FLIGHT-PATH AND AIRSPEED CONTROL DURING LANDING
APPROACH FOR POWERED-LIFT AIRCRAFT

James A. Franklin and Robert C. Innis
Ames Research Center

SUMMARY

Manual control of flight path and airspeed during landing approach has been investigated for powered-lift transport aircraft. An analysis was conducted to identify the behavior of the aircraft which would be potentially significant to the pilot controlling flight path and airspeed during the approach. The response characteristics found to describe the aircraft behavior were (1) the initial flight-path response and flight-path overshoot for a step change in thrust, (2) the steady-state coupling of flight path and airspeed for a step change in thrust, and (3) the sensitivity of airspeed to changes in pitch attitude. The significance of these response characteristics was evaluated by pilots on a large-motion, ground-based simulator at Ames Research Center. Coupling between flight path and airspeed was considered by the pilots to be the dominant influence on handling qualities for the approach task. Results are compared with data obtained from flight tests of three existing powered-lift V/STOL aircraft.

INTRODUCTION

Manual control of STOL transport aircraft operating along steep flight paths is generally more difficult than control of current generation jet transports operating at higher speeds on conventional ILS approach paths. In particular, longitudinal control of STOL aircraft that utilize significant amounts of power to augment aerodynamic lift is adversely affected by low-speed operation, high wing loading, and high inertias typical of the design. Furthermore, operational constraints imposed by airspace, noise, and the time allotted for terminal area operation, by demands for STOL landing field performance and comfortable landing sink rates, and by requirements for adequate operating margins for flight safety are expected to dictate a precision of flight-path and airspeed control for powered-lift aircraft not demanded of conventional jet transports.

This report presents results of an analytical and experimental investigation of flight-path and airspeed control. The study focussed on operation on the glideslope. Problems of controlling large changes in flight path or airspeed associated with transitioning from level flight onto the glideslope or flaring to a landing were not addressed. This report consolidates and extends the work summarized in reference 1, and provides a basis for interpreting the results of reference 1 in terms of the aircraft behavior under pilot control.
Furthermore, the results are related to available flight-test data from V/STOL aircraft.

This report is intended to provide the user with sufficient background information to analyze and make preliminary evaluations of the basic handling qualities of the aircraft for flight-path and airspeed control and to conduct preliminary control system design studies for improving handling qualities. For such purposes, the entire report should be useful: the more casual reader may pass over the details of analysis in section 2 and still have an appreciation of the essential contributions to path and speed control and of the simulation results and flight data.

SECTION 1

BACKGROUND AND REPORT ORGANIZATION

Past experience with several powered-lift aircraft operating along steep approach paths (refs. 2-4) and recent results of ground-based and in-flight simulator evaluations of jet STOL aircraft (refs. 5-9) have emphasized the difficulties of path and speed control which result from

- sluggish flight-path response to attitude changes
- operation on the backside of the drag curve
- large changes in lift and drag with engine power setting
- significant coupling between flight path and airspeed with either attitude or power changes.

Figure 1 illustrates the difficulty of tracking on glideslope with such adverse characteristics. The pilot is forced to make several throttle adjustments to reacquire the glideslope and does so only with considerable difficulty. Also note the poor control. Speed decays after the path is corrected, and the reference approach speed (60 knots) is never reacquired. Time histories that demonstrate the response to attitude and thrust for the STOL aircraft are shown in figure 2. Time histories for a current generation jet transport are included for comparison. The initial change in flight path in response to an abrupt change in pitch attitude (fig. 2(a), constant thrust) is much less for the STOL than for the CTOL aircraft. Furthermore, the direction of the STOL flight-path correction eventually reverses. Flight path is more responsive to a throttle input for the STOL aircraft (fig. 2(b), constant attitude), but the initial correction is partially washed out because of the eventual change in airspeed. The speed change associated with a throttle input is decidedly unconventional in that the airplane decelerates following an increase in power and vice versa.

Such behavior implies that significant demands are placed on the pilot in the way of attention and effort required to control flight-path and speed.
Figure 1.- Example of glide slope tracking for large flight-path/airspeed coupling.

Figure 2.- Flight-path and airspeed response to attitude and thrust (STOL-CTOL comparison).
to achieve acceptable performance during a STOL approach and landing. It thus becomes important to identify the characteristics of the aircraft's behavior which influence the precision with which the pilot can control path and speed on a slow steep approach and the workload associated with the task.

This report is organized as follows. Section 2 presents an analytical description of flight-path and airspeed control. In this analysis, path and speed response to simple inputs through the pilot's primary controls are described. Here the basic response characteristics are discussed and the features important to control precision for the landing approach are identified. So long as the response characteristics are uncomplicated to the pilot and are sufficient to allow him to perform the approach task satisfactorily, the description of the aircraft behavior resulting from these simple, open-loop control applications would provide an adequate basis for analyzing the control task. When the response characteristics are unsatisfactory or when external disturbances such as those imposed by turbulence force the pilot to devote continuous attention to controlling path and speed, the behavior of the aircraft under continuous or closed-loop control by the pilot must be considered. The second step in the analysis defines the characteristics of flight-path and speed response when each is independently controlled by the pilot and, finally, when both are controlled simultaneously. The final step in the analysis is a description of the flight-path and airspeed response characteristics that define the pilot-in-the-loop behavior of the airplane and that are used to structure the experimental program.

Section 3 describes an experimental program devised for a ground-based simulator study of the influence of the individual response characteristics on handling qualities for the STOL approach. Results are presented in terms of pilot ratings and descriptive time histories.

Section 4 compares existing flight data with the results of this simulation. Data from past flight tests which are well tailored for such a comparison are extremely limited; hence the comparison is more qualitative rather than quantitative and conclusive in nature.

SECTION 2

ANALYSIS OF FLIGHT-PATH AND AIRSPEED CONTROL

Flight-Path and Airspeed Response to Thrust and Attitude Control

The pilot's control of flight path and airspeed on the glide slope depends considerably on the ease with which he can make predictable adjustments to the approach path or speed without having to pay excessive attention to the ensuing response or coordinate his controls. The path and speed response of the aircraft to the pilot's control inputs play an important role in that they determine how quickly and predictably the pilot can make a correction in either path or speed without unnecessarily disturbing the other
and how tightly the pilot can control path or speed without having to compensate for deficiencies in the aircraft behavior.

In the discussion which follows, the controls over path and speed used by the pilot are the elevator and engine thrust and the aircraft's response to them is considered. Additional cockpit controls (such as for direct lift or drag) are neither necessary nor desirable because of the increased complexity of the control task and the resulting increase in pilot workload required to coordinate their use. It is well to recognize that the elevator is not normally used to directly control flight path or airspeed but rather to control pitch attitude. Precise control of attitude is essential to establish and hold flight path or airspeed and, in fact, attitude can be used as a command reference by the pilot for path or speed. Consequently, it is appropriate to consider commanded pitch attitude rather than the elevator to be one of the primary path and speed controls.

With pitch attitude tightly controlled, it is shown in appendix A that the response of flight path and airspeed to attitude commands and changes in thrust is described by the equations of motion

\[
\begin{bmatrix}
  s - X_u & -X_\alpha & 0 \\
  -Z_u & V_0s - Z_\alpha & 0 \\
  0 & 1 & 1
\end{bmatrix}
\begin{bmatrix}
  u \\
  \alpha \\
  \gamma
\end{bmatrix}
= \begin{bmatrix}
  -g \cos \theta_0 \\
  V_0s - 3 \sin \theta_0 \\
  0
\end{bmatrix}
\begin{bmatrix}
  X_{\Delta T} \\
  Z_{\Delta T} \\
  \theta_{\Delta T}
\end{bmatrix}
\]

The following relationships expressed in the form of transfer functions for response to a particular command may be derived from these equations:

- **Response to pitch attitude commands:**
  
  **flight path:**
  
  \[
  \frac{\gamma_{\theta}}{\theta_{\Delta T} \theta \rightarrow \delta_e} = \frac{A_{Y\theta} (s + 1/T_{Y_1})}{s^2 + 2\tau_\theta \omega_\theta s + \omega_\theta^2}
  \]  
  \[
  (2a)
  \]

  **airspeed:**
  
  \[
  \frac{u_{\theta}}{\theta_{\Delta T} \theta \rightarrow \delta_e} = \frac{A_{U\theta} (s + 1/T_{U_1})}{s^2 + 2\tau_\theta \omega_\theta s + \omega_\theta^2}
  \]  
  \[
  (2b)
  \]

- **Response to thrust changes:**
  
  **flight path:**
  
  \[
  \frac{\gamma_{\Delta T}}{\theta_{\Delta T} \theta \rightarrow \delta_e} = \frac{A_{YT} (s + 1/T_{YT})}{s^2 + 2\tau_\theta \omega_\theta s + \omega_\theta^2}
  \]  
  \[
  (3a)
  \]
airspeed:

\[
\left( \frac{\Delta u}{\Delta T} \right)_{T \to \delta_e} = \frac{A u_T (s + 1/T u_T)}{s^2 + 2\xi \omega \gamma + \omega^2} \quad (3b)
\]

The path and speed transfer functions to attitude and thrust in equations (2) and (3) appear in the general form:

\[
\frac{\text{response}}{\text{command}} = \frac{A(s + 1/T)}{s^2 + 2\xi \omega \gamma + \omega^2} \quad (4)
\]

with the distinguishing features being the gain \( A \), the numerator root \( 1/T \), and the closed-loop phugoid frequency and damping, \( \omega_0 \) and \( \xi_0 \). The correspondence between these features and a time history of the response to a step command input are shown in figure 3:

- The sign of \( A \) determines the sign of the initial response.
- The sign of \( 1/T \) determines whether the initial and final response are of the same sign.
- The magnitude of \( A \) determines how quickly the airplane responds initially.
- The ratio of \( 1/T \) to \( \omega_0 \) determines the amount of overshoot of the response.
- The magnitude of \( A/T_\omega \) determines the magnitude of the steady-state response.

The wide range of response characteristics illustrated by this example is not generally reflected in the individual path and speed responses. Specific behavior for path and speed response is listed in table 1, which shows the contributions of the individual stability derivatives to the transfer function factors in equation (4). The implications of these individual derivatives in the context of each response transfer function are:

- Flight-path response to attitude
  - Initial response is of the same sign as the attitude with slope \( \dot{\gamma} \) scaled by \( [(-\dot{d} + g \sin \delta)/V_0] \).

</table>

*\( \alpha \Delta T \) and \( Z \Delta T \) are the longitudinal and vertical axial force derivatives due to thrust resulting from thrust-augmented aerodynamics and direct thrust contributions.

- Numerator root \((1/T_\alpha)\) may be negative\(^1\) for which condition the path response will reverse sign in the steady state.
- Steady-state path change will be less in magnitude than the attitude change \((\gamma/\theta_c < 1)\).
- Airspeed response to attitude
  - Sign of the initial response is the same as that of \((X_\alpha - g \cos \theta_0)\) or \((-D_\alpha)\); hence the normal behavior would be to decelerate for an increase in attitude and vice versa.

\(^1\) \(1/T_\alpha < 0\) when \(X_\alpha < (X_u/Z_u)(Z_\alpha - g \sin \theta_0) + g \cos \theta_0\)
and thus since \(X_\alpha = g - D_\alpha\) and \(Z_\alpha = -(g/C_L)(C_L\alpha + C_D)\),
\(1/T_\alpha < 0\) when \(C_D/C_L < [C_D\alpha - C_L(1 - \cos \theta_0)]/(C_L\alpha + C_L \sin \theta_0 + C_D)\)
or approximately \(C_D/C_L < C_D\alpha/C_L\alpha\).
Numerator root \( (1/T_u) \) is normally positive (unless \( D_\alpha < 1 \)); hence the initial and final responses have the same sign.

Numerator root is normally larger than the closed-loop phugoid root \( (1/T_u \omega_\theta > 1) \); hence there is no overshoot in the speed response.

Ratio of speed to path response is determined by \( gT_{\gamma_1} \).

Flight-path response to thrust

- Initial response \( (\dot{\gamma}) \) scales with \( (-Z_A/T/V_0) \) where an increase in thrust produces an increase in flight-path angle.
- Sign of the numerator root \( (1/T_{\gamma_1}) \) is normally positive, but may become negative if \( XA \) has a large enough negative value, which produces a reversal in sign of the steady-state response.
- Numerator root is typically less than the closed-loop phugoid root \( [(1/T_{\gamma_1} \omega_\theta) < 1 \) unless \( XA \) is large enough to make \((-X_u + Z_u XA/T_{\gamma_1} \omega_\theta > \omega_\theta) \); hence there is an overshoot in path response to thrust.
- Magnitude of the response is determined by \( (-Z_A/T/V_0 T_{\gamma_1} \omega_\theta^2) \).

Airspeed response to thrust

- Sign and magnitude of the initial response is determined by the sign and magnitude of \( XA \); hence, if the effective thrust turning exceeds 90°, the initial response to an increase in thrust will be a deceleration.
- Sign of the numerator root \( (1/T_u T) \) is negative when \( 0 < XA < ZA XA/Z \); hence the speed response may reverse in sign.
- Ratio of speed to path response is determined by

\[
\frac{\Delta u_{ss}}{\Delta \gamma_{ss}} = \frac{T_{\gamma_1} \omega_\theta^2}{Z_u/V_0} \left( 1 + \frac{1}{T_{\gamma_1} \omega_\theta^2} \frac{Z \alpha}{V_0} \right)
\]

or

\[
\frac{\Delta u_{ss}}{\Delta \gamma_{ss}} = \frac{(u/\Delta T)_{ss}}{(\gamma/\Delta T)_{ss}}
\]

\[
= \left( \frac{A_u T}{T_{u \omega_\theta^2}} \right) \left( \frac{T_{\gamma_1} \omega_\theta^2}{A_{\gamma_1 T}} \right)
\]

where the individual terms are defined in table 1.

Figure 2 illustrates path and speed response to attitude and thrust for a jet STOL transport configuration. This example indicates the type of response that might be expected from the foregoing discussion.
Considering the response to an attitude change at constant thrust (fig. 2(a)), the nose-up attitude change produces a typical flight-path response for operation on the backside of the drag curve. The glide path initially becomes more shallow but eventually steepens. Speed response is conventional since the aircraft decelerates following a nose-up change in attitude. For an increase in thrust with attitude held constant (fig. 2(b)), flight path responds quickly and is substantially sustained in the long term. The speed response in this instance is decidedly adverse in that the aircraft decelerates after an increase in thrust.

The response characteristics in this example and in the foregoing discussion important to open-loop control on the glide slope are:

- The initial response that determines how quickly a correction can be initiated,
- The relationship of the long-term response to the short-term response (as indicated by the amount of overshoot and whether the long-term response is in the desired direction) which determines how predictably a correction can be made, and
- The extent of coupling between flight path and airspeed in response to an attitude or thrust change which determines the attention the pilot must direct to the state of the aircraft other than the one he is attempting to control.

These response characteristics determine the manual control technique appropriate to the control of path and speed on the glide slope and the ease with which open-loop corrections to path and speed can be made. As subsequently shown, these characteristics also determine the precision with which path and speed can be controlled closed-loop.

Closed-Loop Control Characteristics

Control technique- To evaluate the closed-loop flight-path and airspeed control characteristics, it is necessary to specify how each particular loop is closed, that is to specify the appropriate control technique adopted by the pilot. The nature of the flight-path response to pitch attitude changes of a powered lift aircraft on a steep, slow landing approach (fig. 2) dictates that attitude should not be used to control flight path, at least not in the long term. The reversal in the path response due to operation on the backside of the drag curve is sufficient reason to reject attitude as a path control (see refs. 10 and 11). On the other hand, speed response to attitude is conventional; for this reason, pitch attitude is considered to be the primary control over speed for this type of aircraft in landing approach operations. Flight path responds as rapidly to thrust as to attitude in the short term and is sustained somewhat in the long term. Therefore, thrust is regarded as the appropriate path control. Since speed response to thrust may be either conventional or unconventional in the short term or long term, thrust is not a desirable speed control.
The foregoing description of the pilot's control technique is intended to apply in a general way. For this purpose, it is quite useful for analysis of closed-loop control of path and speed by the pilot. In fact, the analysis strongly indicates that to control path with attitude and speed with thrust is undesirable. This is not to suggest that the pilot does not adopt alternate methods for short-term control such as coordinating his attitude and thrust controls to initiate a path correction and then separating their use to sort out the path and speed responses in a long-term sense. He also may crossfeed his controls or use only one control to correct from a low-fast or a high-slow condition (ref. 12). The foregoing discussion has simply sought to emphasize that the pilot's general control strategy will be appropriate to this aircraft type as indicated in the previous paragraph. This control technique is assumed in the ensuing analysis.

Closed-loop flight-path control- The elements of closed-loop flight-path control are illustrated in figure 4. The relationship of flight path to thrust is described by the transfer function in equation (3a). Engine thrust response to a throttle command is represented by the second-order dynamic relationship with unity steady-state gain (as shown in the figure). The contribution of the pilot is described by a gain factor, a first-order lead, and an equivalent time delay. This representation of the pilot is a suitable approximation for these analyses. It should not be construed as capable of reproducing every detail of his control activity, as might be observed during closed-loop tracking in flight.

Each contribution of the aircraft, the engine response, and the pilot are considered eventually. First, the closed-loop control of flight path without the effects of engine dynamics or of pilot lead and time delay are considered. Figure 5 is a Bode diagram of the thrust to flight-path transfer function. The frequency axis is normalized by frequency \( \omega_b \) to lend more meaningful to the results. The dominant characteristics of the open-loop transfer function which influence the closed-loop characteristics are frequency which determines the frequency bandwidth of the closed-loop system, and the relationship of the numerator to the denominator roots, \( 1/T \gamma \omega_b \), which determines the

![Block diagram of closed-loop flight-path control.](image)

![Oper loop characteristics of flight-path control with thrust.](image)
amount of flight-path overshoot and hence the precision of the long-term or steady-state control of path with thrust. In this case, since there are no constraints on stability, any desired bandwidth may be achieved. In reference 13, a bandwidth corresponding to a gain crossover frequency of 0.5 to 0.7 rad/sec is shown to be desirable for path control. If it is $\omega_{co}$ that the gain crossover frequency $\omega_{co}$ exceeds $\omega$, the gain for the loop closure can be determined from the accompanying sketch to be

$$K_Y = \frac{\omega_{co}}{\omega} \cdot \frac{1}{T_{\gamma} \omega E} \cdot \frac{T_{\gamma} \omega^2}{1 + T_{\gamma} \omega}$$

Thus the relationship of path response to command is

$$\frac{\gamma_{SS}}{\gamma_c} = \frac{K_Y \gamma_{\gamma E}}{1 + K_Y \gamma_{\gamma E}}$$

Therefore, the lower the crossover frequency and the smaller the ratio of the numerator to denominator root $1/T_{\gamma} \omega$, the greater will be the discrepancy between the final path correction compared to the desired (or commanded) correction.

When the contribution of the engine thrust response dynamics is considered, limitations appear on the closed-loop stability of the system. In the second-order model of the engine, the response is assumed to be at least critically damped; for this illustration, the damping ratio is set to unity. Time histories of the engine model are shown in figure 6 and are compared with responses obtained from actual engine response tests reported in references 14 and 15. Note that the $S$ shape of the time history is captured essentially by the second-order response. The Bode plots in figure 5 are repeated in figure 7 with the engine response mode included. Once the separation of the engine and path response modes ($\omega_E/\omega$) is less than
a factor of 2, the ability to close the path loop at frequencies much above \( \omega_0 \) is compromised. In this event, some pilot lead compensation is required to achieve the desired closed-loop bandwidth.

The Bode characteristics (figs. 5 and 7) are based on a normalized frequency scale \((\omega/\omega_0)\) and must be related to specific values of \( \omega_0 \) to indicate the actual limitations on closed loop path control. The relationship for \( \omega_0^2 \) (or \( 1/T_{\theta_1/\theta_2} \) as the case may be) in table 1 suggests a value of \( \omega_0 \) on the order of 2.3 rad/sec for derivatives typical of STOL aircraft. Such a value approximates \( \omega_0 \) quite well for the configuration of references 2, 5, 6, and 9 (for these aircraft, \( \omega_0 \) ranges from 0.25 to 0.31 rad/sec). With \( \omega_0 = 0.3 \) rad/sec, engine response modes of \( \omega_E = 0.6 \) rad/sec or less compromise path control unless lead compensation on the order of \( 1/T_{\theta_1/\theta_2} \) from 1.0 to 2.0 is provided by the pilot (fig. 8). Requirements for pilot-generated lead on the order of \( T_{\theta_1/\theta_2} \) to 1.0 sec or greater are considered in the literature (e.g., ref. 16) to require excessive pilot effort and attention, with a resulting degradation in handling qualities. Contributions of the pilot equivalent time delay \( e^{-\tau_e s} \) in this context seem to be of minor concern in restricting the path-loop closure because of the reasonably wide separation between the equivalent delay factor \( 1/\tau_e \) and \( \omega_0 (1/\tau_0 \omega_0 \approx 8) \). Restrictions on bandwidth will adversely affect the long-term path response with respect to the command.

Speed response to flight-path control is also of interest in terms of the amount of coupling between the two and the attention required of the pilot for both path and speed control. In this regard, the steady-state speed change in response to a flight-path correction is of particular interest. The relationship \((\Delta u_{\text{eq}}/\Delta y_{\text{eq}})_{\Delta T}\) in equation (5) indicates contributions from \( 1/T_{\theta/\omega_0} \), \( \omega_0 \), \( Z_u \), and \( Z_g \). The dominant influence of \( 1/T_{\theta \omega_0} \) on flight-path overshoot in response to thrust was noted previously. The implication of this influence of \( 1/T_{\theta \omega_0} \) (other factors being constant) is that an increase in coupling will cause an increase in flight-path overshoot. Furthermore, the ability to tightly control flight path in the long term will be more difficult with
increased coupling. Representative time histories of the open-loop and closed-loop path and speed response are shown in figure 9 for configurations with and without flight-path overshoot and path-speed coupling. The open-loop time histories for the uncoupled configuration (represented by $1/T_{Y_0\omega} = 1.0$) indicate that a predictable flight-path correction can be made with a simple throttle application and with essentially no variation in speed. When path and speed are coupled (such as for $1/T_{Y_0\omega} = 0.2$), the initial flight-path response for the same throttle input is still comparable to that for the uncoupled configuration. However, the long-term correction washes out to half the short-term increment. When the flight-path loop is closed (as shown on the right in the figure), the desired long-term path correction can be achieved, but at the expense of increased throttle activity and increased speed excursions.

The interrelationship of the flight-path overshoot and the path-speed coupling characteristics previously noted can be associated with the operation of the aircraft on the backside of the drag curve. Some appreciation of this interrelationship can be gained by considering steady-state flight-path - airspeed plots and their companion lift-drag polars. Figure 10 is an example of these curves for a specific powered-lift concept. Lines of constant attitude and constant flight path are superimposed on the polars. Consider a flight-path change performed by increasing thrust with attitude held constant. The example indicated by the arrow shows an increase in $C_L$ on the polar that accompanies the thrust change, which results in the reduction in speed required to maintain steady 1-g flight as shown on the $\gamma$-$V$ plot. If the path correction could be made with no change in $C_L$ and hence at constant speed, this correction would exceed that of the illustrated example for the same thrust increment. The difference in path correction for these two cases arises because of the change in curvature of the polars with increasing $C_L$ for operation on the backside of the drag curve. The point of delineation between the frontside and backside of the drag curve, according to the relationship presented in footnote 1, is defined by $CD/LD \approx C_D/C_L$ (the condition for which the local or perturbation lift-drag ratio is equal to the absolute $L/D$). Any increase in $C_L$ puts the aircraft on the backside of the curve and is accompanied by a proportionally larger increase in $C_D$ so that the total $L/D$ is reduced. This reduction in $L/D$ is the source of the reduced long-term path response. The example in figure 10 is for steady-state conditions. However, so long as $Z_{AT}$, $Z_{\alpha}$, and $Z_u$ are held constant,
flight-path overshoot, a characteristic of the transient response, can be inferred from the reduced steady-state path increment associated with the path-speed coupling.

![Figure 10. Variations in flight-path angle-velocity and lift-drag polars with thrust and pitch attitude.](image)

Closed-loop airspeed control- Variations in airspeed which degrade path control are undesirable and make it necessary for the pilot to pay attention to airspeed control during the approach. It was noted in the discussion of control technique that the pilot would be expected to use pitch attitude to control speed. In closing the speed to attitude loop, two types of attitude command control systems that might be available to the pilot must be considered, as well as their implications for closed-loop speed control.

The first type of attitude control system is an attitude command system as shown in figure 11. The speed response to attitude command is given by the transfer function relationship in equation (2b). The pilot is represented in the closed loop by the gain $K_U$ with no lag. The characteristics of the speed loop closure are illustrated in figure 12. In this instance, no constraints are imposed on closed-loop bandwidth by stability. Desired bandwidths for speed control (ref. 12) relate to crossover frequencies on the order of 0.2 to 0.3 rad/sec. If this crossover frequency exceeds $\omega_0$, the gain for the speed loop closure is approximated by

$$K_U = \frac{(\omega_0/\omega_c)^2}{A_u u_0^2}$$

which gives a total loop gain of

14
Figure 11.- Block diagram of closed-loop airspeed control.

\[
\frac{A_{sb}(s + \frac{1}{\tau_u})}{\tau_u s^2 + 2 \omega_g s + \omega_g^2}
\]

\[Y_{\theta} = K_u\]

Pitch attitude command

\[Y_{\theta} = \frac{\tau_u s + 1}{s}\]

Pitch rate command

For the example shown in figure 12, the ratio of speed response to command is approximately 0.3. Hence, there is a long-term speed standoff error. The extent of the steady-state speed error depends on the relationship of \(\omega_{CO}\) to \(\omega_g\). If the speed error becomes intolerable to the pilot, he will provide an equivalent integral error control to cancel this error.

A pitch attitude control system of the rate command concept also provides a means for eliminating the steady-state speed error so that the pilot need not provide integral control. The rate command system is described in figure 11. This system functions so that a control input commands pitch rate with attitude stabilized when the control input is removed. The numerator time constant should be on the order of a factor of 0.3 to 0.5 of the closed-loop attitude bandwidth for satisfactory pitch rate response sensitivity and minimal overshoot. With this attitude controller, the characteristics of closed-loop speed control are shown in figure 13. The rate command function introduces additional lag at low frequency and, as such, degrades closed-loop stability. If the numerator factors are at high enough frequency, the system becomes unstable for gains that exceed those

\[
\frac{K_u A_{sb}}{\tau_u \omega_g^2} = \left(\frac{\omega_{CO}}{\omega_g}\right)^2
\]
for a crossover at $\omega_0$. However, with the numerator factors as shown in figure 13 and with bandwidths associated with $\omega_{CO} = \omega_0$, the stability appears to be adequate at the corresponding closed-loop gains. Variations in the numerator factors of either the speed to attitude transfer function or the rate command influence closed-loop stability somewhat at these bandwidths and, in fact, the system may be conditionally stable under some circumstances. The factor $1/T_{UL}$ is assured to be greater than $\omega_0$ since the likely minimum value of $1/T_{UL}$ is on the order of $-Z_a/V_0$ and $\omega_0$ will be on the order of $-0.5(X_u + Z_a/V_0)$. The term $1/T_{UL}$ is shown to be four times $\omega_0$ and would have to be at least ten times $\omega_0$ to reduce the stability margin to unacceptable levels at the closed-loop bandwidth. The pitch rate numerator factor $1/T_{\delta}$ is also shown to be four times $\omega_0$ - the proper order of magnitude since the attitude stabilization separates $\omega_0$ and the attitude control loop bandwidth by a factor of 10 and the factor $1/T_{\delta}$ is desired to be about 1/3 to 1/2 the attitude bandwidth. Thus, the general conclusion is that closed-loop speed control evidences no major problems for the bandwidths desired. However, the sensitivity of speed response to attitude changes ($\Delta u/s/\theta_c$) is likely to be of concern to the pilot inasmuch as it determines the gain and the amount of attitude maneuvering required to control speed.

**Closed-loop flight-path and airspeed control**—When airspeed must be controlled by the pilot, closed-loop control of flight path is described by the block diagram in figure 14. Flight-path response to thrust is represented by the closed-loop transfer function (using the matrix nomenclature for multiloop control of ref. 17):

$$\frac{Y}{\Delta T} = \frac{N_Y}{\Delta T + Y_{Pu} Y_{\theta_c} N_{\theta c} Y}$$

where the numerator is the open-loop flight-path to thrust numerator modified by the speed loop closure and the denominator comprises the factors of the characteristic equation with the speed loop closed. No crossfeed of the throttle to attitude control is included in this analysis. The engine dynamics and pilot model are presented in figure 4 (p. 10).

It is worthwhile to evaluate closed-loop path control without the complicating influences of engine dynamics and pilot compensation and time delays. These contributions

![Block diagram of closed-loop flight-path and airspeed control](image-url)
are assessed after the simpler example is considered. The denominator roots that result from the speed loop closure depend on whether attitude was controlled by an attitude or rate command system. Table 2 presents examples of both cases. For the attitude command system, the denominator is represented by a complex pair of roots with frequency somewhat greater than \( \omega_0 \). For the rate command system, the same complex roots exist and, in addition, there is a first-order subsidence.

**TABLE 2.- EXAMPLES OF FLIGHT-PATH/THRUST TRANSFER FUNCTIONS WITH SPEED LOOP CLOSED**

\[
\frac{\gamma}{(\Delta T)_{\theta+\delta e}} = \frac{\gamma_{\Delta T} N_{\theta C} Y_{\theta C} U \gamma}{\Delta + Y_{\theta C} Y_{\theta C} N_{\theta C}}
\]

A key factor in determining whether good closed-loop control of path is possible is the location of the numerator roots. As with the denominator, the nature of these roots depends on the form of attitude control. The numerator for the attitude command system is a first-order factor while the numerator for the rate command system has two first-order factors. For the attitude command system, the numerator gain factor is
The two factors that provide the most variability in sign and magnitude of the time constant are the speed loop gain $K_u$ and the effective thrust turning $X_{AT}/Z_{AT}$. The sign of $K_u$ is negative for speed stabilization under most circumstances, while $X_{AT}/Z_{AT}$ can be either positive or negative depending on whether the thrust turning exceeds 90°. Figure 15 illustrates the contribution to the numerator root of these two factors for values of $X_{at}$, $Z_u$, $X_{a}$, and $Z_{a}$ typical of a powered lift aircraft with an 3810 N/m$^2$ (80 lb/ft$^2$) wing loading flying a 6° glide slope at 75 knots. Values of $K_u$, assuming $\omega C = \omega_0$, are $K_u = 1/(A_{ss}/\theta C)$ and generally range from $-0.3^\circ$ to $-1.0^\circ$ per knot. The intercepts of the constant $X_{AT}/Z_{AT}$ lines with the ordinate indicate the value of the open-loop path to thrust numerator root.

Note that as this root shifts to higher frequencies speed is more tightly controlled.

For the rate command system, the numerator gain factor is

$$A_{\gamma T} = \frac{-Z_{AT}}{V_o}$$

The damping factor is
\[ 2\zeta_Y \omega_Y = \frac{1}{T_Y T} - \frac{A_{UY}}{A_{YT}} \]

\[ = -X_u + Z_u \frac{\Delta T}{Z_{\Delta T}} + K_u T_\delta \left[ X_\alpha - g \cos \theta_o - \frac{\Delta T}{Z_{\Delta T}} (Z_\alpha - g \sin \theta_o) \right] \]

(14)

and the natural frequency is

\[ \omega_Y = \sqrt{\frac{K_u}{A_{YT}}} \left[ X_\alpha - g \cos \theta_o - \frac{\Delta T}{Z_{\Delta T}} (Z_\alpha - g \sin \theta_o) \right] \]

(15)

Contributions of the speed loop gain and effective thrust turning to the damping ratio and natural frequency are shown in figure 16. For speed loop control gains from -0.3 to -1.0⁰/knot, the damping ratio is essentially a function of \( \Delta T/Z_{\Delta T} \) and decreases with increased thrust turning. The frequency \( \omega_Y \), a function of both \( K_u \) and \( X_\alpha/Z_{\Delta T} \), increases as speed is controlled more tightly and decreases with increased thrust turning.

Characteristics of flight-path control with airspeed controlled through the attitude command system are shown in the Bode plot in figure 17. The significant characteristics are the closed-loop frequency \( \omega_\theta \) and the ratio of the numerator root to this frequency \( 1/T_Y \omega_\theta \). This ratio can be defined from equations (1) and (13) and the vehicle characteristics noted in figure 15 by

\[ \frac{1}{T_Y T} + \left( \frac{0.5 X_\alpha/Z_{\Delta T} - 0.18}{\dot{u}_s / \theta_c} \right) \]

(16)
Frequency, rud
Figure 17.- Flight-path control with thrust with airspeed control by pitch attitude (attitude command system).

Figure 18.- Flight-path control with thrust with airspeed control by pitch attitude (rate command attitude control system).

since
\[ \omega_\theta^2 = \omega_\theta^2 + K_u \omega_\theta^2 \left( \frac{A_{u_\delta}}{u_1 \omega_\theta^2} \right) \]

In figure 17, the range of \(1/T_{\omega \theta} \omega_\theta^2\) corresponds to \(-0.4 < X_{\Delta T}/Z_{\Delta T} < 0.1\) and \(A_{U_SS}/\theta_C = -2.0\) knots/deg. The speed loop closure tends to diminish the amount of overshoot in the path response for \(1/T_{\omega \theta} \omega_\theta^2 = 0.2\). Lags introduced into the control loop by the engine dynamic response reduce the path control bandwidth essentially to the same extent noted in figure 7 (p. 12).

Flight-path control characteristics for the rate command attitude control are shown in figure 18. This Bode plot differs somewhat from that in figure 17 in that the numerator is a second-order factor while the denominator has first- and second-order factors. Some overshoot in the path response is still indicated by the peak in the Bode plot near 0.3 to 0.4 rad/sec although it is less than the comparable open-loop case. The bandwidth of the path control is determined to some extent by \(1/T_{\omega T}\). The degrading influences of engine dynamics are similar to those previously noted in figure 17.

A time history of the open- and closed-loop path and speed response and the corresponding throttle and attitude control activity are shown in figure 19 for two different sets of dynamic characteristics. The uncoupled configuration \((1/T_{\omega \theta} = 1)\) provides good flight-path response to a step throttle input with little control activity required to regulate speed. The coupled configuration \((1/T_{\omega \theta} = 0.2)\) exhibits reasonable path response but requires more throttle activity for the same flight-path correction. It also requires that speed be controlled with attitude to obtain this behavior. The amount of attitude control required depends on the extent of path-speed coupling \((A_{U_SS}/\Delta Y_{SS})\Delta T\). Examples of these two configurations without speed control are shown in figure 9 (p. 13).
Figure 19.— Time histories of response for a flight-path correction (speed loop closed).

Summary of closed-loop control characteristics—The foregoing discussion described the contributions that influence closed-loop flight path and airspeed control. In summary, the important factors are

- The bandwidth of path response to thrust as determined by $\omega_\theta$
- The relationship of the steady-state path response to the commanded path correction as influenced by $1/T_\gamma\omega_\theta$
- The amount of speed variation that accompanies a path correction (defined by eq. (5))
- The sensitivity of airspeed to variation in attitude, $\Delta u_{ss}/\theta_C$
- The overshoot and long-term stability of closed-loop flight-path control (airspeed loop closed) as influenced by the effective thrust turning $X_{\Delta T}/Z_{\Delta T}$ (also $1/T_\gamma\omega_\theta$) and by the pilot’s speed control gain $K_u = 1/(\Delta u_{ss}/\theta_C)$.

These factors are important in determining how quickly a flight-path correction can be initiated, how predictable the correction is to the pilot, the attention he must devote to path and speed control, the extent to which he must continuously control path and speed closed-loop, and his ability to achieve the precision of control required for the landing approach.
Response Characteristics for Experimental Evaluation

Closed-loop flight-path and airspeed control ultimately depend on and can be quantified by closed-loop bandwidth, stability margin, the ratio of the final response to the command input, the number of control loops involved, and the control activity in each. While these characteristics can be readily determined analytically, they are difficult to specify or identify experimentally. Fortunately, the factors that have a dominant influence on closed-loop control of path and speed are either directly identifiable or are implicit in the open-loop path and speed response to attitude and thrust. Thus, it is these open-loop characteristics around which an experimental handling qualities evaluation is best structured.

The particular open-loop response characteristics to thrust changes are illustrated in figure 20:

- initial flight-path response represented by the time constant $\tau_Y$
- flight-path overshoot represented by $(\frac{\Delta Y_{\text{max}}}{\Delta Y_{SS}}) \Delta T$
- coupling of flight path and airspeed represented by $(\frac{\Delta u_{SS}}{\Delta Y_{SS}}) \Delta T$

Although not shown in figure 20, the sensitivity of airspeed to attitude commands, $\Delta u_{SS}/\theta_C$, is also important.

Derivation of response characteristics- The analytical basis for deriving the four response characteristics noted above is described in the material that follows. Contributions of the aircraft configuration and operating condition on these characteristics are also noted.

The path response time constant, $\tau_Y$, is defined for a step thrust change by

$$\tau_Y = \frac{\Delta Y_{\text{max}}}{\dot{Y}}$$

$$= \left(\frac{\Delta Y_{\text{max}}}{\Delta Y_{SS}}\right) \left(\frac{\Delta Y_{SS}}{\Delta T} \frac{\Delta T}{\dot{Y}}\right)$$

where $\dot{Y}$ is defined at $t = 0$, that is, $\dot{Y} = -\Delta Y_{SS}/\Delta T/V_0$.
\[ \frac{\Delta \gamma}{\gamma} = \frac{-Z_{\Delta T} A T/V_0 [1/T_{\gamma T} \omega_\theta ^2]}{(-Z_{\Delta T} A T/V_0)} \]

and thus

\[ \tau_{\gamma} = \left( \frac{\Delta \gamma_{\text{max}}}{\Delta \gamma_{ss}} \right) \Delta T \left( \frac{1}{T_{\gamma T} \omega_\theta ^2} \right) \] (17)

Therefore, the initial time response depends on both the ratio \(1/T_{\gamma T} \omega_\theta\), which defines the path overshoot characteristics, and the characteristic frequency \(\omega_\theta\). Figure 21 illustrates these relationships. Note that \(\omega_\theta\) and the inverse time constant \(1/\tau_{\gamma}\) are linearly related for any \(1/T_{\gamma T} \omega_\theta\).

Figure 22 shows the contributions of the transfer function parameters to the amount of flight-path overshoot for a step thrust change. Whether the characteristic roots of the flight-path response are described by \((s^2 + Z_\omega \omega_\theta + \omega_\theta ^2)\) or by \((s + 1/T_\theta_1)(s + 1/T_\theta_2)\), the significant contribution is the ratio of the numerator root, \(1/T_{\gamma T}\), to the lowest frequency characteristic root \(\omega_\theta\) or \(1/T_{\theta_1}\). Less important is the damping ratio \(\zeta_\theta\) (particularly since \(\zeta_\theta\) tends to be greater than 0.8 for most attitude loop closures) or the ratio of \(1/T_{\theta_1}\) to \(1/T_{\theta_2}\) [which can fall between the extremes \(X_\theta/(Z_\alpha/V_0) = 0.1\) when \(X_\alpha = 0\) and \(1.0\) when \((X_\theta + Z_\alpha/V_0)^2 = (4/V_0)(X_\theta Z_\alpha - X_\alpha Z_\theta)\)]. The amount of overshoot can vary approximately by a factor of 5 when the parameters \(1/T_{\gamma T} \omega_\theta\) or \(T_{\theta_1}/T_{\gamma T}\) vary from 0.1 to 1.0.

The coupling of flight path and airspeed was defined previously in equation (5) as
which is a function of $1/T'\gamma_0$ and $\omega_0$, both of which help to define $(\Delta\gamma_{\text{max}}/\Delta\gamma_{\text{SS}})\Delta T$ and $\tau_\gamma$, and also the linear perturbation derivatives $Z_u$ and $Z_\alpha$. Hence the extent that flight-path speed coupling can vary independently of the flight-path response to thrust is determined by the magnitude of the $Z$-axis derivatives due to speed and angle of attack.

Speed sensitivity to attitude changes is simply the steady-state magnitude in equation (2), that is,

$$\frac{\Delta u_{ss}}{\theta_c} = \frac{A_u}{T_{u} \omega_0^2}$$

$$= \frac{g}{V_o} \left( \frac{Z_\alpha \cos \theta_o - X_\alpha \sin \theta_o}{\omega_0^2} \right)$$

(18)

with the definitions of the individual terms as in table 1. If $X_\alpha = 0$ ($D_\alpha = g$) so that $\omega_0^2 = X_u Z_\alpha / V_o$, then $\Delta u_{ss}/\theta_c = g/X_u$. Speed response to attitude may also be related to the slope of the flight-path versus airspeed curve ($dy/dV$) at a particular trim condition. If the trim pitch attitude is sufficiently small that $\cos \theta_o = 1$ and $(X_\alpha/Z_\alpha) \sin \theta_o << 1$, $(X_u/Z_u) \sin \theta_o << 1$, $(g/Z_\alpha) \sin \theta_o << 1$ then

$$\frac{\Delta u_{ss}}{\theta_c} = \frac{-1}{(1/gT'\gamma_1) + (Z_u/Z_\alpha)}$$

$$= \frac{1}{(dy/dV) - (Z_u/Z_\alpha)}$$

(19)

Contributions of aircraft configuration - The contributions to the flight-path and speed control characteristics (shown, respectively, in fig. 22 and eqs. (5), (17), and (18)) are defined in terms of the aircraft $X$- and $Z$-axis (or drag and lift) derivatives due to speed, angle of attack, and thrust. Reference 18 shows that these derivatives may be described in terms of the vehicle configurations and flight condition, that is,

- $X_u$ axial velocity damping; a function of drag coefficient, trim airspeed and wing loading (may be augmented by autospeed control)
- $X_\alpha$ drag due to lift; a function of trim airspeed, wing loading, and induced drag
- $Z_u$ vertical force coupling with axial velocity; a function of trim airspeed
\[ Z_a \text{ vertical velocity damping; a function of lift-curve slope, trim airspeed, and wing loading} \]

\[ X_{\Delta T} \frac{Z_{\Delta T}}{Z_{\Delta T}} \text{ effective thrust line inclination } \theta_T = \cot^{-1}\left(-X_{\Delta T}/Z_{\Delta T}\right) \]

These characteristics are determined for all practical purposes by the flight condition at which the aircraft is being operated, by its wing loading, and by the efficiency of its high lift system. Thus, when landing field length (approach speed), cruise Mach number (wing loading), and high lift system design are selected, the behavior of the aircraft as it appears to the pilot during the approach and landing will be essentially determined.

**SECTION 3**

**REVIEW OF SIMULATION RESULTS**

**Description of Simulation**

A ground-based flight simulation of a powered-lift jet STOL aircraft was used as a basis for pilot evaluation of the flight-path and airspeed response characteristics described previously. The simulation facility was the Flight Simulator for Advanced Aircraft (FSAA) at Ames Research Center, a large-motion facility with a high-resolution visual display (ref. 19). The simulation was based on the NASA/DITC Augmentor Wing Research Aircraft, a modified de Havilland of Canada C-8A Buffalo airframe that incorporates an augmentor flap system to generate high lift coefficients for high wing loading STOL operation and deflected hot thrust for operation on steep flight paths. The aircraft is described in reference 20. Figure 23 presents three views of the aircraft. Figure 24 shows the cockpit interior and control arrangement of the simulator. A real-time digital model of the nonlinear aerodynamic and flight-control system of the aircraft were programmed as described in reference 21. Reference 14 presents the static aerodynamic characteristics as derived from model
Figure 24.- Cockpit arrangement of the simulator.
tests of the vehicle in the Ames 40- by 80-Foot Wind Tunnel. Rotary derivatives were estimated by use of jet flap theory where appropriate. Supporting data for these derivatives are unpublished although the models themselves appear in reference 14. Jet engine acceleration/deceleration characteristics were based on the thrust transients of reference 14. Equivalent response parameters appropriate for the engine model are \( \zeta_E = 1.0 \) and \( \omega_E = 2.5 \text{ rad/sec} \).

The longitudinal flight-control system provided pitch axis command augmentation and alteration of the longitudinal force characteristics by use of vectored thrust. The elevator was mechanically driven through a spring tab system. Augmentation commands were provided by an electro-hydraulic actuator operating in series with the control column inputs of the pilot. Longitudinal force control was achieved by vectoring the hot thrust of the engines about a trim position deflected 90° to the aircraft waterline in response to commands based on errors in airspeed, angle of attack, and throttle position. For thrust vectoring of ±15° about the 90° trim condition, effective alteration of the basic \( X_U, X_\alpha \), and \( X_\delta_T \) derivatives of the aircraft was possible without any significant contribution to the Z-axis force characteristics. Figure 25 shows the orientation of the hot exhaust nozzles for thrust vectoring. Figure 26 is a block diagram of the longitudinal control system. A description of the basic Augmentor Wing Aircraft, in terms of its stability derivatives, characteristic modes, pertinent transfer function numerator factors, and transient response characteristics, is provided in table 3. The dynamics of the elevator-spring tab system are documented in figure 26.

Test Configurations

Flight-path and airspeed control were evaluated using throttle for flight-path control and attitude for speed control as described on page 9. Variations in each of the path and speed response characteristics previously described were achieved by varying the longitudinal force characteristics \( X_U, X_\alpha \), and \( X_\delta_T/Z\delta_T \) (or \( \theta_T \)). The contributions of these derivatives are shown in

Figure 25.- Rolls Royce Spey 801 SF engine and Pegasus nozzle arrangement.

Sets of configurations were selected to permit independent evaluations of the path response time constant $\tau_Y$ and the speed response to attitude $\Delta u_{ss}/\theta_c$ for minimal flight-path overshoot and flight-path/speed coupling. Both the overshoot and coupling parameters were evaluated independently of the effects of initial path response to thrust $(\tau_Y)$ or of speed response to attitude $(\Delta u_{ss}/\theta_c)$. As can be appreciated from the trends of the overshoot and coupling parameters, in figures 27 and 28, it was not possible to evaluate them independently of each other when only $X_u$, $X_\alpha$, or $\Theta_T$ were varied. This point is also demonstrated in figure 29 by a group of experimental configurations selected from table 5 for variations in $X_u$, $X_\alpha$, and $\Theta_T$. The correlation between path overshoot and path-speed coupling in the region $(\Delta \gamma_{max}/\Delta \gamma_{ss})_{\Delta T} > 1.3$ and $(\Delta u_{ss}/\Delta \gamma_{ss})_{\Delta T} < -1.0$ knot/deg is quite strong. Variation of either derivative $\dot{Z}_u$ or $\dot{Z}_\alpha$ could produce independent variation in path overshoot and path-speed coupling, although neither derivative was altered in the test program. The range over which the overshoot and coupling characteristics could be considered independent due to variations in $\dot{Z}_u$ or $\dot{Z}_\alpha$ associated with the range of wing loading and approach speed relevant to powered-lift aircraft is shown by the crosshatched region in figure 29. Evaluation of the test configurations from among those in the region indicated by

</table>
solid symbols gave an appreciation of the contribution of the coupling and overshoot characteristics to handling qualities for path and speed control on the approach. Of course an independent evaluation of these two characteristics over the region of practical importance would be useful to conclusively determine if significant contributions of one characteristic exist independently of the other.

Specific test configurations for the evaluations are listed in table 5. Response parameters (that assume a step thrust input) with their corresponding transfer function factors and stability derivatives are also presented. A suitable pitch-rate command/attitude hold configuration was implemented to reduce the pilot's workload for attitude control. The characteristics of this system are indicated in figure 26.

Evaluation Task and Experimental Data

For the approach and landing, the pilot assumed control of the aircraft with it trimmed and configured for descent on the glide slope and aligned with the localizer. The approach was made to a 457-m (1500-ft) STOL runway, with touchdown zone markings as indicated in figure 30. The aircraft was trimmed at 396 m (1300 ft) for descent on a 7.5° glide slope at an airspeed of 60 knots. Flaps were set at 65°, hot thrust was vectored 90° to the reference waterline of the aircraft, and power was set corresponding to 28.4 kN (6380 lb) of hot thrust. Lateral-directional stability augmentation, including roll damping, spiral mode stabilization, Dutch roll damping, and turn coordination, was used to improve the control of bank angle, heading, and sideslip so that these factors would not influence the pilot's evaluation.

Two Ames engineering test pilots participated in the program. During the approach, the pilots introduced their own disturbances, offsets, and abuses as a means of evaluating each configuration. Both VFR and IFR evaluations were performed in calm air. Approach guidance was provided by raw ILS glide slope and localizer error information. Time histories of aircraft response and the control activity of the pilot were recorded. Pilot opinion ratings and commentary (based on the Cooper-Harper scale described in ref. 22) were obtained for each configuration concerning handling qualities associated with flight-path and airspeed control during the landing approach.
Discussion of Results

Initial flight-path response - The influence of the initial response of flight path to thrust is presented in figure 31. Pilot ratings are shown for a range of flight-path time constants \( \tau_Y \), where the time constants are defined for a step change in thrust. The results are presented for minimal values of flight-path overshoot and flight-path speed coupling, that is, there was essentially no overshoot or coupling for these configurations. A wide range of static flight-path/velocity gradients was included in these configurations, from an extreme backside of the drag curve \( (dy/dV = 0.47 \text{ deg/knot}) \) to an extreme front side \( (dy/dV = -1.23 \text{ deg/knot}) \).

The pilot ratings appear to be insensitive to variations in \( \tau_Y \) over the range of configurations tested. The results are understandable in light of the evaluation task. During the approach, extremely rapid path corrections are not required and, as the pilots indicate, any corrections can be made readily for the various configurations shown in figure 31. For these configurations, with the effects of engine acceleration and deceleration included, figures 7, 17, and 21 verify that the required path control bandwidths of 0.5 to 0.7 rad/sec can be achieved with little demand for compensation placed on the pilot.

Scatter in these pilot rating data somewhat exceed the \( \pm 1/2 \) rating unit variation that has come to be expected from experienced evaluation pilots. If the scatter is anything other than random in origin, it could be considered to result from a moderate influence of the range of flight path/velocity \( (dy/dV) \) gradients included in these configurations. In fact, the pilots were somewhat dissatisfied with the extreme backside or frontside configurations \( (dy/dV = 0.47 \text{ or } -1.23 \text{ deg/knot}) \). However, their objections were based on the excessive sensitivity of speed to changes in attitude of the former and the insensitivity of speed to changes in attitude of the latter. In neither case did any consideration of the stability of closed-loop flight-path control with attitude associated with path or speed divergences influence their ratings.

Note that the configurations of the foregoing discussion were evaluated for a throttle sensitivity of \( Z_{\delta_T} = -0.08 \text{ g/in.} \) (-0.032 g/cm). Thus, the sensitivity of the flight-path response to a throttle input varied in direct proportion to \( \tau_Y \), that is,

\[
\frac{\gamma_{ss}}{\delta_T} = \left( \frac{Z_{\delta_T}}{V_0} \right) \tau_Y
\]

(20)
A group of configurations was selected to assess the pilot's choice of throttle sensitivity $Z_{\delta T}$ (in g/in.) compared to $\gamma_{SS}/\delta_T$ (in deg/in.) for $T_T$ from 2.5 to 4.1 sec. Pilot ratings are shown for the test configurations in figure 32. While no strong trends in pilot rating emerge from these data, the pilot commentary indicated a preference for throttle sensitivity in terms of $Z_{\delta T}$ in g/in. For the variation in $T_T$ shown, a range of $Z_{\delta T}$ from -0.08 to -0.1 g/in. (-0.032 to -0.039 g/cm) is most desirable. Pilot commentary revealed that flight-path response tended to be too insensitive to throttle for $Z_{\delta T}$ below this range. For the highest $Z_{\delta T}$, the commentary indicated some tendency to over-correct path with throttles, although not enough to be exceedingly objection-able. The desired range of $Z_{\delta T}$ is somewhat lower than the optimum throttle sensitivities noted in references 8 and 23 to be approximately -0.15 g/in. (-0.058 g/cm). Sources of this disagreement conceivably lie in differences between the Augmentor Wing Aircraft simulation and the flight task, type of aircraft, and thrust control arrangement for the aircraft in references 8 and 23. These reports contain data from helicopters in flight hover tests and ground-based simulation of STOL transport aircraft. Thrust controls ranged from collective levers to conventional floor pedestal throttles. The Augmentor Wing Aircraft has two throttles located on an overhead quadrant similar to the arrangement in the original de Havilland C-8A Buffalo airframe. With this arrangement, it is more difficult to position the throttles precisely and to maintain a position reference than with a conventional floor pedal throttle.

**Figure 32. Effects of throttle sensitivity on flight-path control.**

The desired range of $Z_{\delta T}$ is somewhat lower than the optimum throttle sensitivities noted in references 8 and 23 to be approximately -0.15 g/in. (-0.058 g/cm). Sources of this disagreement conceivably lie in differences between the Augmentor Wing Aircraft simulation and the flight task, type of aircraft, and thrust control arrangement for the aircraft in references 8 and 23. These reports contain data from helicopters in flight hover tests and ground-based simulation of STOL transport aircraft. Thrust controls ranged from collective levers to conventional floor pedestal throttles. The Augmentor Wing Aircraft has two throttles located on an overhead quadrant similar to the arrangement in the original de Havilland C-8A Buffalo airframe. With this arrangement, it is more difficult to position the throttles precisely and to maintain a position reference than with a conventional floor pedal throttle.

**Flight-path/airspeed coupling** - Flight-path overshoot $(\Delta \gamma_{max}/\Delta \gamma_{SS})_{\Delta T}$ and flight-path/airspeed coupling $(\Delta u_{SS}/\Delta \gamma_{SS})_{\Delta T}$ are two characteristics of response to thrust (as previously noted) which could not be evaluated independently in this program. They are strongly interrelated because of their mutual sensitivity to changes in longitudinal (X-axis) force characteristics (such as trimmed drag, drag due to lift, and thrust inclination). However, this inter-relationship is typical of powered-lift aircraft in general (fig. 29). The evaluation of mutual changes in these two parameters conducted in this program offers insight into their influence on path and speed control for this category of aircraft. Results are presented in figure 33, with pilot ratings plotted against the path-speed coupling parameter $(\Delta u_{SS}/\Delta \gamma_{SS})_{\Delta T}$. The pilots felt that the influence of path-speed coupling was the primary contribution to their evaluation and rating and hence it was the parameter used to interpret the data.

It is apparent that path-speed coupling has a pronounced effect on pilot ratings of path-speed control. In particular, a significant degradation in ratings is noted for values of $(\Delta u_{SS}/\Delta \gamma_{SS})_{\Delta T}$ more negative than -3 knot/deg.
The adverse nature of the open-loop speed response to a flight-path change with thrust is illustrated by the inset diagram at the left of the figure, where an increase in thrust to shallow the path causes the aircraft to decelerate, which, in turn, washes out the intended path correction. Such behavior is particularly undesirable since the strongly coupled response demands that the pilot pay considerable attention to path and speed control and that he work in a continuous, coordinated, closed-loop fashion with attitude and thrust to achieve adequate precision of flight-path control. Furthermore, the attitude control technique required to hold speed constant while making a path correction with thrust is unnatural. The pilot must lower the nose to hold speed while he attempts to reduce the rate of descent and vice versa. For these two reasons, strong path-speed coupling can make the aircraft unacceptable for flying the STOL approach. In particular, for the highly coupled configuration (\(\Delta u_{SS}/\Delta y_{SS} = -10 \text{ knots/deg}\)) corrections back to the glide slope for either high or low offsets were quite difficult to make. An example of glide-slope tracking for this configuration was shown previously in figure 1.

Airspeed-attitude sensitivity- To conclude the discussion of path and speed control for the approach, the significance of speed behavior in response to its primary control, pitch attitude, must be determined. The parameter for evaluation is the steady speed change in response to a change in pitch attitude (\(\Delta u_{SS}/\theta_C\)). It should be clear from the relationships associated with equation (19) that speed response to attitude and path-velocity (dy/dV) characteristics are strongly related through their mutual dependence on the level of trimmed drag and drag due to lift. This interrelation was brought out previously in the peripheral discussion related to figure 31 and the initial flight-path response on page 32. The interrelationship provides for large speed changes with attitude for operation on the backside of the thrust-required curve and small speed changes with attitude for operation on the front side. For the control technique used in these simulation evaluations of path and speed response (speed control with attitude, path control with thrust), considerations related to speed response to attitude appear to be more important than the degree of frontside or backside operation involved.

The significance of speed control with attitude is indicated in figure 34. Pilot ratings for variations in the speed response parameter \(\Delta u_{SS}/\theta_C\) are plotted for otherwise favorable values of \(\tau_y\) and \(\Delta u_{SS}/\Delta y_{SS}\). Variations in speed sensitivity to attitude have only a modest effect on pilot ratings. As expected, the pilots objected, although not too strongly, to insensitive or excessively sensitive speed response to attitude changes.
Poor harmony between speed and attitude either required objectionably large attitude changes for ordinary speed control or an unnecessarily fine touch on attitude control to avoid objectionable speed excursions. Proper harmony for speed control seems to dictate a speed-attitude sensitivity of \( \Delta u_{ss}/\theta_c \) between -1.5 and -2.5 knots/deg.

\[
\frac{\Delta u_{ss}}{\Delta \theta} \leq 12 \\
\frac{\Delta u_{ss}}{\Delta T} \leq 10
\]

Figure 34.- Speed response to pitch attitude.

SECTION 4

COMPARISON WITH FLIGHT DATA

A limited quantity of data exists from flight tests conducted to date on powered-lift V/STOL aircraft operating on steep landing approach paths. The data concerning pilot evaluation of flight-path control and documentation of flight-path and airspeed response to thrust exist in various degree of detail. They are reviewed here to permit a qualitative comparison with the trends obtained from the current simulation results.

The aircraft considered are the NASA/DITC Augmentor Wing Research Aircraft, the Dornier DO-31, and the Breguet 941. Data are in the form of pilot commentary for flight-path control with thrust during landing approach. Where available, open-loop path and speed response to thrust for a constant attitude (or nearly so) are excerpted from flight records. In other cases, these response data are not available from flight records but can be obtained from simulations based on flight-measured performance, stability, and control characteristics. These data are summarized in table 6.

*Flight data poorly suited for measuring the parameter.
*Data not determined from analysis of flight measurements.

NASA/DITC Augmentor Wing Research Aircraft

The aircraft has been described in some detail previously in section 3. It has been in flight status since June 1972 and is currently undergoing flight testing to document its performance, stability, and control characteristics. At this point, no stability augmentation has been provided for longitudinal control. Limited handling qualities evaluations have been conducted for the landing approach and these data are discussed here.

Approaches have been conducted on 7.5° glide slopes at speeds from 60 to 70 knots. The flap setting for these approaches was 65°, with nominal nozzle deflections of either 60° or 75°. Figure 35 shows examples of flight-path and airspeed response to thrust for these flight conditions. Although no attitude stabilization was available in the longitudinal control system, the pilot normally controlled attitude precisely during these approaches. For the 60° nozzle trim conditions, flight-path corrections were made with little associated variation in airspeed. Path-speed coupling \( \frac{\Delta u_{\text{ss}}/\Delta \gamma_{\text{ss}}}{\Delta T} \) measured in flight (table 6) ranges from -0.25 to -0.75 knots/deg. In figure 35, the path correction for the 60° nozzle angle was made with very little overshoot. Attitude is held within ±1° and a small decrease in speed, in the long-term, accompanies the increase in thrust and the positive path correction. For the 75° nozzle trim condition, more significant speed variations accompany path corrections. Path-speed coupling in this case ranges from -2.0 to -3.3 knots/deg. More overshoot is apparent in the path response and, as noted, the speed variations are more substantial than for the 60° nozzle configuration. Attitude variations are again held within ±1° of the nominal.
Pilot evaluations of flight-path control have been obtained to date for V R landing approaches on a 7.5° glide slope in the 75° nozzle configuration. Visual approach guidance was provided by an optical landing aid. Thrust control of flight path has been found to provide a capability for making quite rapid flight-path corrections. However, if appreciable path corrections are attempted, large airspeed excursions occur, as would be expected from the degree of flight-path/speed coupling noted in table 6 and figure 35. The pilot objected to these speed excursions and was reluctant to attempt to control speed tightly because of the wrong sense of the attitude change associated with the flight-path correction (DN/DA negative). A pilot rating of 4-1/2 was given for flight-path control on the approach. Both the pilot commentary and rating support the results of the simulation as noted in figure 33. Additional objections were raised concerning the sensitivity of thrust to throttle movement and the hysteresis in the throttle-fuel control cable and linkage system. Both characteristics made it difficult for the pilot to control flight path with the throttles. However, it was indicated that reduction of the sensitivity and hysteresis would not improve flight-path control substantially due to the path-speed coupling.
Dornier DO-31

The Dornier DO-31 is a jet-lift VTOL transport aircraft powered by two main engines and eight lift engines. Figure 36 is a three-view sketch and perspective of the aircraft. The main engines are located at midspan of each wing and provide thrust vectoring from 10° to 120° referenced to the aircraft waterline (fig. 37). The lift engines are mounted four to a pod in each wing tip and are vectored 15° aft of the vertical. Pitch is controlled through an attitude command system that uses the elevator and pitch nozzle controls. Additional descriptive data are provided in table 7 and reference 3.

![Figure 36 - Dornier DO-31 jet VTOL transport.](image)

Table 6 indicates a path-speed coupling of -4.0 knots/deg. A time history of a path correction with the main engines is also reproduced from reference 3 in figure 38. The flight-path response is first order in nature with a time constant of 2.7 sec. A substantial speed decay accompanies the reduction in

Figure 38. - Flight-path and airspeed response to a thrust change for the DO-31 during a steep, decelerating approach.

approach path angle. In this instance, a 10° nose-down attitude is maintained throughout the run. No flight-path overshoot is present since this flight condition is on the front side of the drag curve.

Pilot evaluations of flight-path control with lift engines or main engines are excerpted from reference 3. Pilots preferred to use lift engines for path control and could achieve good glide-slope tracking if corrections greater than the ±0.1 g authority of the lift engines were not required. Within this range, path control was quite precise and speed excursions were minimal. The pilots felt that path control with the main engines was unsatisfactory because of the undesirable speed perturbations that required them to modulate the nozzle control for thrust vectoring so that speed could be controlled satisfactorily. No pilot ratings were assigned for glide-slope tracking; however, the pilot commentary relative to the aircraft behavior qualitatively supports the results obtained in the current simulation.
The Breguet 941 is a high-wing, turboprop STOL transport aircraft of the deflected-propeller slipstream, mechanical flap concept (fig. 39). It is powered by four interconnected gas turbine engines. The wing is almost fully immersed in the propeller slipstream and is equipped with a large deflection (95°), full-span, triple-slotted flap. Pitch is controlled with the elevator. A propeller "transparency" mode (differential inboard-outboard pitch) is available to increase descent capability. The aircraft is described in more detail in table 8 and in references 2 and 24.

Landing approaches were conducted along a 7.5° glide slope at speeds between 60 and 65 knots for the flight program reported in reference 24. Flaps were set at 98° and full transparency was used. Examples of flight-path and airspeed response to thrust at constant attitude were not available from flight data. As an alternative, these time responses were obtained from a simulation model of the aircraft based on flight-measured performance, stability, and control characteristics obtained from French and NASA flight tests conducted on the aircraft. The simulation responses are documented in reference 25 and are reproduced in figure 40 for an approach speed of 65 knots. As indicated in table 6, path response time constants were 2.5 to 3.0 sec. No overshoot is apparent in the path response. Speed excursions were minimal, with a slight increase in speed at 65 knots ($\Delta u_{SS}/\Delta y_{SS} = 0.4$ knot/deg). Commentary regarding path control (ref. 24) indicates that precise glide-slope tracking could be achieved with power. While attitude was not stabilized through the control system, a throttle interconnect prevented the inherent pitching moments due to thrust from degrading attitude control. No comments concerning speed control problems are noted. As anticipated from the current simulation results, this aircraft provides the capability for satisfactory flight-path control during the landing approach.

CONCLUSIONS

This report presents results of an analytical and experimental investigation of flight-path and airspeed control for powered-lift STOL aircraft. The study focused on operation on the glide slope. Problems of controlling large changes in flight path or airspeed such as would be associated with transitioning from level flight onto the glide slope or flaring to a landing were not addressed.

The conclusions drawn from the simulation program are qualified where appropriate by the technique used by the pilot to control flight path and airspeed on the glide slope. With these qualifications, the following
conclusions are made from the analytical and simulation studies of flight-path and airspeed control.

- With pitch attitude stabilized, flight path controlled with thrust, and airspeed controlled with pitch attitude, the characteristics that define path and speed response as they appear to the pilot are:
  - initial flight-path time constant in response to thrust
  - overshoot in flight-path response to thrust
  - flight-path/speed coupling defined by the change in speed following a path correction with thrust
  - speed change due to a change in attitude

- These path and speed response characteristics can be defined in terms of the following configuration- and flight-condition-dependent characteristics:
  - axial and vertical velocity damping - $X_u$ and $Z_\alpha/V_0$
  - axial to vertical velocity coupling - $X_\alpha$ and $Z_u$
  - effective thrust inclination - $X_{\Delta T}/Z_{\Delta T}$

- For flight-path and airspeed control on the glide slope and over a range of configuration characteristics appropriate to powered-lift STOL,
  - flight-path/airspeed coupling and the attendant flight-path overshoot are the dominant influences on handling qualities
  - the sensitivity of speed to pitch attitude has a moderate influence on handling qualities, and
  - initial flight-path time constant has a negligible effect over the range investigated ($1.5 < \tau_Y < 7$ sec).

It is evident from the results of this simulation that a powered-lift STOL aircraft with the proper response characteristics can be controlled quite satisfactorily during the landing approach.

Only limited flight data pertaining to flight-path and airspeed control are available for powered-lift V/STOL aircraft. In particular, few pilot ratings are available from these flight tests to provide quantitative comparisons with the simulation. However, pilot commentary and documentation of the aircraft response qualitatively support the conclusions drawn from the simulation program, specifically that flight-path coupling with airspeed substantially influences the ability of the pilot to fly the approach precisely.
The next essential step in STOL approach and landing research should be to acquire data from a properly structured set of flight experiments to substantiate the results of the foregoing analyses and simulation. One specific objective of these flight experiments should be to independently evaluate the effects of flight-path overshoot and flight-path/airspeed coupling on glide-slope tracking.

Ames Research Center
National Aeronautics and Space Administration
Moffett Field, Calif., 94035, June 14, 1974
This appendix describes the effects of pitch attitude stabilization on flight-path and airspeed response to commanded changes in pitch attitude or to changes in thrust. From this complete development of the response characteristics, it will be shown that the response relationships can be approximated so that the aircraft equations of motion can be simplified by ignoring the short-term attitude response and by eliminating the pitching moment equation.

\[ \delta \theta = \frac{(\delta \theta_c/\delta_c)N_{\delta \theta}}{\Delta + Y_{\theta}N_{\delta \theta}} \]  

(A1)

The relationship of attitude response to attitude command, using the matrix nomenclature for multi-loop control of reference 17, follows from the longitudinal equations of motion and the control loop structure shown in figure 41:

\[ \Delta = V_o(s^2 + 2\zeta \omega_p s + \omega_p^2) \times \left( s^2 + 2\zeta \omega_p s + \omega_p^2 \right) \]  

(A2)

and, for the attitude-elevator numerator, the factors are

\[ N_{\delta \theta} = V_o(s + 1/T_{\theta_1})(s + 1/T_{\theta_2}) \]  

(A3)

or

\[ = V_o(s^2 + 2\zeta \omega_p s + \omega_p^2) \]  

(A4)

\[ \theta \]

\[ \theta \]

\[ ^2 \text{Strictly speaking, the attitude numerator is approximated by} \]

\[ N_{\delta \theta} = M_{\delta \theta} V_o\left\{ s^2 - [X_u + (Z_{\alpha}/V_o)]s + X_u(Z_{\alpha}/V_o) - (X_{\alpha}/V_o)Z_{u} \right\}. \]

Whether this polynomial factors into a complex pair or into two real roots depends on the magnitude of the derivatives \( X_{\alpha} \) and \( Z_{u} \). Large values of \( X_{\alpha} \) and \( Z_{u} \) tend to produce the complex factors whereas, if \( X_{\alpha} \) and \( Z_{u} \) are small, the factors occur in the more familiar form \( (s + 1/T_{\theta_1})(s + 1/T_{\theta_2}) \). For \( X_{\alpha} = 0 (D_{\alpha} = g) \), the factors are given by \( 1/T_{\theta_1} = -X_u \) and \( 1/T_{\theta_2} = -2\zeta \omega_p/V_o \).
The closed-loop characteristic equation for the feedback control \( Y_\theta \) (fig. 41) is

\[
\Delta + Y_\theta N_\theta^C = V_0 (s^2 + 2\zeta_\text{sp} \omega_\text{sp} s + \omega_\text{sp}^2)(s^2 + 2\zeta_\text{p} \omega_\text{p} s + \omega_\text{p}^2) \tag{A5}
\]

or

\[
= V_0 (s^2 + 2\zeta_\text{sp} \omega_\text{sp} s + \omega_\text{sp}^2)(s + 1/T_\theta^1)(s + 1/T_\theta^2) \tag{A6}
\]

depending on whether the numerator \( N_\theta^C \) factors into two real roots or a complex pair and how tightly the attitude loop is closed. An example of the closed-loop characteristics is shown in the root-locus and Bode plot of figure 42. The compensation provided by \( Y_\theta \) in the feedback loop is intended to produce \( K/s \) characteristics in the crossover region for the attitude transfer function. It is apparent that both the short-period and phugoid mode damping are increased and that the bandwidth of the system is extended to higher frequencies than for the open-loop response. The phugoid roots are driven near the roots of the attitude numerator. The ratio of the frequencies of the short period and phugoid is increased from a factor of 5 to a factor of 10.

The influences of the attitude loop closure on the transfer functions for flight-path and airspeed control with attitude or thrust (section 2) are now described. The path and speed transfer functions with respect to attitude are

\[
\begin{align*}
\left( \frac{\gamma}{\delta_c} \right)_{\theta \rightarrow \delta_e} &= \frac{N_\theta^\gamma}{\Delta + Y_\theta N_\theta^\gamma} \\
\left( \frac{u}{\delta_c} \right)_{\theta \rightarrow \delta_e} &= \frac{N_\theta^u}{\Delta + Y_\theta N_\theta^u}
\end{align*}
\]  

The numerators for these two transfer functions are identical to the elevator control numerators \( N_\delta^\gamma \) and \( N_\delta^u \) and are unmodified by the attitude loop closure. They are, respectively,

\[
N_\theta^\gamma = A_{\theta} (\delta_\gamma / \delta_c) (s + 1/T_{Y_1})(s + 1/T_{Y_2})(s + 1/T_{Y_3}) \tag{A8}
\]

and

\[
N_\theta^u = A_{\theta} (\delta_\gamma / \delta_c) (s + 1/T_{U_1})(s + 1/T_{U_2})(s + 1/T_{U_3}) \tag{A9}
\]

The complete path and speed transfer functions to an attitude command are written:

\[
46
\]
Typical examples of these two transfer functions are seen in the Bode plots of figures 43 and 44. From these Bode plots and from equations (A10) and (A11), it is apparent that path and speed response to attitude are dominated by the closed-loop phugoid mode and the low-frequency numerator roots \( \frac{1}{T_Y} \) and \( \frac{1}{T_{U_1}} \). The magnitude of response at the short period is of little consequence when compared to the phugoid response. Furthermore, the roots at \( \frac{1}{T_Y^2} \) and \( \frac{1}{T_Y^3} \) or at \( \frac{1}{T_{U_2}} \) and \( \frac{1}{T_{U_3}} \) are typically at higher frequency than the closed-loop short period and may be ignored. In fact, these transfer functions can be approximated by neglecting the high-frequency factors and replacing the phugoid roots with their near equivalent, the factors of the attitude numerator, that is,

\[
\begin{align*}
\frac{\delta \gamma}{\theta + \delta_e} &= A_{\gamma \theta} \frac{(\delta_e / \theta_c) (s + T_Y) (s + 1/T_{Y_1}) (s + 1/T_{Y_2})}{(s^2 + 2 \tau_p \omega_p s + \omega_p^2) (s^2 + 2 \tau_{sp} \omega_{sp} s + \omega_{sp}^2)} \\
\frac{\delta u}{\theta + \delta_e} &= A_{u \theta} \frac{(\delta_e / \theta_c) (s + 1/T_{U_1}) (s + 1/T_{U_2}) (s + 1/T_{U_3})}{(s^2 + 2 \tau_{sp} \omega_{sp} s + \omega_{sp}^2) (s^2 + 2 \tau_{sp} \omega_{sp} s + \omega_{sp}^2)}
\end{align*}
\] (A10) (A11)

Figures 43 and 44 compare these approximations with the actual path and speed transfer functions. The path and speed transfer functions with respect to thrust are

\[
\begin{align*}
\frac{\delta \gamma}{\theta + \delta_e} &= \frac{N_{\gamma \Delta T}^\gamma + Y_{\theta \Delta T}^\theta \delta_e}{\Delta + Y_{\theta \delta_e}^\theta} \\
\frac{\delta u}{\theta + \delta_e} &= \frac{N_{\Delta T}^u + Y_{\theta \Delta T}^u \delta_e}{\Delta + Y_{\theta \delta_e}^u}
\end{align*}
\] (A13a) (A13b)

Figures 45 and 46 compare these approximations with the actual path and speed transfer functions. The path and speed transfer functions with respect to thrust are
Figure 45.- Comparison of exact and approximate flight-path response to pitch attitude with pitch attitude stabilized.

It is apparent that the attitude loop closure modifies the basic path and speed numerators with respect to thrust $N_{\Delta T}^Y$ and $N_{\Delta T}^U$. For the flight-path response,

$$N_{\Delta T}^Y = A_{\gamma T}(s + 1/T_{\gamma T_1})(s + 1/T_{\gamma T_2})$$

$$\times (s + 1/T_{\gamma T_3})$$

$$= A_{\gamma T}(s + 1/T_{\gamma T_1})$$

$$\times (s^2 + 2\zeta_{\gamma T} \omega_{\gamma T} s + \omega_{\gamma T}^2)$$

(A14)

and

$$N_{\Delta T}^U\gamma = A_{\delta e}(s + 1/T_{\gamma T})$$

(A15)

The effect of the attitude loop closure on the roots of the numerator

$$N_{\Delta T e+\delta e}^Y = N_{\Delta T}^Y + Y_\theta N_{\Delta T}^e$$

is indicated in figure 47. In accordance with the complex polynomial factorization techniques of reference 26, the sigma Bode locus $|G(-\sigma)|$ graphically illustrates the progression of these roots from the factors of $N_{\Delta T}^Y$ for $K_\theta = 0$ to
for values of $K_\theta$ appropriate to the attitude loop closure of figure 42. One of the roots is essentially equivalent to the factor $1/T_{\gamma T}$ of the coupling numerator $N_{\Delta T \gamma}$. The resulting transfer function for path control with thrust is

$$
\left( \frac{\gamma}{\Delta T} \right)_{\theta+\delta_e} = \frac{A_{\gamma T}(s + 1/T_{\gamma T}) (s^2 + 2\tau_{\gamma} \omega_{\gamma} s + \omega_{\gamma}^2)}{(s^2 + 2\tau_{\gamma} \omega_{\gamma} + \omega_{\gamma}^2)(s^2 + 2\tau_{\gamma} \omega_{\gamma} + \omega_{\gamma}^2)} \quad (A16)
$$

The Bode plot in figure 48 is an example of this transfer function. It is apparent that the dominant contributions are made by the closed-loop phugoid mode and the numerator root at $1/T_{\gamma T}$. The remaining factors occur at high frequency and at such low magnitudes that they are of little consequence to the response.

For the airspeed response,

$$
N_{\Delta T}^u = A_{u T}(s + 1/T_{u T_1})(s + 1/T_{u T_2})
\times (s + 1/T_{u T_3}) \quad (A17)
$$

and

$$
N_{\Delta T \theta}^u = A_{\theta T}(s + 1/T_{\theta T}) \quad (A18)
$$

Typical roots of the numerator

$$
N_{\Delta T \theta+\delta_e}^u = N_{\Delta T}^u + Y_{\theta}N_{\Delta T \theta}^u
$$

are shown in figure 49 using the sigma Bode locus to illustrate the effect of the attitude loop closure. The roots are driven quite close to the numerator factors $N_{\Delta T \theta}^u$ and $Y_{\theta}$. The resulting transfer function for speed control with thrust is

$$
\left( \frac{u}{\Delta T} \right)_{\theta+\delta_e} = \frac{A_{u T}(s + 1/T_{u T_1}) (s^2 + 2\tau_{u} \omega_{u} s + \omega_{u}^2)}{(s^2 + 2\tau_{u} \omega_{u} + \omega_{u}^2)(s^2 + 2\tau_{u} \omega_{u} + \omega_{u}^2)} \quad (A19)
$$

and an example is shown in figure 50. Low-frequency modes dominate speed response, and contributions at the short-period frequency are so small that they can be ignored.

From the nature of the transfer functions for path and speed (figs. 48 and 50), it is reasonable to approximate these relationships by neglecting the higher frequency contributions and adopting a format comparable to that
used in equation (A12), that is,

\[
\frac{\gamma}{\Delta T} \to \delta_e = \frac{A_{\gamma T}(s + 1/T_{\gamma T})}{s^2 + 2\zeta_\gamma \omega_\gamma s + \omega_\gamma^2} \tag{A20a}
\]

and

\[
\frac{u}{\Delta T} \to \delta_e = \frac{A_{uT}(s + 1/T_{uT})}{s^2 + 2\zeta_\delta \omega_\delta s + \omega_\delta^2} \tag{A20b}
\]

Figures 51 and 52 compare these approximations with the actual transfer functions.

The implication of the approximations to the path and speed transfer functions (eqs. (A12) and (A20)) is that the attitude stabilization loop is closed at a sufficiently high gain so that \( \delta = \delta_c \) over the frequency range of interest. In fact, for infinite attitude gain \( (K_\theta = \infty) \), these approximations become exact, with the result that the equations of motion for the
Aircraft with infinitely tight attitude stabilization can be simplified to

\[
\begin{bmatrix}
  s - X_u & -X_\alpha & 0 \\
  -Z_u & V_s - Z_\alpha & 0 \\
  0 & 1 & 1
\end{bmatrix}
\begin{bmatrix}

\( h \) vertical velocity, ft/sec or ft/min, m/sec

\( I_e \) elevator moment of inertia, slug-ft\(^2\), kg-m\(^2\)

\( I_x \) roll moment of inertia, slug-ft\(^2\), kg-m\(^2\)

\( I_y \) pitch moment of inertia, slug-ft\(^2\), kg-m\(^2\)

\( I_z \) yaw moment of inertia, slug-ft\(^2\), kg-m\(^2\)

\( -xz \) cross-product of inertia, slug-ft\(^2\), kg-m\(^2\)

\( \text{IFR} \) instrument flight rules

\( \text{ILS} \) instrument landing system

\( j \) complex number \((-1)^{1/2}\)

\( K_I \) gain for pitch rate command integrator, deg/sec/in., deg/sec/cm

\( K_q \) pitch rate feedback gain to elevator, deg/deg/sec

\( K_u \) airspeed feedback gain to nozzle, deg/knot; pilot airspeed-attitude gain

\( K_\alpha \) angle-of-attack feedback gain to nozzle, deg/deg

\( K_b \) column position feedforward gain, deg/in., deg/cm

\( K_v \) pilot flight-path - throttle gain, percent/deg

\( K_\alpha \) pitch attitude feedback gain to elevator, deg/deg

\( M \) pitching moment, ft-lb, kN-m

\( M_q \) pitch-rate damping, \[ \frac{1}{I_y} \frac{\partial M}{\partial q}, \text{ l/sec} \]

\( M_u \) pitch acceleration derivative due to forward speed, \[ \frac{1}{I_y} \frac{\partial M}{\partial u}, \text{ rad/sec}^2 \text{ per ft/sec, rad/sec}^2 \text{ per m/sec} \]

\( M_\alpha \) longitudinal static angle-of-attack stability, \[ \frac{1}{I_y} \frac{\partial M}{\partial \alpha}, \text{ rad/sec}^2/\text{rad} \]

\( M_\alpha \) pitch acceleration derivative due to rate of change of angle of attack, \[ \frac{1}{I_y} \frac{\partial M}{\partial \dot{\alpha}}, \text{ l/sec} \]
elevator control effectiveness, $\frac{1}{I_y} \frac{\partial M}{\partial \delta_e}$, rad/sec$^2$/rad

pitch acceleration derivative due to nozzle deflection, $\frac{1}{I_y} \frac{\partial M}{\partial \delta_v}$, rad/sec$^2$/rad

pitch acceleration derivative due to thrust, $\frac{1}{I_y} \frac{\partial M}{\partial \Delta T}$, rad/sec$^2$/lb, rad/sec$^2$/kN

aircraft mass, slug, kg

numerator of the transfer function that relates response $r$ to an input $i$

coupling numerator for flight-path response to thrust with attitude to elevator loop closed

coupling numerator for airspeed response to thrust with attitude to elevator loop closed

coupling numerator for flight-path response to thrust with speed to attitude command loop closed

body axis pitch rate, deg/sec

dynamic pressure, lb/ft$^2$, kN/m$^2$

wing area, ft$^2$, m$^2$

Laplace operator, $\sigma = j\omega$

thrust component due to hot jet exhaust, lb, kN

thrust of cold blowing air from augmentor flap, lb, kN

lead time constant of the pilot transfer function for thrust control, sec

lead time constant for $\theta \to \delta_e$ loop

time, sec

real roots of the longitudinal characteristic equation normally associated with the short period mode

real roots of the numerator of the thrust-to-airspeed transfer function

low-frequency root of the numerator of the thrust-to-airspeed transfer function with the attitude to elevator loop closed

$M_{\delta e}$

$M_{\delta v}$

$M_{\Delta T}$

$m$

$N_i$

$N_{\delta e \Delta T}^\theta$

$N_{\Delta T \delta e}^\theta$

$N_{\theta C \Delta T}^\theta$

$q, q_B$

$\ddot{q}$

$S, S_W$

$s$

$T_{\text{hot}}$

$T_{\text{cold}}$

$T_{\text{L}_\gamma}$

$T_{\text{L}_\theta}$

$t$

$\frac{1}{T_{\text{sp}_1}}, \frac{1}{T_{\text{sp}_2}}$

$\frac{1}{T_{\text{uT}_1}}, \frac{1}{T_{\text{uT}_2}}, \frac{1}{T_{\text{uT}_3}}$

$\frac{1}{T_{\text{uT}}}$

54
$\frac{1}{T_{u_1}}, \frac{1}{T_{u_2}}, \frac{1}{T_{u_3}}$
real roots of the numerator of the attitude to airspeed transfer function

$\frac{1}{T_{u_1}}$
real root of the characteristic equation with attitude and airspeed to elevator loops closed (rate command system)

$\frac{1}{T_{\gamma T}}$
low-frequency root of the numerator of the thrust to flight-path transfer function with the attitude to elevator loop closed

$\frac{1}{T_{\gamma T}}$
low-frequency root of the numerator of the thrust to flight-path transfer function with the attitude and airspeed to elevator loops closed

$\frac{1}{T_{\gamma T_1}}, \frac{1}{T_{\gamma T_2}}, \frac{1}{T_{\gamma T_3}}$
real roots of the numerator of the thrust to flight-path transfer function

$\frac{1}{T_{\gamma 1}}$
low-frequency root of the numerator of the attitude to flight-path transfer function (frequently identified in the literature as $\frac{1}{T_{h_1}}$, the low-frequency numerator factor of the elevator-to-altitude transfer function)

$\frac{1}{T_{\gamma 2}}, \frac{1}{T_{\gamma 3}}$
high-frequency real roots of the numerator of the attitude to flight-path transfer function

$T_\delta$
pitch rate command system time constant

$\frac{1}{T_{\theta 1}}, \frac{1}{T_{\theta 2}}$
real roots of the numerator of the elevator to attitude transfer function

$\frac{1}{T_{\theta 1}}, \frac{1}{T_{\theta 2}}$
low-frequency real roots of the longitudinal characteristic equation (with the $\theta + \delta_e$ loop closed) normally associated with the phugoid mode

$u$
perturbation airspeed, knots or $\text{ft/sec, m/sec}$

$u + \dot{\theta}_C$
airspeed to attitude command loop closure

$u_C$
commanded airspeed perturbation, knots or $\text{ft/sec, m/sec}$

$u_\varepsilon$
airspeed error, knots or $\text{ft/sec, m/sec}$

$V_0$
true airspeed, knots or $\text{ft/sec, m/sec}$

VFR
visual flight rules

</table>
$Z_{\Delta T}$ vertical acceleration derivative due to thrust, $\frac{1}{m} \frac{\partial Z}{\partial \Delta T}$, ft/sec^2/1b, m/sec^2/kN

$Z_{\delta v}$ vertical acceleration derivative due to nozzle deflection, $\frac{1}{m} \frac{\partial Z}{\partial \delta v}$, ft/sec^2/rad, m/sec^2/rad

$\alpha$ angle of attack, deg or rad

$\gamma$ flight-path angle, deg or rad

$\gamma + \delta_T$ flight-path to throttle loop closure

$\gamma_c$ commanded flight-path angle, deg or rad

$\gamma_{ss}$ steady-state flight-path angle, deg or rad

$\gamma_e$ flight-path angle error, deg or rad

$\Delta$ characteristic matrix for longitudinal equations of motion; incremental value

$\frac{(\Delta u_{ss})}{(\Delta \gamma_{ss})/\Delta T}$ ratio of change of steady-state airspeed to flight-path due to a change in thrust (constant pitch attitude), knots/deg

$\frac{\Delta u_{ss}}{\theta_c}$ change in steady-state airspeed per unit change in pitch attitude (constant thrust), knots/deg

$\Delta \gamma_{\max}$ maximum flight-path change following a change in thrust, deg

$\frac{(\Delta \gamma_{\max})}{(\Delta \gamma_{ss})/\Delta T}$ ratio of maximum to steady-state change of flight path due to a change in thrust (constant pitch attitude)

$\delta_c$ control column deflection, in., cm

$\delta_e$ elevator deflection, deg

$\delta_{e_c}$ commanded elevator deflection, deg

$\delta_f$ flap deflection, deg

$\delta_T$ throttle deflection, in., cm

$\delta_v$ nozzle deflection, deg

$\zeta_{E, \omega_E}$ damping ratio and natural frequency of engine thrust transfer function

$\zeta_{P', \omega_P}$ damping ratio and natural frequency of the phugoid mode

$\zeta_{P', \omega_P}$ damping ratio and natural frequency of the phugoid mode (with $\theta + \delta_e$ loop closed)
\( \zeta_{sp}, \omega_{sp} \)

damping ratio and natural frequency of the short-period mode

\( \zeta'_{sp}, \omega'_{sp} \)

damping ratio and natural frequency of the short-period mode with \( \theta + \delta_e \) loop closed

\( \zeta'u, \omega'u \)

damping ratio and natural frequency of the numerator roots of the thrust to airspeed transfer function with \( \theta + \delta_e \) loop closed

\( \zeta'_{Y}, \omega'_{Y} \)

damping ratio and natural frequency of the numerator roots of the thrust to flight-path transfer function with \( \theta + \delta_e \) loop closed

\( \zeta'_{Y'}, \omega'_{Y'} \)

damping ratio and natural frequency of the numerator roots of the flight-path to thrust transfer function with the attitude and airspeed to elevator loops closed (rate command system)

\( \zeta_{YT}, \omega_{YT} \)

damping ratio and natural frequency of the numerator roots of the thrust to flight-path transfer function

\( \zeta_{\theta}, \omega_{\theta} \)

damping ratio and natural frequency of the numerator roots of the elevator to attitude transfer function

\( \zeta'_{\theta}, \omega'_{\theta} \)

damping ratio and natural frequency of the low-frequency characteristic roots with attitude and airspeed to elevator loops closed

\( \theta \)

pitch attitude, deg

\( \theta + \delta_e \)

pitch attitude to elevator loop closure

\( \theta_c \)

commanded pitch attitude, deg

\( \theta_e \)

pitch attitude error, deg

\( \theta_T \)

effective thrust inclination, deg

\( \sigma \)

real part of a complex root

\( \tau_Y \)

time constant for initial flight-path response to thrust, sec

\( \tau_e \)

equivalent pilot transport delay, sec

\( \omega \)

frequency, rad/sec

\( \omega_{co} \)

gain crossover frequency

\( \cdot' \)

derivative with respect to time, \( \frac{d(\cdot)}{dt} \)

\( \cdot(\cdot) \)

phase angle of \( \cdot(\cdot) \)
