" values (in the least squares sense) of the ellipticity-drift rate parameters \( c \) are:

\[
\begin{align*}
14.957 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 &= 8\hat{c}_1 + 1.69938\hat{c}_2 + 7.00505\hat{c}_3, \\
2.87010 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 &= 1.69938\hat{c}_1 + 1.74089\hat{c}_2 + 1.19093\hat{c}_3, \\
13.17124 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 &= 7.00505\hat{c}_1 + 1.19093\hat{c}_2 + 6.25910\hat{c}_3.
\end{align*}
\]

The inverse of the matrix of coefficients on the right sides of Equations 22, 23 and 24 is:

\[
(COEFF)^{-1} = \begin{bmatrix}
14.008120 & -3.3905080 & -15.032469 \\
-3.3905080 & 1.4810135 & 3.5127885 \\
-15.032469 & 3.5127885 & 16.315400
\end{bmatrix}
\]

The ellipticity-drift rate parameters

\[
\begin{align*}
(\hat{c}_1) \\
(\hat{c}_2) \\
(\hat{c}_3)
\end{align*}
\]

are then found to be:

\[
\hat{c}(\text{actual data-unadjusted for model error}) = \begin{bmatrix}
1.79210 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 \\
-0.19339 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 \\
0.13546 - 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2
\end{bmatrix}
\]

Thus, from Equations 26 and 5 the best value (unadjusted) of \( \lambda_{22} \) (actual) as sensed by the drift of Syncom II in April-July 1964 is

\[
\hat{\lambda}_{22} (\text{actual data-unadjusted}) = \frac{1}{2} \tan^{-1} \left( \frac{-\hat{c}_3}{\hat{c}_2} \right) = \frac{1}{2} \tan^{-1} \left( \frac{-0.13546}{0.19339} \right)
\]

\[= -17.5^\circ.\]
For the Syncom II elements in Appendix A, using \( a_s \) and \( i_s \) from the second set of elements in the drift period (since they are probably better determined than the first), Equation 2 gives

\[
A_{22} = J_{22} \left[ -72n^2 \times \left( \frac{6378.4}{42228.8} \right)^2 \right] \left[ \frac{\cos^2 32.6^\circ + 1}{2} \right]
\]

\[
= -J_{22} (13.859) \left( \frac{\text{rad}}{\text{sid day}} \right)^2. \tag{28}
\]

From Equations 26 and 6, the best value (unadjusted) of \( A_{22} \) (actual data) as sensed by the drift of Syncom II in April-July 1964 is

\[
\hat{A}_{22} \text{(actual data-unadjusted)} = \left( \hat{C}_2^2 + \hat{C}_3^2 \right)^{1/2} = 23.6 \times 10^{-6} \left( \frac{\text{rad}}{\text{solar day}} \right)^2
\]

\[
= 23.6 \times 10^{-6} \left( \frac{\text{rad}}{\text{solar day}} \right)^2 \times 0.99455 \left( \text{sol. day} \right)^2
\]

\[
= 23.47 \times 10^{-6} \left( \frac{\text{rad}}{\text{sid day}} \right)^2. \tag{29}
\]

Equations 28 and 29 show that the best value (unadjusted) of the magnitude of the equatorial ellipticity of the earth sensed by Syncom II in April-July 1964 is

\[
\hat{f}_{22} \text{(actual data-unadjusted)} = -1.69 \times 10^{-6}. \tag{30}
\]

In adjusting the values given by Equations 27 and 30 for "model error" by means of the biases found in the simulated Syncom II trajectory, it is assumed that all influences on Syncom II drift in this period other than earth, sun and moon gravity, are negligible (see DISCUSSION). The data reduction of the simulated Syncom II trajectory in April-June 1964 in the previous section showed that the simple drift theory presented herein produced a bias in the reduced \( J_{22} \) of \(-0.02 \times 10^{-6}\) and a bias in the reduced \( \lambda_{22} \) of \(+0.4^\circ\). Application of these biases adjusts Equations 27 and 30 for all but higher order longitude-dependent earth gravity effects and gives

\[
\hat{f}_{22} \text{(actual data-adjusted)} = -(1.69) \times 10^{-6} - 0.02 \times 10^{-6} = -1.71 \times 10^{-6}. \tag{31}
\]

\[
\hat{\lambda}_{22} \text{(actual data-adjusted)} = -17.5^\circ + 0.4^\circ = -17.1^\circ. \tag{32}
\]

To gain insight into the allowable variations of \( J_{22} \) and \( \lambda_{22} \) due to the errors of observation and effects not accounted for (model errors) in this gravity experiment, the simplifying assumption
is made that all deviations \( (\epsilon, \text{ in Tables 1 and 2}) \) of the actual or simulated data from the theoretical data are random and are normally distributed with mean zero and variance \( \sigma^2 \). It is to be noted that the "best values" from the simulated data reduction established a most likely "systematic" error in \( J_{22} \) and \( \lambda_{22} \) for the actual experiment. This systematic error was due to all imperfections in the simple model tested by the simulation and equivalent imperfections are likely to be present in the real data (see DISCUSSION).

If the above assumption is made for the deviations \( \epsilon \) in the simulated data, then an unbiased estimate of \( \sigma^2 (\epsilon_{\text{sim}}) \) calculated from the data of Table 1 is

\[
S^2 (\epsilon_{\text{sim}}) = \frac{4.4260 \times 10^{-12}}{10 - 3} \left( \frac{\text{rad}}{\text{day}} \right)^4 = 0.6323 \times 10^{-12} \left( \frac{\text{rad}}{\text{day}} \right)^4.
\]

An unbiased estimate of the standard deviation \( S \) is

\[
S (\epsilon_{\text{sim}}) = \sqrt{(0.6323 \times 10^{-12})^{1/2}} = 0.7952 \times 10^{-6} \left( \frac{\text{rad}}{\text{day}} \right)^2.
\]

It can be seen that only for \( i = 8 \) in Table 1 is the error greater than \( 2S (\epsilon_{\text{sim}}) \) for the experiment as a whole.

The statistical theory for normal distributions (Reference 3) shows that the parameters \( \hat{C}_j \) of the normal equations have expected values \( C_j \) (the actual drift-ellipticity parameters tested for) and variances \( \sigma^2 \), where

\[
\sigma^2 \hat{C}_j = \left( \sigma^2 (\epsilon) \right) (\text{COEFF}_{jj})^{-1}.
\]

\( (\text{COEFF}_{jj})^{-1} \) denotes the diagonal element in the \( j \)th row and \( j \)th column of the inverse of the coefficient matrix of the normal equations for the experiment. An unbiased estimate of \( \sigma^2 \) is

\[
S^2 (\hat{C}_j) = \left( S^2 (\epsilon) \right) (\text{COEFF}_{jj})^{-1}.
\]

It follows from Equation 34, using the values given by Equations 33 and 14, that

\[
S_{C_{2,\text{sim}}}^2 = 0.7952 \times 10^{-6} \times 0.0084 = 0.00984 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2.
\]

\[
S_{C_{3,\text{sim}}}^2 = 0.7952 \times 10^{-6} \times 0.0250 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2.
\]
Thus the standard deviation bounds on \( \hat{\epsilon}_{2,\text{sim.}} \) and \( \hat{\epsilon}_{3,\text{sim.}} \) are

\[
\hat{\epsilon}_{2,\text{sim.}} = -(0.1847 \pm 0.0084) \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 ,
\]

\[
\hat{\epsilon}_{3,\text{sim.}} = (0.140 \pm 0.025) \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 .
\]

The same theory applied to the actual Syncom II data in Table 2 yields

\[
\sigma^2 (\epsilon_{\text{act.}}) = \frac{7.106 \times 10^{-12}}{8 - 3} \left( \frac{\text{rad}}{\text{day}} \right)^4 = 1.4212 \times 10^{-12} \left( \frac{\text{rad}}{\text{day}} \right)^4 ,
\]

and

\[
\sigma (\epsilon_{\text{act.}}) = 1.192 \times 10^{-6} \left( \frac{\text{rad}}{\text{day}} \right)^2 .
\]

Comparison of Equations 39 and 33 shows that the standard error of the simulated experiment (which is free from "observation error") is not much smaller than that of the experiment on the actual data. In Reference 1 it was found that the actual experiment had a standard error about five times that of the simulated. Evidently the set of orbits for Syncom II in April-June 1964 is of much greater precision than those of the two earlier long drift periods.

For the actual Syncom II data treated in the same fashion as the simulated data, the gravity experiment leads to the bounds on \( C \) computed below.

Unbiased estimates of \( \sigma \hat{\epsilon}_{2,\text{act.}} \) and \( \sigma \hat{\epsilon}_{3,\text{act.}} \) are

\[
\sigma \hat{\epsilon}_{2,\text{act.}} = 1.192 \sqrt{1.4817} \times 10^{-6} = 0.0145 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 ,
\]

and

\[
\sigma \hat{\epsilon}_{3,\text{act.}} = 1.192 \sqrt{16.31547} \times 10^{-6} = 0.0481 \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 .
\]

Thus the standard bounds on \( \hat{\epsilon}_2 \) and \( \hat{\epsilon}_3 \) in the actual experiment are

\[
\sigma \hat{\epsilon}_{2,\text{actual data}} = -(0.1934 \pm 0.0145) \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 .
\]

\[
\sigma \hat{\epsilon}_{3,\text{actual data}} = (0.1355 \pm 0.0481) \times 10^{-4} \left( \frac{\text{rad}}{\text{day}} \right)^2 .
\]
It can be seen that though the standard error of the actual experiment is only 1.5 times that of the simulated, the standard bounds on $\hat{C}$ are more nearly twice that in the simulated experiment. This is most probably due to the fact that two additional data points which sense the equatorial ellipticity were used in the simulated experiment.

In establishing standard bounds on $\hat{J}_{22}$ and $\hat{\lambda}_{22}$ from the experiments, all possible combinations of these quantities from the standard bounds on $\hat{C}_2$ and $\hat{C}_3$ are not computed. Clearly, the chance of obtaining $\hat{C}_2 + S_2$ and $\hat{C}_3 + S_3$ simultaneously from the experiment is less than the chance of obtaining a single standard deviation for each separately. In Appendix E the bounds on the adjusted values of $J_{22}$ and $\lambda_{22}$ sensed by the Syncom II drift in April-July 1964 are computed as

$$J_{22} \text{ (actual data)} = -(1.71 \pm 0.22) \times 10^{-6},$$

$$\lambda_{22} \text{ (actual data)} = -(17.1 \pm 4.9^o).$$

**DISCUSSION**

The Syncom II drift data reduction for sensitivity to the equatorial ellipticity of the earth, used in this report, is open to a number of lines of criticism.

In the first place it may be fairly asked whether the observed decrease in drift rate can be explained by some force not considered here. The direct evidence of agreement in almost all particulars between the observed trajectory of Syncom II during the period analysed and a simulated trajectory using a recent set of gravity constants for the earth, sun and moon make it unlikely that such an "outside force" could have had appreciable influence on the drift. A number of such possible outside influences on the orbital energy of the satellite were discussed in Reference 1. Solar radiation pressure was found to have an effect on Syncom II less by many orders of magnitude than that of solar gravity. It has never been proven that gas leaks from the on-board propulsion units during the long drift periods. Even if it did, it would not change the energy of the satellite appreciably provided that the accidental unrecorded "on times" of this leakage were reasonably distributed around the spin cycle of the satellite. The magnitude of effects due to micrometeorite drag on the satellite is difficult to estimate because of insufficient data on this phenomenon.

With respect to all "outside influences" except higher order earth longitude gravity, the almost exact prediction on the basis of longitude-dependent earth gravity alone of the long term drift deceleration between 120° West and 165° West from the observed acceleration between 55° West and 65° West (Reference 1) makes it even more unlikely that any such influence had appreciable effect on Syncom II during its "free drift" periods.
A second line of criticism of the gravity results summarized in Equations 44 and 45 stems from the uncertainty of the separation of systematic and random errors in the experiment. The assumption made in the statement of error bounds in Equations 44 and 45 is that all errors in the observed drift rate are randomly distributed about that theoretically calculated from the model. If the unknown "systematic error" due to high-order longitude gravity is ignored, the results of the simulated trajectory reduction appear to show that "model error" was the principal "noise" source in the actual gravity experiment. This is to say that the systematic error due to the insufficiency of the model to predict the exact results in a full gravity field gives, when treated as a random effect, a standard experimental error only somewhat smaller than that associated with the actual data. Furthermore, one can see directly from Figure 1 the close parallelism of drift rate deviations between the actual and simulated trajectories. These facts suggest that the small overall systematic errors of the simulated experiment (for example, \(0.02 \times 10^{-6}\) in \(J_{22}\) and \(0.4^\circ\) in \(\lambda_{22}\)) are closer to the actual order of magnitude of the standard errors of the ellipticity parameters than that reported in Equations 44 and 45. In other words, the "best" results from the actual experiments are perhaps closer to reality (neglecting higher order gravity effects), with bounds half as wide as reported and with the same degree of confidence.

On the other hand, preliminary, less-refined reductions of more limited Syncom 11 data in this period gave evidence of a longitude effect near the limits of the bounds in Equations 44 and 45 with only a small increase in the standard experimental error. Hence it is felt that until a more refined analysis of this data is undertaken to remove "model error" point for point, Equations 44 and 45 give fair, at best, conservative bounds on the ellipticity of the earth's equator as seen by Syncom 11 during two months of drift over the Central Pacific.

When these results are compared with those for Syncom 11 drift over Brazil (Reference 1) and with expected results on the basis of higher order effects as predicted from other sources of gravity data (Reference 2), it would appear that when the full longitude field is finally mapped the "true" value of \(J_{22}\) will be closer to \(-1.7 \times 10^{-6}\) than \(-1.9 \times 10^{-6}\) as predicted in Reference 2. What this means is that the earth's third-order longitude mass deviations (to which Syncom 11 is next most sensitive) are probably of smaller extent than previously supposed. Exact statements on the bounds of higher order gravity effects as sensed by Syncom 11 must wait on an integrated analysis of all the drift data for this satellite.

**CONCLUSIONS**

1. The steadily decreasing drift rate of Syncom 11 during a two-month excursion over the Central Pacific in April-July 1964 confirms the extent and location of earth equatorial ellipticity predicted earlier from observations on this satellite over Brazil.

2. The results of this new Syncom 11 gravity experiment show a difference in the major and minor radii of the earth's elliptical equator of

\[
a_0 - b_0 = 214 \pm 28 \text{ feet} \quad \left[ J_{22} = -(1.71 \pm 0.22) \times 10^{-6} \right]
\]
The longitude location of the semi-major axis of the earth's elliptical equator as sensed by Syncom II during this period is

\[ \lambda_{22} = -(17.1 \pm 4.9)° \]

3. The above results combined with the results of the independent gravity experiment with this satellite when it was over Brazil (Reference 1) indicate that the earth is more homogeneous, to at least third order, than has been supposed.

4. Tentatively, the "best parameters" of equatorial ellipticity as seen by Syncom II to date are

\[ J_{22} = -1.7 \times 10^{-6} \]

\[ \lambda_{22} = -18° \]

5. Only second-order longitude-dependent earth gravity need be considered in the design of station keeping systems for future 24-hour satellites, and this without appreciable modification for longitude location.

ACKNOWLEDGMENT

Acknowledgment and appreciation are expressed to Joyce Berman of Bethesda, Maryland, summer student in a National Science Foundation Program, who, with patience and accuracy, carried through many of the laborious data reductions incident to this measurement of the earth's shape.

(Manuscript received June 3, 1965)

REFERENCES

Appendix A

Orbital Elements and Partially Reduced Drift Data for Syncom II During April-June 1964

Table A-1 gives the elements for Syncom II during April-June 1964 as derived from radar range and range-rate data in the Goddard Space Flight Center's Data Systems and Tracking Directorate. By means of the particle trajectory digital program called "Item" at GSFC, ascending equator crossing longitudes and times nearest to the epoch dates in Table A-1 plus six hours were calculated. These are listed in Table A-2. The choice of epoch date plus six hours was mainly dictated by the desire to use the crossing that was closest to the "center of gravity" of the data that went into the determination of the orbit. The gravity field used for the short term trajectories in these calculations was virtually the same as that used in the orbit determination program that calculated the elements used at the start of each trajectory (see Appendix D). The only difference was the inclusion of $J_{22}$ and $\lambda_{22}$ in the earth potential of the particle trajectories. Since the values for these constants used in the "Item" program are close to "reality," it is likely that the ascending equator crossings so calculated are even more accurate than an estimation of them made by using precisely the same field as that in the orbit determination program.

Table A-1

Orbital Elements for Syncom II in April-June 1964 as Calculated in the Data Systems and Tracking Directorate at the Goddard Space Flight Center from Radar Range and Range Rate Data (Orbit 12).

NOTES:
The data in columns 2 and 3 were derived from the elements in Table A-1 by the numerical calculation of particle trajectories in an earth, sun and moon gravity field specified by the constants in Table B-2. The longitude rates in column 4 are the first longitude differences of column 3 divided by the first time differences of column 2.
Appendix B

Orbital Elements and Partially Reduced Drift Data from the Simulated Syncom II Trajectory During April-June 1964

Table B-1 gives the set of elements at weekly ascending equator crossing times during a simulated Syncom II trajectory (computed numerically by GSFC's "Item" Program) beginning with the actual elements of Syncom II, epoch 64-04-25-02. The gravity field of the particle trajectory was exactly that used in the orbit determination program for Syncom II with the addition of equatorial ellipticity introduced into the geoid of amount and location given by the constants

\[ J_{22} = -1.68 \times 10^{-6} \]

and

\[ \lambda_{22} = -18^\circ \]

(See Appendix D for a representation of the geoid used in the simulation.)

</table>
In Figure B-1 the elements numerically calculated during this trajectory (semi-major axis and inclination) are compared with those actually reported for Syncom II in April-June 1964. It is noted that among all the elements, only the semimajor axis shows a significant discrepancy in the simulated trajectory. The results in the two sections on data reduction show that the long term trend of the semi-major axis changes after the initial epoch is very well explained by the drift theory of this report. It should be understood that instantaneous drift rate changes of the ground track of the 24-hour satellite are coupled directly to semimajor axis changes by Kepler's third law which relates the semimajor axis to the period of the instantaneous orbit and the central, or gaussian, gravity constant of the principal attracting body.

It is seen in Figure B-1 that the simulated semimajor axes are on an average about one kilometer greater than the actual ones throughout the trajectory. This agrees well (in terms of Kepler's third law) with the drift rate differences between the two trajectories at corresponding

![Graph showing orbital data from Syncom II observations in April-July 1964 compared to data from a numerically integrated trajectory in a full earth, sun and moon field, beginning with the Syncom II elements of Epoch 64-04-25-02 U.T.](image)

Figure B-1—Orbital data from Syncom II observations in April-July 1964 compared to data from a numerically integrated trajectory in a full earth, sun and moon field, beginning with the Syncom II elements of Epoch 64-04-25-02 U.T.
times (Figure 1). This discrepancy then is probably due to the relatively large error in the determination of the semimajor axis for Syncom II (and used in the simulation) at the start of the drift period, epoch 64-04-25-02.

Table B-2 gives drift rate and longitude data from the numerically computed simulated trajectory.

\lambda_{22} &= -18.0^\circ.
\end{align*}
\]
Appendix C

The Error in Estimating that the Mean Velocity of an Accelerating Trajectory Between Two Points in Space Occurs Midway Between the Points

Suppose that a point $m$ at $t = 0$ is at $S = S_0$ with velocity $v = v_0$ and moves with constant acceleration, $a$. On the assumption that $S$, $v$ and $a$ are colinear, the $(S, t)$ graph for the motion is given by

$$S = \frac{1}{2} at^2 + v_0 t + S_0 . \quad (C1)$$

The graph is plotted in Figure C1. The velocity, $v$, at any time in the interval is

$$v = \frac{ds}{dt} = at + v_0 . \quad (C2)$$

and the mean or average velocity, $\bar{v}$, over the time interval $t_1$ is

$$\bar{v} = \frac{v_0 + v_{t_1}}{2} . \quad (C3)$$

since the motion is uniformly accelerated. But at $t_1$ the velocity, from Equation C2 is

$$v_{t_1} = at_1 + v_0 . \quad (C4)$$

Hence, from Equations C3 and C4,

$$\bar{v} = a \left( \frac{t_1}{2} \right) + v_0 . \quad (C5)$$

Comparison of Equations C5 and C2 shows that $\bar{v}$ is the instantaneous velocity of the point at the $t = t_1/2$. The position of the point at this time is, from Equation C1,

$$S' = \frac{1}{2} a \left( \frac{t_1}{2} \right)^2 + v_0 \left( \frac{t_1}{2} \right) + S_0 . \quad (C6)$$

Figure C-1. The $(s, t)$ graph corresponding to the one-dimensional trajectory of a point with constant acceleration.
Now $\Delta s$ (Figure C-1) is clearly

$$\Delta s = \frac{1}{2} at^2 + v_0 t_1 = \ddot{v} \Delta t. \quad \text{(C7)}$$

Hence in estimating $s'$ by $s_0 + \Delta s/2$ an error $\Delta s_e$ is introduced given by

$$\Delta s_e = S_0 + \frac{\Delta s}{2} - S' = S_0 + a \frac{t_1^2}{4} + v_0 \frac{t_1}{2} - a \frac{t_1^2}{8} - v_0 \frac{t_1}{2} - s_0,$$

or

$$\Delta s_e = \frac{at_1^2}{8}.$$

(C8)

If $a$ or $t_1^2$ or both are small, $\Delta s_e$ may be sufficiently small to validate the estimation.

Syncom II drift is given, in terms of the longitude acceleration, as

$$\ddot{\lambda} = A_{22} \sin 2(\lambda - \lambda_{22}). \quad \text{(C9)}$$

Considering the right side of Equation C9 a constant for a limited excursion of $\lambda$, the solution of Equation C9 is in the form of Equation C1 with

$$\lambda = s$$

and

$$A_{22} \sin 2(\lambda - \lambda_{22}) = a.$$

The maximum value of $|A_{22} \sin 2(\lambda - \lambda_{22})|$ is reached when $2(\lambda - \lambda) = \pm \pi/2$, and $\pm 3\pi/2$. From the earlier Syncom II gravity experiment (Reference 1), it was determined that $J_{22} = -1.7 \times 10^{-6}$. For $a_s = 42230$ km and $i_s = 32.6^\circ$ (the Syncom II orbit parameters in April-June 1964),

$$A_{22} = -72\pi^2(R_0/a_s)^2 \left(\cos^2 \frac{i_s}{2} + 1\right) = -23.0 \times 10^{-6} \left(\frac{\text{rad}}{\text{day}}\right)^2.$$

Thus $|a(\text{max.})|$ for this drift period is

$$23.0 \times 10^{-6} \left(\frac{\text{rad}}{\text{day}}\right)^2.$$
From Equation C8, the maximum error made in assigning the mean interval drift rate of Syncom II to the mid-longitude of an interval traversed in ten days is

\[ \Delta \lambda_c = \frac{23 \times 10^{-6} \times 100 \times 57.3}{8} = 0.0165^\circ. \]

This error is sufficiently small to be ignored in the overall data reduction. Thus, in assigning the mean longitude in a Syncom II drift interval of the order of 10 days to the mean drift rate in that interval, one need retain only two decimal figures in the longitude location.
Appendix D

The Earth Gravity Potential and Force Field Used in this Report

The gravity potential used as the basis for the data reduction in this study is the exterior potential of the earth derived in Reference D-1 for geocentric spherical coordinates referenced to the spin axis and the center of mass of the earth. The infinite series of spherical harmonics is truncated after $J_{44}$. The zonal harmonic constants $J_{20}$, $J_{30}$ and $J_{40}$ are derived from Reference D-2.

The radius of the earth, $R_e$, used in this study is

$$R_e = 6378.388 \text{ km}$$

The earth's gaussian gravity constant used is

$$\mu_E = 3.9862677 \times 10^5 \frac{\text{km}^3}{\text{sec}^2}$$

Neither of these values, taken from Reference D-3, nor the "zonal geoid" of Reference D-2, is felt to be the most accurate known to date. They are the values used by the GSFC Tracking and Data Systems Directorate to calculate the orbit elements of Syncom II from radar and Minitrack observations. They were chosen to insure consistency between the data of this study and these published orbits, inasmuch as the "triaxial" reduction for which this study has been undertaken is not significantly affected by the probable errors in these values. The second-order longitude harmonic constants used in the simulation studies were

$$J_{22} = -1.68 \times 10^{-6}$$

and

$$\lambda_{22} = -18^\circ$$

These are the values shown or implied on the "longitude geoid" below (for the $J_{22}$ harmonic). At a later point in the analysis, the slightly different values reported in the abstract were estimated. The most accurate "zonal geoid" is probably that of Kozai (cited in Reference D-4) with the following
earth constants;

\[ R_e = 6378.2 \text{ km}, \quad J_{20} = 1082.48 \times 10^{-6}, \quad J_{30} = -2.56 \times 10^{-6}, \]

\[ \mu_e = 3.98603 \times 10^5 \frac{\text{km}^3}{\text{sec}^2}, \quad J_{40} = -1.84 \times 10^{-6}. \]

The earth's gravity potential as used in the simulations of this report (to fourth order, probably sufficient to account for all significant perturbations on a 24-hour satellite) may be illustrated (following Reference D-4, Appendix B, with the zonal constants of Reference D-2) as follows:

\[
V_E = \frac{\mu_e}{R} \left[ 1 - \frac{J_{20} R_e^2}{2r^2} \left( 3 \sin^2 \phi - 1 \right) - 3J_{22} \frac{R_e^2}{r^2} \cos^2 \phi \cos 2(\lambda - \lambda_{22}) \right. \\
- \frac{J_{30} R_e^3}{2r^3} \left( 5 \sin^3 \phi - 3 \sin \phi \right) - \frac{J_{31} R_e^3}{2r^3} \cos \phi \left( 15 \sin^2 \phi - 3 \right) \cos \left( \lambda - \lambda_{31} \right) \\
- \left. 15J_{32} \frac{R_e^3}{r^3} \cos^2 \phi \sin \phi \cos 2(\lambda - \lambda_{32}) - 15J_{33} \frac{R_e^3}{r^3} \cos^3 \phi \cos 3(\lambda - \lambda_{33}) \right].
\]
The earth gravity field (per unit test mass) whose potential is Equation D1 is given as the gradient of Equation D1, or

\[
\mathbf{F} = \hat{r} F_r + \hat{\lambda} F_\lambda + \hat{\phi} F_\phi = \nabla V_E = \frac{\partial V_E}{\partial r} \hat{r} + \frac{1}{r \cos \phi} \frac{\partial V_E}{\partial \lambda} \hat{\lambda} + \frac{1}{r} \frac{\partial V_E}{\partial \phi} \hat{\phi},
\]  

(D2)
or

\[
F_r = \frac{\mu_e}{r^2} \left\{ -1 + (R_0/r)^2 \left[ \frac{3}{2} J_{20} (3 \sin^2 \phi - 1) + 9 J_{22} \cos^2 \phi \cos 2(\lambda - \lambda_{22}) \right. \right.
\]
\[
+ 2 (R_0/r) J_{30} (5 \sin^2 \phi - 3) \sin \phi + 6 (R_0/r) J_{31} (5 \sin^2 \phi - 1) \cos \phi \cos (\lambda - \lambda_{31})
\]

\]
\[
+ 420 (R_0/r)^2 J_{44} \cos^3 \phi \sin 4(\lambda - \lambda_{44}) \right\} \]  \quad \text{(D4)}

\[
F_\phi = \frac{\mu_e}{r^2} (R_0/r)^2 \left\{ -3 J_{20} \sin \phi \cos \phi + 6 J_{22} \cos \phi \sin \phi \cos 2(\lambda - \lambda_{22}) \right.
\]
\[
- \frac{3}{2} (R_0/r) J_{30} (5 \sin^2 \phi - 1) \cos \phi + \frac{3}{2} (R_0/r) J_{31} (15 \sin^2 \phi - 11) \sin \phi \cos (\lambda - \lambda_{31})
\]
\[
+ 15 (R_0/r) J_{32} (3 \sin^2 \phi - 1) \cos \phi \cos 2(\lambda - \lambda_{32})
\]
\[
+ 45 (R_0/r) J_{33} \cos^2 \phi \sin \phi \cos 3(\lambda - \lambda_{33}) - \frac{5}{2} (R_0/r)^2 J_{40} (7 \sin^2 \phi - 3) \sin \phi \cos \phi
\]
\[
+ \frac{5}{2} (R_0/r)^2 J_{41} [28 \sin^4 \phi - 27 \sin^2 \phi + 3] \cos (\lambda - \lambda_{41})
\]
\[
+ 30 (R_0/r)^2 J_{42} (7 \sin^2 \phi - 4) \cos \phi \sin \phi \cos 2(\lambda - \lambda_{42})
\]
\[
+ 105 (R_0/r)^2 J_{43} (4 \sin^2 \phi - 1) \cos^2 \phi \cos 3(\lambda - \lambda_{43})
\]
\[
+ 420 (R_0/r)^2 J_{44} \cos^3 \phi \sin \phi \cos 4(\lambda - \lambda_{44}) \right\} \]  \quad \text{(D5)}
The actual sea-level surface of the earth is to be conceptualized through Equation D1 as a sphere of radius 6378 km, around which are superimposed the sum of the separate spherical harmonic deviations illustrated. To these static gravity deviations, of course, must be added a centrifugal earth-rotation potential deviation at the earth's surface, to get the true sea level surface (see Reference D-1).

REFERENCES

Appendix E

Estimation of the Standard Error for a Function of Several Variables
Whose Standard Errors, in an Experiment, are Known

Let \( z = z(x_1, x_2, \cdots x_n) \) be the theoretical relationship between \( z \) and a number of variables \( x_i \). Let \( \Delta X_1, \Delta X_2, \cdots \Delta X_n \) be small errors of estimation in each of the \( x_i \) variables. Then from the theorem for the total differential of a function of many variables:

\[
\Delta z = \sum_{i=1}^{n} \frac{\partial z}{\partial x_i} \Delta x_i \tag{E1}
\]

Equation E1 represents the error made in \( z \) for a single trial \( k \) at estimating the \( x_i \)'s. Thus from one estimation \( k \) of the \( x_i \)'s, Equation E1 gives

\[
\Delta z_k = \sum_{i=1}^{n} \frac{\partial z}{\partial x_i} \Delta x_{ik} \tag{E2}
\]

Conceive now of a large number \( M \) of independent estimates \( k \) of the \( x_i \)'s each giving a different error of estimation \( \Delta x_{ik} \). One can ask from this extended experiment what will be the most likely value of the sums of the squares of the individual deviations \( \Delta z_k \).

Thus, from Equation E2

\[
\sum_{k=1}^{M} (\Delta z_k)^2 = \sum_{k=1}^{M} \left( \sum_{i=1}^{n} \frac{\partial z}{\partial x_i} \Delta x_{ik} \right)^2
\]

\[
= \sum_{k=1}^{M} \left( \sum_{i=1}^{n} \left( \frac{\partial z}{\partial x_i} \right)^2 \Delta x_{ik}^2 + 2 \sum_{i, j=1}^{n} \frac{\partial z}{\partial x_i} \frac{\partial z}{\partial x_j} \Delta x_{ik} \Delta x_{jk} \right)
\]

\[
= \sum_{i=1}^{n} \left( \frac{\partial z}{\partial x_i} \right)^2 \sum_{k=1}^{M} \Delta x_{ik}^2 + 2 \sum_{i, j=1}^{n} \frac{\partial z}{\partial x_i} \frac{\partial z}{\partial x_j} \sum_{k=1}^{M} \Delta x_{ik} \Delta x_{jk} \tag{E3}
\]
It is clear that if the \( \Delta X_{ik} \)'s are distributed with reasonable symmetry about zero, the value of

\[
\sum_{k=1}^{M} \Delta X_{ik} \Delta X_{jk}
\]

will be close to zero for \( M \) sufficiently large. In fact, the expected or most likely value of this sum can probably be shown to be zero for any \( M \) when the \( \Delta X_{ik} \)'s are reasonably symmetrically distributed about the expected value of \( \Delta X_{ik} \), which is zero.

Using this result in Equation E3, it is found that

\[
E \left[ \sum_{k=1}^{M} (\Delta Z_{k})^2 \right] = E \left[ \sum_{i=1}^{n} \left( \frac{\partial Z}{\partial X_i} \right)^2 \sum_{k=1}^{M} \Delta X_{ik}^2 \right],
\]

where \( E[ \cdot ] \) indicates the expected value of \( \cdot \), or

\[
\sum_{k=1}^{M} E(\Delta Z_{k}^2) = \sum_{i=1}^{n} \left( \frac{\partial Z}{\partial X_i} \right)^2 \sum_{k=1}^{M} E(\Delta X_{ik}^2). \tag{E4}
\]

Equation E4 follows from the theorem that the expected value of a sum of random variables is the sum of the expected values of those random variables.* But the expected value of \( \Delta Z_{k}^2 \) is just the variance \( \sigma_Z^2 \) of \( Z \), and the \( E(\Delta X_{ik}^2) \) are just the variances of each variable \( X_i \),

\[
E(\Delta X_{ik}^2) = \sigma_{X_i}^2.
\]

Thus Equation E4 becomes

\[
M \sigma_Z^2 = \sum_{i=1}^{n} \left( \frac{\partial Z}{\partial X_i} \right)^2 \left( M \sigma_{X_i}^2 \right),
\]

or

\[
\sigma_Z^2 = \sum_{i=1}^{n} \left( \frac{\partial Z}{\partial X_i} \right)^2 \sigma_{X_i}^2. \tag{E5}
\]

The standard deviation of $Z$ is thus

$$\sigma_Z = \sqrt{\frac{\sum_{i=1}^{n} \left( \frac{\partial Z}{\partial X_i} \right)^2 \sigma_{X_i}^2}{\sum_{i=1}^{n} \left( \frac{\partial Z}{\partial X_i} \right)^2}}^{1/2} \quad (E6)$$

In an experiment with a limited amount of data on the $X_i$ and $\sigma_{X_i}$, if estimates of these, $\hat{X}_i$ and $S_{X_i}$, are obtained, then from Equation $E6$ an estimate of $\sigma_Z$ is

$$S_Z = \left[ \frac{\sum_{i=1}^{n} \left( \frac{\partial Z}{\partial X_i} \right)^2}{\sum_{i=1}^{n} \left( \frac{\partial Z}{\partial X_i} \right)^2} S_{X_i}^2 \right]^{1/2} \quad (E7)$$

In the Syncom II data reduction for $J_{22}$ and $\lambda_{22}$ by way of the ellipticity-drift parameters $C_1$, $C_2$, $C_3$, the functional relationships between $J_{22}$, $\lambda_{22}$ and these parameters are (Equations 5, 6 and 2):

$$\lambda_{22} = \frac{1}{2} \tan^{-1} \left( \frac{-C_3}{C_2} \right) \quad (E8)$$

$$A_{22} = \left( C_2^2 + C_3^2 \right)^{1/2} \quad (E9)$$

$$J_{22} = A_{22} \left[ -72n^2 \left( R_0/a_s \right)^2 \left( \cos^2 i_s + 1 \right) \right] \quad (E9a)$$

Applying Equation $E7$ to Equations $E8$ and $E9$ gives

$$S_{\lambda_{22}} = \frac{1}{2(\tilde{C}_2^2 + \tilde{C}_3^2)} \left[ (\tilde{C}_2)^2 \left( S_{C_3} \right)^2 + (\tilde{C}_3)^2 \left( S_{C_2} \right)^2 \right]^{1/2} \quad (E10)$$

$$S_{A_{22}} = \left( \tilde{C}_2^2 + \tilde{C}_3^2 \right)^{1/2} \left[ (\tilde{C}_2)^2 \left( S_{C_2} \right)^2 + (\tilde{C}_3)^2 \left( S_{C_3} \right)^2 \right]^{1/2} \quad (E10a)$$

Using the values of $S_{\tilde{C}_2}$, $S_{\tilde{C}_3}$, $\tilde{C}_2$ and $\tilde{C}_3$ from the actual gravity experiment, Equations 40 through 43, in Equations $E10$ and $E10a$ gives

$$S_{\lambda_{22,\text{actual}}} = \frac{1}{2(0.1934^2 + 0.1355^2)} \left[ (0.1934 \times 0.0481)^2 + (0.1355 \times 0.0145)^2 \right]^{1/2}$$

$$= 0.0852 \text{ radians} = 4.87^\circ \quad (E11)$$
\[ S_{22, \text{actual}} = \frac{10^{-4} \, \text{(rad/day)}^2}{(0.1934^2 + 0.1355^2)^{1/2} \left[ (0.1934 \times 0.0145)^2 + (0.1355 \times 0.0481)^2 \right]^{1/2}} \]

\[ = 3.00 \times 10^{-6} \, \text{(rad/solar day)}^2 = 3.00 \times 10^{-6} \, \text{(rad/solar day)}^2 \times 0.9945 \left( \frac{\text{sol day}}{\text{sid day}} \right)^2 \]

\[ = 2.98 \times 10^{-6} \, \text{(rad/sid day)}^2. \]

Thus,

\[ S_{22, \text{actual}} = \frac{2.98 \times 10^{-6}}{13.859} \left[ \text{See (28)} \right] = 0.215 \times 10^{-6}. \]

(E12)

The "best values of \( J_{22} \) and \( \lambda_{22} \) sensed from Syncom II drift over the Central Pacific with their standard errors given by Equations E11 and E12, are thus:

\[ J_{22} = (1.71 \pm 0.22) \times 10^{-6}, \]

\[ \lambda_{22} = -(17.1 \pm 4.9)^\circ. \]

(E13)

"The aeronautical and space activities of the United States shall be conducted so as to contribute . . . to the expansion of human knowledge of phenomena in the atmosphere and space. The Administration shall provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof."

—National Aeronautics and Space Act of 1958

NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

TECHNICAL REPORTS: Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

TECHNICAL NOTES: Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

TECHNICAL MEMORANDUMS: Information receiving limited distribution because of preliminary data, security classification, or other reasons.

CONTRACTOR REPORTS: Technical information generated in connection with a NASA contract or grant and released under NASA auspices.

TECHNICAL TRANSLATIONS: Information published in a foreign language considered to merit NASA distribution in English.

TECHNICAL REPRINTS: Information derived from NASA activities and initially published in the form of journal articles.

SPECIAL PUBLICATIONS: Information derived from or of value to NASA activities but not necessarily reporting the results of individual NASA-programmed scientific efforts. Publications include conference proceedings, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

Details on the availability of these publications may be obtained from:
