ABSTRACT

Continuum mechanics solutions are derived for the static load-carrying capacity of scarf and stepped-lap adhesive-bonded joints. The analyses account for adhesive plasticity and adherend stiffness imbalance and thermal mismatch. The scarf joint solutions include a simple algebraic formula which serves as a close lower bound, within a small fraction of a per cent of the true answer for most practical geometries and materials. The scarf joint solutions are believed to be the first such results ever obtained for dissimilar adherends. Digital computer programs have been developed and, for the stepped-lap joints, the critical adherend and adhesive stresses are computed for each step. The scarf joint solutions exhibit grossly different behavior from that for double-lap joints for long overlaps inasmuch as that the potential bond shear strength continues to increase with indefinitely long overlaps on the scarf joints. The stepped-lap joint solutions exhibit some characteristics of both the scarf and double-lap joints. The stepped-lap computer program handles arbitrary (different) step lengths and thicknesses and the solutions obtained have clarified potentially weak design details and the remedies. Indeed, the program has been used effectively to optimize the joint proportions.

FOREWORD

This report was prepared by the Douglas Aircraft Company, McDonnell Douglas Corporation, Long Beach, California under the terms of Contract NAS1-11234. One summary report (NASA CR 2218) and four technical reports (NASA CR 112235, -6, -7, and -8) cover the work, which was performed between November 1971 and January 1973. The program was sponsored by the National Aeronautics and Space Administration's Langley Research Center, Hampton, Virginia. Dr. M. F. Card and Mr. H. G. Bush were the Contracting Agency's Technical Monitors.

SYMBOLS

\( A_0, \ldots A_n \) = Coefficients of power series for shear stress distribution in adhesive layer

\( a, c \) = Extents of plastic stress state in adhesive at ends of bonded joint (in.)

\( b \) = Extent of elastic trough in adhesive (in.)

\( C, D \) = Integration constants

\( C_{\text{THERM}} \) = Non-dimensionalized adherend thermal mismatch coefficient

\( d \) = Length of elastic zone in adhesive bond (in.)

\( E \) = Young's modulus (longitudinal) for adherend (psi)

\( E_{\text{TR}} \) = Adherend extensional stiffness ratio

\( F \) = Adherend allowable (or ultimate) stress (psi)

\( G \) = Adhesive shear modulus for elastic-plastic representation (psi)

\( \xi \) = Overlap (length of bond) (in.)

\( P \) = Applied direct load on entire joint (lb in. / in.)

\( S_{\text{GNDL}} \) = Distinguisher between tensile and compressive shear loads

\( T \) = Direct stress resultants in adherends (lb / in.)

\( \Delta T \) = Temperature change \( (T_{\text{operating}} - T_{\text{cure}}) \)

\( t \) = Thickness of adherend (in.)

\( x \) = Axial (longitudinal) coordinate parallel to direction of load

\( \alpha \) = Coefficient of thermal expansion (\( ^\circ \text{F} \))

\( \gamma \) = Adhesive shear strain

\( \gamma_e \) = Elastic adhesive shear strain

\( \gamma_p \) = Plastic adhesive shear strain

\( \delta \) = Axial (longitudinal) displacement of adherend (in.)

\( \zeta, \xi, x \) = Non-dimensionalized axial coordinates (different origin and/or sense from \( x \))
\( \eta \) = Thickness of adhesive layer (in.)
\( \theta \) = Scarf angle (small) (\(^{\circ}\))
\( \lambda \) = Exponent of elastic shear stress distribution (in.\(^{-1}\))
\( \nu \) = Poisson's ratio for adherend(s)
\( \tau \) = Adhesive shear stress (psi)
\( \tau_{av} \) = Average adhesive shear stress (psi)
\( \tau_p \) = Plastic (maximum) adhesive shear stress (psi)
\( \phi \) = \( x/\ell \) = Non-dimensionalized coordinate

SUBSCRIPTS

\( a,c \) = Adhesive (cement)
\( e,p \) = Elastic and plastic values
\( i,o \) = Inner and outer adherends of symmetric bonded joint
\( 1,2 \) = Different adherends at each end of joint
\( 1,2,..n \) = Power series counter
SUMMARY

It has long been known that bonded scarf joints have a higher efficiency than uniform lap joints and that the latter are limited in strength and unsuitable for joining thicker sections. What has not been well understood until recently is that, in the bonding together of dissimilar adherends in a scarf joint, any adherend stiffness imbalance or thermal mismatch imposes a limitation on the joint efficiency. As a consequence the adhesive layer is not (essentially) uniformly stressed along its length as it is for a scarf joint between identical adherends. One objective of this report is to analyze and quantify these limitations on efficiency of unbalanced scarf joints. In doing so, adhesive plasticity is accounted for by the Douglas elastic-plastic model which has been demonstrated to be effective for uniform lap joints. One dominant characteristic deduced for scarf joints is that for long overlaps, regardless of any adhesive ductility and/or adherend thermal mismatch, the ratio of the average adhesive shear stress to the peak adhesive shear stress is equal to the lower ratio (<1) of the adherend extensional stiffnesses. The governing differential equations do not possess an explicit solution in terms of standard functions, so a series solution was employed. Even so, an algebraic expression was deduced for a lower bound which proved to be so close to the more precise solutions that it could be employed directly for practically all realistic joint proportions. Severe adverse effects of adherend thermal mismatch are confined to a specific overlap range. The effects decrease asymptotically to zero for very short or very long overlaps.

Stepped-lap joints represent a cross between scarf joints and uniform lap joints. The stepped-lap joint overcomes the upper limit on joint strength of uniform lap joints but retains the severe adhesive strain concentration at the end of each step. One advantage of stepped-lap joints over scarf joints is that the alignment and fit is far less critical when there are joints on more than a single interface. Another is that it is more suitable for boron-epoxy laminates than is a scarf joint because of the thick brittle filaments. This is particularly important for the titanium edge members frequently used in conjunction with boron-epoxy panels. Because the graphite fibers are so much thinner and more flexible than boron filaments, the former can take advantage of the higher efficiency of the scarf joint.
Digital computer FORTRAN IV programs are included for the iterative solutions necessary for these problems. The scarf joint solutions are in terms of non-dimensionalized parameters. The stepped-lap joint program is dimensional and permits each step to be varied independently so as to be able to identify and improve the most critical detail(s) of the joint. One key factor in the design of stepped-lap joints is that the bond load transfer is concentrated at the end of the joint from which the softer (less stiff) adherend extends. Consequently, it is necessary to restrict the length of the end step of the stiffer adherend to prevent it from being overloaded. Another characteristic of stepped-lap joints identified by the analyses is that the end three steps of the more critical end dominate the internal load distribution and effectively determine the load capacity. The steps at the less critical end are found to have practically no effect on the load capacity.
I. INTRODUCTION

It is generally recognized that, in the bonding together of thick sections, the use of either scarf or stepped-lap joints is mandatory if an acceptable structural efficiency is to be realized. References (1) and (2) explain how, for uniform lap joints, the maximum possible joint efficiency decreases with increasing thickness (extensional stiffness) of the members being bonded together. The objective of this report is to apply the elastic-plastic adhesive analysis techniques developed in References (1) and (2) to the scarf and stepped-lap joints. The approach used remains that of continuum mechanics rather than finite elements. The governing differential equations were relatively straightforward to set up but, in most cases, specific closed-form solutions could not be derived. Severe numerical accuracy problems had to be overcome in developing the FORTRAN IV digital computer programs employed and this phase of the work represented by far the bulk of the investigation. The computer programs are listed in the Appendices and representative non-dimensionalized solutions are illustrated to show the effect of the governing scarf joint parameters. Specific solutions are presented for stepped-lap joints.

This scarf joint analysis is concerned with the non-uniform adhesive shear stresses necessarily associated with the bonding together of dissimilar adherends. It is well-known that the stresses are uniform if the adherends are identical. It has only recently begun to be appreciated that the adhesive shear stresses are markedly non-uniform if the adherends are dissimilar. Indeed, the literature contains very few references to this problem. The mechanism whereby these non-uniform stresses are developed is illustrated in Figure 1 for the case of thermal mismatch between stiffness-balanced adherends. The first publication on scarf joints between dissimilar adherends appears to be that of Lubkin [Reference (3)] who, in 1957 sought the particular scarf angle associated with uniform adhesive stress for a particular ratio of adherend elastic moduli. He omitted consideration of any adherend thermal dissimilarity. Unfortunately the predictions of his equation [10] are such as to indicate the appropriate scarf angle $\theta$ is so great (typically in excess of 45 degrees) as to be of no practical interest for bonding aerospace materials together. For realistic adhesives and adherend materials, the scarf angle should be restricted to less than 4 degrees in order for the potential bond
strength to exceed the adherend strength(s). Working independently, in 1971, the present author [Reference (4)] and Erdogan and Ratwani [Reference (5)] demonstrated by calculation the non-uniform adhesive shear stress associated with scarf joints between dissimilar adherends. The former work was based on a perfectly-plastic adhesive analysis, while the latter derived from a linearly-elastic formulation. Consequently neither afforded a complete solution but both demonstrated clearly that the adhesive load transfer is concentrated at that end of the joint from which the softer adherend extends. The present solution utilizes an elastic-plastic adhesive model with linearly elastic adherends and accounts for adherend stiffness and thermal imbalances. Eccentricities in the load path are excluded and, in keeping with common design practice, the scarf angle is considered to be so small that adhesive tension (or compression) stresses may be neglected in comparison with the shear stresses.

In 1968, an elastic finite-element analysis of scarf joints was performed by Richards [see Reference (6)]. Boron/epoxy-to-boron/epoxy and boron/epoxy-to-aluminum joints were analyzed. Thermal effects were neglected. In the former case, relatively small (<4%) stress concentrations were identified in the vicinity of the ends of the scarf. Their existence had not been demonstrated prior to that investigation. In the latter case a markedly non-uniform stress distribution was deduced, with significantly more load being transferred to and from the 0° plies in the laminate than occurred with the ±45° plies. This is to be expected in view of the much lower modulus of the cross plies.

While the mathematical complexity of equations governing the scarf joint has restricted the number of solutions obtained, a number of investigations of the stepped-lap adhesive-bonded joint have been performed. Finite-element elastic solutions are reported in References (5) to (9) but none of these include any thermal mismatch effects. Reference (10) included adhesive and adherend non-linear behavior in the analysis but, for the stepped-lap joint, encountered convergence difficulties at high load levels. Grimes, Calcote, Wah, et al. [Reference (10)] also performed non-linear iterative theoretical analyses of double-lap, single-lap and stepped-lap joints which they compared with their discrete element analyses, showing good agreement for the first two. They also formulated the scarf joint equations (see their Appendix A) in greater detail than is done here, but were unable to solve them. Corvelli and Saleme
[Reference (11)] developed analysis techniques for bonded joints which included analytical solutions for stepped-lap joints, but in a less comprehensive form than presented here.

Past attempts to include non-linear adhesive behavior in the analytical solutions have centered around the Ramberg-Osgood representation which has a smooth continuous characteristic. This has precluded the derivation of any explicit closed-form solutions. The present author had earlier derived such solutions for double- and single-lap adhesive-bonded joints using an elastic-plastic adhesive formulation [see References (12) and (13)]. These showed that the adhesive shear strain energy per unit bond area was the necessary and sufficient adhesive characteristic governing the potential bond shear strength. The precise shape of the stress-strain curve appeared to be unimportant. This belief was further reinforced in Reference (1) by the derivation of precisely the same potential bond shear-strength for any arbitrary bi-elastic adhesive characteristic having the same strain energy and failure stress and strain. In addition, the author's elastic-plastic solution was in good agreement with the discrete element solutions by Teodosiadis [Reference (14)], who represented the adhesive and interlaminar shear characteristics by six straight segments. The success of this elastic-plastic adhesive approach in these simpler problems led to the decision to apply the same techniques to the scarf and stepped-lap joints in this report.

The adhesive-bonded stepped-lap joint is of practical interest principally because of extensive use in the bonding of boron-epoxy to titanium edge members. The boron filaments are too thick (0.005 inch), and too hard to machine, to be as suitable for the more efficient scarf joints as the very thin graphite fibers are. In practice the stepped-lap joint contains a large number of small steps and closely approximates the behavior of the equivalent scarf joint. The only difference is marked for very brittle (high-temperature) adhesives and is the adhesive shear stress (and strain) concentrations at the ends of each step, particularly at the outermost steps. It transpired that peel stresses imposed more severe limitations for thick double- and single-lap joints than did the adhesive shear stresses [see References (1) and (2)]. In actual design practice for scarf and stepped-lap joints, the slope is small and the end step is
invariably thin so there is no way for severe peel stresses to develop. For any unusual stepped-lap joint, with a thick outer end step, the analysis in Reference (1) can be employed to assess any potential peel problem.

This report considers in turn elastic and elastic-plastic analyses of scarf and stepped-lap joints and discusses parametric effects and design procedures. The digital computer programs prepared from the analyses are recorded in the Appendices, along with brief instructions for their use.
2. ELASTIC ANALYSIS OF SCARF JOINTS

Figure 2 depicts the geometry and nomenclature for the analysis of a non-eccentric bonded scarf joint. The diagram serves for both the elastic and elastic-plastic solutions. In the former case, the plastic adhesive zones should be considered removed. That is, set \( a = c = 0 \) and \( b = \ell \). The scarf angle \( \theta \) is considered so small that \( \cos \theta = 1 \) and \( \theta = 0 \). In other words, the effect of adhesive peel stresses is omitted from consideration. This is quite legitimate for the small scarf angles associated with practical aerospace materials.

The conditions of horizontal equilibrium for a differential element \( dx \) within the joint are

\[
\frac{dT_1}{dx} + \tau = 0 , \quad \frac{dT_2}{dx} - \tau = 0 .
\]

The stress-strain relations for the adherend materials, accounting for thermoelastic effects, yield

\[
\frac{d\delta_1}{dx} = \frac{T_1}{(Et)_1} + \alpha_1 \Delta T , \quad \frac{d\delta_2}{dx} = \frac{T_2}{(Et)_2} + \alpha_2 \Delta T ,
\]

in which the adherend thicknesses, as a function of the axial coordinate \( x \) are

\[
(ET)_1 = E_1 t_1 \left( 1 - \frac{x}{\ell} \right) , \quad (ET)_2 = E_2 t_2 \left( \frac{x}{\ell} \right) .
\]

The adhesive shear strain is taken to be uniform across the thickness of the bond. That is

\[
\gamma = (\delta_2 - \delta_1)/n .
\]

The elastic adhesive shear stress follows as

\[
\tau = G\gamma = G(\delta_2 - \delta_1)/n .
\]

In solving these equations it is desirable to non-dimensionalize the solution with respect to the peak adhesive shear stress \( \tau_p \) and the bond overlap. Thus, introducing the non-dimensionalized axial co-ordinate

\[
\phi = x/\ell ,
\]
a series solution is sought, having the form

\[
\frac{\tau}{\tau_p} = \sum_{n=1}^{\infty} A_n \phi^{n-1}. \tag{7}
\]

We define the adherend 1 end of the joint as critical so that

\[A_1 = 1,\tag{8}\]

if necessary by interchange of the identifying subscripts 1 and 2. While a single non-linear differential equation has been derived from the equations above, it cannot be solved directly. This is why a series solution is employed here and, in this case, it is more straightforward to work in terms of the equations above than the derivative governing equation.

The solution proceeds from equation (7). Substitution into equation (1) yields, for the adherend forces per unit width,

\[T_1 = \tau_{av} \frac{\tau}{\tau_p} \sum_{n=1}^{\infty} A_n \phi^n, \quad T_2 = \tau_p \sum_{n=1}^{\infty} A_n \phi^n. \tag{9}\]

Now equation (5) is differentiated.

\[
\frac{d(\tau / \tau_p)}{d\phi} = \frac{G}{\tau_p} \left[ \frac{d\delta_2}{d\phi} - \frac{d\delta_1}{d\phi} \right]. \tag{10}\]

Substitution of the series (7) and (9), with the aid of equations (2), leads to the solution

\[
\sum_{l=1}^{(n-1)} A_n \phi^{(n-2)} = \frac{G\ell}{\tau_p} \left\{ \left( \alpha_2 - \alpha_1 \right) \Delta T + \frac{\tau_p}{E_2} \sum_{n=1}^{\infty} A_n \phi^{(n-1)} \right. \\
- \frac{\tau_{av}}{E_1 t_1 (1 - \phi)} + \frac{\tau_p}{E_1 t_1 (1 - \phi)} \sum_{n=1}^{\infty} A_n \phi^n \left\}. \tag{11}\]
Multiplication throughout by \((1 - \phi)\) converts the equation directly into a form suitable for solution by recurrence relations.

\[
(1 - \phi) \sum_{n=1}^{\infty} (n-1) A_n \phi^{(n-2)} = \frac{G\ell}{\tau_p} \left( \alpha_2 - \alpha_1 \right) \Delta T (1 - \phi) - \frac{G\ell^2 \tau_{av}}{nE_{t1} \tau_p} \\
+ \frac{G\ell^2}{n} \left[ \frac{(1 - \phi)}{E_{t2}} \sum_{n=1}^{\infty} A_n \phi^{(n-1)} + \frac{1}{E_{t1}} \sum_{n=1}^{\infty} A_n \phi^n \right]. \quad (12)
\]

In order to give the solution the greatest coverage with the minimum number of independent variables, certain non-dimensional parameters are introduced. The non-dimensionalized overlap is given by the square root of

\[
(\lambda \ell)^2 = \frac{G\ell^2}{n} \left[ \frac{1}{E_{t1}} + \frac{1}{E_{t2}} \right] = \frac{\tau_p G\ell^2}{n \gamma_e} \left[ \frac{1}{E_{t1}} + \frac{1}{E_{t2}} \right], \quad (13)
\]

the non-dimensionalized thermal mismatch term is

\[
CTERM(1) = \frac{\lambda (\alpha_2 - \alpha_1) \Delta T}{\tau_p \left( \frac{1}{E_{t1}} + \frac{1}{E_{t2}} \right)}, \quad CTERM(2) = - CTERM(1), \quad (14)
\]

and the adherend stiffness ratio is

\[
ETR(1) = \frac{E_{t1}}{E_{t2}}, \quad ETR(2) = \frac{E_{t2}}{E_{t1}}. \quad (15)
\]

It is interesting to note that precisely the same variables govern the double-lap joint [see Reference (1)]. Equation (12) then becomes

\[
\sum_{n=1}^{\infty} (n-1) A_n \phi^{(n-2)} = (\lambda \ell) \times CTERM(1) \times (1 - \phi) - \frac{(\lambda \ell)^2 \tau_{av}}{[1 + ETR(1)]} \\
+ \frac{(\lambda \ell)^2 ETR(1)}{[1 + ETR(1)]} \sum_{n=1}^{\infty} A_n \phi^{(n-1)} + \frac{(\lambda \ell)^2 [1 - ETR(1)]}{[1 + ETR(1)]} \sum_{n=1}^{\infty} A_n \phi^n . \quad (16)
\]
By rearranging the limits of the series it follows that

\[ \sum_{n=1}^{\infty} \left[ (n+1)A_{n+2} - nA_{n+1} \right] \phi^n = (\lambda \xi) \times \text{CTHERM}(1) \times (1 - \phi) - \frac{(\lambda \xi)^2}{[1 + \text{ETR}(1) \tau_p]} \]

\[ + \frac{(\lambda \xi)^2 \text{ETR}(1)}{[1 + \text{ETR}(1)]} \sum_{n=1}^{\infty} \frac{A_{n+1}}{n-1} \phi^n + \frac{(\lambda \xi)^2 \text{ETR}(1)}{[1 + \text{ETR}(1)]} \sum_{n=1}^{\infty} \frac{A_n}{n} \phi^n. \]  \tag{17}

For large values of \( n \), on setting to zero the coefficient of the term \( \phi^{n-2} \), the recurrence relation is deduced as

\[ A_n = \left\{ (n-2)A_{n-1} + (\lambda \xi)^2 \left[ \frac{\text{ETR}(1)}{1 + \text{ETR}(1)} A_{n-1} + \left( \frac{1 - \text{ETR}(1)}{1 + \text{ETR}(1)} \right) A_{n-2} \right] \right\} / (n-1). \]  \tag{18}

It remains now to establish the initial conditions by examining the coefficients of the \( \phi^0 \) and \( \phi^1 \) terms. From the coefficient of \( \phi^0 \),

\[ A_2 = (\lambda \xi) \times \text{CTHERM}(1) - (\lambda \xi)^2 \left[ \frac{1}{1 + \text{ETR}(1)} \right] \tau_p + (\lambda \xi)^2 \left[ \frac{\text{ETR}(1)}{1 + \text{ETR}(1)} \right] A_1 \]  \tag{19}

while, from the coefficient of \( \phi^1 \),

\[ 2A_3 - A_2 = - (\lambda \xi) \times \text{CTHERM}(1) + \frac{(\lambda \xi)^2}{[1 + \text{ETR}(1)]} \left\{ [1 - \text{ETR}(1)] A_1 + \text{ETR}(1) \frac{A_2}{2} \right\}. \]  \tag{20}

It follows from equation (19) that, quite generally, for long overlaps (large values of \( \lambda \xi \)),

\[ \frac{\tau_p}{\tau_p} \rightarrow \text{ETR}(1) \leq 1. \]  \tag{21}

This surprisingly simple result proves to dominate the entire behavior of bonded scarf joints, even for elastic-plastic adhesives. This equation demonstrates conclusively the importance of maintaining adherend stiffness balance whenever possible. When this is maintained, in the absence of any thermal mismatch, the adhesive is essentially uniformly stressed throughout the entire overlap of any length. The only minor exception is the local end effect identified by Richards in Reference (6).
Returning now to the solution, in terms of equations (18) to (20), it follows by integrating equation (7) that

\[
\frac{\tau_{av}}{\tau_p} = \sum_{n=1}^{\infty} A_n.
\] (22)

In using this series it is necessary to employ two arbitrary constants to satisfy the boundary conditions. The first two are chosen. That is

\[
\frac{\tau_{av}}{\tau_p} = A_1 \times \text{SIG}(3) + A_2 \times \text{SIG}(4)
\] (23)

and, because of equation (8),

\[
\frac{\tau_{av}}{\tau_p} = \text{SIG}(3) + A_2 \times \text{SIG}(4).
\] (24)

The summations \text{SIG}(3) and \text{SIG}(4) are the quantities formed by evaluating the coefficients in equation (22) by means of equations (20) and (18) after setting, in turn,

\[
A_1 = 1, \quad A_2 = 0 \quad \text{for \text{SIG}(3)}
\] (25)

and

\[
A_1 = 0, \quad A_2 = 1 \quad \text{for \text{SIG}(4)}.
\] (26)

The solution procedure employed in the FORTRAN IV digital computer program listed in Appendix A1 is as follows. The coefficient \(A_3\) for each set of initial values (25) and (26) is evaluated in terms of equation (20). Then a number of higher order coefficients are evaluated in turn through the recurrence relation (18), the same number being evaluated for \text{SIG}(3) as for \text{SIG}(4). The results of these summations are then substituted into equation (19) which takes on the form

\[
A_2 \left\{ 1 + \frac{(\lambda \xi)^2}{[1 + \text{ETR}(1)]} \right\} \text{SIG}(4) = (\lambda \xi) \text{CTERM}(1) + \frac{(\lambda \xi)^2 \text{ETR}(1)}{[1 + \text{ETR}(1)]}
\]

\[
- \frac{(\lambda \xi)^2}{[1 + \text{ETR}(1)]} \text{SIG}(3).
\] (27)
The unknown $A_2$ is then to be evaluated and substituted into equation (19) re-arranged in the form

$$\frac{\tau_{av}}{\tau_p} = \frac{1 + ETR(1)}{(\lambda l)^2} \frac{C_{therm}(1)}{(\lambda l)^2} - \left(\frac{1 + ETR(1)}{(\lambda l)^2}\right) A_2$$

(28)

This equation establishes the potential bond shear strength.

The detailed discussion of parametric effects is presented in Section 5 but certain features of the mathematics of the numerical solution merit elaboration at this stage. The most important feature is the decision to evaluate the terms $A_n/n$ of the average stress series (22) directly rather than the quantities $A_n$ of the series (7). To do so, equation (18) is re-organized to the form

$$\left(\frac{A_n}{n}\right) = \frac{(n-1)(n-2)\left(\frac{A_{n-1}}{n-1}\right) + (\lambda l)^2 \left[ \frac{1 + ETR(1)}{1 + ETR(1)} \left(\frac{A_{n-1}}{n-1}\right) + \frac{1 - ETR(1)}{1 + ETR(1)} \left(\frac{A_{n-2}}{n-2}\right) \right]}{[n(n-1)]}$$

(29)

The reason for this is the factor $(\lambda l)^2$ in equations (29) and (18). Because of this, for long overlaps, a much higher value of $n$ is needed to reach negligible values of $A_n$ from equation (18) than to reach negligible values of $A_n/n$ from equation (29). Indeed, even with the use of equation (29) rather than equation (18) it remained impossible to compute reliable internal stress distributions for long overlap joints, even with as many as 50 terms of the shear stress series because of overflow in the computer. Such a computation is of little importance, however, since the critical location must be at one end or other of the joint. In spite of this problem, however, equation (27) converges rapidly, usually within the first five successive evaluations (for progressively increasing $n$) of $\Sigma(3)$ and $\Sigma(4)$. The program in Appendix A1 used 20 terms. In addition to this, because $A_2$ is divided by $(\lambda l)^2$ in equation (28), an extremely reliable value of $\tau_{av}/\tau_p$ can be computed readily. The program identifies the more critical end by the simple expedient of estimating the strength starting from each end of the joint and selecting the lower value. It is obvious that a computation of $\tau_{av}/\tau_p > 1$ signifies simply that condition (8) was violated. A negative value of $\tau_{av}/\tau_p$ indicates such severe thermal mismatch between adherends that the joint will break apart prior to application of any mechanical loads.
The computation of joint strength proceeding from the other end of the joint is effected by simply interchanging the subscripts 1 and 2 on all affected quantities. With regard to adherend stiffness imbalance alone, it is always possible to identify from equation (28) that the more critical end (1) is that for which \( E_{TR}(1) \leq 1 \). The possible ambiguity arises as the result of the thermal mismatch terms. Since \( C_{\text{THERM}}(1) \) may be either negative or positive independently of whether \( E_{TR}(1) \) is less than or greater than unity, severe thermal mismatch may nullify or even overpower any stiffness imbalance effects. This possibility is evidently greatest for short overlaps because of the factor \((\lambda\lambda)\) in the denominator of the thermal term in equation (28). It follows that the critical end of the joint between given adherends may well change as the overlap changes and, indeed, such behavior was predicted by the computer program output.

Equations (1) and (2) have been set up for applied tensile loads in the adherends. In the event that the applied load is compressive, it can be seen with reference to Figure 2 that all quantities except the thermal strain terms will change sign. This implies that, in the absence of any thermal mismatch effects, the same end of the joint is critical for both tensile and compressive adherend loads and that the joint strength is the same. Rather than change the sign of all quantities with the exception of the thermal terms, the program merely changes the signs of \( C_{\text{THERM}}(1) \) and \( C_{\text{THERM}}(2) \) to account for compressive loading rather than tensile loading. It should be noted that, as a consequence, the opposite end of the same joint may be critical for a reversed load and that the strength may not be the same if there is also stiffness imbalance between the adherends. Likewise, just as for double-lap joints, if the thermal mismatch terms nullify any stiffness imbalance effects for one load direction, they must aggravate the stress concentrations for a load in the reverse direction. By analogy with the double-lap joint analyses in Reference (1), the case of in-plane shear loading is covered by the analysis above replacing \( E_1 \) and \( E_2 \) in equation (2) and those equations based on it by the shear moduli \( G_1 \) and \( G_2 \) and neglecting the thermal affects which induce bond stresses at right angles to those of concern for mechanical in-plane shear loads except at the sides of the joint. The direct adherend forces \( T_1 \) and \( T_2 \) are replaced by shear forces \( S_1 \) and \( S_2 \) per unit length. A more precise representation of thermal effects for in-plane shear loading would necessarily require a two-dimensional
analysis rather than the one-dimensional solution above and the justification for doing so is minimized by the small amount of adhesive plasticity that even the real brittle adhesives exhibit.
3. ELASTIC-PLASTIC ANALYSIS OF SCARF JOINTS

The preceding elastic analysis covers essentially the most difficult formulative portions of the elastic-plastic scarf joint analysis. New numerical difficulties of major proportions were encountered in the generation of specific answers by the computer program, but the plastic part of the analysis is straightforward. The necessary additional geometry and nomenclature are identified in Figure 2. Equations (1), (2) and (4) continue to apply, with the substitutions

\[ dx = \xi \, d\xi = \xi \, d\chi = \xi \, d\zeta \]  

as appropriate. Equation (5) is supplemented by the relation

\[ \tau = \tau_p \quad \text{for } 0 \leq \xi \leq a \quad \text{and} \quad 0 \leq \chi \leq c \]. (31)

The relations (4) for the adherend stiffnesses are replaced by

\[ (Et)_1 = E_{1t}(1 - \xi) = E_{1t}(1 - \frac{a}{\xi} - \chi) = E_{1t}(1 - \frac{a}{\xi} - \frac{b}{l} - \zeta) \]  

and

\[ (Et)_2 = E_{2t}(1 + \xi) = E_{2t}(\frac{a}{\xi} + \chi) = E_{2t}(\frac{a}{\xi} + \frac{b}{l} + \zeta) \]. (33)

In the elastic zone, the location of which has yet to be determined, the same power series solution is sought:

\[ \tau = \sum_{n=1}^{\infty} A_n \chi^{(n-1)} \quad \text{or} \quad \tau_p = \sum_{n=1}^{\infty} A_n \chi^{(n-1)} \]  

again with \( A_1 = 1 \) by definition of adherend 1 as the more highly loaded end of the joint.

In the left adhesive plastic zone of the joint illustrated in Figure 2, the adherend forces per unit width follow from equations (1) and (31) as

\[ T_1 = \tau_{av} \chi - \tau_p \chi \]  

and

\[ T_2 = \tau_p \chi \]. (35)
Substitution into equation (4), making use of equations (2), yields

\[
\gamma = \frac{\delta_2 - \delta_1}{n} = \frac{1}{n} \left[ \frac{(\alpha_2 - \alpha_1) \Delta T \xi}{1} + \int_0^\xi \frac{T_2 \xi d\xi}{(Et)_2} - \int_0^\xi \frac{T_1 \xi d\xi}{(Et)_1} \right],
\]

(36)

\[
\gamma = \frac{1}{n} \left[ (\alpha_2 - \alpha_1) \Delta T \xi + \frac{\tau_p \xi^2}{E_2 t_2} + \int_0^\xi \frac{\tau_p}{(E(t)_1)(1 - \xi)} \xi + \frac{(\tau_p - \tau_{av}) \xi^2}{E_1 t_1} + C \right],
\]

(37)

\[
\gamma = \frac{1}{n} \left[ (\alpha_2 - \alpha_1) \Delta T \xi + \frac{\tau_p \xi^2}{E_2 t_2} + \left( \frac{1}{E_2 t_2} - \frac{1}{E_1 t_1} \right) \xi - \frac{(\tau_p - \tau_{av}) \xi^2}{E_1 t_1} \right] + C.
\]

(38)

The appropriate boundary conditions are that

\[
\gamma = \gamma_e + \gamma_p \quad \text{at} \quad \xi = 0
\]

(39)

and

\[
\gamma = \gamma_e \quad \text{at} \quad \xi = a/\lambda.
\]

(40)

Consequently, from equations (39) and (38),

\[
C = (\gamma_e + \gamma_p)
\]

(41)

so that, from equations (40) and (38),

\[
\gamma_p = \frac{1}{n} \left[ (\alpha_2 - \alpha_1) \Delta T \xi \left( \frac{A}{\lambda} \right) + \frac{\tau_p \xi^2}{E_2 t_2} \left( \frac{1}{E_1 t_1} \right) \left( \frac{A}{\lambda} \right) - \frac{(\tau_p - \tau_{av}) \xi^2}{E_1 t_1} \ln \left( 1 - \frac{a}{\lambda} \right) \right].
\]

(42)

Equation (42) may be non-dimensionalized by use of the quantities in equations (13) to (15). It then adopts the form

\[
\gamma_p^{- \gamma_e^{- \lambda \xi \text{C} \text{other}}(1)} \left( \frac{A}{\lambda} \right) + (\lambda \xi)^2 \frac{1}{1 + \text{ETR}(1)} + \frac{(\lambda \xi)^2}{1 + \text{ETR}(1)} \ln \left( 1 - \frac{a}{\lambda} \right).
\]

(43)

In solving for the joint strength it is necessary to maintain continuity at the transition ($\xi = a/\lambda$) from plastic to elastic adhesive behavior. The continuity of adherend stresses requires that there be no change in $d\gamma/dx$.

From equations (4) and (2)

\[
\frac{d\gamma}{dx} = \frac{1}{n} \left[ (\alpha_2 - \alpha_1) \Delta T + \frac{T_2}{(Et)_2} - \frac{T_1}{(Et)_1} \right].
\]

(44)
or, in non-dimensionalized form, for the plastic side of the transition

\[ \frac{d(Y/Y_e)}{d\xi} \bigg|_{\xi = a/\ell} = (\lambda \xi) \, CTHERM(1) - (\lambda \xi)^2 \frac{1 - ETR(1)}{1 + ETR(1)} + \frac{(\lambda \xi)^2 [1 - (\tau_{av}/\tau_p)]}{[1 + ETR(1)][1 - (a/\ell)]}. \]

(45)

For the elastic side, equation (34) requires that

\[ \frac{d(Y/Y_e)}{d\chi} \bigg|_{\chi = 0} = A_2. \]

(46)

Since \( A_1 = 1 \), the elastic stress distribution can now be evaluated by a recurrence formula, just as in Section 2.

Under certain combinations of stiffness and thermal mismatch between adherends there will be no second plastic adhesive shear stress zone at the far end of the joint while under others there will be. In the former case, the evaluation of the elastic adhesive shear stress at \( \chi = 1 - (a/\ell) \) by means of the series (34) will lead to a result \( \tau_{end}/\tau_p \leq 1 \). A value of this ratio greater than unity indicates a need for evaluating the affects of the presence of a second plastic adhesive zone, at the far end of the joint. Referring again to Figure 2, the adherend forces per unit width are evaluated through equations (1) and (31) as

\[ T_1 = \tau_p \ell \left( \frac{C}{\ell} - \xi \right), \quad T_2 = \tau_{av} \ell - \tau_p \ell \left( \frac{C}{\ell} - \xi \right). \]

(47)

Substitution of equations (47) and (33) into equation (44) leads to the expression

\[ \frac{d(Y/Y_e)}{d\xi} = \frac{G}{\tau_P} \left( a_2 - a_1 \right) \Delta T \ell - \frac{\tau_p \ell^2}{E_1 t_1} + \frac{\tau_p \ell^2}{E_2 t_2} - \frac{(\tau_p - \tau_{av}) \ell^2}{(E_2 t_2)[1 - C/\ell + \xi]}. \]

(48)

The transition relation at \( \xi = 0 \) follows as

\[ \frac{d(Y/Y_e)}{dY} \bigg|_{\xi = 0} = (\lambda \xi) \, CTHERM(1) - (\lambda \xi)^2 \left[ \frac{1 - ETR(1)}{1 + ETR(1)} \right] - \frac{(\lambda \xi)^2 [1 - (\tau_{av}/\tau_p)]ETR(1)}{[1 + ETR(1)][1 - (C/\ell)]}. \]

(49)
Equation (48) may be integrated once, yielding

\[
\left( \frac{\gamma}{\gamma_e} \right) = (\lambda \lambda) \text{CTERM}(1) \zeta - (\lambda \lambda)^2 \frac{1 - \text{ETR}(1)}{1 + \text{ETR}(1)} \zeta - \\
- (\lambda \lambda)^2 \frac{[1 - (\tau_{av}/\tau_p)] \text{ETR}(1)}{[1 + \text{ETR}(1)]} \ln(1 - \frac{c}{\lambda}) + \zeta + c, \tag{50}
\]

in which, since

\[
\gamma = \gamma_e \text{ at } \zeta = 0, \tag{51}
\]

\[
1 = - (\lambda \lambda)^2 \frac{[1 - (\tau_{av}/\tau_p)] \text{ETR}(1)}{[1 + \text{ETR}(1)]} \ln(1 - \frac{c}{\lambda}) + c. \tag{52}
\]

Signifying by \(\gamma_{\text{max}}\) the peak adhesive shear strain at the less critical (by definition) right hand end of the joint,

\[
\left( \frac{\gamma}{\gamma_e} \right) > \frac{\gamma_{\text{max}}}{\gamma_e} = (\lambda \lambda) \text{CTERM}(1) \frac{c}{\lambda} - (\lambda \lambda)^2 \frac{[1 - \text{ETR}(1)]}{[1 + \text{ETR}(1)]} \frac{c}{\lambda} \\
+ (\lambda \lambda)^2 \frac{[1 - (\tau_{av}/\tau_p)] \text{ETR}(1)}{[1 + \text{ETR}(1)]} \ln(1 - \frac{c}{\lambda}). \tag{53}
\]

A comparison of equations (43) and (53) shows complete consistency upon interchanging subscripts 1 and 2. While equation (53) could be employed to identify whether the left or right hand end of the joint in Figure 2 is more critical once the extent of the second plastic zone \((c/\lambda)\) had been established, there is an inherent numerical difficulty in the step by step computation of the strength by the procedure outlined above. It was explained in Section 2 that, for the perfectly-elastic adhesive, only the average adhesive shear stress could be computed and not the stress distribution as a function of position along the joint. In the computer program in Appendix A3, the only reason why it proved possible to evaluate the extent of the elastic trough, for long overlaps, was the factor \([1 - (a/\lambda) - (c/\lambda)]^n - 1 < 1\) in equation (34). At high values of \(n\), this very small term was able to overpower the influence of the \((\lambda \lambda)^2\) factor in the numerator of the recurrence formula (18). This numerical accuracy problem prevented the reliable evaluation of \(d(\gamma/\gamma_e)/dx\) at \(x = (b/\lambda)\) to match boundary conditions at the transition of the second plastic adhesive zone. Consequently an iterative solution had to be employed to evaluate the maximum possible
extent of the elastic trough.

Referring to equations (45) and (46), it can be seen that, in the iterative solution process, the second term of the elastic adhesive shear stress series \( A_2 \) depends on the preceding estimates of both \((a/\ell)\) and \((\tau_{av}/\tau_p)\). In the early development of the digital computer program for elastic-plastic scarf joints insurmountable convergence difficulties were encountered if the initial estimates for \((\tau_{av}/\tau_p)\) and \((a/\ell)\) were not sufficiently close to the true values. This difficulty was eventually overcome by the following technique. Equation (43) was re-arranged to read

\[
\left( \frac{\tau_{av}}{\tau_p} \right) = 1 - \frac{\left\{ \frac{[1 + ETR(1)](\gamma_p)}{(\lambda \ell)^2 \gamma_e} + \left[ \frac{1 + ETR(1)}{\gamma_e} \right] - \left[ 1 - ETR(1) \right] \left( \frac{a}{\ell} \right) \right\}}{\ln[1 - (a/\ell)]}.
\] (54)

This can be differentiated with respect to \((a/\ell)\) so that

\[
d\left( \frac{\tau_{av}}{\tau_p} \right) / d(a/\ell) = 0 \quad \text{when}
\]

\[
\left( 1 - \frac{a}{\ell} \right) \ln(1 - \frac{a}{\ell}) = \frac{\left\{ \frac{[1 + ETR(1)](\gamma_p)}{(\lambda \ell)^2 \gamma_e} + \left[ \frac{1 + ETR(1)}{\gamma_e} \right] - \left[ 1 - ETR(1) \right] \left( \frac{a}{\ell} \right) \right\}}{\ln[1 - (a/\ell)]}.
\] (55)

Substitution of equation (55) into equation (54) yields, for the minimum (stationary) value of \((\tau_{av}/\tau_p)\)

\[
\frac{\tau_{av}}{\tau_p} = ETR(1) + \frac{[1 + ETR(1)]CTHERM(1)}{(\lambda \ell)}
\]

\[
+ \frac{a}{\ell} \left\{ \left[ 1 - ETR(1) \right] - \frac{[1 + ETR(1)]CTHERM(1)}{(\lambda \ell)} \right\}.
\] (56)

This is evidently consistent with the elastic solution \((a/\ell) = 0\) for large overlaps and, upon subsequent comparison with the more precisely estimated joint strengths, proved to be an extremely close lower bound for all cases of practical interest. It is significantly conservative only for very short overlaps [small values of \((\lambda \ell)\)] or very brittle adhesives [very small values of \((\gamma_p/\gamma_e)\)]. The adhesive shear strain capacity \(\gamma_p\) is involved in equation (56) implicitly through the extent \((a/\ell)\) of the plastic zone. Equation (55)
is solved by iteration to evaluate \((a/L)\) and the result substituted into equation (56) or (54). Appendix A2 contains a listing of the FORTRAN IV digital computer program employed to solve equations (55) and (54), together with sample outputs and brief user instructions. The iteration technique eventually adopted proved to be quite convergent, after other re-arrangements of equation (55) demonstrated strongly divergent characteristics.

This program in Appendix A2 served to provide the initial estimates of \((a/L)\) and \((\tau_{\text{av}}/\tau_p)\) in the more precise solution listed in Appendix A3. The sequence of variables used in the solution is \((a/L)\), \((\tau_{\text{av}}/\tau_p)\) and \((c/L)\) after which \((\tau_{\text{av}}/\tau_p)\) is recomputed and the estimate of \((a/L)\) adjusted until convergence is attained. In those cases in which the critical end is not evident by inspection, the potential bond shear strength is computed from each end of the joint and the lower value adopted. Brief user instructions and sample outputs are included in Appendix A3.

The analyses above for scarf joints pertain to adhesive shear stresses and it is demonstrated that a small enough scarf angle can always be found to transfer the full adherend strength through the bond with an adequate margin. There is, of course, a potential problem with the adherend strength(s) if the scarf angle is too small. Specifically, one adherend will fail if the scarf angle \(\theta\) is so small that

\[
\theta < \frac{\tau_p}{F_u},
\]

(57)

(where \(F_u\) is the ultimate adherend stress in tension, compression, or shear, as appropriate) at the more critical end of the joint (identified by the adhesive shear stress analysis). Should this situation arise, the solution is to decrease the adherend stiffness imbalance across the joint by local reinforcement of the softer adherend. It is evident from equation (17) that this potential problem of breaking off the tip of (usually) the stiffer adherend is more likely to arise with the brittle adhesives (higher values of peak adhesive shear stress \(\tau_p\)) than with ductile adhesives. This is one important reason for preferring to effect the load transfer with a shorter overlap of ductile adhesive than with a longer overlap of brittle adhesive. The extreme case of making the overlap so extremely long that the peak adhesive shear
stress actually developed is restricted to a small fraction of its capacity when adherend failure occurs outside the joint has theoretical appeal only, frequently being quite impractical.
4. DISCUSSION OF PARAMETRIC EFFECTS

Representative solutions from Sections 2 and 3 for unbalanced bonded scarf joints are illustrated in Figures 3 through 7. Figures 3 and 4 show the separate effects of adherend stiffness and thermal mismatch, respectively, on the elastic joint strength. The deviations from unity in the \( \frac{\tau_{av}}{\tau_p} \) ratio, for a given overlap \( \lambda \), are proportional to the individual imbalances. The effect of stiffness imbalance is a smooth decrease from a fully-efficient bond \( \tau_{av} = \tau_p \) to a less efficient bond \( \tau_{av} < \tau_p \) asymptoting towards the solution given in equation (21). This diagram, more than any other, characterizes the dominant feature of the scarf joint behavior. This is that the potential bond strength continues to increase indefinitely with increasing overlap. This is in marked contrast to the behavior of uniform lap joints [References (1) and (2)], which develop maximum strengths which remain effectively constant beyond intermediate overlaps. The effect of this characteristic on the potential bond strength of scarf joints is that, by making the scarf angle sufficiently small, one can always design a joint in which the potential bond strength exceeds the adherend strength by any specified factor. This is amply demonstrated by curve D in Figure 4. While adherend stiffness and thermal mismatch combine to decrease the bond efficiency below the unit value of curve A, the bond strength for long overlaps ends up being proportional to the overlap. As a consequence of this characteristic, the elastic adhesive shear stresses play a far more important role in the strength of scarf joints than they do in the case of uniform lap joints. Nevertheless, it would be erroneous to conclude that one could always design an unbalanced scarf joint within the capabilities of an elastic adhesive. The limiting problem is that, as the scarf angle becomes very small, there is a strong probability of breaking off the tip of the stiffer adherend. While not as acute a design detail problem as its counterpart for stepped-lap joints, this feature restricts the scarf angle to exceed the value

\[ \theta = \arctan\left(\frac{\tau_p}{F_u}\right) \]  

(58)

in which \( F_u \) is the adherend ultimate strength (in tension, compression, or shear, as appropriate for the applied load).

The effect of adherend thermal mismatch on the potential bond strength of scarf joints is shown in Figure 4. It is clear that the effects are insignificant for very short and very long overlaps, being significant only for those
overlaps of practical interest. The effects are maximum at \((\lambda \ell) = 2\) for all values of the thermal mismatch coefficient \(\text{CTHERM}\).

Figure 5 shows the interaction between adherend stiffness and thermal mismatch. Curves B, D and E represent one set of solutions, with curve B showing the effect of stiffness imbalance alone. Curve D adds the influence of compounding thermal mismatch as well. Curve E demonstrates the behavior of self-cancelling adherend imbalances at \((\lambda \ell) = 3\). For values of \((\lambda \ell)\) less than 3, the thermal mismatch effects dominate over those arising from stiffness mismatch and the more critical end of the joint is reversed. Curves A, C and F form another set showing how, for severe adherend thermal mismatch, there is a range of overlaps for which the residual thermal stresses are so severe that the joint will split apart without the application of any mechanical loads. Quite unlike the behavior of uniform lap joints [References (1) and (2)], this problem can be eliminated completely by sufficient extension of the overlap.

Just as is the case for uniform lap joints adhesive plasticity can increase the potential bond shear strength. The extent of this strength increase is shown in Figures 6 and 7 for stiffness and thermal mismatch, respectively. For each amount of adhesive plastic shear strain, there is an associated overlap below which the bond can be uniformly stressed. For indefinitely large overlaps the asymptotic solution (21) again holds, masking completely the influence of any adhesive plasticity. In the overlaps of practical interest, the actual amount of adhesive plasticity available from real structural adhesives can improve the potential joint strength greatly. One benefit of using a ductile adhesive of moderately high peak shear stress rather than a brittle adhesive of very high peak shear stress is that the joint is better able to withstand the variation in joint load which inevitably occurs as the result of manufacturing imperfections and non-uniform load distribution. Another benefit is that the problem of breaking off the tip of the adherend at the more critically loaded end [see equation (58)] is greatly alleviated. If the tip of the stronger adherend were allowed to be broken off, this would impose an effective net area loss on the cross-section of the weaker adherend.
5. ELASTIC ANALYSIS OF STEPPED-LAP JOINTS

The analysis for the strength of stepped-lap adhesive-bonded joints contains features of both the uniform lap joints [References (1) and (2)] and the scarf joint above. Peel stress problems are ignored on the grounds that the outermost end steps are invariably thin enough (in good design practice) not to induce significant peel stresses in the adhesive. Likewise, the small eccentricity in the load path has been ignored in the interests of obtaining a useful uncomplicated design tool.

A representative idealized stepped-lap joint is shown in Figure 8, along with the sign convention and nomenclature necessary for the analysis. Just as for the scarf joint analysis, the same diagram serves also for the elastic-plastic analysis, so it contains information not necessary for the elastic analysis. This begins with the equilibrium equations for a differential element of one of the steps.

\[
\frac{dT_o}{dx} + 2\tau = 0 , \quad \frac{dT_i}{dx} - 2\tau = 0 . \quad (59)
\]

Here the subscripts \(o\) and \(i\) refer to the "outer" and "inner" adherends, respectively, and the factors 2 in equations (59) account for the two bond surfaces surrounding the inner adherend. Consequently the adherend thicknesses \(t_o\) and \(t_i\) refer to the total cross-section and the forces \(T_o\) and \(T_i\) do likewise. The nature of the solution is such that it is, on occasions, necessary to interchange the subscripts \(o\) and \(i\) mathematically. The thermo-elastic relations for the adherends are

\[
\frac{d\delta_o}{dx} = \frac{T_o}{E_o t_o} + \alpha_o AT , \quad \frac{d\delta_i}{dx} = \frac{T_i}{E_i t_i} + \alpha_i AT . \quad (60)
\]

The adhesive shear strain, for tensile lap shear loading, is

\[
\gamma = \frac{(\delta_i - \delta_o)}{h} . \quad (61)
\]

while the elastic adhesive shear stress is related to the shear strain by the relation

\[
\tau = G\gamma = G(\delta_i - \delta_o)/h . \quad (62)
\]
The solution proceeds just as in Reference (1).

\[
\frac{dT}{dx} = G \left[ \frac{d\delta_i}{dx} - \frac{d\delta_o}{dx} \right] = \frac{G}{n} \left[ \frac{T_i}{E_i} - \frac{T_o}{E_o} + (\alpha_i - \alpha_o) \Delta T \right],
\]

(63)

\[
\frac{d^2T}{dx^2} = \frac{G}{n} \left[ \frac{2}{E_i} + \frac{2}{E_o} \right] \tau = \lambda^2 \tau.
\]

(64)

The solution of equation (64) is

\[
\tau = A \cosh(\lambda x) + B \sinh(\lambda x)
\]

(65)

where the integration constants \( A \) and \( B \) are to be determined by boundary conditions for each step. Substitution of equation into equation (59) yields

\[
T_o = T_{o,ref} - 2 \frac{A}{\lambda} \sinh(\lambda x) - 2 \frac{B}{\lambda} [\cosh(\lambda x) - 1]
\]

(66)

and

\[
T_i = T_{i,ref} + 2 \frac{A}{\lambda} \sinh(\lambda x) + 2 \frac{B}{\lambda} [\cosh(\lambda x) - 1].
\]

(67)

The values of \( T_{o,ref} \) and \( T_{i,ref} \) depend upon the origin of \( x \) adopted. In the solution it proves convenient to adopt the start of each step as the origin for that step. Integrating again, by means of equations (69),

\[
\delta_o = \delta_{o,ref} + \alpha_o \Delta T x + \frac{1}{E_o} \left[ T_o x - \frac{A}{\lambda^2} \cosh(\lambda x) - \frac{B}{\lambda^2} [\sinh(\lambda x) - (\lambda x)] \right]
\]

(68)

and

\[
\delta_i = \delta_{i,ref} + \alpha_i \Delta T x + \frac{1}{E_i} \left[ T_i x + \frac{A}{\lambda^2} \cosh(\lambda x) + \frac{B}{\lambda^2} [\sinh(\lambda x) - (\lambda x)] \right].
\]

(69)

In the FORTRAN IV digital computer program, listed in Appendix A4, used to solve the equations above for the elastic stepped-lap joint, the technique of solution is as follows. The solution proceeds, one joint step at a time starting with assumed values of the load and initial adhesive shear strain (or stress). The latter is set at the maximum adhesive allowable and remains so unless it is computed that the peak adhesive shear strain is greater elsewhere (most probably at the other end of the joint) in which case the initial strain is reduced as much as necessary to avoid exceeding the allowable. The key
equation in the solution is equation (65). The integration constant $A$ is evaluated as the specified (or subsequently computed) adhesive shear stress at the start of the step under consideration.

$$A = \tau_x = 0 \quad \text{(70)}$$

The other constant $B$ derives from equation (63), also evaluated at the start of that step. That is

$$\frac{d\tau}{dx} = A\lambda \sinh(\lambda x) + B\lambda \cosh(\lambda x) = \frac{G}{\eta} \left( \frac{T_i}{E_{i1}} - \frac{T_o}{E_{o1}} + (\alpha_i - \alpha_o)\Delta T \right) \quad \text{(71)}$$

so that at $x = 0$

$$B = \frac{G}{\eta} \left( \frac{T_i}{E_{i1}} - \frac{T_o}{E_{o1}} + (\alpha_i - \alpha_o)\Delta T \right) \bigg|_{x=0} \quad \text{(72)}$$

The values of $\tau$, $T_o$, $T_i$, $\delta_o$ and $\delta_i$ at the end of that step then follow from equations (65), (66), (67), (68), (69) and (62), respectively. If, after one complete set of computations, the load computed to be transferred out of the far end of the joint does not match that assumed to act at the near (starting) end, the initial estimate is adjusted until the two quantities do match. At that stage, a check is made throughout the joint, step by step, to identify the most critical adhesive and adherend locations. If any negative margins are identified, the load and peak adhesive shear stress are reduced as much as is necessary to eliminate them.

While the formulation of the equations and analysis scheme above is quite straightforward, the actual numerical solution of the problem proved to be quite difficult. Even with double precision it was almost invariably impossible to compute values for all steps of the joint in a single pass, even if the initial conditions (load and peak adhesive shear stress) were precisely correct to 16 significant figures. A change of 1 in the 16th significant digit of an initial condition would frequently effect a change by a factor of up to $10^7$ in a quantity computed in the fourth or fifth step. This was not the result of a poorly conditioned mathematical formulation. It follows directly from strong physical characteristics of stepped-lap joints. It is the nature of stepped-lap joints, be they bonded or bolted, that any non-uniformities in the load transfer are dominated by the geometry and materials of the end three
steps. What happens in between has only negligible effect on the critical loads which almost invariably occur at one end or other of the joint. Likewise, in a uniform lap joint, practically all the load is transferred through the end three (rows of) bolts or through a narrow effective end zone of adhesive. Because of this characteristic the initial coding of the equations led to a highly accurate estimate of the load (assuming that the adhesive was critical at one end of the joint) but was unable to compute the internal loads and check on the adherend strength margin. The technique finally employed for dealing with this problem took advantage of the seemingly undesirable characteristics and is summarized as follows. By printing out intermediate computations it became clear that, if the initial load estimate on a given step was too high (even if only minutely), on the step just before computations for a subsequent step caused overflows and underflows in the computer the computations would diverge in a characteristic way, precisely the opposite of that for an initial underestimate of that load. Therefore upper and lower bounds were placed on the load estimate and the trial load was taken as the average of these. If the trial load was found to be too high, it served as the new upper bound and, were it too low, it was used to raise the lower bound. This technique was found to bring the upper and lower bounds into precise agreement rapidly. Once this had occurred the computations for the start of that step were frozen and the solution proceeded to perturb each successive step in turn, using the same convergence check above, until the load transferred out of the far end of the joint precisely equalled that input at the near end. Then a check is made, at the ends of each step, on the adhesive and adherend stresses to ensure that neither exceeds the allowable. Due allowance is made for the sign of the quantities involved. In the absence of any thermal mismatch this last operation of checking on the allowables can be performed by simple linear scaling. However, if there is any adherend thermal mismatch present, this adjustment must be performed by iteration since, as is evident from equation (62), the thermal stress terms do not scale in proportion to the adhesive and adherend stresses. A necessary check on the accuracy of the numerical processes has been accomplished by checking that precisely the same solution is obtained regardless of whether the computations commence at the more critically loaded end of the joint or at the other end.
In view of the numerical problems encountered with this analytical solution, it stands to reason that they will have their counterpart in any finite-element solution. Very fine grids would be needed in the high stress gradient areas.
6. ELASTIC-PLASTIC ANALYSIS OF STEPPED-LAP JOINTS

In addition to the equations of Section 5 for the perfectly elastic analysis of stepped-lap joints, the elastic-plastic analysis requires, instead of equation (62), that

\[ \tau = \tau_p \quad \text{for} \quad \gamma \geq \gamma_e , \quad (73) \]

and

\[ \tau = G\gamma \quad \text{for} \quad \gamma < \gamma_e . \quad (74) \]

The elastic-plastic solution is best carried out in terms of the adhesive shear strains rather than the shear stresses. In the plastic adhesive zones, from equations (61) and (60),

\[ \frac{d\gamma}{dx} = \frac{1}{n} \left[ \frac{\delta_i}{\delta_o} - \frac{\delta_o}{\delta_i} \right] = \frac{1}{n} \left[ \frac{T_i}{E_{i_{ref}}} - \frac{T_o}{E_{o_{ref}}} + (\alpha_i - \alpha_o)\Delta T \right] \quad (75) \]

whence, from equations (59)

\[ \frac{d^2\gamma}{dx^2} = \frac{2}{n} \left[ \frac{1}{E_{i_{ref}}} + \frac{1}{E_{o_{ref}}} \right] \tau_p = \frac{\lambda^2}{G} \tau_p = \text{constant} . \quad (76) \]

Therefore, in the plastic zone,

\[ \gamma = \frac{\lambda^2}{2G} \tau_p x^2 + Cx + D \quad (77) \]

and

\[ T_o = T_{o_{ref}} - 2\tau_p x , \quad T_i = T_{i_{ref}} + 2\tau_p x \quad (78) \]

while

\[ \delta_o = \delta_{o_{ref}} + \alpha_o \Delta T x + \frac{1}{E_{o_{ref}}} \left[ T_o - \tau_p x^2 \right] \quad (79) \]

and

\[ \delta_i = \delta_{i_{ref}} + \alpha_i \Delta T x + \frac{1}{E_{i_{ref}}} \left[ T_i - \tau_p x^2 \right] \]
In equation (77), $D$ is set equal to $\gamma$ at the start of any step, since a new zero for $x$ is chosen at that location for each step. The other constant $C$ follows from equations (75) and (77). Thus
\[
C = \left. \frac{d\gamma}{dx} \right|_{x=0} = \frac{1}{\eta} \left[ \frac{T_i}{E_i} - \frac{T_o}{E_o} + (\alpha_i - \alpha_o) \Delta T \right]_{x=0}.
\] (80)

Very few individual steps of stepped-lap joints have fully-plastic adhesive throughout the entire joint. Any adhesive plasticity is frequently confined to the end(s) of the step(s). Therefore, in performing an elastic-plastic analysis of a stepped-lap joint, it is necessary to be able to compute the extent of the plastic zones. Therefore, beginning at the left hand end of the step element shown in Figure 8 and assuming a sufficiently high load intensity for the adhesive to be in the plastic state, the first computation is that of the maximum possible extent of the plastic zone. This is then compared with the actual extent of the step. If necessary, a second computation is performed of the maximum possible extent of the elastic trough in that same step. Starting from equation (77) with $\gamma = \gamma_{ref}$ at $x = 0$,
\[
\gamma = \frac{\lambda^2}{2G} \tau_p x^2 + Cx + \gamma_{ref}
\] (81)
where the constant $C$ is given by equation (80). It is necessary to find the lesser value of $x$ for which $\gamma = \gamma_e$. Equation (81) is re-arranged to read
\[
\frac{\lambda^2 \tau_p}{2G} x_p^2 + C x_p + (\gamma_{ref} - \gamma_e) = 0
\] (82)
so that the maximum extent of plastic adhesive zone is given by
\[
x_p = -C \pm \sqrt{C^2 - 2\lambda^2 \tau_p (\gamma_{ref} - \gamma_e)}.
\] (83)
Now, since $C = d\gamma/dx < 0$ at $x = 0$ the minus sign in front of the radical holds. Once $x_p$ has been computed, it is compared with the step length $\lambda_{step}$. If $x_p > \lambda_{step}$, that particular step is fully-plastic throughout and the values of the various quantities at the far end of the step are evaluated from equations (73) to (80). Should $x_p$ be less than $\lambda_{step}$, the difference is examined elastically, to see whether it remains elastic throughout or becomes plastic again at the far end. For $x_p < \lambda_{step}$, the values of the various stresses, strains,
displacements and forces are evaluated in terms of equations (73) to (79) and the subscripts \( p \) \( e \) serve to identify the plastic-to-elastic transition. Likewise \( ep \) identifies the possible elastic-to-plastic transition at the far end of the joint. It is necessary that \( dy/dx \) be maintained at these transitions, as is evident from equation (75). The maximum possible extent of elastic trough must be deduced from equation (65). In doing so, it is mathematically far simpler to shift the \( x \) origin to the middle of the elastic trough (of extent \( 2x_e \)) so that

\[
\tau = \tau_p \frac{\cosh(\lambda x)}{\cosh(\lambda x_e)}
\]  

(84)

At the \( pe \) transition (\( x = -x_e \)) equation (62) requires that

\[
\frac{dT}{dx} = G \left[ \frac{T_i}{E_{t1}} - \frac{T_o}{E_{t0}} + (\alpha_i - \alpha_o)A_T \right]_{pe} = -\tau_p \lambda \tanh(\lambda x_e)
\]

(85)

so that the elastic trough could extend, if \( l_{step} \) were great enough, a distance

\[
2x_e = \tanh^{-1} \left\{ \frac{1 - \frac{1}{\lambda} \frac{T_i}{E_{t1}} - \frac{T_o}{E_{t0}} + (\alpha_i - \alpha_o)A_T}{\lambda \eta_e \frac{T_i}{E_{t1}} - \frac{T_o}{E_{t0}} + (\alpha_i - \alpha_o)A_T} \right\}_{pe}
\]

(86)

By use of known formulas for hyperbolic functions in terms of exponentials and the interrelation between exponential and logarithmic functions, the solution (85) is more conveniently expressed as

\[
2x_e = \frac{1}{\lambda} \ln \left\{ \frac{1 - \frac{1}{\lambda} \frac{T_i}{E_{t1}} - \frac{T_o}{E_{t0}} + (\alpha_i - \alpha_o)A_T}{1 + \frac{1}{\lambda} \frac{T_i}{E_{t1}} - \frac{T_o}{E_{t0}} + (\alpha_i - \alpha_o)A_T} \right\}_{pe}
\]

(87)

In the event that \( x_e \) does not extend beyond the far (right hand) end of the step being analyzed, it is necessary to compute the load transferred between the adherends throughout the elastic trough. In doing so, it is quite simple to take the value of \( 2x_e \) from equation (87) and substitute it back into equations (65) to (72) for the standard elastic analysis of the preceding section. Should the elastic trough not extend to the far end of the step under analysis, equations (73) to (80) are employed for the plastic zone to the end of the step.
Equation (77) now becomes

\[ \gamma = \frac{\lambda^2 \tau}{2G} x^2 + Cx + \gamma_{ep} \]  

(88)

with

\[ \tau = \tau_p \quad \text{for} \quad x > x_{ep} . \]  

(89)

The constant \( C \) in equation (88) is evaluated in terms of equation (75)

\[ C = \left. \frac{d\gamma}{dx} \right|_{ep} = \frac{1}{\eta} \left[ \frac{T_i}{E_i t_i} - \frac{T_o}{E_o t_o} + (\alpha_i - \alpha_o) \Delta T \right]_{ep} \]  

(90)

In the last steps of the joint at the far end, the adhesive may be fully plastic throughout in which case, in equation (87), \( \gamma_{ep} \) should be replaced by \( \gamma_{ref} \). Likewise, in those steps, near the middle of the joint, in which the adhesive shear strains are so small as not to reach the plastic state at either end of the step, the step will be elastic throughout and equations (65) to (72) are employed in the analysis. Towards the far end of the joint there may be a step which starts elastically and becomes plastic. In this case the actual extent of elastic behavior is determined by iteration, using equations (65) to (72) with a cut off (either positive or negative) on the shear stress.

If it should transpire that, at the end of the step, \( \gamma \) exceeds \( \gamma_e + \gamma_{ep} \) or \( T_i \) or \( T_o \) exceed their respective allowables, this does not cause any analytical difficulty. An iterative procedure is employed in the analysis to reduce the external load and initial adhesive strain whenever necessary. While this does not represent any analytical difficulty, one should recognize that exceeding the allowables on an inner step can occur only as the result of poor detail design. The improvement of such details can increase the potential joint strength.

No new numerical difficulties were encountered in the program listed in Appendix A5 for the elastic-plastic analysis of stepped-lap joints which did not have a direct counterpart in the perfectly elastic analysis. However, the logic associated with keeping track of the locations of the transitions between elastic and plastic adhesive behavior, and vice versa, as they moved with each successive iteration posed a formidable problem. One small computational
problem was that, if the load estimate at some early stage in the iteration sequence was too far removed from the correct value, the computer would predict physically unrealizable large negative shear strains in the adhesive. A special set of instructions was prepared for this quirk.

The computer program, as basically written, checks simultaneously for the allowable adherend and adhesive strengths at the most critical locations in each step. Since stepped-lap joints are frequently more critical in the adherend than in the adhesive, a special feature has been added to increase greatly all adherend strengths artificially in order to print out also the potential adhesive bond strength and confirm that it exceeds the adherend strength by an adequate margin.

The analysis above is presented for the case of tensile lap shear loads being positive and the sign convention is in accordance. The computer programs have been so coded that, by a single input for the variable SGNLD, the respective solutions for tensile shear loading (SGNLD = +1) and compressive shear loading (SGNLD = -1) can be printed out. In the event that there are simultaneous stiffness and thermal mismatches between the adherends, the joint strength will not be the same for each load sense. Such a situation is common in the bonding of titanium edge members to boron-epoxy panels.
7. DISCUSSION OF DESIGN OF STEPPED-LAP JOINTS

The digital computer programs developed above to analyze stepped-lap joints can serve also as a useful design tool. Three clear dominant joint characteristics have been confirmed by studies with this program. The first is that the joint load capacity is defined by the end three steps at the more critical end of the joint. If other steps have a significant influence it will be adverse and be due to poor design detailing. The second is that, once the joint is essentially well-designed, quite major changes can be made to other than the critical end three steps without any significant impact on the joint strength. Third is that, in a well-designed joint, it is the very end step that is likely to precipitate joint failure unless its length is restricted in the design process. The necessary restriction is that the product of maximum adhesive shear stress and total bond area on the end step must not exceed the product of adherend material allowable and, cross section of the end step. Consequently, a ductile adhesive with higher strain energy provides stronger joints than a brittle adhesive with higher peak stress but less strain energy. It should be noted also that minimizing adherend stiffness imbalance increases the potential bond shear strength.

Mathematically speaking, the stepped-lap family of joints represent perturbations about the scarf joint solution. These perturbations become progressively greater as the number of steps decreases until the stepped-lap solution reduces to a single-lap joint for one step. Stepped-lap joints with only two or three steps are usually confined to thin adherends for which the potential bond shear strength is far in excess of the adherend(s) strength. In such cases the added strain concentrations in the bond due to the step discontinuities are not very important. Most applications of stepped-lap joints contain a large number of steps and, with a ductile adhesive softening the most severe of the adhesive stress spikes, the behavior very closely approaches that of the scarf joint. For this reason, preliminary design of practical stepped-lap joints by means of the scarf joint solution appears to be quite realistic. In doing so, however, one should exercise caution with regard to the critical end step of the adherend. The stepped-lap joint analysis, and practical experience, have identified the end step of the stiffer adherend as a prime candidate for the most critical design detail. If the extensional modulus of a composite adherend is
significantly less than that of a metal adherend to which it is bonded, most of the shear load transfer will be concentrated at the composite end of the joint with the probable result that tip fracture of the stiffer adherend will occur. One simple remedy to this potential difficulty is to be found in the concept of the dual-slope scarf joint illustrated in the upper part of Figure 9. In this joint, in order to protect the tip of the adherend, the scarf angle $\theta_1$ is set to exceed

$$\theta_{1_{\text{min}}} = \frac{\tau_p}{F_u}$$

in which $\tau_p$ is the peak adhesive shear stress and $F_u$ is the appropriate adherend allowable stress in tension, compression, or shear as dictated by the nature of the applied load. The next step in the preliminary design process is to estimate the total scarf length necessary to effect the transfer of the entire load $P$. A reasonable approximation to this is given by the approximation

$$P = \left(\frac{\tau_{\text{av}}}{\tau_p}\right) P = \left[\frac{E_1 t_1}{E_2 t_2}\right] \frac{\tau_p}{P}$$

for the asymptotic scarf joint solution for very long overlaps, whence

$$l = \frac{P}{\tau_p} \left[\frac{E_2 t_2}{E_1 t_1}\right].$$

The optimum location of the transition from scarf angle $\theta_1$ to $\theta_2$ can then be determined by trial and error using the stepped-lap joint computer program developed in Section 6. As a preliminary guide, it is suggested that one third of the total thickness be tried. The conversion of this conceptual scarf joint design into a practical stepped-lap joint is illustrated schematically in the lower part of Figure 9. It should be noted that the steps are thinner in the more critical load transfer region, and at the extreme opposite end for a single step to minimize potential peel stress problems. Normally peel stresses will not be a problem with stepped-lap joints for practical design configurations but the double-lap joint analysis can serve as a check if appropriate. The larger step sizes in the lightly loaded area effect an economy of fabrication which offsets the greater expense of proper detailing in the more critical areas.
For reasons evident from the discussion above, the dual-slope scarf joint has merits in its own right as well as for a model for approximate stepped-lap joint analysis. The steepening of the scarf angle at one end is particularly important for the brittle adhesives for which $\tau_p$ is much higher than for the ductile adhesives. This greater importance follows from equation (91).

One characteristic of the internal stress distribution within stepped-lap bonded joints is directly traceable to double-lap joint phenomena and has no counterpart in scarf joint behavior. This characteristic is that, once each or any step is sufficiently long to contain a fully-developed elastic trough in the adhesive shear-stress distribution, an increase in that step length does not alter the joint shear strength. Indeed, as confirmed by application of the computer programs A4EF and A4EG, the internal adherend and adhesive stresses at the ends of each and every step are invariant with respect to such step length increases, whether one, some, or all of the step lengths are increased. That this should be so follows directly from the governing equations for each step of the joint. These are precisely the same as for an unbalanced double-lap joint, the shear strength of which is independent of overlap beyond some value. The impact of this phenomenon on the design of stepped-lap bonded joints is that, if analysis indicates inadequate bond strength and the overlap is already reasonably great, no further increase in step lengths can accomplish an improvement in joint strength. It is necessary to increase the number of steps and decrease the incremental step thickness.

The technique of refining the preliminary analysis developed by the rules above is as follows. An analysis is performed, and the limiting (critical) detail identified. If this is the strength of the end step of the stiffer adherend, the appropriate procedure is to decrease this length and increase the length of the other steps. A halving of the step thickness increment and doubling of the number of steps at the more critical end of the joint will also help. This situation can be identified by a solution in which the maximum adhesive shear strain developed is less than the allowable. In rare instances it may not be the very end but one or two steps inside which are critical. The procedure for improving the joint strength is the same. Reduce the length of the critical steps and increase the others. In doing so, it should be remembered that any fully-elastic step will not transfer much more load even if its length is
increased. Furthermore, if the adhesive shear stresses at each end of the step are less than their plastic value, increasing the step length indefinitely will not introduce a plastic zone. If the adhesive shear strain is predicted to be the limiting feature rather than the adherend strength, the joint strength may be improved by increasing the number of joint steps. In doing so, steps at one end of the joint will tend to become critical and length increases in the remaining (elastic) steps will continue to increase the joint strength, but at a decreasing rate. The behavior of bonded scarf joints (Figure 6) serves to explain this approach. Since the average bond stress on a scarf joint approaches a fixed fraction of the maximum bond shear stress, an overlap sufficiently long can always be found to develop a potential strength 50 percent in excess of the adherend strength. The only inherent difficulty in this approach is the care needed not to exceed the adherend allowables near the more critical end of the joint. One may look upon an optimally designed stepped-lap joint as an approximation to a dual slope scarf joint with a small angle at the less critical end to build up the total load transferred and a steeper angle (still small) at the more critical end to prevent breaking off the tip of the adherend.

In the presence of adherend thermal mismatch (advanced composite-to-metal for example), a reversal of load direction can reverse the more critical and less critical ends of the joint. Therefore it is necessary in such cases to design for both the maximum tensile shear and compressive shear loads to be applied.

Figures 10 to 12 illustrate solutions obtained to stepped-lap bonded joint analyses using the computer programs above. The joint is drawn to scale in Figures 10 and 11 and the material properties can be found in the sample printout included in the Appendix. The brittle and ductile adhesives referred to are, respectively, Narmco Metlbond 329 and Hysol EA951 which have the shear characteristics illustrated in Figure 13. The elastic solutions in Figure 10 show dramatically the sharp spikes in the shear stress distribution at the ends of each step. These spikes, separated by relatively lightly-loaded troughs, represent the influence of the uniform thickness steps. It is evident also from Figure 10 that the ductile adhesive, with its lower modulus and higher elastic shear strain carries slightly more load elastically than does the brittle adhesive. Figures 10 to 12 omit the influence of thermal mismatch between adherends and, had this been included, the elastic strength disparity in
Figure 10 would have been very pronounced in favor of the ductile adhesive for a tensile shear loading. Figure 11 shows the computed bond shear stress distributions, corresponding with Figure 10, when the adhesive properties are modified to account for plasticity. As is to be expected from the adhesive characteristics in Figure 13, this modification does not increase the joint strength of the brittle adhesive sufficiently for the bond to be stronger than the weaker adherend. The ductile adhesive, on the other hand, is computed to have a potential bond strength nearly as great as the strength of the titanium outside the joint. Actually, by the time the adhesive has used up only 15 percent of its total shear strain capacity, the load level is so high as to cause the end (thin) titanium step to yield, as shown in the middle illustration of Figure 11. The ductile adhesive has a considerable strength margin over the composite adherend. Figure 12 demonstrates how the theory identifies the end metal step as being prone to fatigue failure, even though the end step had been shortened to alleviate the problem. In the static load case the theory predicts that, once the titanium has yielded locally, as shown in the second illustration of Figure 12, the load level will increase until failure occurs in the composite at the end of the joint, as shown in the fourth illustration. Figures 11 and 12 depict only the most critical conditions within each step because the computer program does not normally output a continuous solution. The adhesive shear stress distribution throughout the lightly loaded regions is not crucial to the design/analysis cycle. For illustrative purposes one can easily artificially divide each step into a number of short segments in order to avoid adding another computation sequence to the programs. This has been demonstrated to be free from convergence problems (as confirmed by Figure 10) but, naturally, takes more computer time.

The following table enumerates a number of solutions obtained with the stepped-lap joint computer programs above. The effects of thermal stresses are included, as also is the influence of the direction of the applied load. Of interest is the way in which the adherend thermal and stiffness imbalances compound to decrease the joint strengths for tensile loading while they counteract each other for the compressive loading. The failure modes predicted are identified by the comment codes 1 through 5 which are explained at the foot of the table. All cases except those for optimized step lengths have the joint geometry shown in Figure 10. In optimizing the joint proportions, the computer program

was used to identify the most critical location and the step lengths were modified by hand for re-analysis until the minimum tensile and compressive joint strengths matched the composite adherend strength. This took only two iterations to achieve the results shown and this feature is one of the more beneficial merits of the complete internal joint analysis.

Figure 14 illustrates the bond shear stress distributions for both ductile and brittle adhesives. A comparison is effected between a joint of uniform step lengths, at left, and that with optimized lengths, at right. A small loss in elastic joint strength is incurred by shortening the end steps (and some of this could be recovered by increasing the lengths of the other steps to compensate) but the problem of yielding the end titanium step has been eliminated for the ductile adhesive. It is interesting to observe that the brittle adhesive had insufficient strain energy in shear for the problem to arise. Another important phenomenon revealed is that the ductile adhesive uses up only about a third of its ultimate shear strain capacity in breaking the composite adherend just outside the joint. This leaves a generous margin for dealing with
stress concentration due to irregularities in load intensity or bond thickness across the width of the joint. Because of these ever-present considerations, the brittle adhesive should not be expected to develop the full predicted joint strength over each inch of a wide panel. Failure would be initiated by a local effect and then be propagated rapidly.

Figure 14 omits consideration of thermal effects in order not to complicate the comparisons made. Figure 15 includes these effects for both tensile and compressive shear loading with the ductile adhesive. This figure compares the performance of the preliminary design (Figures 10 and 11) with the optimized design. Improvements in ultimate compressive strength and tensile fatigue load capacity are demonstrated.
8. CONCLUSION

This report presents elastic and elastic-plastic analysis methods for adhesive-bonded scarf and stepped-lap joints. The solutions obtained are analytic in form and the necessary digital computer FORTRAN IV programs are listed in the Appendices. These solutions are believed to be the first for such joints which account for adhesive plasticity. They include also the effects of adherend stiffness- and thermal-mismatch. While the precise solutions require iterative numerical solutions, explicit algebraic formulas are derived for a close lower-bound on the strength of scarf joints. The dominant characteristic of scarf joints is that, for long overlaps, the average bond stress asymptotes towards a fixed fraction of the peak bond stress, that fraction equalling the lesser ratio of adherend extensional stiffnesses. Unlike uniform lap joints, which reach a definite strength limit which cannot be exceeded by using longer overlaps, the potential bond strength of scarf joints increases indefinitely with overlap so that a design can always be devised in which the failure is forced to occur outside the joint. In using this approach, however, it is necessary also to check on the adherend stresses at the tip of the stiffer adherend to ensure that the scarf angle is not too small. Stepped-lap joints exhibit some characteristics of both the scarf joint and uniform double-lap joints. Those steps near the middle of a stepped-lap joint carry significantly more load than that transferred in the corresponding area of a uniform lap joint but the load so transferred is usually not a major contribution. Most of the load transfer is effected through the end three steps at one or both ends of the joint, depending on the nature of the adherend imbalances and the direction of the load. Within each step, since the governing equations are precisely the same as for an unbalanced double-lap joint, it is found that no further load can be transferred once the overlap has exceeded a determinable value. In other words, unlike scarf joints, the potential shear strength of stepped-lap joints cannot be increased indefinitely by increasing the overlap(s). The appropriate procedure is to employ more steps of finer thickness increments in order to augment the load capacity. Because scarf and stepped-lap joints can efficiently transfer load between thicker adherends than is possible with uniform double-lap joints, the latter are restricted to thinner sections in practical applications.

The inclusion of adhesive plasticity in the analysis has a marked effect on the
strength predictions. On the other hand, the elastic adhesive stresses play a far more important role in the behavior of scarf and stepped-lap joints than they do for uniform lap joints. The inclusion in the analyses of thermal mismatch effects permits their application to the bonding of titanium to the advanced composite laminates and explains how the joint strength changes with the load direction in such a situation.

The elastic-plastic analysis of the internal stresses within stepped-lap bonded joints provides sufficient information for the joint proportions to be optimized. Analyses should be performed for each load direction and at the extremes of the environmental temperature range, taking due account of material property changes with temperature, in the optimization sequence.

APPENDICES

A.1 Computer Program A4EC For Elastic Strength of Bonded Scarf Joints

The FORTRAN IV digital computer program associated with the analysis in Section 2 is listed below. This program has been checked out thoroughly and sample solutions are illustrated in Section 4. Only shear stresses are considered, with the peel stresses neglected in accordance with the very small scarf angles used in practice. As discussed in Section 2, there are severe convergence problems associated with the series solution to this problem. While the average shear stresses computed are considered very reliable, no computation sequence for the stress distribution was found which was considered sufficiently accurate over the far end of the joint (z/L = 1). The peak shear stress is located correctly by program A4EC at one end or other of the overlap. The only real need for a shear stress distribution is as an intermediate step in the computation of the internal adherend stresses. Since the convergence of the series was enhanced greatly by prior integration into the contributions to the average shear stress, it is recommended that any attempt to pursue the adherend stress distribution should proceed along similar lines. The adhesive shear stress distribution series can be integrated mathematically so that a more tractable series solution is obtained for the adherend stresses. The first two terms follow from the average shear stress solution and the subsequent ones would derive from recurrence formulae. The condition under which a need for such information could arise is the possible breaking off of the thin tip of the stiffer adherend for a very small scarf angle. Such a situation is unlikely for perfectly elastic adhesives because the shear stress drops off very rapidly away from the ends. A simpler procedure is available for the elastic-plastic adhesive.

The format of the input data necessary to operate the A4EC computer program is as follows:

CARD 1:

FORMAT (415)
IMAX = Number of thermal mismatch coefficients. IMAX .LE. 20.
JMAX = Number of non-dimensionalized overlaps. JMAX .LE. 40.
(Note that this is one more than the number of overlaps to be read in. The limiting case of OL(1)=0 is set by the program.)

KMAX = Number of adherend stiffness imbalances. KMAX .LE. 10.
(Note that this controls the number of columns of answers printed across the page and cannot be increased indefinitely.)

NMAX = Number of terms in power series. 10 .LE. NMAX .LE. 50.
(Note NMAX = 20 is recommended.)

CARDS 2, 2A, 2B, etc.:
FORMAT (12F6.2)
OL(J)= Non-dimensionalized overlaps. Number restricted to 40 by dimension statement. (Note that OL(J) must be read in in ascending order and that OL(2), which is the first entry on card 2, must not exceed 0.5 because of internal computations. OL(1) = 0 is set by program as limiting case.) Values of OL(J) exceeding 50 are impractically large.

CARDS 3, 3A, 3B, etc.:
FORMAT (10F5.2)
ETR(K)=Adherend stiffness ratios (E_{1t1})/(E_{2t2}). Number restricted to 10 by dimension statement. (Subscripts 1 and 2 must be identified so that 0 .LT. ETR .LE. 1. Array should be read in in ascending or descending order.)

CARDS 4, 4A, 4B, etc.:
FORMAT (10F7.3)
CTHERM(I) = Adherend thermal mismatch coefficients in non-dimensionalized form. Number restricted to 20 by dimension statement. (Note that equal and opposite values must be read in consecutively to account for the difference between tensile and compressive application of the shear load. Values of up to ±5 are sufficient for the available range of adhesives. Greater values are usually associated with failure of the joint under residual thermal stresses alone.)
The complete listing follows, along with sample output pages. The output tables come in pairs with the ratio of the average to maximum adhesive shear stress (τ_{av}/τ_p) and the non-dimensionalized joint strength (τ_{av}/τ_p)(λ_2) as functions of the adherend extensional stiffness ratio ETR = E_1t_1/E_2t_2 ≤ 1 horizontally and the non-dimensionalized joint overlap λ_2 = \sqrt{G/(E_1t_1/E_2t_2)} vertically.

Each table is prepared for a single value of thermal mismatch coefficient C_{therm} = (α_2 - α_1)ΔT_λ and equal and opposite values are treated in turn to cover both tensile and compressive shear loadings.

A.2 Computer Program A4ED For Lower Bound Elastic-Plastic Strength of Bonded Scarf Joints

This FORTRAN IV digital computer program covers a simple efficient approximate solution for the elastic-plastic strength of most bonded scarf joints of practical proportions and materials. Its development was needed as a sufficiently close starting point for convergence to proceed in the more precise program A4EE. It transpired, on examination of the equivalent results computed by A4EE that the quicker computations of A4ED were satisfactory as final answers provided that (1) and adhesive non-linear behavior was not negligible, i.e., that $\gamma_p/\gamma_e > 0.5$, (2) the thermal mismatch coefficient is not too high, i.e., that $c_{therm} < 2$, and (3) that the stiffness mismatch between adherends be not too great, i.e., that $0.2 \leq ETR \leq 1$.

The input data for program A4ED is precisely the same as for program A4EE with the exception that $\gamma_p/\gamma_e$ for the adhesive cannot be equal to zero for A4EE. In other words, perfectly elastic adhesive behavior must be excluded from A4EE. On the other hand, the values computed by A4ED for zero adhesive plasticity are unduly conservative.

A listing of the program and sample outputs follow.
C PRINT OUT INPUT DATA
C
C NEED CTHERM(1) ARRAY TO CONTAIN BOTH POSITIVE AND NEGATIVE VALUES
C STIFFNESS RATIOS SHOULD BE IDENTIFIED ADHERENDS
C READ IN STIFFNESS IMBALANCE ARRAY

---

**Note:** The table entries represent the extensional stiffness ratios for different scaled load ratios. The values are expressed in terms of thickness ratios, with the ratios calculated for various load fractions ranging from 0.1 to 1.0. The entries are based on the assumption of both ends equally critical in the elastic-plastic analysis.}
A.3 Computer Program A4EE For Elastic-Plastic Strength of Bonded Scarf Joints

This FORTRAN IV digital computer program provides for the precise series solution for the average shear stress on bonded scarf joints with small scarf angles. It accounts for adherend stiffness and thermal imbalance as well as adhesive plasticity. The governing analysis is presented in Sections 3 and 4. This program A4EE will not handle perfectly elastic adhesives for which the program A4EC was developed. Severe convergence difficulties were encountered in the development of the numerical program. This contributed to the omission of a solution for the adherend and adhesive shear stress distributions. Whether or not the adherend allowable stresses are exceeded can be determined simply by evaluating the ratio of the adhesive peak shear stress to the adherend allowable direct stress. If this ratio exceeds the tangent of the scarf angle, the scarf angle is too small and the tip will either break off or be yielded depending on the nature of the adherend material.

The input data required to operate program A4EE is as follows.

CARD 1:

FORMAT (5I5)

IMAX = Number of thermal mismatch coefficients. IMAX .LE. 20.

JMAX = Number of non-dimensionalized overlaps. JMAX .LE. 40.
(Note that this is one more than the number of overlaps to be read in. The limiting case of OL(1)=0 is set by the program.)

KMAX = Number of adherend stiffness imbalances. KMAX .LE. 10.
(Note that this controls the number of answers printed across the page and cannot be increased indefinitely for a single pass through the program.)

LMAX = Number of plastic-to-elastic adhesive shear strain ratios.
LMAX .LE. 20.

NMAX = Number of terms in power series. 10 .LE. NMAX .LE. 50.
(Note NMAX = 20 is recommended.)
CARDS 2, 2A, 2B, etc.:

FORMAT (12F6.2)

OL(J) = Non-dimensionalized overlaps. Number restricted to 40 by dimension statement. (Note that OL(J) must be read in in ascending order and that OL(2), which is the first entry on card 2, must not exceed 0.5 because of internal computations. OL(1) = 0 is set by the program as a limiting case.) Values of OL(J) exceeding 50 are impractically large.

CARDS 3, 3A, 3B, etc.:

FORMAT (10F5.2)

ETR(K) = Adherend stiffness ratios \((E_{1t_1})/(E_{2t_2})\).

Number of values restricted to 10 by dimension statement.

(Subscripts 1 and 2 must be identified such that \(0 < ETR(K) \leq 1\). Array should be read in in ascending or descending order.)

CARDS 4, 4A, 4B, etc.:

FORMAT (10F7.3)

CTHERM(I) = Adherend thermal mismatch coefficients in non-dimensionalized form. Number restricted to 20 by dimension statement. (Note that equal and opposite values must be read in consecutively to account for the difference between tensile and compressive application of the shear load. Values up to \(\pm 5\) are sufficient for the available range of adhesives and adherends. Greater values are usually associated with failure of the joint under residual thermal stresses alone.)

CARDS 5, 5A, 5B, etc.:

FORMAT (14F5.2)

GPOVGE(L) = Ratio of adhesive plastic-to-elastic strain ratios. Number of entries restricted to 20 by dimension statement. (Value of zero, for elastic case, is rejected by program A4EE to prevent breakdown of the computational sequence, but accepted by A4ED.)
A complete listing and sample outputs follow. The output tables come in pairs with the ratio of the average to maximum adhesive shear stress ($\frac{\tau_{av}}{\tau_p}$) and the non-dimensionalized joint strength ($\frac{\tau_{av}}{\tau_p} (\lambda \lambda)$) as functions of the adherend extensional stiffness ratio $ETR = \frac{E_1 t_1}{E_2 t_2} \leq 1$ horizontally and the non-dimensionalized joint overlap $\lambda \lambda = \sqrt{\frac{G}{n \left( \frac{1}{E_1 t_1} + \frac{1}{E_2 t_2} \right)^2}}$ vertically. Each table is prepared for a single value of thermal mismatch coefficient $CTHERM = \frac{\alpha_2 - \alpha_1}{E_1 t_1 + \frac{1}{E_2 t_2}}$ and equal and opposite values are treated in turn to cover both tensile and compressive shear loadings. Each table is prepared for a single value of the plastic-to-elastic adhesive shear strain ratio $\gamma_p / \gamma_e$. The quantity $TRANSL$ listed at the foot of each column of the non-dimensionalized strength table defines the transitional overlap at which the adhesive behavior changes from fully-plastic to elastic-plastic.

A.4 Computer Program A4EF For Elastic Strength of Stepped-Lap Bonded Joints

The analysis in Section 5 has been prepared as the FORTRAN IV digital computer program A4EF. The program computes the elastic joint strength of any stepped-lap bonded joint and prints out the most critical adherend and adhesive stresses for each step of the joint. In order to obtain a more complete internal stress distribution, each step can be subdivided and a series of shorter steps input instead. The input data is printed out to supplement the solution output. Eccentricities are excluded from the joint and a symmetric two-sided bonded joint is analyzed in which the thicknesses of the two outer adherends are lumped together in evaluating the joint strengths. The reason for this is the greater utilization of the back-to-back stepped-lap joint than of the single-sided joint. A single-sided joint can be analyzed with this program in one of two ways. One can add a mirror image of the actual joint and halve the strength predicted for this joint of twice the actual thickness and twice the bond area or one can change certain factors of 2, identified in the listing, to 1 for single-sided joints. The program accounts for arbitrary combinations of adherend stiffness and thermal imbalances as well as non-uniform step thickness increments and step lengths. It has been used successfully in optimizing the joint proportions in order to maximize the joint strength.

A complete listing of the program A4EF follows after the input and output have been described.

CARD 1:

FORMAT (I2)

M = Number of configurations (each requiring a complete set of data) to be solved.

CARDS 2, 2A:

FORMAT (8F10.3)

TAUMAX = \( \tau_p \) = Peak adhesive shear stress.

G = Elastic adhesive shear modulus.
GAMMAX = \gamma_e + \gamma_p = \text{Maximum adhesive shear strain.} \ (\text{This may be set less than } \gamma_e \text{ to cover partial loads.})

GAMMAE = \gamma_e = \text{Elastic adhesive shear strain.}

ETA = \eta = \text{Bond line thickness.}

ALPHAO = \alpha_0 = \text{Coefficient of thermal expansion of outer adherend.}

ALPHAI = \alpha_i = \text{Coefficient of thermal expansion of inner adherend.}

DELTMP = \Delta T = T_{\text{operating}} - T_{\text{stress-free}} = T_{\text{operating}} - T_{\text{cure}} = \text{Temperature differential.}

SGNL = SGNL = +1 \text{ for tensile shear load, and } -1 \text{ for compressive shear load.}

ANSTEP = \text{Number of steps in the joint. This serves to control the number of adherend property cards read in.}

CARDS 3, 3A, 3B, . . . etc., 3(N = ANSTEP + 1)
FORMAT (7F10.3)
THICKO(N) = \text{Sum of thicknesses of outer adherends for nth step.}

THICKI(N) = \text{Thickness of nth step of inner adherend.}

STEPL(N) = \text{Length of nth step.}

ETOTR(N) = \text{Net extensional stiffness of outer adherends at nth step.}

ETINR(N) = \text{Extensional stiffness of inner adherend at nth step.}

STROTR(N) = \text{Net strength of outer adherends at nth step.}

STRINR(N) = \text{Strength of inner adherend at nth step.}
The output is in tabular form with one row devoted to each step or step portion. Those entries not defined in the input description above are: TAU the adhesive shear stress, GAMMA the adhesive shear strain, DELTAO the displacement of the outer adherends, DELTAI the displacement of the inner adherend, with TOUTER and TINNER being the loads ($\sigma t$) in the outer and inner adherends, respectively.

The more accurate solution is obtained by starting the iterative solution from the more critically loaded end. Therefore, in those cases in which the a priori identification of the more critical end is not possible, the program outputs solutions from each end, and the second one is to be preferred. Such cases have been run and the computational procedure in double precision has been shown to be sufficiently accurate from either end. The need for this higher precision on IBM computers arises from the precision loss throughout the nested do loops in the iteration sequence. The greater number of significant digits employed by CDC machines has been found to obviate the need for this and the program can be modified to single-precision operation on CDC machines in a straightforward manner.
CHECK Adhesive-Joint Stresses

1. IDENTIFY ADHESIVE-BOND JOINTS
2. STRESS ANALYSES
   - AXISY, LAMINATES (AXIAL)
   - STRESS BUT OUTFLL CONSIDERATION OF ADHESIVE PEEL STRESS ON THE JOINT INTERFACE
3. GROUND-THAT OUTER END STEP IS USUALLY SUFFICIENTLY THIN FOR STRESS ANALYSIS
4. NOTE THAT CONVERGENCE PROBLEM IS ACUTE FOR STEPED-LAP JOINTS. EVEN WITH PRECISION, STEPS TAKEN HERE TO CONSTRAINT TENDENCY
5. OPERATE AFTER trying 20 TIMES MORE AND LESS STRINGENT TECHNIQUES
6. ALSO TRYING TO ATTACH THE SHEAR STRENGTH OF THE JOINT INTERFACE
7. SINGLE PASS STRAIGHT THROUGH THE JOINT FROM END TO END, IN CONTACT WITH THE OUTER END OF EACH OF THE OUTER STEPS.
8. THE UNDERLYING DIFFICULTY IS ONE OF NUMERICAL ACCURACY LOSS IN THE METHOD.
9. PREVIOUSLY HIGH ADHESIVE SHEAR STRESS GRADIENTS AT THE OUTER ENDS OF EACH OF THE OUTER STEPS.
10. END.
C Perfectly-Plastic Bond Capacity will be closer to asymptote of shear.

C Actual load capacity may be significantly lower than plastic estimate.

C Actual load capacity may be significantly less if thermal mismatch.

C Between adherends is severe.

C Cementation in load to account for limited adherend strength.

C Accomplished later in program.

C Provide outer load to adjust adhesive peak shear stress at start of test.

C In cases where either adhesive is more critical.

C Other end of joint or adherends are more critical than adhesive.

IF (TINER(1) = 2.) THEN TAURIP = 2. * TAINAX

C Note that program is prevented from handling problem in which shear.

C Stress in adhesive reverses sign, when computations start from.

C The less critical end. Solution-trivially from other end.

C Note also that if the maximum shear stress and applied loads have.

C Opposite signs, joint must break apart under residual thermal.

C Stress alone without any externally applied load, so no cases of.

C Special concern has been excluded by the restriction above.

A.5 Computer Program A4EG For Elastic-Plastic Strength of Stepped-Lap Bonded Joints

The elastic-plastic strength of stepped-lap joints is covered by the analysis in Section 6. The digital computer program A4EG has been prepared as a design tool for the analysis of such joints. By printing out detailed internal stresses, the program can serve to aid in design improvement by changing the joint proportions in such a manner as to reduce the load transfer in the more critical regions and to increase it in those less severely loaded areas.

In addition to those features of the elastic solution A4EF, this elastic-plastic program A4EG seeks the existence and extent of any plastic adhesive zones within any step or step portion. The convergence of the nested iterative do loops is complicated by the addition of an extra loop accounting for the maximum adhesive shear strain. This is only rarely a known quantity for ductile adhesives because the end step of the stiffer adherend is usually the most critical detail.

A complete listing of the program A4EG follows. Precisely the same input data is used as for program A4EF and the output format is the same except inasmuch as A4EG prints out separate elastic and elastic-plastic solutions.
