TUNNEL DIODE LOW-LEVEL DETECTION

By W. F. Gabriel

Goddard Space Flight Center
Greenbelt, Md.
ABSTRACT

An analysis of tunnel diode low-level detection is presented for the purpose of explaining some of the unusual detection characteristics that occur under certain bias conditions. For example, in the vicinity of its inflection bias point, a tunnel diode exhibits a discriminator-like rectification behavior with two sensitivity peaks. When biased at one of these peaks, the diode is capable of unusually high sensitivities, at least an order of magnitude better than the sensitivity of any other known diode. It is shown that these high sensitivities are proportional to \((1 - \Gamma^2)\), where \(\Gamma^2\) is the RF power gain of the detector viewed as a reflection-type amplifier. The resultant gain-bandwidth (or sensitivity-bandwidth) limitations of the detector are discussed. Unusually high sensitivities are also possible at the lower microwave frequencies when the tunnel diode is biased at its peak current point.

A knowledge of the diode static characteristics, the reflection coefficient, and the video circuit permits an accurate analytical evaluation of the sensitivity performance of any tunnel diode, and calculations are carried out for an example diode and compared against measured data. This report also contains a specific comparison of the relative sensitivity performance of the example tunnel diode vs. a hot carrier diode.

INTRODUCTION

Microwave low-level detection, which was entirely dependent upon the rather unpredictable silicon point-contact crystal rectifier (Reference 1) for so many years, has been advanced considerably by the development of tunnel diode (or back diode) detectors and hot carrier diode detectors. Both of these solid junction devices have demonstrated advantages of lower noise (particularly 1/f noise), higher rectification current sensitivity, low temperature variation, high burn-out capability, high resistance to noise impulse generation under shock and vibration, aging stability, broad bandwidth capability, and accurate analytical performance evaluation from measured static characteristics.

The excellent performance of the hot carrier diode under bias conditions has been reported in the literature (References 2 and 3), together with an adequate analysis. In the case of the tunnel diode, however, despite numerous references (References 4 to 10) reporting on specific examples of sensitivity performance, the analyses are found to be restricted and incomplete such that important features of the overall behavior of this versatile detector are overlooked. For instance, it is not generally appreciated that the tunnel diode, when biased in its negative resistance region, is capable of at least an order of magnitude greater sensitivity than any other diode detector for frequencies below resistive cutoff. Also, that it is capable of bi-polar amplitude modulation of its video output. The former capability can be of considerable advantage in sensitive TRF (tuned radio frequency) receivers (References 11 and 12) such as those employed in compact solid-state transponders for missiles, spacecraft, and aircraft.

The purpose of this report is to present a low-level detector analysis which is general enough to cover tunnel diode behavior for any bias condition, and to demonstrate detection features which are peculiar to the tunnel diode. Super-regenerative detection and converter action are not included in this discussion; i.e., the tunnel diode detector circuit is assumed to be in a stable condition at all times.

In the work described herein, the rectification current sensitivity, $\beta$, is expressed as a function of the reflection coefficient, $\Gamma$. It is shown that a knowledge of this quantity, together with the diode static characteristics and the video circuit, permits accurate analysis of low-level detection performance for any bias condition. Calculations are carried through on an example diode and compared against measured data.
When a tunnel diode detector is biased in its negative resistance region and operated below resistive cutoff frequency, it is an RF amplifier and must look into an impedance that insures stable operation; i.e., it requires a non-reciprocal isolator or circulator to insure stability against spurious oscillations. As an amplifier, it exhibits the usual gain-bandwidth limitations. Examples of sensitivity behavior versus RF bandwidth are also discussed.

The final section of the report discusses diode figure of merit, \( M \), and here a specific comparison with the hot carrier diode is made in order to illustrate relative sensitivity capability.

**EQUIVALENT CIRCUIT AND DIODE CHARACTERISTICS**

Microwave low-level detectors usually consist of a combination of transmission line circuits and lumped reactances, plus the diode. The complete detailed equivalent circuit can be quite complicated, particularly in the case of broadband designs, but for the purposes of the present analytical discussion it is preferably to reduce it to the simple equivalent circuit shown in Figure 1. This circuit is referenced to the diode junction and is often utilized for diode analysis (References 13 to 17). Circuit elements \( R_g \) and \( L \) are both functions of frequency since they represent the series equivalent of the impedance that includes the diode series inductance, the diode package capacitance, and the entire external RF input circuit.

The differential junction resistance, \( R \), may assume either positive or negative values. When it is negative, the circuit represents a negative-resistance reflection-type amplifier where the voltage gain is simply equal to the reflection coefficient, \( \Gamma \), referred to \( R_g \), i.e.,

\[
\Gamma = \frac{(Z - R_g) - R_g}{(Z - R_g) + R_g} = \frac{Z - 2R_g}{Z}.
\]

where \( Z \) is the total series impedance of the circuit.

\[
Z = \left[ R_g + R_s + \frac{R}{1 + (\omega CR)^2} \right] + j \left[ \omega L - \frac{R(\omega CR)}{1 + (\omega CR)^2} \right].
\]

This type of tunnel diode amplifier and its stability considerations are widely discussed in the literature (References 13 to 21). Circuit stability criteria must be satisfied at all frequencies below the resistive cutoff frequency in order to insure finite values for \( \Gamma \) and avoid spurious oscillations.
For Figure 1, a safe and sufficient (Reference 18) stability criterion* may be written in the form,

\[ |R| > (R_s + R_e) > \frac{L}{|R||C|} \text{ for negative } R. \]  \hspace{1cm} (3)

A small-signal analysis of the Figure 1 circuit is carried out in Appendix A for the purpose of deriving a general expression for \( \beta \). This shows that the basic diode quantities required are \( G \), \( R_s \), \( C \), and \( G' \), where \( G' \) is the first derivative of the diode differential junction conductance, \( G \). (Note that \( G \) is the reciprocal of \( R \), so that the determination of either quantity is sufficient. Both will be utilized freely in accordance with their convenience to the discussion.) Of these quantities, all except \( C \) can be evaluated from the measured static V-I (voltage-current) characteristic. For purposes of practical illustration and experimental confirmation, the measured characteristics of an actual diode example, a selected MS-1012 back diode, will be utilized throughout the discussion.

A back diode (Reference 21) or "backward diode," as they are sometimes called, is simply a tunnel diode with a low peak current wherein the "forward voltage" direction is reversed (backwards) from the usual tunnel diode polarity. This reversed presentation happens to be very convenient for comparison with other types of diode detectors because it results in the same direction of rectified current flow for typical bias conditions, and so it will be utilized throughout this report. Figure 2 illustrates the V-I characteristic of the example diode and also that of a typical hot carrier diode. Three distinct bias points, labelled "o", "p", and "i", are denoted on the back diode curve because (1) they are often referred to throughout the report and (2) they are frequently used as subscripts on the voltage and current;

"o" - refers to the diode zero bias point,
"p" - refers to the diode peak current bias point,
"i" - refers to the diode inflection bias point.

Although the low peak current \( (I_p = -0.286 \text{ma}) \) qualifies the example diode to be called a back diode, it will be referred to as a tunnel diode throughout this report because (1) it has a

\*In addition to the RF circuit, the detector video circuit and d.c. bias circuit must also satisfy their stability criteria.
resistive cut-off frequency of about 9 Gc, and, (2) it was chosen specifically to demonstrate the detection behavior that can be obtained when biased into the negative resistance region.

A calculation of the derivatives, $G$ and $G'$ from Figure 2 requires an analytical expression for the tunnel diode current. This problem is treated in Appendix B, and the results are plotted in Figure 3 for the diode voltage range of greatest interest. Note that the voltage scale in Figure 3 is the diode junction voltage instead of the diode bias voltage; i.e.,

$$V_b = V + IR_s,$$

where $V$ is the internal junction voltage and $V_b$ is the external bias voltage across the diode terminals. The junction voltage is required for the calculations. The expressions $G$ and $G'$ for a tunnel diode behave in a different manner than the similar derivatives of a hot carrier or point contact diode in that they do not bear a constant ratio to one another, they do have a zero point, and they can assume negative values as well as positive values.

The diode series resistance, $R_s$, can be found from the forward conduction characteristic (a standard technique) as described in Appendix B, if it is not given as part of the manufacturer's data. A value of 8 ohms for $R_s$ was measured on the example diode with an estimated accuracy of 5 percent.

Diode junction capacitance $C$ must be measured if not given by the manufacturer. Applicable measurement techniques include the familiar RF bridge (Reference 22) method, microwave impedance determination, or resistive cut-off frequency determination. For the example diode, the latter approach was employed. The resistive cut-off frequency, $f_r$, occurs at...
the point where the equivalent series resistance of the diode goes to zero, and it is readily shown that

$$f_r = \frac{\sqrt{|R|}}{2\pi C|C|} - 1$$

for negative $R$.\(\text{(5)}\)

Since the total series resistance is zero at $f_r$, it follows that the diode will look like a short circuit at resonance whereby $\Gamma = -1$. Thus, the technique consists of tuning the detector to resonance at any convenient microwave frequency, and recording the bias voltage required to give a reflection coefficient exactly equal to unity at that frequency. The frequency thereby becomes an $f_r$ value; $R_s$ is known; $R$ can be determined from Figure 3b since the bias voltage is known; and this then permits solving for $C$ from Equation 5. A value of 0.3 picofarads was arrived at for the example diode via this technique.

The $f_r$ technique is easy to implement and use, and it has a great advantage in that it is independent of the diode package capacitance.

**RECTIFICATION CURRENT SENSITIVITY, $\beta$**

The rectification current sensitivity, $\beta$, is defined as the ratio of the detector rectified output current, $I_r$, to the RF power, $P_i$, incident upon the detector, or

$$I_r = \beta P_i \text{.}\(\text{(6)}\)$$

A general equation for $\beta$ is derived in Appendix A on the basis of a small-signal analysis of the detector equivalent circuit shown in Figure 1,

$$\beta = \frac{2G^* R_s |Z_j|^2}{(1 + G R_s) |Z|^2}$$

where

$$Z_j = \frac{1}{G + j\omega C} \text{.}\(\text{(8)}\)$$

and $Z$ is given by Equation 2. Equation 7 holds for either positive or negative values of $G$, subject to the restriction that the tunnel diode circuit be stable. An inspection of the various terms in Equation 7 shows that $\beta$ will vary principally as a function of three parameters:

(a) diode bias voltage

(b) equivalent source resistance, $R_s$

(c) frequency
A variation in the diode bias voltage causes a variation in $G$ and $G'$ as illustrated in Figure 3. Junction capacitance, $C$, also changes with bias, (Reference 15) but the effect is of minor importance compared to $G$ and $G'$.

$R_g$ determines the reflection coefficient, $\Gamma$, as given by Equation 1.* Because of the familiar interpretation of $\Gamma$ for tunnel diodes and the fact that it is a readily measured microwave quantity, it becomes desirable to convert the series impedance, $Z$, in Equation 7 to $\Gamma$. Solving for $Z$ from Equation 1 results in,

$$Z = \left( \frac{2R_g}{1-\Gamma} \right),$$

(9)

and substituting this into (7) permits $\beta$ to be written as

$$\beta = \frac{G' \cdot |(1-\Gamma)|^2}{2R_g (1+GR_g) \left[G^2 + (\omega C)^2\right]}. $$

(10)

It will be noted that $\beta$ can increase almost in direct proportion to the RF power gain, $|\Gamma|^2$, of the tunnel diode, thus indicating the possibility of very large current sensitivities.

Equation 10 can be manipulated into several interesting forms by applying appropriate restrictions upon $\Gamma$ and $G$. If we apply the restriction that $\Gamma$ be real (circuit resonance condition), then from Equations 2 and 1:

$$Z = R_g + R_s + r,$$

(11)

and

$$\Gamma = \frac{R_s + r - R_g}{R_s + r + R_g},$$

(12)

where

$$r = \frac{R}{1 + (\omega C R)^2}.$$  

(13)

$r$ is the equivalent series resistance of the diode junction. Solving for $R_g$ from Equation 12 and substituting into Equation 10 results in

$$\beta_1 = \beta_0 \left[ \frac{(1-\Gamma^2)}{1 + (\frac{R_s G (\omega C R)^2}{R + R_g})} \right] \quad \text{Restrictions:} \quad \Gamma \text{ is real}$$

(14)

*This interpretation is dependent upon $R_g$ representing only the generator source resistance. If $R_g$ includes any loss components, then Equation 1 and Equation 7 must be corrected to incorporate the loss factor.
where

\[ \beta_0 = \frac{G'}{2G(1 + GR_s)^2} \]  

(15)

If we next restrict \( G \) to positive values only, then Equation 14 may be written as,

\[ \beta_2 = \beta_0 \left[ \frac{1 - \Gamma^2}{1 + \left(\frac{f}{f_c}\right)^2} \right] \quad \text{Restrictions:} \]

\[ \Gamma \text{ is real} \]
\[ G \text{ is positive} \]

(16)

where

\[ f_c = \frac{\sqrt{|R_s| + 1}}{2\pi CR} \]  

(17)

Equation 16 applies to hot carrier and point contact diodes as well as tunnel diodes. The frequency \( f_c \) is the usual "cutoff" frequency defined for diodes. For a positive \( G \), \( |\Gamma| \leq 1 \), so that the optimum value of \( \beta_2 \) occurs for matched conditions, i.e., \( \Gamma = 0 \), whereupon Equation 16 becomes identical to the usual current sensitivity expressions found in the literature (References 1 and 3).

A special form for \( \beta \) occurs when we impose the restriction of biasing the tunnel diode at its peak current point \((I_p, V_p)\) where \( G \) goes to zero. From Equations 9, 10, and 11 one obtains the simple expression

\[ \beta_\sigma = \frac{G'(1 - \Gamma^2)}{2R_s (\omega C)^2} \quad \text{Restrictions:} \]

\[ \Gamma \text{ is real} \]
\[ G \text{ is zero} \]

(18)

Like \( \beta_2 \) above, \( \beta_\sigma \) is optimized for \( \Gamma = 0 \).

If we restrict \( G \) to negative values only, then Equation 14 may be written as

\[ \beta_3 = \beta_0 \left[ \frac{1 - \Gamma^2}{1 - \left(\frac{f}{f_r}\right)^2} \right] \quad \text{Restrictions:} \]

\[ \Gamma \text{ is real} \]
\[ G \text{ is negative} \]

(19)

where

\[ f_r = \frac{\sqrt{|R| - 1}}{2\pi C |R|} \]  

(20)

the frequency \( f_r \) will be recognized as the resistive cutoff frequency of a tunnel diode, above which the diode cannot supply RF gain; i.e., \( |\Gamma| < 1 \) for \( f > f_r \). It follows that for \( f > f_r \), \( \beta_3 \) will be optimized when \( \Gamma = 0 \).
When \( f = f_r \), the \( \beta_3 \) expression becomes indeterminate and one must go back to the general Equation 10 to compute \( \beta \), utilizing the fact that \( \Gamma = -1 \) for this particular condition.

Finally, when \( f < f_r \), Equation 12 shows that \( |\Gamma| > 1 \) and may be made arbitrarily large by adjusting \( R_o \), so that no optimum value for \( \beta_3 \) can be defined and it may be increased without limit, at least in theory.

A plot of the two frequencies, \( f_c \) and \( f_r \), vs. bias for our example tunnel diode is shown in Figure 4. Knowing these values, it is then a simple matter to compute the gross frequency behavior of \( \beta \) from Equations 16 or 19 for a given \( \Gamma \). The data points shown in Figure 4 were the frequencies at which \( f_r \) measurements were made in order to determine the value of the diode junction capacitance (refer back to pages 4 and 5 for description of measurement).

Figure 5 illustrates the gross frequency behavior of \( \beta \) for the example diode under various bias conditions and specified values of \( \Gamma \). The optimum curves for zero bias, \( v = -0.02 \) volts, and \( v = -0.04 \) volts are calculated from Equation 16 since \( G \) is positive, and the \((\beta_0 f_c)\) product tends to be constant for these positive conductance bias conditions. The zero bias curve shows good sensitivity capability in the millimeter-wave frequency region.

The optimum curve for the peak current bias point, \( v_p = -0.046 \) volts, is calculated from Equation 18 since \( G \) is zero, and it demonstrates the unique 6 db per octave constant slope obtained for
this particular bias condition. Note that this constant slope behavior results in unusually high sensitivities at the lower microwave frequencies, and full advantage may be taken of this if the circuit losses can be kept small; i.e., the detector circuit Q is inversely proportional to frequency \( Q = \frac{1}{2 \pi CR} \) for the \( v_p \) bias condition.

The dashed-line curve for \( v = -0.07 \) volts, \( \Gamma = -10 \), and \( f < f_r \) is calculated from Equation 19 since \( G \) is negative, and it clearly shows the high sensitivities that can be obtained at microwave frequencies below resistive cut-off when a tunnel diode is biased in its negative resistance region. An interesting feature of this curve is that \( \beta \) tends to approach infinity as the frequency approaches \( f_r \). This behavior is simply the result of assuming a constant value for \( \Gamma \), whereby the circuit Q would increase rapidly as \( f_r \) was approached. In actual practice, an operation close to \( f_r \) requires such low generator impedances to maintain a given value of \( \Gamma \) that coupling circuit losses become important and the resultant attenuation of the incident RF power must be taken into account.

The importance of \( f_r \) in tunnel diode detection cannot be emphasized too strongly, because detection sensitivity drops rather abruptly beyond \( f_r \) and results in poor sensitivity performance. This behavior is illustrated by the dashed-line optimum curve for \( v = -0.07 \) volts, \( f > f_r \) which is also calculated from Equation 19. Note that this curve drops below the zero bias curve by a factor of about ten in the millimeter wave region.

The calculated curves of Figure 5 have been experimentally verified for the example diode at spot frequencies of 3, 5, 6, and 7 Gc. Experimental confirmation at many other values of \( \Gamma \) was also obtained, but the data has been omitted in the interest of keeping the family of curves as simple as possible.

From Figure 5 it is evident that there must be a continuous variation in \( \beta \) vs. bias under stable operating conditions, and a typical example of this type of variation is illustrated in Figure 6(a) for the example diode. The solid curve was calculated from Equation 10 under the conditions of \( R_g = 85 \) ohms and detector circuit resonance at 3 Gc. Note the bipolar behavior of \( \beta \) caused by the change in sign of \( G' \) as the diode is biased through the inflection point (Figure 3). The tunnel diode changes its direction of rectification when biased beyond the inflection point. Figure 6(b) illustrates the associated variation in \( |\Gamma|^2 \) vs. bias, which demonstrates the fact that rectification passes through zero at the peak RF gain point (under single-tuned conditions). This rectification reversal results in a discriminator-like characteristic with two sensitivity peaks, one above and one below the inflection bias point. The upper peak point has the highest sensitivity and is generally utilized as the operating bias point for high-sensitivity detectors. Practical bias adjustment procedure consists of "rocking" the bias back and forth to find the maximum video output point.

The discriminator-like characteristic can be utilized for bipolar amplitude modulation of output video signals via bias voltage control. This property would be useful, for example, in feedback control of tunnel diode amplifier operating bias point.

Experimental data points measured at 3 Gc for the assumed conditions are also shown plotted in Figure 6. The equivalent generator impedance of 85 ohms was initially approximated by adjusting the detector for an RF power gain of 15.6 db (calculated from Equation 12 for \( R_g = 85 \Omega \)) with the diode.
biased at its inflection point. The discrepancies between the measured data and calculated curves appear reasonable in view of the \( R_g \) approximation plus expected error in the values of \( G, G', \) and \( C. \)

As a practical note, it should be pointed out that the zero rectification point provides an extremely sensitive means for locating the exact inflection point on a tunnel diode characteristic.

**BANDWIDTH BEHAVIOR OF \( \beta \)**

The gross frequency behavior of \( \beta \) shown in Figure 5 was determined on the basis of constant values of \( \Gamma \) for all frequencies. If \( \Gamma \) could be so maintained, then by Equation 16 a maximum \( \beta \)-bandwidth product equal to \((\beta_0 f_c)\) would exist when the diode is biased in the positive conductance region, and by Equation 19 a product in excess of \((\beta_0 f_c (1 - \Gamma^2))\) would exist when the diode is biased in the negative conductance region. However, practical detector mounts cannot be designed to maintain \( \Gamma \) constant over the frequency range plotted in Figure 5, therefore actual \( \beta \)-bandwidth products are always less than the above values.

In general, bandwidth will be inversely proportional to the \( Q \) factor of the equivalent circuit shown in Figure 1, which may be written

\[
Q = \left( \frac{\omega_0 L}{R_g + R_s + r_o} \right),
\]

where

\[
r_o = \frac{R}{1 + (\omega_0 CR)^2}.
\]

\( \omega_0 \) is taken to be the center frequency of the passband and \( r_o \) is the equivalent series resistance of the diode junction at \( \omega_0 \). For purposes of illustration, it is convenient to calculate the simple case of fixed element,
single-tuned, series resonance* wherein the bandwidth, $\Delta f$, is given by the familiar ratio of $f_0/Q$, so that from Equation 21 obtains,

$$\Delta f = \frac{f_0}{Q} = \frac{R_g + R_e + r_0}{2\pi L}. \quad (23)$$

Upon substituting for $L$ from the single-tuned resonance condition,

$$\omega_0 L = r_0(\omega_0 CR) \quad (24)$$

and expressing $R_e$ in terms of reflection coefficient, $\Gamma_0$, Equation 23 may be manipulated into the form

$$\Delta f = \frac{1 + \left(\frac{R_g}{\Gamma_0}\right)}{\pi RC(1 + \Gamma_0)}. \quad (25)$$

An inspection of Equation 25 shows that bandwidth becomes inversely proportional to the RF voltage gain of the tunnel diode circuit. Also, the maximum gain-bandwidth product is equal to $(1/\pi RC)$, which is in agreement with derivations contained in the literature (Reference 13) for the single-tuned circuit case.

Figure 7 illustrates a plot of $\beta$ vs. bandwidth, with values of $\Delta f$ calculated from Equation 25 for the example diode under conditions of $V = -0.07$ volts and circuit resonance at 6 Gc. Figure 7 also contains a plot of $\beta$ vs. bandwidth as measured on the tuned detector mount that was utilized for obtaining the experimental C-band data. This particular detector mount design did not have a bandwidth performance equal to that of a fixed element, single-tuned circuit because of the variation in $R_e$ and $L$ with frequency. Note the characteristic slope of approximately 6 db per octave in $\beta$ vs. $\Delta f$.

Bandwidth performance is always dependent upon the particular circuits that are utilized in coupling the generator source to the

*It is assumed that the reader recognizes the fact that the circuit of Figure 1 is not actually a fixed element, single-tuned circuit because of frequency dependence in $R_g$, $L$, and $r$. 

Figure 7—$\beta$ vs. RF bandwidth for example diode under conditions $V = -0.07$ volts and circuit resonance at 6 Gc. The calculated curve assumes that $R_g$, $L$, and $r_0$ are frequency independent.
diode. In the extensive literature that exists on the gain-bandwidth products of amplifiers (References 23 to 32), Matthaei (Reference 23) and others have pointed out that considerable bandwidth improvements may be obtained through proper design of more complex impedance transformation circuits between the generator source and the diode.

NOISE OF TUNNEL DIODE AND VIDEO CIRCUIT

From the standpoint of low-level video detection, one of the most important characteristics of the tunnel diode is its low $1/f$ (flicker) noise. Investigators (References 4, 33, and 34) have found that the $1/f$ noise corner frequency is on the order of 1 Kc when the diodes are operated in the low-voltage, positive-conductance region. In fact, for this bias region the tunnel diode (or back diode) has a low-noise performance comparable to the hot carrier (Reference 3) diode. When biased to the peak current point and beyond into the negative resistance region, the $1/f$ noise corner frequency increases steadily (References 22, and 34 to 37) and can deteriorate markedly as the valley region is approached, apparently because of the noisy character of the valley region excess current. Valley region excess video noise varies from one diode to another (Reference 34) but it is generally always high enough that this region of operation should be avoided for high-sensitivity applications. Therefore, the present video noise discussion will proceed on the assumption that the tunnel diode bias voltage excursion shall avoid entering the valley region in order that $1/f$ noise may remain reasonably small.*

If $1/f$ noise is neglected, then the diode video noise can be attributed to shot noise and thermal noise components which have been shown (References 17, 38 and 39) to be represented by the equivalent circuit of Figure 8(a), where $e_n^2$ and $i_n^2$ are given by

\[ e_n^2 = 4kT B_v R_{eq} \]

\[ i_n^2 = 2qI_{eq} B_v \]  

*Obviously, if the "video bandwidth" upper frequency limit happens to be in the kilocycle range of frequency, then the $1/f$ noise may not be negligible and its contribution must be accounted for.
where

\[ B_v = \text{video noise bandwidth}, \]
\[ q = 1.6 \cdot 10^{-19} \text{ coulombs}, \]
\[ I_{eq} = \text{equivalent shot noise current}, \]
\[ K = \text{Boltzmann's constant}. \]

The equivalent shot noise current, \( I_{eq} \), is related to the actual diode bias current, \( I \), by the derived expression (Reference 17)

\[ I_{eq} = I \coth \frac{qV}{2kT}. \quad (28) \]

A plot of \( I_{eq} \) for our example diode is shown in Figure 9, where it will be noted that \( I_{eq} \) departs considerably from \( I \) near zero bias. At zero bias, \( I_{eq} \) must equal the value corresponding to the thermal noise of the conductance, \( G_0 \); i.e.,

\[ i_n^2 = 4kT G_0 B_v \text{ or } I_{eq0} = \frac{2kT G_0}{q}. \quad (29) \]

In addition to the diode noise, a practical video detector is always associated with an equivalent video circuit resistance, \( R_v \), which generates the thermal noise voltage \( 4kT R_v \). The resistance \( R_v \) includes the bias circuit for the diode plus the input impedance of the amplifier utilized with the detector. Figure 8(b) illustrates the midband* equivalent video noise circuit, where \( R_v \) noise plus diode noise contributions have been lumped into the equivalent noise current generator, \( I_n^2 \). \( I_n^2 \) will be equal to

\[ I_n^2 = \frac{2q I_{eq} B_v}{(1 + GR_s)^2} + \frac{4kT B_v R_s}{(R + R_s)^2} + \frac{4kT B_v}{R_v}. \quad (30) \]

The output noise voltage, \( E_n^2 \), produced by \( I_n^2 \) is therefore

\[ E_n^2 = I_n^2 R_i^2. \quad (31) \]

*Midband* refers to the middle of the video passband determined by the video amplifier.
where

\[ R_i = \frac{R_v (R_s + R)}{R_v + R_s + R} \]  \hspace{1cm} (32)

\( R_i \) is the total equivalent resistance, being the parallel combination of \( R_v \) and \((R_s + R)\). It should be pointed out that Equation 32 is particularly significant for a tunnel diode detector because of the fact that \( R \) can become large and may also be negative. Either condition will restrict the maximum value that \( R_v \) can take. For instance, the stability criteria for the video circuit requires that \( R_i \) be positive, so that from Equation 32 one obtains the necessary condition that

\[ R_v < |R_s + R| \text{ for negative } R. \]  \hspace{1cm} (33)

Furthermore, it may be necessary to place an upper bound upon \( R_i \) in order to obtain sufficient video bandwidth, and this upper bound on \( R_i \) will, in turn, restrict the maximum value that \( R_v \) may have.

Amplifier excess noise, which is always present in high-sensitivity video detection, can be represented by placing an equivalent noise generating resistance (References 1, and 40) \( R_{eq} \), between the detector video circuit and an ideal amplifier with an infinite input impedance as shown in Figure 8(c). The total noise voltage, \( E_n^2 \), therefore has \( e_n^2 \) added to Equation 31, becoming

\[ E_n^2 = I_n^2 R_i^2 + 4KT B_v R_{eq}. \]  \hspace{1cm} (34)

Values of \( R_{eq} \) are readily determined from measurements of the amplifier gain, bandwidth, and r.m.s. output noise under known input circuit conditions.

Video noise bandwidth has never been satisfactorily standardized and is usually different for each detector application, so that it is desirable to normalize all noise contributions in terms of noise per cycle of video bandwidth. Thus, dividing Equation 34 and Equation 30 by \( B_v \) we obtain,

\[ \frac{E_n^2}{B_v} = \frac{I_n^2}{B_v} R_i^2 + 4KTR_{eq}. \]  \hspace{1cm} (35)

and

\[ \frac{I_n^2}{B_v} = \frac{2q I_{eq}}{(1 + GR_s)^2} + 4KT \left[ \frac{1}{R_v} + \frac{R_s}{(R + R_s)^2} \right]. \]  \hspace{1cm} (36)

A plot of \( \sqrt{I_n^2/B_v} \) versus diode junction voltage for our example diode is shown in Figure 10 under two \( R_v \) conditions: (a) \( R_v \) held constant at 265 ohms for all bias voltages; (b) Maximum \( R_v \) for each
bias voltage subject to the restriction that $R_i$ represents a typical design value for wideband video detector circuits, and the two $R_v$ conditions encompass the resultant design range for $R_v$. For diode junction voltage above -0.04 volts, $R_v$ can be infinite so that this segment of the lower curve (maximum $R_v$) in Figure 10 represents the noise current contributed by the diode alone. The measured data points shown in Figure 10 were obtained from r.m.s. noise voltage measurements* on the example diode, and they agree with the calculated curves within the limits of experimental measurement error.

Figure 11 illustrates the total r.m.s. noise voltage per $\sqrt{c.p.s.}$, $\sqrt{E_{n}/B_v}$, versus diode junction voltage for the same conditions utilized in Figure 10 plus the addition of amplifier excess noise. The set of curves for $R_{eq} = 0$ give the noise voltage that could be obtained with an ideal noiseless amplifier, and the set of curves for $R_{eq} = 1K$ illustrates the noise voltage that would be obtained with a typical transistor video amplifier of recent design. Note that the experimental measured data points* on the example diode are in very close agreement with the calculated curves.

*The video amplifier utilized in conducting the noise measurements on the example diode had the following characteristics: Gain = 10,000; Bandwidth = 2 mc.; Input Impedance = 50 K and 60 pf; Noise $R_{eq} = 730$ ohms. Noise due to $R_{eq}$ was subtracted out in order to obtain diode noise data.
These noise curves point up several interesting features associated with tunnel diode video detectors:

(a) The considerable variation in noise voltage level versus diode bias reflects the variation that occurs in $R_i$ (Equation 32). Video resistance $R_v$ affects the shape and peak value of the $R_i$ variation.

(b) In the vicinity of zero bias where $R_i$ becomes less than 100 ohms, amplifier noise can easily dominate the diode noise and thus degrade sensitivity.

(c) When the diode is biased near its peak current point or beyond into the negative resistance region, $R_i$ increases such that the diode noise becomes dominant over the amplifier noise. This latter situation is very desirable for practical high-sensitivity detection.

**TANGENTIAL SENSITIVITY**

Tangential sensitivity (References 41 and 42) is defined as that signal level which raises the noise by its own width on an oscilloscope pulse-plus-noise presentation. This sensitivity criterion has the disadvantage of being somewhat dependent upon particular receiver conditions and particular observer interpretation, but it is still the most practical criterion available for measuring the sensitivity performance of low-level video detectors. It is generally found to be consistent within ±1 db in RF power level for given receiver conditions and a given observer. To overcome the problem of changing receiver conditions and/or changing observers, it is necessary to measure the average signal-to-noise ratio actually associated with a given receiver-observer set-up, and then correct the measured data to the fixed reference value of 8 db which is utilized in the literature for calculation and comparison of tangential sensitivity performance. 8 db results in a voltage ratio of 2.5 in the video circuit, and this value will be employed in the calculations to follow.

The minimum video detector equivalent circuit* needed for computing tangential sensitivity is shown in Figure 12. It consists of the midband video equivalent noise circuit discussed in the preceding section, plus the rectification current generator, $I_r$, and the total shunt capacitance, $C_v$. Shunt capacitance includes the amplifier input capacitance, the detector RF bypass condenser, and the shielded cable capacitance, if present. The presence of $C_v$ places an upper bound on the values that $R_i$ may have because of bandwidth considerations. The bandwidth of the circuit must be adequate for the pulse response required and, in addition, it is always desirable to have the input circuit bandwidth

---

*The terminology "minimum circuit" is used in the sense that there can never be fewer components than shown in Figure 12. Needless to say, actual detector video circuits are often times considerably more complicated due to the presence of chokes, transformers, pulse peaking circuits, etc.
exceed the amplifier bandwidth in order to minimize amplifier noise contribution. The 3 dB bandwidth point will occur when \( \omega R_i C_v = 1 \), so that we require

\[
R_i < \frac{1}{2 \pi C_v B_v}.
\]  

(37)

This upper bound on \( R_i \) may also be expressed in terms of \( \tau \), the pulse rise time between 10 and 90 percent amplitude points, since video bandwidth and pulse rise time have the approximate product (Reference 43)

\[
\tau B_v \approx 0.35,
\]

(38)

so that

\[
R_i < \frac{\tau}{2.2 C_v}.
\]

(39)

This restriction upon \( R_i \) results in a restriction upon the maximum value of \( R_v \) via Equation 32; i.e., from (32) we obtain

\[
R_v = \left[ \frac{\frac{R_i}{1 - \frac{R_i}{R_s + R}}}{R_i} \right].
\]

(40)

Assuming that \( R_i \) is adjusted for adequate safety margin in Equation 37, the voltage \( E_s \) developed is simply

\[
E_s = I_r R_i = \beta P_i R_i,
\]

(41)

where \( \beta P_i \) was substituted for the rectification current from Equation 6. The tangential sensitivity ratio defines a particular input RF power level, \( P_i = P_t \), such that the 6 db ratio of \( E_s \) to \( \sqrt{E_n^2} \) is obtained,

\[
\frac{E_s}{\sqrt{E_n^2}} = 2.5 = \frac{\beta R_i P_i}{\sqrt{B_v} \left( \frac{I_{n0}}{B_v} \right) R_i^2 + 4 K T R_{eq}}.
\]

(42)

or

\[
P_t = \left( \frac{2.5 \sqrt{B_v}}{\beta} \right) \sqrt{\frac{I_{n0}^2}{B_v}} \left( \frac{4 K T R_{eq}}{R_i^2} \right).
\]

(43)
Note that when the amplifier noise contribution becomes negligible, Equation 43 simplifies to

\[ P_t = 2.5 \cdot \frac{I_n}{\beta} \]  

Equation 44 can be plotted vs. frequency for our example diode by utilizing values of \( \beta \) from Figure 5 and values of \( \sqrt{I_n^2/B_v} \) from Figure 10. The resultant tangential sensitivities are shown plotted in Figure 13. The left hand scale gives \( P_t/\sqrt{E_v} \) in dbm per \( \sqrt{c.p.s.} \), and the right hand scale gives \( P_t \) in dbm for a video noise bandwidth of 1 mc. The comments which were made on the \( \beta \) curves of Figure 5 would apply equally well to Figure 13, since there is only a small relative shift in the curves caused by the change in noise-current with bias voltage. In addition, it will be noted that the tangential sensitivities that can be achieved at frequencies below \( f_r \) are at least an order of magnitude better than the performance of other types of diodes (References 1 to 3).

The calculated curves of Figure 13 have been experimentally verified with the example diode at frequencies of 3, 5, 6, and 7 Gc, as illustrated by the data points plotted.

The experimental receiver set-up for measuring tangential sensitivity had a consistent value of 4 for the ratio of observer interpreted peak-to-peak noise amplitude on the oscilloscope as compared to the measured r.m.s. value. This results in a tangential sensitivity signal to noise ratio of 12 db on the video side for the experimental measurements. Since the calculated curves are based upon the fixed reference value of 8 db, all experimental data was corrected by the square root of the difference, or 2 db, in order to obtain a valid comparison with the calculated curves. (The square root of the 4 db difference must be taken because low-level detection is square-law and the video difference must be referred to the RF side of the detector.)

A typical variation in tangential sensitivity vs. bias for the example diode is shown in Figure 14, calculated by utilizing values of \( \beta \) from Figure 6(a) and values of \( \sqrt{E_n^2/B_v} \) from Figure 11 with maximum \( R_v \) for \( R_i \leq 1K \) and amplifier noise \( R_{eq} \) either zero or 1K as denoted on the curves. It will be noted that amplifier noise reduces tangential sensitivity significantly in the vicinity of zero bias, but becomes negligible when the diode is biased near the peak current point or beyond. Sensitivity drops to zero very sharply at the inflection point where \( \beta \) goes through zero (Figure 6(a)). The highest peak tangential sensitivity point is readily
determined via bias adjustment and is usually chosen as the detector operating bias point. This operating point will shift slightly as a function of $\Gamma$ and/or frequency, shifting closer to the inflection point for increasing values of $\Gamma$ and/or frequency.

A typical variation in tangential sensitivity vs. RF bandwidth for the example diode is shown in Figure 15. These were calculated by utilizing values of $\beta$ and $\Delta f$ from Figure 7 which were determined on the assumption of fixed element, single-tuned circuit behavior. The associated noise current was obtained from Figure 10 for an operating bias point of -0.07 volts. Figure 15 also contains a plot of $P_t$ vs. $\Delta f$ as measured on the example diode in a tuned C-band detector mount. This particular mount did not have a bandwidth performance equal to that of a fixed element, single-tuned circuit because of the frequency dependence of $R_g$ and $L$. Since the tangential sensitivity variations mainly reflect the variations that occur in $\beta$, the bandwidth comments in the previous section apply directly here.

An example of the increased bandwidth that can be obtained from a more complex circuit design is shown in Figure 16 where the performance of a double-tuned response design is compared with a single-tuned response design. In this particular instance the bandwidth was improved by a factor of three.

As a practical note, it should be pointed out that a $P_t$ vs. $\Delta f$ plot provides a very effective means for evaluating the relative performance of tunnel diodes when measured in the same detector mount at the same resonant frequency.

**FIGURE OF MERIT, COMPARISON WITH HOT CARRIER DIODE**

The figure of merit, $M$, which is often utilized as a criterion of excellence for video
detectors, is defined as (Reference 1)

\[
M = \frac{4KTB_V}{P_i} \cdot \frac{E_s}{\sqrt{E_n^2}}
\]

Substituting Equations 41 for \(E_s\) and 34 for \(E_n^2\), one obtains,

\[
M = \frac{\beta}{\sqrt{\frac{I_n^2}{4KTB_V} + \left(\frac{R_{eq}}{R_i}\right)^2}}
\]

Utilizing values of \(\beta\) from Figure 6(a) and noise current from Figure 10, substitution into Equation 46 results in a typical figure of merit plot vs. junction voltage shown in Figure 17 for amplifier noise \(R_{eq}\) of zero and 1K. It is important to note that when the diode is biased into the negative resistance region, amplifier noise is no longer significant and figures of merit in the thousands are readily achieved.

The figure of merit criterion offers the best means for comparing the relative sensitivity performance of a tunnel diode against a hot carrier diode. For the purposes of this comparison, it is reasonable to neglect amplifier noise, i.e., let \(R_{eq} = 0\), so that Equation 46 simplifies to

\[
M = \frac{\beta}{\sqrt{4KTB_V}}
\]

For the tunnel diode, values of \(\beta\) are calculated from Equations 16, 18, or 19 depending upon whether \(G\) is positive, zero, or negative; and the noise current is calculated from Equation 30.

For the hot carrier diode, values of \(\beta\) are calculated only from Equation 16 since \(G\) is
always positive; and the noise current may be approximated by the thermal conductance noise (Reference 3), since this is a unique low-noise property of the diode if the video bandwidth lies above the flicker noise corner frequency.

\[(\text{hot carrier diode}) I_n^2 \approx \frac{4KT B_T}{R_s + R} \]  

Upon substituting Equations 16 and 48 into 47 and assuming optimum performance \((\Gamma = 0)\), the figure of merit for a hot carrier diode, denoted as \(M_{hc}\), becomes

\[
M_{hc} = \frac{\beta_0 \sqrt{R_s + R}}{\left[1 + \left(\frac{f}{f_c}\right)^2\right]} \tag{49}
\]

\(\beta_0\) is particularly simple for a hot carrier diode because the ratio of \(G\) and its first derivative remains constant, i.e., the diode current may be written as (Reference 2)

\[
I = I_s (e^{aV} - 1) \tag{50}
\]

where

\[
a = \frac{qV}{nKT} \approx 38
\]

\(I_s = \) saturation current, and

\(V = \) diode junction voltage.

Then

\[
G = \frac{dI}{dV} = a I_s e^{aV}, \quad \text{and} \tag{51}
\]

\[
G' = \frac{dG}{dV} = a^2 I_s e^{aV}. \tag{52}
\]

Thus, the ratio of \(G'\) to \(G\) is equal to \(a\) and substitution into Equation 15 results in

\[
(\text{hot carrier diode}) \beta_0 = \frac{a}{2(1 + GR_s)^2} \approx \frac{19}{(1 + GR_s)^2} \tag{53}
\]
Upon substituting this $\beta_0$ into (49) and simplifying, $M_{hc}$ becomes

$$M_{hc} \approx \frac{19 \sqrt{R}}{(1 + GR_e)^{3/2}} \left[ 1 + \left( \frac{f}{f_c} \right)^2 \right] = \frac{M_{hce}}{1 + \left( \frac{f}{f_c} \right)^2} \quad (54)$$

where $f_c$ is given by Equation 17.

For calculation, the published characteristics of typical hpa-2350 diodes (Reference 3) were utilized: series resistance $R_s \approx 12$ ohms, junction capacitance $C \approx 0.75$ pf, and $I_s = 8 \cdot 10^{-9}$ amperes. The figure of merit performance for this particular hot carrier diode is illustrated by the dashed-line curves in Figure 18 for three bias conditions: zero bias, $I = 27\mu$ amps, and $I = 300\mu$ amps. These calculated curves are found to be in close agreement with the published tangential sensitivity data for the diode (Reference 3) when cross-checked via the relationship derived from Equation 45,

$$\left( \frac{\sqrt{R}}{P_t} \right) \left( \frac{M}{2.5 \sqrt{4KT}} \right) = 3.16 \cdot 10^9 \ M \quad (55)$$

The curves clearly illustrate the trade off between $M_{hce}$ and $f_c$ as the bias current, $I$, is increased.

The example diode was utilized for calculating the tunnel diode performance as illustrated by the lines labelled "T.D." in Figure 18 for four junction voltage conditions; zero bias, $V = -0.04$ volts, $V = V_p$, and $V = -0.07$ volts. Some experimental confirmation data points are included. It is noteworthy that the tunnel diode has a better sensitivity capability than the hot carrier diode for the examples shown here, even when the tunnel diode is restricted to positive conductance biasing. When biased to $V_p$ or beyond into the negative resistance region, as illustrated by the broken-line curve for $V = -0.07$ volts, the tunnel diode is capable of at least an order of magnitude improvement in sensitivity over the hot carrier diode for frequencies below $f_r$.

The reader is cautioned against over-generalization of the relative diode sensitivity performance shown in Figure 18, because it is noteworthy that the curves are based upon only two particular diode examples and, also, the $1/f$ noise was assumed to be negligible for both diodes. When biased in its negative resistance region, a tunnel diode will have a much higher $1/f$ noise corner
frequency than the hot carrier diode, and this factor can become important for video bandwidths below 1 megacycle.

CONCLUSIONS

A low-level detection analysis of the tunnel diode has been presented with the aim of covering its detection behavior for any bias condition, particularly in the negative resistance region. It has been shown that for negative resistance biasing, the tunnel diode exhibits the following interesting detection properties:

(a) For a bias excursion through the inflection point, the detector shows a discriminator-like, rectification reversal behavior, with the zero output point anchored precisely at the inflection bias point.

(b) For frequencies below resistive cut-off, sensitivity is proportional to $(1 - r^2)$, where $r^2$ is the RF power gain of the detector viewed as a reflection-type amplifier, so that unusually high sensitivities can be achieved.

(c) For frequencies above resistive cut-off, the sensitivity drops rather abruptly and quickly becomes inferior to the zero bias sensitivity.

The unusually high sensitivities which are made possible via control of $r^2$ must necessarily be subject to all of the trade offs that are associated with high-gain RF amplifiers, and it was shown that the usual gain-bandwidth product applies directly, i.e., a higher sensitivity can only be achieved at the expense of a smaller bandwidth. Other trade offs, familiar to the tunnel diode amplifier art, include greater temperature variation, more critical bias regulation, a lower saturation power level, and more critical circuit stability conditions. If one is willing to accept the trade offs, then sensitivities an order of magnitude better than any other video detector are readily achieved. In fact, the sensitivity can actually be pushed to the point of being competitive with a superheterodyne receiver under certain conditions.

A practical by-product of this detection study was the observation that the rectified current from a tunnel diode amplifier provides a very sensitive and valuable tool during the design and adjustment phase of an amplifier since it can be utilized to monitor bias stability, spurious oscillation, bandpass shape, bandwidth adjustment, temperature effects, saturation effects, extraneous signals, etc. The rectified current could also be incorporated into a feedback loop for bias point control or automatic gain control.

Special mention must be made of the peak current bias point of a tunnel diode. It was shown that this particular bias point results in a sensitivity inversely proportional to the square of the frequency, and this behavior results in unusually high sensitivities at the lower microwave frequencies. The easy stability conditions involved in peak current biasing make it a very attractive operation point.
REFERENCES

Appendix A

Derivation of $\beta$

The rectification current sensitivity, $\beta$, is given by the ratio of $I_r$ to $P_i$,

$$\beta = \frac{I_r}{P_i}$$  \hspace{1cm} (A1)

where $I_r$ is the rectified current and $P_i$ is the RF power incident upon the detector. The evaluation of $I_r$ presents a formidable, if not impossible, non-linear circuit analysis task if $P_i$ is not restricted to low levels. However, by restricting $P_i$ to low levels such that the RF voltage excursion on the non-linear diode characteristic is small compared to the radius of curvature, then Taylor series approximations (Reference 1) can be employed to derive an accurate expression for low level rectification.

Figure A1 illustrates a model of a simple tuned microwave detector with dc return, where $C_b$ represents the RF by-pass condenser, $R_v$ is the video circuit resistance, $S_1$ and $S_2$ are lengths of RF transmission line of characteristic impedances $Z_{o1}$ and $Z_{o2}$ respectively; $Z_g$ represents the connected generator source impedance, and $V_b$ is the applied dc bias voltage across the diode. A detailed equivalent circuit representation of this detector is shown in Figure A2 where the diode equivalent circuit (References 1 and 17) elements are defined as follows:

- $R$ - differential junction resistance of diode
- $C$ - junction capacitance of diode
- $R_s$ - series resistance of diode

![Figure A1—Model of a simple tuned microwave detector with dc return.](image1)

![Figure A2—An equivalent circuit representation of the detector shown in Figure A1.](image2)
**Equation A2**

\[ E_g = b e^{j\omega t} \quad b \ll 1 \]

The non-linear V-I characteristic of the diode junction causes a non-linear relationship between the current \( I_g \) and the applied voltages \( (V_b + E_g) \). If we assume that \( E_g \) is a very small sinusoidal signal,

**Equation A3**

\[ I_g = \phi(V_b + E_g) \approx \phi(V_b) + \phi'(V_b) \cdot E_g + \frac{1}{2} \phi''(V_b) \cdot E_g^2 + \cdots \]

The first term is the dc bias current, \( I_b \). The second term is the linear RF current component,

**Equation A4**

\[ \phi'(V_b) \cdot E_g = \frac{E_g}{Z} \]

where \( Z \) is the total series impedance of the circuit at the bias point, i.e.,

**Equation A5**

\[ Z = \left[ R_g + R_s + \left( \frac{R}{1 + (\alpha CR)^2} \right) \right] + j \left[ \alpha L - \left( \frac{\alpha CR^2}{1 + (\alpha CR)^2} \right) \right] \]
The third term may be evaluated by squaring the real part of $E_g$, whereupon

$$
\frac{1}{2} \phi''(V_b) \cdot b^2 \cos^2 \omega t = \frac{1}{2} \phi''(V_b) \cdot b^2 \cdot (1 + \cos 2\omega t). \tag{A6}
$$

This consists of the rectified current plus a second harmonic component. The second harmonic component is of no interest here, so that Equation A3 may be written,

$$
I_g \approx I_b + \frac{E_g}{Z} + I_r. \tag{A7}
$$

Utilizing this approximation for $I_g$, it follows that the voltage, $V$, across the diode junction is given by

$$
V \approx V_b - R_s(I_b + I_r) + \frac{Z_j}{Z} \cdot E_g. \tag{A8}
$$

where $Z_j$ is the equivalent series impedance of the diode junction,

$$
Z_j = \left( \frac{1}{G+j\omega C} \right). \tag{A9}
$$

Note that $R_s$ does not enter into the dc voltage drop in (A8) because $R_s$ is zero at dc. If we define $V_{jb} = (V_b - E_g I_b)$, then (A8) becomes

$$
V \approx V_{jb} - R_s I_r + \left( \frac{Z_j}{Z} \right) E_g. \tag{A10}
$$

Next define

$$
\nu = V - V_{jb} \approx - R_s I_r + \left( \frac{Z_j}{Z} \right) E_g, \tag{A11}
$$

i.e., $\nu$ will be the excursion of $V$ about the bias point $V_{jb}$.

Having thus defined $\nu$, the next step is to evaluate the current, $I$. Figure A4 illustrates a nominal non-linear junction V-I characteristic. Since the excursions about the bias point $(V_{jb}, I_b)$ are assumed to be very small, it is again convenient to write the non-linear function as a Taylor series expansion of three terms about the bias point,

$$
I = f(V_{jb} + \nu) \approx f(V_{jb}) + f'(V_{jb}) \cdot \nu + \frac{1}{2} f''(V_{jb}) \cdot \nu^2 + \cdots. \tag{A12}
$$
The first term, \( f(V_{jb}) \), is simply the bias current \( I_b \). The second term is the linear RF current determined by the differential junction conductance, \( G \), at the bias point,

\[
f'(V_{jb}) = \frac{dI}{dV_{V_{sb}V_{jb}}} = G = \frac{1}{R}.
\]

(A13)

In the third term, the second derivative of the function may also be written as the first derivative of the conductance, i.e.,

\[
f''(V_{jb}) = \left( \frac{d^2I}{dV^2} \right)_{V=V_{jb}} = \frac{dG}{dV}_{V=V_{jb}} = G'
\]

(A14)

Thus, Equation A12 may be written

\[
I \approx I_b + Gv + \frac{1}{2} G' v^2.
\]

(A15)

The current, \( I \), may now be combined with the current through the condenser, \( C \frac{dv}{dt} \), to give the current \( I_g \), i.e.,

\[
I_g = I + C \frac{dv}{dt}
\]

(A16)

or

\[
I_g \approx I_b + Gv + C \frac{dv}{dt} + \frac{1}{2} G' v^2.
\]

(A17)

Upon substituting (A2) into (A11), \( v \) may be converted into the form

\[
v \approx b \left( \frac{Z_j}{Z} \right) e^{j\omega t} - R_s I_r,
\]

(A18)

and if we now substitute this \( v \) into (A17),

\[
I_g \approx I_b + (G + j \omega C) b \left( \frac{Z_j}{Z} \right) e^{j\omega t} - GR_s I_r + \frac{1}{2} G' \cdot \left[ b \left( \frac{Z_j}{Z} \right) e^{j\omega t} - R_s I_r \right]^2
\]

(A19)
or

\[ I_g \approx I_b - GR_s I_r + \frac{E_g}{Z} + \frac{1}{2} G' \left[ b \left| \frac{Z_j}{Z} \right| e^{i(\omega t + \vartheta)} - R_s I_r \right]^2. \]  

(A20)

Upon equating this \( I_g \) to the \( I_g \) found in Equation A7, the \( I_b \) term and the linear \( E_g/Z \) term will drop out, leaving

\[ I_r \approx -GR_s I_r + \frac{1}{2} G' \left[ b \left| \frac{Z_j}{Z} \right| e^{i(\omega t + \vartheta)} - R_s I_r \right]^2. \]  

(A21)

Only the average value of the squared term is of interest, so that it is necessary to take the real part thereof. Furthermore, the voltage drop \( (R_s I_r) \) is very small compared to the RF magnitude of \( v \), i.e.,

\[ b \left| \frac{Z_j}{Z} \right| >> R_s I_r. \]  

(A22)

Therefore, \( R_s I_r \) can be neglected in the squared term and Equation A21 becomes

\[ I_r (1 + GR_s) \approx \frac{1}{2} G' \left[ b \left| \frac{Z_j}{Z} \right| \cos(\omega t + \vartheta) \right]^2. \]  

(A23)

from which the average value is obtained to arrive at the rectified current,

\[ I_r \approx \frac{G' b^2 |Z_j|^2}{4(1 + GR_s) |Z|^2}. \]  

(A24)

In Figure A3, if the resistance \( R_g \) is derived entirely from the generator source impedance,* then the incident RF power may be expressed in terms of \( E_g \) as

\[ P_i = \frac{1}{2} \cdot \frac{|E_g|^2}{4R_g} = \frac{b^2}{8R_g}. \]  

(A25)

Upon dividing Equation A24 by Equation A25, the expression for the rectification current sensitivity, \( \beta \), is obtained,

\[ \beta = \frac{I_r}{P_i} \approx \frac{2G' R_g |Z_j|^2}{(1 + GR_s) |Z|^2}. \]  

(A26)

*If \( R_g \) includes resistance other than from the generator, then a loss correction must be calculated.
Appendix B

Tunnel Diode V-I Characteristic

The voltage-current characteristic of a tunnel diode has not been rigorously derived as yet, so that no single equation is known that is capable of accurately predicting the entire curve (References 15, 16, and 17). However, a reasonably accurate piecewise approximation can be obtained by curve-fitting with an exponential function of the type derived in Nergaard and Glicksman (Reference 15) for an assumed tunnel diode model,

\[ I = 2.44 I_p (aV)^{1.5} e^{av} \]  \hspace{1cm} (B1)

where

\[ a = \frac{q}{kT} = \frac{1.6 \cdot 10^{-19} \text{ coulombs}}{4 \cdot 10^{-21} \text{ watts/cycle}} \]

\( I_p = \) peak current

\( V = \) voltage across diode junction.

For curve-fitting, it is desirable to utilize the general form of Equation B1, together with its first two derivatives,

\[ I = A(aV)^{\gamma} e^{av} \]  \hspace{1cm} (B2)

\[ \frac{dI}{dV} = I \left( \frac{\gamma}{V} + a \right) = G \]  \hspace{1cm} (B3)

\[ \frac{d^2I}{dV^2} = I \left[ a^2 + \frac{2a\gamma}{V} + \frac{\gamma(\gamma - 1)}{V^2} \right] = G' \]  \hspace{1cm} (B4)

It will be noted in Equation B3 that the first derivative is the junction conductance, \( G \), of the diode, and in B4 that the second derivative is therefore \( G' \).

The above relationships apply only to the diode junction, so that it is necessary to add a fourth equation in order to account for the series resistance, \( R_s \),

\[ V_b = V + IR_s \]  \hspace{1cm} (B5)
where \( V_b \) now represents the external voltage across the diode terminals. The value of \( R_s \) must be known accurately not only because of its effect upon the \( V-I \) characteristic but, also because of its effect upon the microwave performance of the diode. \( R_s \) is usually provided as part of the manufacturer's data on the diode but, if it is not known or is in question, then it may be determined from \( I-V_b \) slope measurements under forward bias conditions. The necessary relationship is readily obtained by differentiating Equation B5,

\[
\frac{dV_b}{dI} = \frac{dV}{dI} + R_s = \frac{1}{\left(\frac{dI}{dV}\right)} + R_s
\]

Substituting for \( \frac{dI}{dV} \) from Equation B3 then results in

\[
\frac{dV_b}{dI} = \frac{1}{\left(\frac{V}{V} + a\right)} \cdot \left(\frac{1}{1} \right) + R_s
\]

If the forward bias voltage is large enough to obtain the condition \( \gamma/V \ll a \), then Equation B7 simplifies to

\[
\frac{dV_b}{dI} = \frac{1}{aI} + R_s, \text{ for } \gamma/V \ll a
\]

which is a straight-line graph of \( \frac{dV_b}{dI} \) versus \( \frac{1}{I} \) with \( R_s \) given by the intersection of the straight line with the \( \frac{dV_b}{dI} \) axis. Figure B1 illustrates such a graph plotted for the example diode where it will be noted that \( R_s \) is 8 ohms. The forward current becomes relatively large during this measurement, so that it is necessary to utilize pulses of low duty cycle in order to prevent heating of the diode junction.

In curve-fitting the forward characteristic of the diode, it has been found that satisfactory accuracy may be obtained by utilizing the \( I-V_b \) slope measured at zero bias, plus the reverse bias peak current point values of \( I_p, V_{bp} \). The zero bias slope, \( G_{d0} \), is finite and requires a current component \( I_{1} \), for which the value of \( \gamma \) in Equation B2 is unity,

\[
I_1 = A_1(a_1 V)e^{a_1V}
\]

\[
\frac{dI_1}{dV} = G_1 = A_1a_1e^{a_1V} + a_1 I_1
\]

and

\[
\frac{dI_1}{dV} \bigg|_{V=0} = G_b = A_1 a_1
\]
At the peak current point, $g_i$ must go to zero so that from (B9) and (B10) we obtain,

$$\frac{dI_1}{dV} \bigg|_{V = V_p} = 0 = I_p I_1 \left( \frac{1}{V_p} + \alpha_i \right)$$

or

$$\alpha_i = \frac{1}{-V_p}.$$  \hspace{1cm} (B12)

$V_p$ can be obtained from Equation B5,

$$V_p = V_{bp} - I_p R_s,$$  \hspace{1cm} (B13)

so that $\alpha_i$ is determined. Then $A_i$ is evaluated from Equation B11. Utilizing the MS-1012 diode as an example, the following values were measured:

$$R_s = 8 \ \Omega$$
$$I_p = -0.285 \ \text{ma}$$
$$V_{bp} = -0.0483 \ \text{volts}$$
and $$G_{do} = 0.0133 \ \text{mhos}.$$ Then from Equation B13 we obtain

$$V_p = -0.0483 + 0.000286 \cdot 8$$
and $$V_p = -0.046$$
from Equation B12

$$\alpha_i = \frac{1}{0.046} = 21.75.$$ \hspace{1cm} (B14)

$$R_o + R_s = R_{do} = \frac{1}{G_{do}} = \frac{1}{0.0133} = 75 \ \Omega,$$
or

$$R_o = 75 - 8 = 67 \ \Omega = \frac{1}{G_o}.$$ and from Equation B11

$$A_i = \frac{G_o}{\alpha_i} = \frac{1}{21.75 \cdot 67} = 0.687.$$ The calculated $I_1$ vs. $V_b$ characteristic is shown in comparison with the measured data in Figure B2. Its accuracy holds within 4 percent of the measured data for forward bias up to about 40 millivolts and for reverse bias to about -8 millivolts. Therefore, the $I_1$ equation is satisfactory for
calculating first and second derivatives under limited forward bias conditions and in the vicinity of zero bias.

Under reverse bias conditions beyond -10 millivolts, current $I_1$ is not quite accurate enough. For instance, upon substituting Equation B12 into B9 the peak current $I_{p1}$ will be found to be

$$I_{p1} = \frac{-A_1}{e^{\frac{-A_1}{2.718}}} = \frac{-0.0687}{2.718} = -0.253 \text{ ma}, \quad (B15)$$

whereas the measured value is -0.286 ma, resulting in an error of 11.5% in $I_{p1}$. Also, the $I_1$ equation results in excessive derivative errors near the inflection point, such that it is desirable to either add a second current component based upon $\gamma = 1.5$, or utilize a single equation with an intermediate value of $\gamma$. The latter approach results in greatest simplicity.

A single equation curve fit of the negative characteristic is best accomplished by utilizing the inflection point data together with $V_p$. At the inflection point the second derivative must vanish, so that from Equation B4 one obtains

$$\left. \frac{d^2I}{dV^2} \right|_{V=V_i} = \alpha^2 I_i \left[ 1 + \frac{2\gamma}{\alpha V_i} + \frac{\gamma(\gamma - 1)}{(\alpha V_i)^2} \right] = 0 \quad . \quad (B16)$$

which has the solution

$$\alpha V_i = - (\gamma + \sqrt{\gamma}) \quad . \quad (B17)$$

Upon substituting the peak current condition obtained from setting Equation B3 equal to zero,

$$\left. \frac{dI}{dV} \right|_{V=V_p} = 0 = I_p \left( \frac{\gamma}{V_p} + \alpha \right)$$

or

$$\alpha = \frac{\gamma}{-V_p} \quad . \quad (B18)$$
Then Equation B17 may be written as

\[ V_i = V_p \left(1 + \frac{1}{\sqrt{\gamma}}\right). \]  

(B19)

By substituting Equations B18 and B19 into Equation B2 one can relate the inflection point current to the peak current,

\[ I_i = \left(1 + \frac{1}{\sqrt{\gamma}}\right)^\gamma \left(1 + \frac{1}{\sqrt{\gamma}}\right)^{\gamma(-1)} \cdot I_p. \]  

(B20)

The final relationship needed is the slope (conductance) at the inflection point, and this is obtained by substituting Equations B18, B19, and B20 into Equation B3,

\[ G_i = I_i \left(\frac{\gamma}{V_i} + a\right) = -\frac{\gamma^{1-\gamma/2} (1 + \sqrt{\gamma})^{\gamma(-1)}}{e^{\sqrt{\gamma}}} \cdot \frac{I_p}{V_p}. \]  

(B21)

which may then be written as,

\[ -\frac{\gamma^{1-\gamma/2} (1 + \sqrt{\gamma})^{\gamma(-1)}}{e^{\sqrt{\gamma}}} = \left(\frac{V_p}{I_p R_i}\right). \]  

(B22)

where \( R_i \) is the inflection point negative resistance.

Equation B22 results in the ratio of \( V_p \) to \( I_p R_i \) as a function of \( \gamma \) only. In curve-fitting to the actual diode characteristic, only three of the five conditions \((I_p, V_p, I_i, V_i, R_i)\) can be satisfied by the three constants available to us in the single Equation B2, so that the remaining two quantities must be compromised. In practice, it has been found that the most satisfactory compromise is obtained by using the measured values of \( V_p \) and \( R_i \), and choosing the inflection point to lie on the measured data curve. This throws most of the compromise error into the magnitude of \( I_p \), but the price paid is small. Again utilizing the MS1012 diode as an example, the measured values of \( V_p \) and \( R_i \) were found to be

\[ V_p = -0.046 \] as determined previously

\[ R_{di} = -360 \Omega \] measured maximum slope

then

\[ R_i = R_{di} - R_s = -360 - 8 = -368 \Omega. \]  

(B23)

Knowing \( V_p \) and \( R_i \), we can now utilize Equations B20, B22, and B19 to calculate pair values of \( I_i \) and \( V_i \) for various values of \( \gamma \). The equation for \( I_i \) simplifies to,

\[ I_i = -\frac{(1 + \sqrt{\gamma})}{\gamma} \left(\frac{V_p}{R_i}\right). \]  

(B24)

Upon converting \( V_i \) into \( V_{bi} \) values via the relationship

\[ V_{bi} = V_i + I_i R_s. \]  

(B25)
we then obtain pair values of \((I_i, V_{bi})\) that can be plotted directly on the measured current-voltage characteristic of the diode to obtain an intersection point as illustrated in Figure B3. The intersection point occurs at an interpolated value of \(\gamma = 1.275\). Upon using this value of \(\gamma\) one can calculate the following values from the associated equations:

- \(I_i = -0.209\) mA from Equation B24
- \(V_i = -0.0867\) volts from Equation B19
- \(V_{bi} = -0.08837\) volts from Equation B25
- \(R_1 = -368\) \(\Omega\) from Equation B3 and B18
- \(I_p = -0.2875\) mA from Equation B20.

The values of \(I_i, V_{bi},\) and \(R_1\) show perfect agreement as one would expect, since the curve fitting was performed there. However, note that the calculated value for \(I_p\) agrees very closely with the measured peak-current value of \(-0.286\) mA and, in fact, is accurate within the overall measurement accuracy of about 0.5 percent. The calculations by this method of curve fitting are very sensitive to the value of \(V_p\).

Let us identify this portion of the piecewise current approximation by \(I_2\) and evaluate the associated constants of \(A_2\) and \(a_2\). Thus, from (B2) we have

\[
I_2 = A_2 (a_2 V)^{\gamma_2} e^{a_2 V},
\]

where \(\gamma_2 = 1.275\) as calculated above

\[
a_2 = \frac{\gamma_2}{-V_p} = \frac{1.275}{0.046} = 27.73 \text{ from Equation B18}.
\]

Upon substituting \(a_2\) and \(V_p\) into Equation B26 we get \(I_{p2}\). So

\[
I_{p2} = A_2 (-\gamma_2)^{\gamma_2} e^{-\gamma_2} = A_2 \left(\frac{-\gamma_2}{e}\right)^{\gamma_2}
\]

and

\[
A_2 = I_{p2} \left(\frac{e}{-\gamma_2}\right)^{\gamma_2} = 2.626 \cdot 0.2875 = 0.755 \text{ mA}.
\]
The calculated $I_2$ vs. $V_b$ characteristic is shown in Figure B4 in comparison with measured data. It is very accurate in the vicinity of the inflection point, where it was curve fitted, and it holds within 3 percent accuracy of the measured data for reverse bias voltage range of approximately -20 to -130 millivolts. Beyond -130 millivolts the "valley region" of the diode characteristic commences and leads into the reverse voltage breakdown, so that $I_2$ accuracy becomes progressively worse. The accuracy also deteriorates as one approaches zero bias, and continues to be poor for forward bias. Therefore, the $I_2$ equation is satisfactory for calculating first and second derivatives under reverse bias conditions only, and it should be restricted to the range of approximately -10 to -150 millivolts.

Appendix C

Symbols and Definitions

A - constant in diode current equation, Appendix B
b - amplitude of $E_g$
$B_v$ - video bandwidth
C - diode junction capacitance
$C_b$ - rf by-pass condenser
$C_v$ - total video shunt capacitance
$C_p$ - diode package and mounting capacitance
$E_g$ - series equivalent rf signal generator voltage
$\sqrt{E_n^2}$ - total r.m.s. noise voltage
f - rf frequency
$f_c$ - diode cut-off frequency for positive $R$
$f_r$ - diode resistive cut-off frequency for negative $R$
$\Delta f$ - rf bandwidth
G - diode differential junction conductance, $(dI/dV)$
$G'$ - first derivative of G
I - resistive component of diode junction current
$I_b$ - diode dc bias current
$I_g$ - total diode current, $(I_g = I + C (dV/dt))$
$I_p$ - tunnel diode peak point current value
$I_i$ - tunnel diode inflection point current value
$I_r$ - detector rectified output current
$I_{eq}$ - equivalent shot-noise-producing dc current

$\sqrt{I_{n}^{2}}$ - total r.m.s. noise current due to diode and $R_v$

$k$ - Boltzmann's constant, $(1.38 \cdot 10^{-16}$ ergs/degree Kelvin)$

$L$ - equivalent rf circuit series inductance plus $L_s$

$L_s$ - diode series inductance

$M$ - diode figure of merit

$P_i$ - rf power incident upon the detector

$P_t$ - tangential sensitivity input rf power level

$q$ - electronic charge, $(1.6 \cdot 10^{-19}$ coulombs)$

$Q$ - circuit Q factor

$R$ - diode differential junction resistance, $(dV/dI)$

$R_g$ - equivalent series resistance of rf circuit

$R_s$ - diode series resistance

$R_v$ - equivalent video circuit resistance

$R_i$ - total equivalent resistance of diode in parallel with $R_v$ (Note: $R_i$ is also used in Appendix B to denote the inflection point negative resistance value of $R$)

$R_{eq}$ - amplifier excess noise equivalent resistor

$r$ - series equivalent junction resistance of diode

$r_0$ - value of $r$ at $\omega_0$

$T$ - temperature in degrees Kelvin

$V$ - diode junction voltage

$V_b$ - diode dc bias voltage

$V_{j_b}$ - junction dc bias voltage, $(V_{j_b} = V_b - I_bR_s)$

$v$ - excursion of $V$ from $V_{j_b}$, $(v = V - V_{j_b})$

$Z$ - total equivalent series impedance of diode plus rf circuit

$Z_j$ - equivalent series impedance of diode junction
\(\alpha\) - constant in diode current equation, Appendix B

\(\beta\) - rectification current sensitivity

\(\gamma\) - constant in diode current equation, Appendix B

\(\Gamma\) - reflection coefficient referred to \(R_s\)

\(\tau\) - pulse rise time between 10 and 90 percent amplitude points

\(\omega\) - frequency in radians per second

\(\omega_0\) - value of \(\omega\) at center of rf passband

Subscripts:

\(0\) - refers to diode zero bias point except for \(\omega_0\), \(\alpha_0\), \(\beta_0\), \(\Gamma_0\)

\(p\) - refers to diode peak current bias point

\(i\) - refers to diode inflection bias point except for the special case noted for \(R_i\)
