THE RELATION OF VARIATIONS IN TOTAL MAGNETIC FIELD AT HIGH LATITUDE WITH THE PARAMETERS OF THE INTERPLANETARY MAGNETIC FIELD AND WITH DP2 FLUCTUATIONS

R. A. Langel

Geophysics Branch
NASA Goddard Space Flight Center
Greenbelt, Maryland 20771
ABSTRACT

Distrubances in total magnetic field magnitude, $\Delta B$, are generally positive from 2200 to 1000 magnetic local time (MLT) and negative from 1000 to 2200 MLT. The maximum disturbances from the positive and negative regions of $\Delta B$ (Bp and Bn, respectively) are investigated with respect to their correlation with 1) the average N-S component, Bz, 2) the average angle with respect to the solar magnetospheric equitorial plane, $\theta$, 3) the variance, $\sigma_i$, and 4) the magnitude, Bi, of the interplanetary magnetic field. These quantities were averaged over a period, T, ranging from 20 min. to 8 hours prior to the measurement of Bp or Bn. In the correlation with Bz two methods were used: 1) direct correlation with Bz and 2) correlation with the sum $B_\Sigma = \sum B_z / T$ where $Bz < 0$. Bp vs. Bz showed the best correlation, -0.79, for $T = 120$ minutes. For Bn vs $B_\Sigma$, data were divided into an equinoctial and winter period. Maximum correlations of 0.63 at $T = 200$ minutes and 0.70 at $T = 60$ minutes were obtained for equinoctial and winter, respectively. In all cases the peak in the correlation coefficient, when plotted against T, was very broad. Correlations with all other parameters was smaller than for $B_\Sigma$. Examination of Bp as a function of average Bz shows that an approximately linear relation holds for $Bz < 0$ and that for $Bz > 0$, Bp is relatively constant. Significant magnitudes of $\Delta B$ are found to occur in both the positive and negative regions even when the interplanetary field has been northward for over an hour.

Comparison of the occurrence of disturbance in $\Delta B$ and in occurrence of DP2 fluctuations indicates no correlation between the two phenomenon.
Variations (i.e., disturbances) in total magnetic field magnitude have been studied (Langel, 1974a, b) utilizing data from the Polar Orbiting Geophysical Observatory satellites (OGO 2, 4, and 6), unofficially referred to as POGO. These data, from October 1965 through December 1969, covered the altitude range from 400-1510 km. Analysis is carried out in terms of the quantity $\Delta B$, which is the measured field magnitude minus the field magnitude computed from a spherical harmonic analysis of the POGO data from especially chosen quiet days. The satellite, instrumentation, data accuracy, and details of the POGO (8/71) spherical harmonic analysis are given in earlier papers by Farthing and Folz (1967), Langel (1967, 1974a, b), Cain and Langel (1971), and Cain et al. (1967).

$\Delta B$ is found (Langel, 1974a) to be positive from near $22^h$ to near $10^h$ MLT (magnetic local time) and negative from near $10^h$ to near $22^h$ MLT. These regions are designated the positive $\Delta B$ region and the negative $\Delta B$ region, respectively. Figure 1 is a contour plot of average $\Delta B$ for one season, magnetic disturbance level, and altitude range. Both the positive and negative $\Delta B$ region are clearly discernible. This basic pattern prevails for all seasons and magnetic disturbance levels. Amplitude variations with altitude, season, and magnetic disturbance level are described in Langel (1974a). Variations with interplanetary magnetic sector are described in Langel (1974c).

Although the negative $\Delta B$ region can be accounted for in terms of ionospheric currents, this is not true for the positive $\Delta B$ region (Langel, 1974b). Some of the positive $\Delta B$ region disturbance is attributed to the ECS (equatorial current sheet = ring current) and some to the westward electrojet, but some data are not accounted for by this combination of sources. Equivalent ionospheric currents which could cause the variations in POGO data in the negative $\Delta B$ region (and also most of the surface $\Delta Z$ and $\Delta H$ in this local time region) were derived
by Langel (1974b) and denoted HLS (for High Latitude, Sunlit). HLS is a latitudinally broad current, as opposed to a jet-type current which has narrow (~3-6°) latitudinal extent, and is similar to the DPC current, proposed by Feldstein (1969) to account for high latitude surface magnetic variations on quiet summer days, and to the afternoon vortex of the DP2 current system proposed by Nishida and his co-workers (1966).

The purpose of this paper is to explore the relationships between variations in the ∆B as seen in the POGO data and variations 1) in the DP2 fluctuations reported by Nishida and co-workers and 2) in the N-S component, Bz, the variance, σ$_i$, and the magnitude, B$_i$, of the interplanetary magnetic field. The southward component of interplanetary magnetic field (Bz < 0) has been found to be highly correlated with magnetic disturbance, particularly substorm activity (Arnoldy, 1971; Foster et al. 1971). Indeed, some workers (e.g. Coroniti and Kennel, 1972, 1973) believe that magnetospheric disturbances are generally initiated by a southward turning interplanetary magnetic field. Burch (1973) found that the latitudes of the poleward and equatorial boundaries of the magnetospheric cusp region could be ordered according to the average value of Bz or the average value of $\bar{\epsilon}$ for some period prior to the boundary measurement. This ordering was much better for Bz than for $\theta$ and for a period of 45 min prior to the boundary measurement rather than 15, 30, or 60 min.

This study will show that detailed correlation between the interplanetary parameters and the disturbance magnitude at POGO is not present on individual passes but that statistical correlations between disturbance magnitudes in both the negative and positive ∆B regions do exist. Also, no correlation is found between ∆B at POGO and the occurrence of DP2 fluctuations.
RELATION WITH PARAMETERS OF THE
INTERPLANETARY MAGNETIC FIELD

Statistical correlations. For each individual pass the following parameters are defined:

\( B_n \): the minimum \( \Delta B \) in the negative \( \Delta B \) region.

\( B_p \): the maximum \( \Delta B \) in the positive \( \Delta B \) region.

Associated with each \( B_n \) or \( B_p \) are the following:

\( B_\Sigma (T) = \Sigma B_z / T \) for the interplanetary field points where \( B_z < 0 \).

\( \langle B_z (T) \rangle \) : the average value of \( B_z \).

\( \langle \theta (T) \rangle \) : the average angle of the interplanetary field with respect to the solar magnetospheric equatorial plane,

\( \langle \sigma_1^2 (T) \rangle \) : the average variance of the interplanetary magnetic field

\( \langle B_i (T) \rangle \) : the average magnitude of the interplanetary field.

The sum \( B_\Sigma (T) \) and the various averages are taken over a time span of \( T \) minutes prior to the time of measurement of \( B_n \) or \( B_p \). All interplanetary field parameters are computed from Explorer 34 twenty second average data in the solar magnetospheric coordinate system. For these studies, POGO data were restricted to altitudes below 550 km for \( B_n \), to minimize effects of altitude variations, and to altitudes above 700 km for \( B_p \), to minimize the effects of altitude variations and of the electrojet currents.

Correlation coefficients have been computed for \( 20 \leq T \leq 480 \) minutes.

First consider the positive \( \Delta B \) region. The computations with \( B_z \) have been carried out three ways, first with data at all times up to \( T \) minutes prior to the time of \( B_p \), second, omitting the data within 10 minutes of the time of \( B_p \) and third, omitting the data within 20 minutes of the time of \( B_p \). In all cases the
maximum correlations occurred for $T = 120$ min. Only small differences occurred between the three methods of data selection. Figure 2 shows the correlation coefficient, $R$, between $B_\Sigma$ and $B_p$ as a function of $T$ for the second method of data selection. $R$ is less than $-0.6$ from $T = 40$ min. to 480 min. with a very broad peak of $-0.786$ at $T = 120$ min. $R$ for $B_p - \langle \phi \rangle$ and $B_p - \langle B_z \rangle$ is $-0.48$ and $-0.69$ at the maximum (cf. Table 1) and in both cases has a broad peak similar to that for $B_p - B_\Sigma$. The broadness of this peak indicates that whatever magnetospheric phenomena is causing the near earth positive $\Delta B$ is affected to some extent by southward $B_z$ as far as 8 hours in the past. Study of $B_\Sigma$ as a function of time for individual measurements of $B_p$ confirms this. In some cases of large $B_p$, $B_\Sigma$ is relatively high for $T < 120$ min. and decreasing thereafter, implying that the interplanetary field-magnetospheric interaction is higher for $T < 120$ min. In other cases, with $B_p$ of comparable magnitude, $B_\Sigma$ becomes larger in magnitude with increasing time, in some cases reaching its maximum at $T = 480$ min. The significance of the observed correlations may be tested by calculation of the probability that such a correlation could arise, by random sampling, from an uncorrelated population. This test is accomplished by use of the t-distribution (Fisher, 1958). For the present case, $t$ is given by

$$t = \frac{R \cdot \sqrt{N - 2}}{\sqrt{1 - R^2}}$$

where $N$ is the number of pairs of observations. For $B_p$ vs. $B_\Sigma$ the probability of obtaining the correlation coefficients of Figure 2 from an uncorrelated population is below 0.1 for $20 \leq T \leq 480$ min. and is below 0.06 for $120 \leq T \leq 240$ min. Thus a great deal of significance should be attached to this correlation.
For $B_p$ vs $\langle \vartheta \rangle$, this probability is always above 0.25 and reaches 0.5 at $T = 480$ minutes. For $B_p$ vs. $\langle B_z \rangle$ the probability is between 0.14 and 0.33. The correlations of $B_p$ with $\langle B_z \rangle$ and, especially, with $\langle \vartheta \rangle$ are much less significant than that with $B_\Sigma$.

It is instructive to examine plots of $B_p$ vs. $B_\Sigma$, $\langle B_z \rangle$, and $\langle \vartheta \rangle$. These are given in Figure 3 for $T = 120$ min. In all cases there is a great deal of scatter. $B_p$ vs. $B_\Sigma$ is relatively linear and a least squares fit to the 68 data points in Figure 3a gives:

$$B_p = 17.75 - 8.15 B_\Sigma(y).$$

(1)

The standard deviation to this fit is 23.3 $\gamma$. As expected, the minimum standard deviation occurs for the same $T$ as the maximum $|R|$. There are a large number of points for which $|B_\Sigma|$ is small and $B_p$ is large (> 20 or 30 $\gamma$). This is reflected in the fit to the data which gives $B_p = 18 \gamma$ for $B_\Sigma = 0$. Some disturbance can occur when the interplanetary field has been northward for some time. Figures 3b and 3c show $B_p$ vs. $\langle B_z \rangle$ and $\langle \vartheta \rangle$, respectively. In both cases the plot characteristics change as the average field direction goes from south to north. Two hand-drawn lines are shown in Figure 3b to illustrate this effect. Thus there is a clear statistical difference in the magnetospheric response, in this case $B_p$, to southward and northward fields. The scatter in both of these plots is large and it is larger for $\langle \vartheta \rangle$ than for $\langle B_z \rangle$ which implies that the magnitude of the southward component is more important than the field angle with respect to the solar magnetospheric equatorial plane. A similar difference in the response of the equatorward boundary of the dayside cusp to variations in $B_z$ between northward and southward $B_z$ was found by Burch (1973). Between
$B_z = 0$ and $B_z = -6\gamma$ this boundary moves equatorward by $5^\circ$ whereas between $B_z = 0$ and $B_z = 6\gamma$ this boundary moves poleward only $1.5^\circ$. The statistical results presented for $B_p$ are summarized in Table 1 along with the rest of the statistical results of this study. All data used in this study are from the northern hemisphere.

**Negative $\Delta B$ Region.** Seasonal effects are large in the negative $\Delta B$ region so available data from this region are divided into two seasonal groups, an early equinoctial period from August 5 to September 10, 1967, and a winter period from November 5 to December 15, 1967. Because the level of negative $\Delta B$ is much lower in the winter, and because the number of data points available for winter (35) is lower than for equinox (88), care should be made when comparing the seasons or drawing conclusions based on analysis of the winter data. Figure 4 shows the correlation coefficients for $B_n$ vs. $B_\Sigma$ as a function of $T$. As for the positive $\Delta B$ region, the peak of each curve is very broad. For the equinox data $R$ reaches 0.63 at $T = 200$ minutes and for the winter data $R$ reaches 0.70 at $T = 60$ minutes. The probabilities for obtaining these results from an uncorrelated population are very small. For the equinox data the probability is always less than 0.025, and usually less than 0.02, for $20 \leq T \leq 480$ min. For the winter data the probability is always less than 0.036. Plots of $B_n$ vs. $B_\Sigma$ are shown in Figure 5. Least squares fits to these data yield

$$B_n = -44.0 + 8.05 B_\Sigma(\gamma)$$  \hspace{1cm} (2)

with a standard deviation of 27.1 $\gamma$, for the equinox data and

$$B_n = -21.7 + 3.4 B_\Sigma(\gamma)$$  \hspace{1cm} (3)
with a standard deviation of 14.8 $\gamma$, for the winter data. The scatter for the equinox data is very large, larger than was found in the positive $\Delta B$ region, and the scatter for the winter data is smaller but still significant. As for the positive $\Delta B$ regions, a considerable number of points occur for which $|B_{\Sigma}|$ is small and $|B_n|$ is large. Equations (2) and (3) both indicate that considerable disturbance is expected even when the interplanetary field has been northward for some time.

Other Interplanetary Parameters. Garrett (1974) has shown that fluctuations in the interplanetary magnetic field (e.g. measured by the variance of the field fluctuations, $\sigma_i^2$) play a role in determining the magnitude of substorm activity. Another candidate interplanetary field parameter for correlation with magnetospheric disturbance phenomena is the magnitude, $B_i$, of the interplanetary field. Because of the dominance of the correlation of $B_p$ and $B_n$ with $B_{\Sigma}$, and because the temporal relation between $\sigma_i^2$, $B_i$, or $B_{\Sigma}$ and $B_p$ or $B_n$ may be different, the correlations found between $\sigma_i$ or $B_i$ and $B_p$ or $B_n$ are not as conclusive as the correlation between $B_{\Sigma}$ and $B_p$ or $B_n$. Computation of the correlation coefficient, $R$, between $\langle\sigma_i^2\rangle$ or $\langle B_i \rangle$ and $B_p$ or $B_n$ was carried out in the same manner as the computation between $B_{\Sigma}$ and $B_p$ or $B_n$ and the results are summarized in Table 1. The correlation coefficients have somewhat greater magnitudes in the positive $\Delta B$ region than in the negative $\Delta B$ region but it is not clear that this is a significant difference. If it is significant, the difference may be a reflection of the different sources of disturbance, i.e. ionospheric for the negative $\Delta B$ and mostly non-ionospheric for the positive $\Delta B$ (esp. at these altitudes, $> 700$ km).

For completeness, the coefficients $C_n$ in

$$B_p = C_1 B_{\Sigma}(T_1) + C_2 \cdot \langle \sigma_i^2(T_2) \rangle + C_3 \cdot \langle B_i(T_3) \rangle$$  

(4)
were determined by least squares. \( T_n \) is taken to be the time of maximum correlation coefficient for the corresponding variable. The correlation coefficient of \( B_p \) computed from (4) with the measured \( B_p \), and the \( \sigma \) of the fit are given in Table 1. Some improvement in the representation of \( B_p \) or \( B_n \) is obtained in each case.

Most of the computations described were repeated for subsets of the data to check for bias in data selection. No such bias was found. In particular, data subdivided by interplanetary magnetic sector showed no sector differences considered to be statistically significant.

**Examples from Individual Satellite Passes.** It is particularly noteworthy that both \( B_p \) and \( B_n \) can be large when \( B_z \) has been northward for some time. Several passes have been chosen to illustrate this point further. Two such passes, together with the pertinent \( B_z \), are shown in Figure 6. In the top figure (7/29/67), \( B_z \) has been northward for several hours and nearly constant for about one hour, yet both positive and negative \( \Delta B \) regions show peak \( |\Delta B| \) greater than 50 \( \gamma \). In the bottom figure (8/11/67), \( B_z \) fluctuates more than in the top figure but is still quite positive for about 1.5 hours prior to the pass. \( \Delta B \) in the positive \( \Delta B \) region reaches only \( \sim 35 \gamma \), but the satellite track does not pass through the MLT where maximum \( \Delta B \) generally occurs. Although there is a data gap in the negative \( \Delta B \) region, it is still clear that \( |\Delta B| \) reached at least 40\( \gamma \).

Although the statistical correlation of \( B_p \) and \( B_n \) with \( B_\Sigma \) and \( B_z \) is clear, pass by pass correlation with \( B_z \) is not clear. This is illustrated by Figure 7 which gives a time history of \( B_z \) and of the POGO data for 31 hours on August 12-13, 1967. The satellite passes are numbered 1-9 and the times of these passes indicated on the \( B_z \) plot. Disturbance in both the positive and the negative \( \Delta B \)
regions is present in all cases, although the magnitude of $\Delta B$ varies considerably, but since the satellite track does not cover the same MLT in each case, detailed comparison of $\Delta B$ magnitude is not attempted.

$B_z$ is southward until $1^h$ UT on 8/12, at which time it swings north and, after some agitation, settles down to a positive value from about 2.5 - 5.8$^h$ UT. Pass 1 occurs during a southward period for $B_z$ in the period of agitation, and both positive and negative $\Delta B$ are high ($|\Delta B| \text{ max } \sim 80\gamma$). Pass 2 occurs after $B_z$ has been northward for more than 30 min., and $|\Delta B|$ is lower in both regions, although the change in positive $\Delta B$ is greater than in negative $\Delta B$. From 6$^h$ to 18.5$^h$ UT on 8/12, $B_z$ is mainly northward but is quite agitated. Pass 3 occurs during this period, and $\Delta B$ is significant in both regions and, in fact, is stronger than in pass 2. Perhaps the disturbance level here is influenced by the amount of variation as well as by the direction of $B_z$ (cf. Garrett, 1974). From 19-22$^h$ UT $B_z$ is southward, although the magnitude of $B_z$ is not large ($\sim 1.5\gamma$). Passes 4-6 are from this period, and $|\Delta B|$ in both regions shows a small but definite increase as time progresses, as expected from the discussion of Figure 2. Although $B_z < 0$ during and before pass 4, and $B_z > 0$ during and before pass 3, the disturbance level for both regions is higher during pass 3 than during pass 4. $B_z$ is northward from just before 23$^h$ UT on 8/12 to about 15 min. into 8/13, when it becomes agitated and, mainly, southward. Pass 7 occurs just after $B_z$ has turned southward, and both regions show strong $|\Delta B|$. $|\Delta B|$ in pass 8 is large in both regions (note the scale change to 150$\gamma$) although the southward $B_z$ is small in magnitude. Again, the variation in $B_z$ might increase the disturbance level. Pass 9 occurs after $B_z$ has been northward for about 2$^h$,
but with a significant amount of agitation. Disturbance in the negative $\Delta B$ region is small ($\sim -25\gamma$) although $\Delta B$ in the positive $\Delta B$ region reaches $60\gamma$, which is as large as for those passes (4, 5, 6, 7, 8) where $B_z < 0$.

**Discussion.** A close correlation between instantaneous $B_z$ and $|\Delta B|$ does not occur. Correlation between $\Delta B$ and $B_z$ history for about 30 min. to several hours prior to the $\Delta B$ measurement is strong, and, possibly, some correlation with the interplanetary field magnitude and its degree of variation. A correlation exists with the amount of southward field for the previous 8 hours, at least. The time constants of 30-60 min. found between $B_z$ and substorms are shorter than those found in the present study. If time constants are to be assigned, and because of the broadness of the peaks of $R$ (cf. Figures 3 and 4), and because the interplanetary field parameters are averaged for $T$ minutes and not instantaneous, it is not clear that this is meaningful, the times in Table 1 might be appropriate (although, since quantities are averaged for $T$ minutes, $T/2$ might also be appropriate). The time constant associated with $B_{\Sigma}^z$, i.e. the effects of southward $B_z$, is 120 minutes for positive $\Delta B$ and 200 minutes for negative $\Delta B$ in equinox. The value of 60 minutes obtained for winter in the negative $\Delta B$ region may indicate a seasonal dependence but should be treated with caution because of the low amplitude of the negative $\Delta B$ in winter and the poor statistics compared to the other computations. The times associated with $\langle \sigma^2 \rangle$ and $\langle B_i \rangle$ are not as well determined as those associated with $B_{\Sigma}$ because the variation of $R$ as a function of $T$ is much less for these variables. In particular, the value of 440 minutes for $\langle B_i \rangle$ in the positive $\Delta B$ region is not well determined.

That the time constants found for the correlations of interplanetary parameters with $\Delta B$ are greater than those found by previous workers between
southward $B_z$ and substorm activity does not contradict these earlier results because Langel (1974b) found that the major sources of $\Delta B$ were separate from the electrojet currents but that there is a tendency for the $\Delta B$ magnitude to be high during periods of substorm activity.

Although it is magnetospheric rather than ionospheric in origin, the high latitude positive $\Delta B$ is not predicted by the most recent theoretical field models (Sugiura and Poros, 1973; Olson, 1972; Olson and Pfitzer, 1973). These models are also deficient in their representation of $\Delta B$ near the magnetopause in day-side high latitudes (i.e. near the cusp). Sugiura and Poros (1973) point out that this seems to indicate deficiencies in the theoretical model for the magnetopause currents. They also point out that the theoretical models do not include the current system associated with the polar cusp which is likely to have a substantial affect on $\Delta B$ at high latitudes. It is not known if a correct theoretical description of the magnetic fields beyond $2R_e$ will also provide an explanation of the near earth positive $\Delta B$.

RELATION WITH DP2

The DP2 Current System. Nishida and co-workers (1966) noted that certain fluctuations in polar cap and equatorial magnetic field occur in-phase. Analysis of such data (see also Nishida, 1968a, b, 1971; Nishida and Maezawa, 1971) led these workers to identify these disturbances with $S_0^p$ except that they noted that the disturbance is worldwide and not confined to the polar cap. These workers also stress a high correlation between DP2 and the southward component of the interplanetary magnetic field. DP2 is supposed to have a peak-to-peak correspondence with the southward field with a time lag of 10-20 min. for disturbances of duration near 1 hr. Auroral electrojet activity, in this notation, is
called DP1. Nishida and Kokubun (1971) claim that, for Kp greater than about 4, DP2 becomes less evident and DP1 dominates. DP1 and DP2 are not seen to be mutually exclusive, Iijima and Nagata (1968, 1972) and Kokubun (1971, 1972) find that DP2 or SP activity precedes DP1 activity by one to two hours; they identify DP2 with a growth phase for magnetic substorms.

**Relation Between Satellite ∆B and DP2.** A DP2 current system would cause negative and positive ∆B in the negative and positive ∆B regions, respectively, which raises questions concerning the correlation of DP2 with the POGO ∆B measurements. In particular, (1) could DP2 be responsible for some of the disturbance in the positive ∆B region (in addition to the ECS and westward electrojet), and (2) is HLS a part of the DP2 current system? An attempt has been made to relate instances of DP2 with the satellite ∆B. As an example, Figure 8 shows $B_z$ (interplanetary N-S component), X and Y from AT, and H from a selected group of low latitude observatories. (Table 2 gives observatory mnemonics and locations.) According to Nishida and co-workers, DP2 consists of simultaneous fluctuations in X and Y at polar cap stations (such as AT) and H at low latitude observatories. Most examples cited utilize an equatorial observatory at dawn to dusk local times. These fluctuations are supposed to be correlated with fluctuations in $B_z$. In Figure 8, 20 "fluctuations" are noted in the X and Y components at AT, as indicated by the shaded portions labeled A, B, etc. Fluctuations in $B_z$ and low latitude H, which we felt correlated in a reasonable manner with the fluctuations at AT, are also shaded and labeled. Some fluctuations in data from AT occur which we have not considered; these generally do not correlate well with the other data. Local times of 6 h, 12 h,
18\(^h\), and 24\(^h\) are indicated for each low latitude observatory as DA, N, DU, and M, respectively.

Of the 29 examples correlation with \(B_z\) is found for 20 cases (A, B, D, E, F, H, I, J, K, L, M, N, P, Q, R, S, T, W, AB, AC). Of the other 9 examples, 3 do not have the characteristics of DP2 at low latitudes (X, Y, AA), 5 are either weak and/or only seen at one or two stations at low latitudes (G, O, U, V, Z), and one (C) has all of the characteristics of DP2.

For the 20 cases where \(B_z\) is correlated with data from AT, 7 are either weak and/or only seen at one or two stations at low latitudes (M, N, P, R, T, U, V), and 2 (F, V) have low latitude fluctuations which are not simultaneous with the AT data.

Although an extensive discussion of the nature and reality of DP2 is not attempted, several comments resulting from the study of this and other time periods are appropriate. First, it is extremely difficult, and seemingly somewhat arbitrary, to choose "fluctuations" which meet the criteria for DP2. Second, fluctuations occur frequently in all of the data involved, and it is unclear that the supposed DP2 are more than coincidence, at least for the data we have considered. The occurrence of examples C, G, O, U, V, and Z, which show many of the characteristics of DP2 but do not correlate with \(B_z\), lend weight to the idea of coincidence in unrelated fluctuations, as does the occurrence of cases like M and N which are seen only weakly at one low latitude station although \(B_z\) and X component at AT correlate well (see also Onwumechili et al., 1973, for further comments of the nature of DP2).

Assuming that DP2 does exist, and is identified as the 20 examples where \(B_z\) correlates with data from AT, consider the relation with simultaneous
POGO data. The time period under consideration is the same as that of Figure 7, and the times of the nine satellite passes are indicated on Figure 8 by numbered arrows. Pass 1 occurs during a high level of substorm activity and will not be considered in the correlation. From 3\textsuperscript{h} UT on the 12th to 8\textsuperscript{h} UT on the 13th substorm activity is low and should not mask any DP2 present. A summary of results is given in Table 3.

In passes 3, 5, and 9 an additional source(s), besides the westward electrojet and the ECS, is necessary to account for the positive \( \Delta B \) (see Langel, 1974a). None of these passes occur during an apparent DP2 event, although passes 3 and 5 occur during other types of fluctuations in \( X \) at AT. Three passes (4, 8, and 9) occur during periods when DP2 is certainly absent, yet both positive and negative \( \Delta B \) are evident in the POGO data. On pass 8 very large magnitudes of \( \Delta B \) occur in both regions. Only on pass 7 is there a case of DP2 occurrence at a time of significant \( \Delta B \).

On the basis of these and other data where significant \( \Delta B \) is present in the absence of DP2 fluctuations, no correlation between the DP2 fluctuations and the \( \Delta B \) at POGO is found, and it is concluded that HLS is not a portion of the current system associated with DP2 fluctuations as defined by Nishida and his co-workers. Although no correlation is found with DP2 fluctuations, estimates of non-electrojet positive \( \Delta B \) are not so well determined that a positive \( \Delta B \) contribution from a current of the DP2 type can be excluded. Such a current would, of course, not be associated with "DP2 fluctuations," as shown above, and would not be a dominant source, as shown by Langel (1974b).
ACKNOWLEDGEMENTS

I would like to thank D. Fairfield for the use of Explorer 34 data and J. Burch for critical review of the manuscript resulting in valuable suggestions.

$B_p^c = C_1 \cdot B_\Sigma (T_1) + C_2 \cdot \langle \sigma_i^2 (T_2) \rangle + C_3 \cdot \langle B_i (T_3) \rangle$, where $T_1$, $T_2$ and $T_3$ are the times of maximum R and the $C_N$, are determined by least squares.

**For $\langle B_i \rangle$ and $\langle \sigma_i^2 \rangle$, R and $\sigma$ varied very little for $0 < T < 480$ minutes.

FIGURE CAPTIONS

Figure 1  Average ΔB from OGO 2, 4 and 6. Data is from months 3, 4, 9, and 10, the northern hemisphere, and is at altitudes less than 550 km. Kp was 2- to 3+. Coordinates are magnetic local time and dipole latitude.

Figure 2  Correlation coefficient of B_p vs. B_{Σ}(T) as a function of T.

Figure 3  a) B_p vs. B_{Σ}. B_{Σ} is for T = 120 min. Dashed line is best fit to data in a least squares sense. b) B_p vs. \langle B_z \rangle. \langle B_z \rangle is for T = 120 min. The dashed lines are hand drawn to illustrate the change in behavior for \langle B_z \rangle > 0 and \langle B_z \rangle < 0. c) B_p vs. \langle θ \rangle. \langle θ \rangle is for T = 120 min.

Figure 4  Correlation coefficients of B_n vs. B_{Σ}(T) as a function of T. a) is for an equinoctial period and b) is for a winter period.

Figure 5  B_n vs. B_{Σ}. a) is for the equinoctial period, 8/5-9/10, 1967, and for T = 200 min., b) is for the winter period, 11/5-12/15, 1967, and for T = 60 min.

Figure 6  Examples of significant ΔB magnitude at times when the interplanetary magnetic field has been southward for some time. On the OGO data plots the straight line is the satellite location and also the ΔB = 0 axis. The scale lines project away from the ΔB = 0 axis in the direction of positive ΔB and are labeled with the scale, altitude, and universal time.
Figure 7  A series of OGO-4 passes and the simultaneous values of the north-south component of the interplanetary magnetic field. The format of the OGO-4 plots is the same as Figure 6.

Figure 8  Simultaneous plots of the north-south component of the interplanetary magnetic field, the magnetic field at a high latitude observatory (AT), and the horizontal components of magnetic disturbance at eight low latitude observatories. Possible occurrences of DP2 fluctuations are shaded and labeled.
