SUBJECT: Announcement of NASA-Owned U.S. Patents in STAR

In accordance with the procedures contained in the Code GP to Code USI memorandum on this subject, dated June 8, 1970, the attached NASA-owned U.S. patent is being forwarded for abstracting and announcement in NASA STAR.

The following information is provided:

U.S. Patent No.: 3,350,033
Corporate Source: Goddard Space Flight Center
Supplementary Corporate Source: 

NASA Patent Case No.: XGS-02629

Enclosure: Copy of Patent
ABSTRACT OF THE DISCLOSURE

A satellite stabilization apparatus in which the function of a reaction wheel stabilizer and an optical horizon scanner are combined in a single device wherein the flywheel as an integral part of the reaction wheel produces the rotation of the scan means and where the stationary parts of the optical scanner are within the shaft of the flywheel and concentric thereto. A salient feature is the great efficiency afforded with respect to weight, power consumption, volume and reliability by elimination of gear trains, motors, bearings and other components.

The invention described herein may be manufactured and used by or for the Government of the United States of America for governmental purposes without the payment of any royalties thereon or therefor.

This invention relates to an orientation method and apparatus, and more specifically to a means for orienting a space vehicle with respect to the earth. The invention employs a novel reaction wheel formed integrally with a scanning means for sensing infra-red radiation changes between earth and sky observations. The reaction wheel is employed to develop and store momentum. Since an uncontrolled spacecraft will tumble erratically in orbit, means must be employed to stabilize the craft so that, for example, a sensor for a particular experiment may be pointed in a desired direction. Inertia wheels are one of several types of devices employed to stabilize or align spacecraft. An inertia wheel or a reaction wheel may be viewed as a servo motor with a large inertia rotor. The operation of reaction wheels is based upon Newton's third law of motion which states that for every action there is an equal and opposite reaction. To illustrate the law, a person stepping from a canoe (action) imparts an opposite motion (reaction) to the canoe. In a similar manner, if an electric motor is employed to increase the turning speed of a reaction wheel in one direction, an opposite torque or turning motion is imparted to the motor mount. The motor mount being coupled to the spacecraft structure causes the structure to move accordingly. By accelerating or decelerating the reaction wheel by varying the current to the motor, the attitude or orientation of the spacecraft can be controlled.

The command signal for reaction wheel operation may be self-generated by the spacecraft system or may be transmitted to the spacecraft from an external station. Depending upon the spacecraft mission, the spacecraft may be controlled from a sun sensor, a star tracker, an horizon scanner or a gyro platform.

Accelerating and decelerating the reaction wheel will permit many alignments of the spacecraft. However, the reaction wheel may reach its maximum allowed rotational speed and from there on, that reaction wheel can be employed to orient the spacecraft in one direction only, the direction obtained by decelerating the wheel since further acceleration of the wheel is not possible. The wheel must now be unloaded, or returned to a speed between its minimum and maximum. Thus, the maximum amount of angular momentum stored in the reaction wheel must now be reduced and this is accomplished by the application of an opposite torque to the spacecraft, for example, by reaction jets. The unloading speed and direction of rotation signal is obtained from a tachometer positioned within the reaction wheel unit.

Although the command for reaction wheel operation may originate with a number of systems as hereinbefore set forth, the present invention will be illustrated and described with reference to a horizon scanner. The scanner senses infra-red radiation changes between earth and sky observations and by manipulating this information, controls the current to the reaction wheel motor. Heretofore, the reaction wheel and the scanner have been separate units which were highly inefficient with regard to weight, volume, power consumption, in comparison with the present invention. The present invention incorporates a unique construction wherein reaction wheel and scanner are formed as an integral unit thus reducing the number of motors required as well as effecting a great saving in weight, space, and power consumption. Certain elements of the scanner are coupled to the flywheel of the reaction wheel scanner and rotate due to the rotational energy imparted thereto.

Accordingly, it is the principal object of the present invention to improve methods and apparatus for orienting a free body.

It is a further object of the present invention to improve methods and apparatus for stabilizing or aligning a free body such as a spacecraft.

It is a further object of the present invention to reduce the weight, volume, and power consumption of apparatus employed to orient and stabilize a space vehicle.

It is a further object of the present invention to provide a reaction wheel incorporating its own scanner, in a single package, and when the device is employed in pairs, the reaction wheel is responsive to the scanner output to orient and stabilize the space vehicle.

It is a further object of the present invention to provide a plurality of inertia wheels, some of which employ a unique construction, wherein the reaction wheel and horizon scanner are incorporated into a single package, the unique reaction wheel scanners being employed to derive outputs for pitch and roll correction signals and being capable of receiving an input correction signal to realign the space vehicle about its respective axis.

It is a further object of the present invention to reduce the viscous drag of reaction wheel scanners by providing a construction wherein an air bearing is incorporated in the apparatus thereby eliminating the drag produced by lubricants and conventional bearings.

These and other objects of the present invention are accomplished by providing a reaction wheel and scanner of unitary construction (the reaction wheel and scanner are incorporated into a single package, the flywheel of the reaction wheel supplying rotary power to certain elements of the scanner), when employed in pairs will provide information for deriving pitch and roll correction signals by sensing infrared radiation changes between earth and sky observation. The sensed information is employed to detect the earth horizon and thereby generate correction signals for orienting or aligning the space vehicle in a desired position.

In an illustrative environment set forth for the practice of the invention, the reaction wheel scanners are employed in pairs which derive information indicative of pitch and roll correction signals. After processing, the correction signal for roll reorientation is applied to the pair of reaction wheel scanners in the form of a varying current while the pitch correction is applied to a separate pitch reaction wheel. In a known manner, yaw information signals are derived from a gyro and after these signals
are processed in a control logic box, correction signals are directed to a yaw reaction wheel which is similar to the pitch reaction wheel.

Since an uncontrolled space vehicle tumbles erratically in orbit, means must be employed to orient, stabilize and align the space vehicle at least during certain periods of the flight so that various experiments may be conducted and useful information derived. In systems of this type, the system weight, volume, and power consumption is of paramount importance in that these parameters must be maintained at a minimum. The reaction wheel scanner of the present invention meets all of these requirements. The use of a pair of reaction wheel scanners in place of two infrared horizon scanners and a separate reaction wheel reduces the number of motors required from three to two, and will reduce the number of bearings required which introduce viscous drag and produce other losses.

In the reaction wheel scanner, a prism and lens combination is centrally secured to a momentum flywheel surrounding a shaft, which in the particular embodiment illustrated, is a hollow shaft; rotational energy being supplied by a pancake type of motor. The hollow shaft permits the stationary radiation sensor, in the form of a bolometer, to be in line with the rotating objects. The unit is housed in a sealed container with a germanium window. The shaft of the reaction wheel scanner in one direction to only between a minimum and a maximum speed, which is the speed range that the infrared signal processor is capable of handling. The reaction wheel scanners are employed in back-to-back pairs such that when they are rotating in opposite directions at the same speed, there is no net momentum. As the reaction wheel scanners rotate, an error signal will ultimately be produced. To correct for the error, the reaction wheels of the reaction wheel scanners speed up or slow down to orient the spacecraft to the zero error position.

The invention both as to its organization and method of operation together with further objects and advantages thereof will best be understood by reference to the following specification taken in conjunction with the accompanying drawings in which:

FIGURE 1 is a block diagram of an illustrative environment in which the reaction wheel scanners of the present invention may be utilized;

FIGURE 2 is an elevational schematic view of a spacecraft in orbit about the earth and illustrating the scanning pattern as viewed by the spacecraft optics;

FIGURE 3 is a schematic plan view of the satellite or space vehicle of the FIGURE 2 and illustrating the measurements which are derived by the reaction wheel scanners to provide pitch and roll correction signals;

FIGURE 4 is a sectional view of a reaction wheel scanner and having the principal parts of a stator, a rotor-flywheel, and an optical system for the scanner portion; and

FIGURE 5 is an elevational view of another embodiment of a reaction wheel scanner, the major difference from the embodiment of the FIGURE 4 being that the usual bearings have been eliminated and an air bearing is incorporated in the apparatus.

FIGURE 6 illustrates an example of a complete system incorporating the novel reaction wheel scanner of the present invention and for attaining stabilization and orientation of a free body about pitch, roll and yaw axes. If a reaction wheel (or wheels) assigned to control a particular axis is secured to the body, the variation of current to the reaction wheel will cause more or less momentum to be stored in the flywheel of the reaction wheel so that the reaction wheel through its coupling with the spacecraft, will orient the spacecraft or body about its particular assigned axis.

More specifically, a first reaction wheel scanner 10 and a second substantially identical reaction wheel scanner 12 forming the salient teaching of the present invention are disposed about the roll axis of the body and operate in diametrically opposed pairs. The reaction wheel scanners 10 and 12 are rotated in opposite directions so that when their speed is equal, there is no net momentum. As the reaction wheel scanners sense an error, to be hereinafter described, the reaction wheel scanners 10 and 12 speed up or slow down so as to reorient the spacecraft about its roll axis and to the zero error position.

Infrared radiation is received by the optics system, to be hereinafter described, from the satellites local vertical. The bolometer output from the reaction wheel scanner 10 is supplied to an analogue to pulse converter 14 while the output from the reaction wheel scanner 12 is supplied to an analogue to pulse converter 16. The analogue to pulse converters 14 and 16 converts the analogue output of the bolometers to a pulse representation of the magnitude of the signal.

The outputs from the analogue to pulse converters 14 and 16 can now be employed to determine pitch and roll orientation so as to derive correction signals in a satellite logic box 18 which will now be described with reference to the FIGURES 2 and 3.

In the FIGURES 2 and 3, schematic views of a satellite in orbit about a planet such as Earth are illustrated and the optical scanners in the reaction wheel scanners 10 and 12 traverse in area so as to detect the earth's horizon by sky observations. The "a" and "b" pulse signals, received from the bolometers and directed to the control logic box 18 via the analogue to pulse converters 14 and 16, are proportional to the distances "a" and "b" illustrated in the FIGURE 3. The pulse lengths of the "a" and "b" signals are compared and the resulting difference signals are determined by operating on L1 and L2 signals. Each scanner electronics passes a signal representative of L1 and L2 to the FIGURE 3 to the control logic box 18 and a difference signal is derived. The control logic box 18 receives an output from tachometer 66 during each revolution of the flywheel. The positional relationship of the tachometer pickoff, is established when the reaction wheel scanner is mounted on the satellite so that the tachometer output signal identifies the instant in which the scan is directed perpendicular to the plane formed by the pitch and roll axis of the satellite. This tachometer signal, which may be a pulse, therefore serves as the local vertical reference of the satellite. Accordingly, it can be seen, that a signal which occurs at the time the optical scan is on the local vertical serves to divide the L1 or L2 signal into its "a" and "b" components utilized for the logic control function. The circuitry in the control logic box 18 then averages the two difference signals (between the "a" and "b" signals from the two scanner electronics) and applies a signal in accordance therewith to both the reaction wheel scanners 10 and 12 via the conductors 20 and 22, respectively, to vary the current to the reaction wheel scanners 10 and 12 so that they will function at the desired speed level so as to torque the spacecraft to the proper attitude about the roll axis. It is to be understood that in order to develop the roll error signals it is not necessary that the tachometer output be adjusted to occur exactly on the vertical reference, and that other arrangements are possible. For example, in discrete type tachometers, as long as the angular displacement of the tachometer from the satellite local vertical is known (displacement can be determined by measurements during manufacture and the information can be stored in the satellite control logic box), and as long as the reaction wheel speed is available, it is seen that a signal can be generated which depicts that instant when the optical scan is along the local vertical.

In like manner, the difference signals representing the difference between the L1 and L2 signals is applied via a conductor 24 to a pitch reaction wheel 26, as shown in the FIGURE 1.

A gyro 28 of the FIGURE 1 and of known construction,
supplies yaw information via a conductor 30 to the circuitry of the satellite control logic box 18 which then generates the proper signal to a yaw reaction wheel via a conductor 34 to torque the spacecraft about the yaw axis. A pneumatic system 36 of the FIGURE 1 is illustrated in block form and comprises a gas supply, solenoids, and gas jets (all of which are not shown) which are employed to unload the reaction wheels.

The system is a closed loop servo system in which the reaction wheels and reaction wheel scanner speed are fed back to the attitude computer in the control logic box 18 so that the reaction wheel scanner 10, 12, 26 and 32 when the wheels reach their maximum speed. The gas jets are fired in such a direction so that their thrust will torque the spacecraft in the direction which generates the proper signal to a yaw reaction wheel via a conductor 34 to provide one rotary support for the flywheel 70 while the leftward projection 76 of the flywheel 70 cooperates through a bearing 86 and the trunnion 80 to provide the other rotary support for the flywheel 70. Suitable seals are provided adjacent the bearings 84 and 86, as shown.

With continued reference to the reaction wheel scanner of the FIGURE 4, a window 88 is axially positioned upon the housing 40 and includes an annulus 90 secured to the housing 40 by a plurality of studs 92. The annulus 90 houses a germanium window 94 which is seated in the annulus 90 between a pair of resilient sealing members, as shown in cross-hatched section.

Whereas the germanium window 94 and the bolometer 54 are stationary with respect to the base member 38 and the housing 40, certain elements of the optical system rotate along with the flywheel 70. These elements are an optical baffle 96 which is seated within a sleeve 98, the sleeve 98 being fitted within the housing 40 by a plurality of studs 92. The annulus 90 houses a germanium window 94 which is seated in the annulus 90 between a pair of resilient sealing members, as shown in cross-hatched section.

Thus, the reaction wheel scanner of the FIGURE 4 is the rotor 68, the flywheel 70 including the rightward projection 74 and its leftward projection 76, the sleeve 98, the optical baffle 96 and the lens 100. The revolutions of the flywheel 70 may be determined by the tachometer 66, previously described, which senses the rotary motion through a ring 102 embedded in the flywheel 70 immediately adjacent the tachometer 66. The electrical conductors for performing the various functions within the reaction wheel scanner and their outputs are coupled to any external apparatus through a connector 104, as shown. In addition, a valve, not shown, may be employed which leads from the outside to the inside of the reaction wheel scanner so that the atmosphere within the reaction wheel scanner may be maintained at a desired pressure or type of fluid other than air.

Thus, one of the salient features of the invention is clearly visible in that the reaction wheel and the scanner have been combined into a single structure with the flywheel of the reaction wheel providing the rotary motion for the optical assembly which requires rotation. In this manner, the effective momentum of the flywheel is increased due to the addition of the additional weight produced by the rotating optical element.

Whereas the reaction wheel scanner of the FIGURE 4 employs conventional, although perhaps modified, bearings between the flywheel and stationary elements, the reaction wheel scanner of the FIGURE 5 is a hydrodynamic gas bearing reaction wheel scanner. A base member 106 has a housing 108 of generally circular configuration secured along and around the inner surface of the leftward manner. An annulus 110 is secured to the base member 106 and supports an outwardly directed ring 112 which forms the core for the stator windings 114. A hollow shaft 116 is secured to the base member 106 and extends axially to a circular flange 118 secured to the shaft 116 at its free end. Within the shaft 116 and toward the leftmost end of the shaft is positioned an optical baffle 120 which is aligned with a bolometer 122 having a pair of output conductors 124.

A window 126 which may be of germanium is supported by the housing 108 and in axial alignment with the baffle 120 and the bolometer 122. A connector 128 permits the conductors 124 to pass through the base member.
The present invention may be embodied in other specific forms without departing from the spirit and the essential characteristics of the invention. The present embodiment is, therefore, intended to be embraced therein.
14. The means as defined in claim 12 wherein said scanning means includes a lens and optical baffle driven in rotary engagement with said flywheel rotor.

15. A reaction wheel scanner comprising a flywheel rotor, a stator adjacent said rotor, and scanning means juxtaposed said flywheel rotor for deriving signals to control the current to said stator wherein said scanning means is concentric with said rotor and stator, portions of which are driven by said flywheel rotor.

16. A reaction wheel scanner comprising a base member, a centrally positioned axial sleeve extending from said member, a stator supported from the outer surface of said sleeve, a rotor surrounding said stator, a flywheel surrounding said rotor and secured thereto, said flywheel including a circular web formed integrally therewith and an inner sleeve formed on said web and oppositely directed from said web, a portion of said inner sleeve projecting into said axial sleeve and journaled for rotation therein, a housing surrounding said flywheel and secured to said base member, said housing having an inwardly directed trunnion secured therein and surrounding a portion of said inner sleeve, on a side opposite of said web which projects into said axial sleeve, said portion of said inner sleeve being journaled for rotation in said trunnion.

17. The combination as defined in claim 16 including sensing means positioned within said inner sleeve.

18. The combination as defined in claim 17 wherein said sensing means includes a rotating lens and optical baffle for directing radiant energy upon a stationary bolometer.

19. The combination as defined in claim 18 including a germanium window in axial alignment with said lens, baffle and bolometer and secured to said housing.

20. A reaction wheel scanner comprising a base member, a centrally positioned axial sleeve extending from said base member, a stator supported from the outer surface of said sleeve, a rotor surrounding said stator, a flywheel surrounding said rotor and secured thereto, said flywheel including a circular web formed integrally therewith and an inner sleeve formed on said web and having a first portion projecting from one side of said web and into said axial sleeve and a second portion projecting from the opposite side of said web, a housing surrounding said flywheel and secured to said base member, said housing having an inwardly directed trunnion secured thereto and surrounding said second portion of said sleeve, bearing means surrounding said first and second portions of said sleeve and engaging, respectively, the inner surfaces of said axial sleeve and said trunnion for permitting rotation of said flywheel and rotor, a bolometer positioned within said first portion of said sleeve, a lens and baffle secured within said second portion of said sleeve, and a germanium window in axial alignment with said inner sleeve and secured to said housing.

21. The combination as defined in claim 20 including means for sensing the rotation of said flywheel.

22. The combination as defined in claim 20 including temperature sensing means positioned adjacent said bolometer.

23. A reaction wheel scanner comprising a base member, a hollow axial shaft extending therefrom, a stator surrounding said shaft and secured to said base member, a flywheel surrounding said shaft, the inner surface of said flywheel and the outer surface of said shaft forming a fluid bearing, a rotor surrounding said stator and secured to said flywheel, optical sensing means positioned within said hollow shaft, and a lens secured for rotation to said flywheel and focused upon said sensing means.

24. The combination as defined in claim 23 including a housing surrounding said flywheel and secured to said base member, and a germanium window supported by said housing and aligned with said lens and sensing means.

25. The combination as defined in claim 23 including pick-up means for sensing the revolutions of said flywheel.

26. A reaction wheel scanner comprising a base member, a hollow axial shaft extending therefrom, a stator surrounding said shaft and secured to said base member, a flange secured to the free end of said shaft, a flywheel surrounding said shaft and flange, the outer surface of said flywheel and the outer surface of said shaft forming a fluid bearing, a rotor surrounding said stator and secured to said flywheel, optical sensing means positioned within said hollow shaft, a lens secured for rotation to said flywheel and focused upon said sensing means, pick-up means for sensing the revolutions of said flywheel, a housing surrounding said flywheel and secured to said base member, and a germanium window supported by said housing and aligned with said lens and sensing means.
