POLARIZATION AND INTENSITY MEASUREMENTS
OF HYDROGEN LYMAN ALPHA IN THE DAY AIRGLOW

Since the discovery of hydrogen Lyman alpha in the night airglow in 1955 by
Byram, et al., (1957) and the spectrophotometric measurements of the night and
day airglow in 1962 by Fastie, et al., (1964) numerous experiments have been
flown and theories proposed to explain the source, and the intensity of Ly-\alpha.1
Brandt and Chamberlain (1960) discussed the importance of a polarization meas-
urement for understanding the hydrogen problem.

This paper is concerned with the measurements of polarization and intensity
in the day airglow of Ly-\alpha. The polarization and intensity were measured as a
function of altitude for the principal far ultraviolet day airglow emission features
from 1200Å to 2000Å. These included the hydrogen Ly-\alpha line at 1216Å, the
resonance lines of OI at 1304Å, and the group at 1355Å, and an unidentified
source of emission in the region from 1450Å to 2000Å. The experimental details
of the multichannel, far ultraviolet, polarization photometer, and the measure-
ments of the features other than Ly-\alpha will be treated in separate papers.

This experiment, with experiments for measuring direct solar Ly-\alpha, the
broad band solar flux in four intervals from 1450Å to 3000Å and two electron
density and temperature probes were flown on an Aerobee 150 rocket from White
Sands, New Mexico. The flight from WSMR (latitude 32°24' north, longitude

1A summary of these works is contained in a review paper by Donahue (1966)
7h05° west) was initiated at 8:20 A.M. M.S.T. on August 29, 1966. At the time of launching, the three hour geomagnetic planetary index was Kp = 2. During the previous 3 hour period, the index was Kp = 4, which marked the end of 5 quiet days. The rocket carried, in addition to its experimental payload, a solar aspect sensor and two magnetometers. The attitude of the rocket was controlled by an inertial attitude control system², and it reached a peak altitude of 200 km. At the time of launch the solar zenith angle was 58° and its azimuth 10° south of east. The geomagnetic field at WSMR is at 60° elevation, and 12.5° west of south in azimuth. A zenith-azimuth angle plot of the photometer view as a function of flight time is given in figure 1.

The polarization photometer had a field of view of 4.0° (0.39 × 10⁻² steradians). A geneva action filter wheel successively interposed; no filter, calcium fluoride, barium fluoride, sapphire, and a blank. For each filter position the analyzer rotated through an angle of 720°. The filters provided the short wavelength cut-offs, and the "solar blindness" of the cathode of an ASCOP 542G photomultiplier limited the long wavelength response. Consequently the signals from the five filter wheel positions were due to radiation from 1200A-2000A, 1230A-2000A, 1335A-2000A, 1435A-2000A, and the dark current. The signal currents were detected and converted into a telemetry input voltage with a four decade range switching linear electrometer. Subtractive techniques were used to isolate the signal in wavelength intervals 1435A-2000A, 1335A-1435A, 1230A-1335A, and 1200A-1230A. The relative intensities are accurate to ±2-3%, while the absolute intensities which were obtained by calibration against a NO ionization cell are thought to

be accurate to ±15%. In reducing the data it was assumed that the principal day airglow emission in the interval from 1200Å-1435Å are those reported by Fastie, et al. 1964.

The transmission polarization analyzer consisted of 8 cleaved plates of lithium fluoride which were set at Brewster's angle for the incident Ly-α radiation. The analyzer had measured major and minor principal transmittances at 1216Å of $k_1 = 0.088$ and $k_2 = 0.0037$ respectively. The transmittance of the analyzer for unpolarized light is given by the relation.

$$T = \frac{1}{2} (k_1 + k_2) \quad (1)$$

where $k_1$ and $k_2$ are transmittances measured parallel to and perpendicular to the plane of maximum transmission for linear polarized light. The degree of linear polarization is given by the relation

$$P = \frac{k_1 + k_2}{k_1 - k_2} \left( \frac{I_{\text{max}} - I_{\text{min}}}{I_{\text{max}} + I_{\text{min}}} \right) \quad (2)$$

where $I_{\text{max}}$ and $I_{\text{min}}$ are the maximum and minimum of the telemetry signals resulting from the rotation of the analyzer.

The altitude profile of the intensity of Ly-α (kilorayleighs) for the down leg portion of the flight is given in figure 2. Prior to $t = 234$ seconds all radiation channels showed evidence of scattered light. This corresponds to solar illumination of the photometer axis at angles less than 80°. The maximum intensity

---

5 The polarization analyzer was fabricated by the Harshaw Chemical Co.
6 For Ly-α 1 kR = $1.30 \times 10^{-3}$ ergs/cm² sec steradian
was about 20 kR with a possible increase of 1 kR between 200 km and 130 km. The triangular and the adjacent circular data points give the magnitude of the horizon-azimuth effect which amounts to an increase of 37% in going from a zenith angle of 32° to 65° and in azimuth from 304° to 351°.

The direct solar Ly-α flux measured at apogee was 5.8 ergs/cm² sec.

No polarization of Ly-α was detectable, and from an analysis of the telemetry records one can state that the maximum possible polarization is less than 1.5%. Two sample telemetry records are shown in figure 3. The upper one (A) is representative of the Ly-α data after t = 234 sec. The lower record (B) is typical of those showing the effect of sunlight which was polarized (P = 19%) by scattering off the baffle of the photometer. For (B) the solar flux was incident at 58° to the axis of the photometer.

The polarization of resonance radiation is directly related to the Zeeman effect which depends upon level hyperfine structure. Brandt and Chamberlain (1960) have calculated that at 90° to the sun the total Ly-α line should show a polarization of 16% for completely separated hyperfine levels, and 27% for no hyperfine splitting of the upper 2P3/2 level. These results are for single scattering so consequently the polarization would be reduced for multiple scattering.

Donahue (1966) made resonance scattering calculations of the zenith intensity above 120 km, as a function solar zenith angle for different optical thicknesses measured above 100 km based on the 1962 solar flux. A zenith intensity of 14 kR for a solar zenith angle of 60° would require about 3.5 optical thickness above 100 km, or about 1.8 optical thicknesses above 120 km. The problem which
should be investigated is how many optical thicknesses of hydrogen are required above 200 km so that an initial polarization of 16–27% for single resonance scattering is reduced to less than 1.5% through multiple scattering.

Alternatively Kondo and Kupperian (1967) have proposed that a part of the diffuse night Ly-α glow is due to the interaction of neutral hydrogen with the charged particles in the radiation belts. Their theory predicts a general increase of intensity in the direction of the geomagnetic poles, and a decrease in the direction of the geomagnetic equator. This mechanism does offer a source of unpolarized radiation.

In conclusion, the polarization photometer measurements require a composite source to explain the Ly-α day airglow. Multiple resonance scattering is required to explain the absence of polarization. In support of this there are the recent mass spectrometer measurements on Explorer 32 by Reber (1967) which indicate there is much more neutral hydrogen than was previously believed. Finally a collisional source of excitation such as proposed by Kondo and Kupperian (1967) is necessary to explain the horizon brightening.
