for

NATIONAL AERONAUTICS AND SPACE ADMINISTRATION
ABSTRACT

Feasibility of utilizing the Random Decrement method in conjunction with a Signature analysis procedure to determine the dynamic characteristics of an aeroelastic system for the purpose of on-line prediction of potential on-set of flutter has been examined.

Digital computer programs were developed to simulate sampled response signals of a two-mode aeroelastic system. Simulated response data were used to test the Random Decrement method. A special curve-fit approach was developed for analyzing the resulting Signatures. A number of numerical "experiments" were conducted on the combined processes. The method was found to be capable of determining frequency and damping values accurately from Randomdec Signatures of carefully selected lengths.
FOREWORD

The Technical Representatives for NASA were Mr. J.T. Foughner, Jr., and Dr. R.M. Bennett, Aeroelasticity Branch, Structures and Dynamics Division, Langley Research Center. The principal NTI investigator was C.S. Chang. Computer programs were developed by G.O. Dennis and refined by G.A. Aramayo. C. Hsu provided technical consultation in all phases of work described in this report.

SUMMARY

An ensemble averaging method for determining the characteristic response function of an aeroelastic system from its turbulence-induced random vibrations was developed recently by Henry A. Cole, Jr. The most significant feature of this (the Random Decrement) method is that very little knowledge about the excitation is required to obtain useful results (Randomdec Signatures). Provided an automated numerical procedure can be developed to analyze Signatures, the Random Decrement method can be very useful for on-line prediction of the on-set of flutter during subcritical wind tunnel or flight testing.

The Signature analysis procedure selected for investigation under this project is that of a curve-fitting nature. A Randomdec Signature is approximated by the theoretical homogeneous solution of the mathematical model of the aeroelastic system under consideration. An error function between the Signature and the analytical expression is defined, determined and numerically minimized. Those coefficients in the theoretical solution which lead to a minimum error are said to be the best approximations of the dynamic properties of the aeroelastic system.

Digital simulation techniques were employed to carry out numerical experiments for investigating effects of variation of system, data acquisition, Randomdec and curve-fit parameters on the accuracy of the overall approach.
Section 1

INTRODUCTION

The need for an accurate, reliable and rapid means to forecast the onset of flutter during subcritical wind-tunnel and flight tests of aeroelastic structures is widely recognized. That this need exists today is evidenced by the number and variety of current and recently completed research and development programs in the United States and abroad (References 1, 2 and 3), as well as by the differences among methods used by various organizations (References 4, 5, 6 and 7).

Coupry (Reference 4) and Cole (References 5, 6, 8 and 9) both advocate the utilization and on-line processing of wind induced dynamic response signals from the test specimen for flutter prediction and failure detection. Their approaches have obvious advantages over other methods in which "controlled" excitations (impulsive, periodic and/or other kinds of forces) must be applied to induce responses in those vibrational modes which eventually flutter.

Coupry relies on rapid PSD analyses of the response signal and modal identification in the frequency domain. The accuracy of the method suffers when flutter modes are closely spaced on the frequency axis. The method also depends on the PSD of the excitation (in this case, the effects of turbulence) being reasonably flat over the frequency range in which the flutter modes reside.

Cole first introduced the concept of what was later named the Random Decrement method in Reference 5 while investigating applications of the correlation functions. He subsequently used it at NASA/Ames Research Center for detecting fatigue failures in a Space Shuttle wing flutter model (Reference 6). The method received full treatment by the inventor in References 8 and 9.
The Random Decrement method is essentially an ensemble averaging procedure which determines the characteristic response function (the Randomdec Signature) of an aeroelastic specimen under test from its turbulence-induced random vibrations.

To obtain a Randomdec Signature, one simply collects a number of segments of time series representing the random responses of a system, and ensemble-averages them. If the system is linear and the excitation random, the average time series converges towards the transient response of the system due to a set of initial conditions. The order of the system is arbitrary. The initial conditions to which the Signature corresponds can be manipulated almost at will by judicial "triggering" (selection of the starting point) of each ensemble member. For failure detection and for property identification of nonlinear structures, Cole favors triggering at a constant response level. The resulting Signature is an approximating time series of the characteristic response function* of the specimen in its natural environment at an amplitude which is equal to the trigger level. For flutter prediction in linear systems, constant-level triggering is not necessary, and various other methods become optionally available. Since the ensemble averaging procedure cannot be carried out indefinitely in practical situations, the Randomdec Signature will contain a certain amount of error which generally makes direct (visual) interpretation and determination of system dynamic characteristics difficult. The main objective of this study is to investigate the feasibility of utilizing the Random Decrement method in conjunction with a Signature analysis procedure to determine the dynamic characteristics of an aeroelastic system under test for the purpose of on-line prediction of potential on-set of flutter.

*The existence of a characteristic response function for a nonlinear system is an assumption.
The Signature analysis procedure selected for investigation under this project is that of a curve-fitting nature. A Random Decrement Signature is approximated by the theoretical homogeneous solution for the mathematical model of the aeroelastic system. An error function between the Signature and the analytical expression is defined, determined and numerically minimized. Those coefficients in the theoretical solution which lead to a minimum error are said to be the best approximations of the dynamic properties of the aeroelastic system.

Digital computer programs were developed to simulate sampled response signals of a two-mode aeroelastic system. Simulated response data were used to test the Random Decrement method. A special curve-fit approach was developed for analyzing the resulting Signatures. A number of numerical "experiments" were conducted on the combined processes. Results of these experiments indicate definite feasibility of combination of the approaches.

Analyses of the Random Decrement method and the curve-fit procedures are presented in Sections 3 and 4 of this report, respectively. Section 5 deals with the simulation of response signals and the implementation of the Random Decrement procedures. Numerical results of the investigation are summarized in Section 6.

Computer programs developed for this study are described in Appendix A. A sample test case with typical input and output is included in Appendix B.
All symbols used in the text portion of this report are defined when they are first introduced. The following is a cross-reference of these symbols arranged in alphabetical order.

</table>
\( e(\omega) \) Infinite Fourier Transform of measured velocity response of an aeroelastic system, including effects of low-pass filters

\( E \) Error function used to gauge the degree of success of a curve-fitting process

\( E^\ell \) Error function \( E \) after \( \ell \) iterations of the curve-fit process

\( f^0 \) Bandwidth of the response simulation process, Hertz

\( f^1_i(t) \) Inverse Laplace Transform of the factor in the transfer function on the \( i \)th mode which distinguishes an aeroelastic system from a purely mechanical system. For a purely mechanical system, \( f^1_i(t) \) is a Dirac Delta function

\( F^j_k \) Sequences of random numbers used to construct \( Q^i_k \) in the simulation process

\( g \) A dummy integer subscript used in intermediate steps in the curve-fit process

\( h^1_i(t) \) Impulse response function of the \( i \)th mode due to an impulse applied at \( t=0 \)

\( h^1'_i(t) \) Convolution of \( f^1_i(t) \) and \( h^1''_i(t) \)

\( h^1''_i(t) \) Inverse Laplace Transform of the factor in the transfer function in the \( i \)th mode, which is responsible for flutter of an aeroelastic system when its poles move on to the imaginary axis

\( i \) A subscript identifying modal parameters and variables, \( i=1, \ldots, I \)

\( I \) See definition of \( i \).

\( j \) Index used to identify those modes in which generalized forces are statistically related, \( j=1, \ldots, J<1 \)

\( J \) See definition of \( j \).

\( k \) Sample counter, \( k=1,2, \ldots, K \)

\( k^1_i \) Total generalized stiffness in the \( i \)th mode

\( k^1'_i \) Generalized stiffness of the structure in still air

</table>
Displacement in the ith mode at \( t=t_{no} \), which is also the initial modal displacement of the nth member used in the Random Decrement process.

Generalized force in the ith mode.

Part of generalized force in the ith mode which is statistically independent of generalized forces in all other modes.

Part of generalized force in the ith mode which is statistically related to a similar component in the jth mode.

Mean-squared value of the generalized force in the ith mode.

Mean-squared value of \( Q'_i \).

Mean-squared value of \( Q''_i \).

Simulated random components of generalized force for the ith mode. \( Q_{ik} \) is simulated at discrete time points \( \kappa=0 \) only.

Intermediate variable used in the curve-fit process.

Intermediate variable used in the curve-fit process.

Coefficients relating generalized forces in different modes which are statistically dependent.

Laplace Transform variable.

"Signal" part of a Randomdec Signature.

Ideal Randomdec Signature obtained by ensemble averaging infinitely many statistically independent response samples.

Time.

Running variable for time for all members collected by the Random Decrement process. It is also used as the independent variable for the ensemble average of all members (the Randomdec Signature).

Running independent variable for the nth member collected in the Random Decrement process, \( t_n = t - t_{no} \).
| $t_{no}$  | Time at which the $n$th ensemble member begins. It is also the $n$th triggering time in the Random Decrement process. |
| $T$      | Length of a Randomdec Signature |
| $T_b, T_c$ | Time constants of simulated low-pass filters used in data acquisition system |
| $T_i$    | Time constant in the generalized force in the $i$th mode associated with $A_i(s)$ |
| $(-T_i/b_i)$ | Real pole of the transfer function in the $i$th mode of an aeroelastic system |
| $U(t)$   | Measurable response of a dynamic system |
| $\overline{U^2}$ | Mean-squared value of system response |
| $U_n(t')$ | Total response function collected as the $n$th member of the ensemble by the Random Decrement process |
| $U_N(t')$ | Ensemble average of $U_n(t')$ |
| $U_{nk}$ | Value of the $k$th point in the Randomdec Signature |
| $y(t')$ | Theoretical homogeneous solution of a purely mechanical system used to approximate an aeroelastic system |
| $y_k$ | $y(t') \bigg|_{t'=k\delta}$ |
| $z(y_k)$ | A weighting functional |
| $\alpha_1$ | Equivalent to $B_1$ |
| $\alpha_2$ | Equivalent to $\zeta \omega_1$ |
| $\alpha_3$ | Equivalent to $\frac{1}{\omega_1}$ |
| $\alpha_4$ | Equivalent to $D_1$ |
| $\alpha_5$ | Equivalent to $B_2$ |
| $\alpha_6$ | Equivalent to $\zeta \omega_2$ |
| $\alpha_7$ | Equivalent to $\frac{1}{\omega_2}$ |
\( \alpha_8 \) Equivalent to \( D_2 \)

\( \alpha_m \) General representation of \( \alpha_1, \alpha_2, \ldots, \alpha_8 \)

\( \beta_n \) Intermediate variable used in the curve-fit process

\( \gamma_N(t') \) "Noise" part of a Randomdec Signature

\( \gamma_N^2 \) Mean-squared value of the noise term in a Randomdec Signature

\( \gamma_N^2(t') \) Expected value of the noise term, \( \gamma_N(t') \) in the Randomdec Signature

\( \gamma_{IN}^2(t') \) Expected squared value of the noise term in a Randomdec Signature attributed to the ith modal response

\( \delta \) Sampling period in a data acquisition process

\( \Delta f \) Frequency resolution of the response simulation process in units of Hertz

\( \varepsilon_n \) Intermediate variable used in the curve-fit process

\( \zeta \) Larger of \( \zeta_1 \) and \( \zeta_2 \)

\( \zeta_i \) Damping factor of the ith mode

\( \zeta_i' \) Real parts of the complex poles of the transfer function in the ith mode of an aeroelastic system

\( \zeta_i'' \) Best approximation of \( \zeta_i' \) determined by least-squares curve-fit

\( \eta \) \((-1)^{\frac{1}{2}}\)

\( \kappa \) An integer subscript used as a counter for simulated sampled response data

\( \ell \) An integer superscript used as a counter in the iterative curve-fit process

\( \nu \) See definition of \( \rho_\nu \)

\( \rho_\nu \) Multiplying scale factors for optimize step size in searching for least-squares curve fit, \( \nu=1,2,3 \ldots \)

\( \rho_\nu = (0.5)^{(\nu - 1)} \)
\( \xi \) Integration (dummy) variable for \( t \)

\( \omega_{mgk} \) Intermediate variable used in the curve-fit process

\( \omega_{mg} \) Intermediate variable used in the curve-fit process

\( \omega_i \) Natural frequency of the \( i \)th mode

\( \omega_i' \) Imaginary part of the complex poles of the transfer function in the \( i \)th mode of an aeroelastic system

\( \omega_i' \overline{\omega_i} \) Damped natural frequency of the \( i \)th mode, \( \overline{\omega_i} = (1 - \zeta_i^2) \omega_i \)

\( \overline{\omega_i'} \) Abbreviation for \( (1 - \zeta_i^2) \omega_i' \)

\( \omega_i' \overline{\omega_i} \) Best approximation of \( \omega_i' \) determined by least-squares curve-fit
Section 5
MATHEMATICAL FOUNDATIONS OF RANDOM DECREMENT

The mathematical foundation of the Random Decrement method is derived in the following for a linear time-invariant system.

Let $t = \text{time}$, the independent variable, $-\infty < t < \infty$;

$U(t) = \text{measurable response of a system};$

$i = \text{a subscript used to identify modal parameters and variables, } i=1, 2, \ldots I, \text{ (the system is of order } 2I);$

$q_i(t) = \text{modal responses};$

$Q_i(t) = \text{generalized forces};$

and $h_i(t) = \text{modal response functions after an impulse applied at } t=0.$

The measured (total) response is the sum of all modal responses:

$$U(t) = \sum_{i=1}^{I} q_i(t).$$

For physically realizable (casual), second-order modes, we have

$$h_i(t) = \begin{cases} 
0, & 0 < t; \\
-\xi_i \omega_i t e^{-\xi_i \omega_i t} \sin[(1-\xi_i^2)\frac{1}{2} \omega_i t], & t > 0, 
\end{cases} \quad (1)$$

and $h_i(t)$ has a finite discontinuity at $t=0$. In the above expressions, $\omega_i$ is the undamped modal natural frequency and $\xi_i$ the modal damping factor. For any point $t_{n_0}$ ($n=1, 2, \ldots N$) on the time axis, let

$$q_{i_{n_0}} = q_i(t)\big|_{t=t_{n_0}},$$
The response function in each mode may be written, in general, as

\[ q_i(t) = (p_{ino} + 2\zeta_i\omega_i q_{ino}) h_i(t - t_{no}) + q_{ino} h_i(t - t_{no}) \]

\[ + \int_{t_{no}}^{t} Q_i(\tau) h_i(t - \tau) d\tau \]

where \( \tau \) is an integration (dummy) variable. For each \( n \), we define a new independent variable

\[ t_n = t - t_{no}, \]

and a new modal response function

\[ q_{in}(t) = q_i(t + t_{no}), \]

which may be written for each \( n \) as

\[ q_{in}(t_n) = (p_{ino} + 2\zeta_i\omega_i q_{ino}) h_i(t_n) + q_{ino} h_i(t_n) \]

\[ + \int_{0}^{t_n} Q_i(\tau - t_{no}) h(t_n - \tau) d\tau. \]

Since \( t_n \) starts from zero for each \( n \), it is unnecessary to distinguish them in the last equation. We may, therefore, use a common independent variable \( t' \) for all \( t_n \) and write

\[ q_{in}(t') = (p_{ino} + 2\zeta_i\omega_i q_{ino}) h_i(t') + q_{ino} h_i(t') \]

\[ + \int_{0}^{t'} Q_i(\tau - t_{no}) h_i(t' - \tau) d\tau. \]
Summing over \( I \) modes, the response function for each observation beginning with \( t = t_{\text{no}} \) is

\[
U_n(t') = \sum_{i=1}^{I} \left( p_{i\text{no}} + 2\zeta_i \omega_i q_{i\text{no}} \right) h_i(t')
\]

\[
+ \sum_{i=1}^{I} q_{i\text{no}} \dot{h}_i(t')
\]

\[
+ \sum_{i=1}^{I} \int_{0}^{t'} Q_i(\tau - t_{\text{no}}) h_i(t' - \tau) d\tau.
\]

The ensemble average of \( N \) such observed results is

\[
U_N(t') = \frac{1}{N} \sum_{n=1}^{N} \sum_{i=1}^{I} U_n(t')
\]

\[
= \frac{1}{N} \sum_{n=1}^{N} \sum_{i=1}^{I} \left( p_{i\text{no}} + 2\zeta_i \omega_i q_{i\text{no}} \right) h_i(t')
\]

\[
+ \frac{1}{N} \sum_{n=1}^{N} \sum_{i=1}^{I} q_{i\text{no}} \dot{h}_i(t')
\]

\[
+ \frac{1}{N} \sum_{n=1}^{N} \sum_{i=1}^{I} \int_{0}^{t'} Q_i(\tau - t_{\text{no}}) h_i(t' - \tau) d\tau
\]

\[
= \sum_{i=1}^{I} h_i(t') \left[ \frac{1}{N} \sum_{n=1}^{N} p_{i\text{no}} \right]
\]

\[
+ \sum_{i=1}^{I} 2\zeta_i \omega_i h_i(t') \left[ \frac{1}{N} \sum_{n=1}^{N} q_{i\text{no}} \right]
\]

\[
+ \sum_{i=1}^{I} \dot{h}_i(t') \left[ \frac{1}{N} \sum_{n=1}^{N} q_{i\text{no}} \right]
\]

\[
+ \frac{1}{N} \sum_{i=1}^{I} \sum_{n=1}^{N} \int_{0}^{t'} Q_i(\tau - t_{\text{no}}) h_i(t' - \tau) d\tau.
\]
The quantities \( \frac{1}{N} \sum_{n=1}^{N} p_{1n} \) and \( \frac{1}{N} \sum_{n=1}^{N} q_{1n} \) are the average (over \( N \) observations) initial modal velocity and displacement, \( p_{10} \) and \( q_{10} \), respectively. We may, therefore, regard the ensemble average of the response functions as being of two parts. The first part has a deterministic functional form, and its magnitude is established by \( p_{10} \) and \( q_{10} \). We shall call this part the "signal", and represent it by

\[
S_N(t') = \sum_{i=1}^{I} [(p_{10} + 2\tau_{1i} \omega q_{10})h_{1}(t') + q_{10}h_{1}(t')]. 
\]

(4)

The second part, the last term in Equation (3), is the system response to the generalized forces, and in our discussions below, it will be called the "noise", represented by \( \gamma_N(t') \). It is the ensemble average of forced responses and its characteristics are dependent on the characteristics of the generalized forces \( Q_i(t) \). By interchanging the order of summation and integration operations, the noise term in Equation (3) may be re-written in the following form:

\[
\gamma_N(t') = \frac{1}{N} \sum_{i=1}^{I} \int_{0}^{t'} h_{1}(t' - \tau) \left[ \sum_{n=1}^{N} Q_{i}(\tau - t_{no}) \right] d\tau 
\]

Shorthand notations

\[
Q_{iN}(\tau) = \sum_{n=1}^{N} Q_{i}(\tau - t_{no}), \quad \text{and} 
\]

\[
\gamma_{iN}(t') = \int_{0}^{t'} h_{1}(t' - \tau)Q_{iN}(\tau) d\tau. 
\]

will be used.
For a given set of \( Q_i \), the noise term may be evaluated. Since \( Q_i(t) \) may be related to one another, it is necessary to split each generalized force into unrelated components \( Q_i'(t) \) and \( Q_{ij}''(t) \) as follows:

\[
Q_i(t) = Q_i'(t) + \sum_{j=1}^{J} R_{ij} Q_j''(t), \text{ for each } i,
\]

where coefficients \( R_{ij} \) control which and how the generalized forces are related.

We consider first the simple case defined by

\[
R_{ij} = 0
\]

for all combinations of \( i \) and \( j \), and where each \( Q_i'(t) \) is an independent and stationary random white noise. Then the expected squared value of the noise term as a function of \( t' \) in each mode may be evaluated by the technique outlined in Section 6.2, Reference 10, and is as follows:

\[
\gamma_{1N}(t') = N \bar{Q}_i^2 \int_{0}^{t'} h_i^2(t' - \tau) d\tau,
\]

where \( \bar{Q}_i^2 \) is the mean-squared value of the generalized force \( Q_i(t) \).

The expected value of \( \gamma_N^2(t') \) is, therefore,

\[
\gamma_N^2(t') = \frac{1}{N} \sum_{i=1}^{I} \bar{Q}_i^2 \int_{0}^{t'} h_i^2(t' - \tau) d\tau.
\]

Cross products containing different indices do not appear because of the assumed statistical independences among the various generalized forces. Each integral on the right-hand side of Equation (6) can be evaluated:
\[
\int_0^{t'} h_i^2(t' - \tau)d\tau = \int_0^{t'} e^{-2\zeta_1 \omega_1(t' - \tau)} \sin^2[(\omega_1(t' - \tau)]d\tau
\]

\[
= \frac{1}{4\zeta_1 \omega_1} \left[ 1 - \zeta_1^2 e^{-2\zeta_1 \omega_1 t'} \right] \left( 1 - \zeta_1^2 \cos 2\omega_1 t' + \zeta_1 (1 - \zeta_1^2) \frac{1}{2} \sin 2\omega_1 t' \right)
\]

where \( \omega_1 = (1 - \zeta_1^2) \omega_1 \).

For small values of \( \zeta_1 \), the above equation may be replaced by the approximation:

\[
\int_0^{t'} h_i^2(t' - \tau)d\tau \approx \frac{1}{4\zeta_1 \omega_1} (1 - e^{-2\zeta_1 \omega_1 t'}). \tag{7}
\]

Using Expression (7) in Equation (6) we obtain

\[
\bar{\gamma}_N(t') = \frac{1}{N} \sum_{i=1}^{N} \frac{1}{2} \int_0^{t'} Q_i^2(1 - e^{-2\zeta_1 \omega_1 t'})/(4\zeta_1 \omega_1). \tag{8}
\]

The last equation may be cleared of the generalized forces explicitly by noting that the mean-squared response for each mode is

\[
\bar{q}_i^2 = \lim_{t \to \infty} q_i^2(t) = Q_i^2/4\zeta_1 \omega_1.
\]

Therefore,

\[
\bar{\gamma}_N(t') \approx \frac{1}{N} \sum_{i=1}^{N} \frac{1}{2} \int_0^{t'} q_i^2(1 - e^{-2\zeta_1 \omega_1 t'})/(4\zeta_1 \omega_1), \tag{8}
\]

and \( \bar{\gamma}_N = \lim_{t \to \infty} \bar{\gamma}_N(t') \approx \frac{1}{N} \sum_{i=1}^{N} \frac{1}{2} \bar{q}_i^2 \).
On account of the assumed statistical independency of the generalized forces, the modal response components are also independent of one another. The mean-squared value of the measured response is, consequently, the sum of the mean-squared modal responses:

\[ \overline{U^2} = \sum_{i=1}^{I} \overline{q_i^2}. \]

So that

\[ \overline{\gamma_N^2} = \frac{1}{N} \overline{U^2}. \] (9)

If the generalized forces are not completely independent of one another as we have assumed in the first example, the general expression of Equation (5) should be used. Instead of Equation (6), a more complex expression will be obtained for \( \overline{\gamma_N^2(t')} \). The added complexity, however, is only bookkeeping in nature and presents no fundamental difficulties. We will demonstrate, via a second example, that the same estimate on the noise term is still valid when the generalized forces are related to one another.

Let us restrict our attention to a two-mode system (i.e., \( I = 2 \)), with generalized forces

\[ Q_1 = Q''_1 + Q''_2, \]

and \[ Q_2 = Q''_2. \]

In other words, we set

\[ Q'_1(t) = Q'_2(t) = 0, \]

\[ R_{11} = R_{12} = R_{22} = 1, \]
and \( R_{21} = 0 \), in Equation (5) for \( I = 2 \). The noise term in Equation (3) is in this case

\[
\gamma_N(t') = \frac{1}{N} \int_0^{t'} h_1(t' - \tau) \left[ \sum_{n=1}^{N} Q_1''(\tau - t_{no}) \right] d\tau + \frac{1}{N} \int_0^{t'} \left[ h_1(t' - \tau) + h_2(t' - \tau) \right] \left[ \sum_{n=1}^{N} Q_2''(\tau - t_{no}) \right] d\tau.
\]

Since \( Q_1''(t) \) and \( Q_2''(t) \) are statistically independent,

\[
\overline{\gamma_N^2(t')} = \frac{1}{N} \frac{(Q_1'')^2}{(Q_1'')^2} \int_0^{t'} \overline{h_1^2(t' - \tau)} d\tau + \frac{1}{N} \frac{(Q_2'')^2}{(Q_2'')^2} \int_0^{t'} \overline{[h_1(t' - \tau) + h_2(t' - \tau)]^2} d\tau
\]

\[
= \frac{1}{N} \left[ (Q_1'')^2 + (Q_2'')^2 \right] \int_0^{t'} \overline{h_1^2(t' - \tau)} d\tau + \frac{1}{N} (Q_2'')^2 \int_0^{t'} \overline{h_2^2(t' - \tau)} d\tau + \frac{2}{N} (Q_2'')^2 \int_0^{t'} \overline{[h_1(t' - \tau)h_2(t' - \tau)]} d\tau.
\]

where \( (Q_1'')^2 \) and \( (Q_2'')^2 \) are the mean-squared values of \( Q_1''(t) \) and \( Q_2''(t) \), respectively. We know from the first example that

\[
\left[ (Q_1'')^2 + (Q_2'')^2 \right] \int_0^{t'} \overline{h_1^2(t' - \tau)} d\tau \approx \overline{q_1^2(1 - e^{-2\xi_1\omega_1 t'})}.
\]

and \( \overline{Q_2''} \int_0^{t'} \overline{h_2^2(t' - \tau)} d\tau \approx \overline{q_2^2(1 - e^{-2\xi_2\omega_2 t'})}.
\]

The last integral in Equation (10) is the only one which we have not seen until now. Upon carrying out the indicated integration, however, we find its magnitude to be of the order \( \zeta \), the greater of \( \xi_1 \) and \( \xi_2 \). For a
lightly damped system, therefore, Equations (8) and (9) can still be used to estimate the mean-squared value of the noise term.

We now summarize results as follows: The ensemble average of N sample series of the total response function is the sum of a signal term, \( S_N(t') \), and a noise term \( \gamma_N(t') \):

\[
U_N(t') = S_N(t') + \gamma_N(t'),
\]

where the form of \( S_N(t') \) is deterministic, and its magnitude is controlled by the average values of the modal responses and their derivatives at the beginning of all samples \( t=t_{no}, n=1, 2, \ldots N \); and where \( \gamma_N(t') \) has a mean-squared value which grows from a near-zero value at \( t'=0 \), to one Nth of the mean-squared value of the measured response at large \( t' \). A pictorial representation of \( U_N(t') \) is shown in Figure 1 for a one-mode system.

If the starting times \( t_{no} \) of all sample series are selected on the basis of the total response, its derivative, or a combination of both, in such a manner that \( S_N(t') \) does not continually diminish with increasing \( N \), i.e., if

\[
\lim_{N \to \infty} U_N(t') = S_\infty(t') \neq 0 \text{ for all } t'.
\]

Since \( S_\infty(t') \) contains parameters required to specify the system, it will be called the Ideal Signature of the system.

A Randomdec Signature (of N averages), on the other hand, is the truncated function:

\[
U_N(t') = S_N(t') + \gamma_N(t'), \quad t' \leq T, \text{ a finite "signature length"},
\]

where \( S_N(t') \) is defined by Equation (4).
The selection of starting times \( t_{no} \) is called "triggering". A proper triggering method is required to guarantee the convergence of the ensemble average to a usable\(^*\) Randomdec Signature in a reasonable\(^**\) time. Two examples of triggering methods are shown in Figure 2. With the Level Triggering method, \( t_{no} \) = every time response signal crosses a preselected level, regardless of the sign of the slope. With the Zero-Crossing Triggering method, \( t_{no} \) = every time response crosses zero with a plus slope. A third method which is not shown in Figure 2 is the Every-Point Triggering method where \( t_{no} \) = every sampling time. Each triggering method will lead to a Randomdec Signature with a different apparent form. For a linear system, they all contain the same information so far as system dynamic properties are concerned. This is because

\[
h_i(t') = e^{-\zeta_i \omega_i t'} \sin \omega_i t', \quad \text{and} \\
h_i(t') = -e^{-\zeta_i \omega_i t'} (\zeta_i \omega_i \sin \omega_i t' - \omega_i \cos \omega_i t')
\]

so that \( U_N(t') \) may be written in the following general form for all Randomdec Signatures regardless of the trigger methods used, see Equations 3, 4 and 5:

\[
U_N(t') = \sum_{i=1}^{I} e^{-\zeta_i \omega_i t'} (B_i \sin \omega_i t' + D_i \cos \omega_i t') + Y_N(t'). \tag{12}
\]

Different triggering methods merely give us different combinations of \( B_i \) and \( D_i \).

\(^*\) The usefulness of a Randomdec Signature depends on the method employed to analyze it, and is one of the main objectives of our study. More discussions will be found in Section 6.

\(^**\) Our main concern is the minimum amount of data required to obtain a useful Randomdec Signature. Time is most appropriately measured in terms of the period of the lowest frequency content of interest.
Let us turn our attention to the forcing function on an aeroelastic structure at subcritical velocities. We will continue to assume that the structural properties are invariant with respect to time, and that the forcing function is stationary. In other words, the following analysis is applicable when the velocity is constant and below the flutter velocity. Let us consider the state of affairs in a typical mode. The generalized force may be split up into three basic parts: the first part, \( Q_i(t) \), is independent of modal responses and is stationary, wideband and random; a second part which is dependent on the modal response, and can be further divided into aerodynamic inertia, damping and stiffness components; and a third part which is dependent on the response history. For the \( i \)th mode, let

\[
\begin{align*}
m'_i & = \text{generalized mass of the structure in still air,} \\
m''_i & = \text{generalized mass due to aerodynamics,} \\
m_i & = m'_i + m''_i, \\
c'_i & = \text{modal damping coefficient of the structure in still air,} \\
c''_i & = \text{modal damping coefficient due to aerodynamics,} \\
c_i & = c'_i + c''_i, \\
k'_i & = \text{generalized stiffness of the structure in still air,} \\
k''_i & = \text{generalized stiffness due to aerodynamics,} \\
k_i & = k'_i + k''_i, \\
q_{i1}(0) & = \text{modal initial displacement, and}
\end{align*}
\]
\[ q_i(0) = \text{modal initial velocity}. \]

The equation of motion for each mode of the aeroelastic systems can be expressed most readily with the help of the Laplace Transform and can be written as

\[
[m_{i} s^2 + c_{i} s + k_{i} + A_i(s)]q_i(s) = m_{i}q_i(s) + m_{i}q_i(0)s + m_{i}q_i'(0) + c_{i}q_i(0)
\]

where \( s \) is the transform variable, and

\[ q_i(s) = L\{q_i(t)\}, \]

\[ Q_i(s) = L\{Q_i(t)\}. \]

The term \( A_i(s) \) is a general representation of the history-dependent components of the unsteady aerodynamic forces. The simplest version of \( A_i(s) \) is a first-order lag:

\[
A_i(s) = \frac{a_i}{T_i s + 1}
\]

where \( a_i \) is the quasi-steady aerodynamic force and \( T_i \) is the associated time constant.

The following solution of the modal response function is obtained from Equation (13):

\[
q_i(s) = \frac{[m_i q_i(s) + m_i q_i(0)s + m_i q_i'(0) + c_i q_i(0)](T_i s + 1)}{(m_i s^2 + c_i s + k_i)(T_i s + 1) + a_i}
\]  

The denominator can be expanded, factored and put into the form

\[ m_i(s^2 + 2c_i \omega_i^2 s + \omega_i^4)(T_i s + b_i), \]

*The same symbol will be used for the variable and its Laplace Transform. The independent variables will always be used to distinguish them. However, when a symbol is used to represent an initial condition, the "o" in parentheses indicates that the quantity in question is a constant (the value of the associated variable at \( t=0 \) or \( t'=0 \)).
with \( b_i, \omega_i', \) and \( \zeta_i' \) related to the original set of coefficients by the following expressions:

\[
b_i = 1 - 2(\zeta_i' \omega_i - \zeta_i' \omega_i) T_i, \tag{15}
\]

\[
\omega_i'^2 = \omega_i^2(1 + a_i/k_i)/b_i, \quad \text{and} \quad \tag{16}
\]

\[
2\zeta_i' \omega_i' = [2\zeta_i' \omega_i - (\omega_i'^2 - \omega_i^2) T_i]/b_i. \tag{17}
\]

The modal response can now be written as

\[
q_i(s) = \frac{Q_i(s) + q_i(o)s + q_i(o) + 2\zeta_i \omega_i' q_i(o)}{s^2 + 2\zeta_i' \omega_i^2 s + \omega_i'^2} \times \frac{T_i s + 1}{T_i s + b_i}. \tag{18}
\]

Let

\[
L^{-1}\left\{\frac{1}{s^2 + 2\zeta_i' \omega_i^2 s + \omega_i'^2}\right\} = h''_i(t), \tag{19}
\]

\[
L^{-1}\left\{\frac{T_i s + 1}{T_i s + b_i}\right\} = f_i(t), \quad \text{and} \tag{20}
\]

\[
h''_i(t) * f_i(t) = h'_i(t). \tag{21}
\]

The time-domain solution for the stationary subcritical response function can then be written in terms of \( h'_i(t) \), the initial conditions, and the motion-independent forcing function as follows:

\[
q_i(t) = q_i(o) h'_i(t) + [\dot{q}_i(o) + 2\zeta_i' \omega_i q_i(o)] h'_i(t) \tag{22}
\]

\[+ \int_0^t Q_i(\tau) h'_i(t - \tau) d\tau. \]
As \((a_i/k_i)\) and \((T_i\omega_i')\) approach zero,

\[ b_i \rightarrow 1, \]
\[ \omega_i' \rightarrow \omega_i, \]

and \(2\zeta_i^2 \omega_i' + 2\zeta_i \omega_i'\),

so that \(h_i''(t) \rightarrow h_i(t)\) and \(f_i(t)\) becomes a Dirac delta. The solution consequently approaches that for a purely mechanical system. As \((a_i/k_i)\) and \((T_i\omega_i')\) deviate from zero, the impulse response function \(h_i'(t)\) must be evaluated by the convolution between \(h_i''(t)\) and \(f_i(t)\). The corresponding Randomdec Signature is

\[ U_N(t') = \sum_{i=1}^{I} \left( (p_{i0} + 2\zeta_i \omega_i q_{i0}) h_i'(t') + q_{i0} h_i'(t') \right) \]  

\[ + \gamma_N(t'). \]

We see that for an aeroelastic system at a subcritical velocity, the Random Decrement procedure will produce a Signature which differs from that of a purely mechanical system, only in the difference between \(h_i'(t)\) and \(h_i(t)\). In representing the solution by Equations (15)-(22), the above mathematical differences between solutions of the two types of systems are more easily related to the physical differences.

In any case, we see that the addition of the lag term does not increase the number of independent initial conditions beyond two per mode.
Finally, we remark that by (1) setting $l=2$, $a_1=a_2$, $T_1=T_2$, and $Q_1(t)=Q_2(t)$, (2) linearly combining $q_1(t)$ and $q_2(t)$, and (3) disregarding all initial conditions, we will be able to simulate with Equation (14) the special case used by Houbolt (Equation (49), Reference 11).
Section 4
SYSTEM IDENTIFICATION VIA SIGNATURE CURVE FITTING

The Randomdec Signature is a truncated approximation of the characteristic response function (transient response function due to initial conditions) of the system in question. It contains information on the system characteristics. From subcritical flutter testing point of view, it is important to be able to determine the natural frequencies and damping ratios from the Signature. The method selected to accomplish this objective is described below.

Our efforts are concentrated on a two-mode aeroelastic system which is characterized by the ten parameters $\omega_1', \omega_2', \zeta_1', \zeta_2', m_1, m_2, a_1, a_2, T_1$ and $T_2$. The generalized masses $m_1$ and $m_2$ cannot be determined from Randomdec Signatures because they appear explicitly only in forced response solutions. Fortunately their determination is not needed in subcritical testing as they are only multiplying constants for the responses and do not directly relate to stability.

To completely specify a Randomdec Signature for a two-mode system, four additional parameters corresponding to the initial amplitudes and velocities in the Signature as governed by the triggering method are required. The data acquisition equipment and process is assumed to introduce yet another three parameters: the sampling period, $\delta$ and two filter time constants, $T_b$ and $T_c$. The objective of the curve-fit procedure is to determine the best estimates for the four most important system parameters $\omega_1', \omega_2', \zeta_1'$, and $\zeta_2'$ in the presence of all others, from an imperfect Signature in which not all effects of the forcing function have been averaged out. We will try to curve-fit the Signature, $U_N(t')$, by
\[ y(t') = \sum_{i=1}^{I} e^{-\zeta'_i \omega'_i t'} (B_i \sin(\omega'_i t') + D_i \cos(\omega'_i t')) \]

with \( \omega'_1 = (1 - \omega'_1^2) \omega'_1 \).

In approaching the problem this way, we are assuming that

(a) In a real test situation, the response transducer and signal conditioning equipment and process are reasonably good, so that the cut-off frequencies \( \omega_b \) and \( \omega_c \) corresponding to \( T_b \) and \( T_c \), respectively, are very high in comparison with \( \omega'_1 \) and \( \omega'_2 \).

(b) The effects of \( a_1 \) and \( T_1 \) are primarily on the natural frequencies and damping ratios, and by using \( \omega'_1 \) and \( \zeta'_1 \) in \( h'_1(t) \), most of the differences between the impulse response functions of the aeroelastic system and a purely mechanical system has already been accounted for. Putting it in another way, the convolution indicated by Equation (21) is assumed to produce only small differences between \( h''_1(t) \) and \( h'_1(t) \). (The consequent error can be estimated by the difference between \( f_1(t) \) and the Dirac Delta.)

In view of Equation (18), our approach is valid because flutter is reached when \( \zeta'_1 \) or \( \zeta'_2 \) (not when \( \zeta_1 \) or \( \zeta_2 \)) become non-positive.

We begin the curve-fit procedure by defining an error-measuring function \( E \). The most commonly used function for this purpose is the mean-squared error:

\[ E = \frac{1}{K} \sum_{k=1}^{K} (y_k - U_{N_k})^2, \]

In the case where \( U_N(t') \) is defined only at \( t' = k\delta \), \( k=1,2, \ldots, K \), (i.e., if sampled data are used), \( E \) is written as

\[ E = \frac{1}{K} \sum_{k=1}^{K} (y_k - U_{N_k})^2, \]
where \( y_k = y(k\delta) \),

and \( U_{Nk} = U_N(k\delta) \).

A more general approach is to introduce weighting and use

\[
E = \frac{1}{K} \sum_{k=1}^{K} [z(y_k) - z(U_{Nk})]^2. \tag{24a}
\]

Parameter values \( B_1, D_1, \omega_1' \) and \( \xi_1' \) which minimize \( E \) will be considered as the optimum approximations of the true parameters.\(^*\)

The method of minimization is based on the Gauss-Newton method (Reference 12) modified by Roman (Reference 13) and further modified during the course of this project. An initial estimate of parameter values is made. This estimate is upgraded by information based on the slopes of the error function \( E \) with respect to variation of each of the parameters. For purpose of the following discussion, it will be convenient to rename the parameters in accordance with the following:

\[
\begin{align*}
\alpha_1 &= B_1 \\
\alpha_2 &= \xi_1' \omega_1' \\
\alpha_3 &= \overline{\omega}_1' \\
\alpha_4 &= D_1 \\
\alpha_5 &= B_2 \\
\alpha_6 &= \xi_2' \omega_2' \\
\alpha_7 &= \overline{\omega}_2' \\
\text{and} \quad \alpha_8 &= D_2.
\end{align*}
\]

\(^*\)The parameters \( B_1 \) and \( D_1 \) are not system properties but have to be determined in the curve-fit process.
Let $\alpha_m^0$, $m=1,2,3,4,5,6,7$ and $8$ be an initial set of estimated values of $\alpha_m$, and let

$$C_k^\ell = (dz/dy)_k$$

be the indicated derivatives evaluated at $t'=k\delta$ during the $\ell$th iteration. In addition, we calculate

$$B_{mk}^\ell = C_k^\ell (\partial y/\partial \alpha_m)_k^\ell,$$

$$\phi_{mgk}^\ell = b_{mk}^\ell b_{gk}^\ell,$$

$$\psi_{mg}^\ell = \sum_{k=1}^K \phi_{mgk}^\ell,$$

$$r_{gk}^\ell = \beta_{gk}^\ell [z(y_k^\ell) - z(\Pi_{mk}^\ell)],$$

$$R_{g}^\ell = \sum_{k=1}^K r_{gk}^\ell.$$

$$[d_m^\ell] = - [\psi_{mg}]^{-1} [R_{g}^\ell],$$

and $$\varepsilon_m^\ell = d_m^\ell / \alpha_m^\ell.$$

In the Gauss-Newton method, if

$$|\varepsilon_m^\ell| > \varepsilon = \text{a predetermined band for all } m,$$

improved, $(\ell + 1)^{th}$ parameters are obtained by

$$d_m^{\ell + 1} = \alpha_m^\ell + d_m^\ell.$$
modified as follows:

\[ a_m^{(\ell + 1)}_m, v = a_m^\ell + \frac{1}{2} \rho v. \]  

(26)

Initially, \( v = 1 \), and \( \rho_1 = 1 \) is used.

If the resulting error function

\[ E^{(\ell + 1)} > E^\ell, \]

the step size is halved, i.e.,

\[ \rho_2 = 0.5, \]

and the error function is checked again. The process continues \( (v = 3, 4, ...) \) until

\[ E^{(\ell + 1)} < E^\ell. \]

The resulting set of new estimates \( a_m^{(\ell + 1)} \) will then be used to repeat the entire process until the condition

\[ |a_m^{(\ell + 1)} - a_m^\ell| < \varepsilon \]

(27)

is satisfied for all \( m \).

The curve-fit procedure is outlined in Figure 3. In addition to the above logic, the computer program is implemented to conduct both a four-parameter (one-mode) and an eight-parameter (two-mode) fit each time. For the one-mode case, the initial estimate for (a) the natural frequency is obtained by counting the number of samples per each "period" of the Signature; (b) the amplitude is the magnitude of maximum peak; (c) the damping is set to zero. For the two mode case, the above set of initial estimates are used for one of the modes, and the frequency and
amplitude results of the one-mode curve-fit are used as initial estimates for the other mode. Damping is again set to zero.
Section 5

SUBCRITICAL AEROELASTIC RESPONSE SIMULATION

The simulation of desired response signals of an aeroelastic system may be achieved in the time domain by direct numerical integration of the governing differential equations, or by convolving, again in the time domain, the forcing function with the impulse response function of the system. The simulation of desired response signals may also be achieved by complex multiplication of the forcing function with the frequency response function of the system in the frequency domain. The last approach was chosen in this study because it leads to the implementation of a more general computer program which can be easily altered to simulate different types of systems.

The velocity response of an aeroelastic structure in a subcritical condition will be simulated. Velocity signal is chosen for simulation because in practice it offers an optimum balance between low- and high-frequency signal magnitudes under normal test environments.

From Equation (14) the modal response velocity is

\[ p_i(s) = s q_i(s) - q_i(o) \]

\[ = \frac{[s Q_i(s) + s q_i(o) - \omega_i^2 q_i(o)](T_i s + 1) - a_i q_i(o)/m_i}{s^2 + 2 \zeta_i \omega_i s + \omega_i^2}(T_i s + 1) + a_i/m_i. \]  \hspace{1cm} (28)

The Fourier transform for the modal velocity is obtained when \( s \) is replaced by \( \pi \omega(\eta = \sqrt{-1}, -\infty < \omega < \infty) \) in Equation (28):

*Including initial conditions which may be considered as special forcing functions.
\[ p_i(\omega) = \frac{[\eta_i q_i(\omega)/\omega_i^2 + \eta_i q_i'(\omega)/\omega_i^2 - q_i(\omega)](\eta_i T_i + 1) - a_i q_i(\omega)/(m_i \omega_i^2)}{(1 - \omega^2/\omega_i^2 + 2 \eta_i \omega/\omega_i)(\eta_i T_i + 1) - a_i/(m_i \omega_i^2)} \]  

(25)

The measured total velocity signal has a Fourier transform

\[ e(\omega) = \frac{1}{\sum_{i=1}^{1} p_i(\omega)}. \]  

(26)

Of course, when \( e(\omega) \) is inverse transformed, the resulting time series simulates the velocity response signal.

The computer program developed during this investigation (Appendices A & B) uses an existing fast Fourier transform (FFT) subroutine to carry out all required forward and inverse transformations. The following restrictions are imposed on the simulation by the FFT*:

(a) Only equally spaced, sampled response data, in segments of finite lengths can be simulated, since the FFT is a finite discrete Fourier transform procedure.

(b) The transform of a sampled time series is computed for a finite number of equally spaced frequencies only. Both bandwidth and frequency resolution are limited.

(c) The number of data points in the time domain is the same as the number of complex frequency components computed in the frequency domain.

Based on procedural requirements of the Random Decrement method, on desired frequency resolution and bandwidth, and on computer core size limitations, simulated response signals are generated in 2,048-point

*Implications of, and solutions to overcome, these restrictions are discussed subsequently.
segments. Displacement and velocity components for each mode at the end of a segment are computed and used as initial conditions for the following segment.

The simulation procedure is outlined in the simplified flow diagram* of Figure 4. Generalized forces are created in the sampled time domain first. For each mode, the force can contain a random component and two deterministic components. Random components for both modes are generated simultaneously from two independent sequences of Gaussianly distributed random numbers, \( F_{jk} \), in accordance with the following mixing formula:

\[
Q_{ik} = Q_i(\kappa \delta) = \sum_{j=1}^{2} R_{ij} F_{jk}
\]

where \( i=1,2 \) and \( \kappa=1,2, \ldots, 2,048 \) for each segment of simulation, \( \delta \) is the sampling period, and \( \kappa \delta \) are the times at which the simulated sampling takes place. Values of the mixing coefficients, \( R_{ij} \), are selected by the desired amount of "correlation" between the two generalized forces. Sequences \( F_{1k} \) and \( F_{2k} \) have zero means and unity standard deviations.

Deterministic generalized force components include a periodic part, \( P_{ik} \) and a "box-car" part \( BC_{ik} \). The amplitudes, frequencies and phase displacements of \( P_{ik} \), as well as the rise- and fall-times of \( BC_{ik} \) are user selected via input data. The total generalized force for each mode is

\[
\overline{Q}_{ik} = Q_{ik} + P_{ik} + BC_{ik}, \ i=1,2.
\]

For each mode the above array is transformed into the discrete frequency domain by the FFT. The transform operates on an array of 4,096.

*Detailed flow diagrams of all computer programs are found in Appendix A.
real points. The first half of the array contains $\overline{q}_\nu$; the second array are filled with zeroes*. After the transformation, only the first 2,048 complex points in the frequency domain are used. They are combined with terms containing initial conditions in accordance with Equation (29), and complex-multiplied with modal and filter frequency response functions. The real part of the product array of 2,048 complex points is extended symmetrically about the frequency origin, the imaginary part antisymmetrically. The resulting array of 4,096 complex points is then inverse transformed into the time domain. There will be 4,096 real points, of which only the first 2,048 are correct data simulating the sampled, filtered modal velocity response.

The process is repeated for the other mode. Modal responses are then summed point by point to obtain the desired total response signal. All three series are kept for subsequent Random Decrement processing.

The following are the two basic relationships among sampling period, $\delta$ (seconds), frequency resolution, $\Delta f$ (Hertz), and bandwidth, $f_o$ (Hertz):

$$\delta(\Delta f) = (1/4096)$$

$$f_o = 4096(\Delta f)$$

In addition, at a frequency $2,048(\Delta f)$, the number of samples per cycle is exactly two.

On account of the truncation of the frequency response function, the frequency resolutions should be set in such a manner that natural frequencies of the simulated system is less than $f_o/2$. Similarly, modal damping factors causing significant truncation errors in the time

*A standard preliminary procedure for subsequent convolution via frequency domain multiplication, see Reference 14.
domain (on the impulse response functions) should be avoided.

In the computer program, Random Decrement trigger points, $t_{no}$, are established by inspecting the total filtered response signals. The actual ensemble averaging processes are performed on individual modal components as well as the total response signal. This represents a luxury not enjoyed in real test conditions where modal components are not individually available. The added step is used in the simulation process to provide study data on how ensemble samples of individual responses converge.
Section 6
PARAMETRIC STUDIES

The digital computer programs were used to conduct a number of numerical experiments to establish the feasibility and performance characteristics of the Random Decrement, the Signature curve-fit and the combined processes.

6.1 FEASIBILITY OF RANDOM DECREMENT

The feasibility of applying the Random Decrement method to obtain an approximate characteristic response function was demonstrated for a two-mode system with and without aerodynamic lag forces. The two test cases were designed to accomplish the goal without relying on the Signature curve-fit procedure.

In the first test case, the aerodynamic lag forces were set to zero; the natural frequencies of the two modes are 5.908 Hz and 6.519 Hz (i.e., a difference of 9.836%); and the modal damping factors are both 0.020 (of critical). Referring to Equations (29) and (30), this test case is specified by the following set of parameters:

\[
\Delta f = 0.02546 \text{ Hz} \\
\dot{q}_1(o) = \dot{q}_2(o) = q_2(o) = 0 \\
q_1(o) = 1.0 \text{ in.} \\
\omega_1 = 37.12 \text{ rad/sec (5.098 Hz)} \\
\omega_2 = 40.96 \text{ rad/sec (6.519 Hz)} \\
\zeta_1 = 0.020 \\
\zeta_2 = 0.020
\]
\[ m_1 = 1.00 \quad \text{lb-sec}^2/\text{in} \]
\[ m_2 = 1.00 \quad \text{lb-sec}^2/\text{in} \]
\[ R_{11} = 1.00 \quad \text{lb/(lb-sec}^2/\text{in}) \]
\[ R_{12} = R_{21} = 0 \]
\[ R_{22} = 1.00 \quad \text{lb/(lb-sec}^2/\text{in}) \]
\[ a_1 = a_2 = 0 \]
\[ T_1 = T_2 = T_b = T_c = 0. \]

Zero-crossing and every-point trigger methods were used. Results are summarized in the series of "log peak plots"* (LPP's) in Figures 5 (zero-crossing triggering) and 6 (every-point triggering). The first series of LPP's (Figures 5-a through 5-f) show the convergence of the Signature of the 5.908-Hz Model, the second series (Figures 5-g through 5-l) the 6.519-Hz mode, and the last series (Figures 5-m through 5-q) the total system. The number of ensembles used are indicated on the figures. These results readily demonstrate that triggering on the total response signal does indeed lead to a system Signature which corresponds to the sum of two individual Modal Signatures. They also show the left-to-right convergence trend characterizing the Random Decrement process, as hinted in earlier discussions. The ideal system Signature is shown in Figure 5-r.

Figures 6-a and 6-b are interim Modal Signatures obtained by the every-point trigger method. The amount of response data used to obtain these interim Signatures are the same as those used to obtain Signatures shown in Figures 5-d and 5-j, respectively. A comparison of

*The computer program finds both the positive and negative peaks in a Signature; it computes \( \log(\text{Positive Peak Values}) \), and plots the results as Peak Nos. 0, 2, 4, ...; and it computes \( \log(-\text{Negative Peak Values}) \), and plots the results on the same graph as Peak Nos. 1, 3, 5, ... Damping for a single mode can be determined easily from this plot of the Signature peaks by the slope of the curve. For reference, the straight line connection points (0,0) and (77,-42dB) represents a modal damping of 0.02. Figures 5 and 6 also illustrate the print-plot capability developed for the Univac 1108.
these results indicates that the every-point trigger method requires just as much data to achieve a given Signature accuracy. This method was, consequently, deleted from the computer program.

The following parameter set defines the second test case in which modal aerodynamic lag forces are present:

\[ \Delta f = 0.0200 \text{ Hz} \]

\[ q_1(0) = q_2(0) = q_1'(0) = q_2'(0) = 0 \]

\[ \omega_1 = 67.25 \text{ rad/sec} \]

\[ \omega_2 = 108.23 \text{ rad/sec} \]

\[ \zeta_1 = 0.03175 \]

\[ \zeta_2 = 0.00588 \]

\[ m_1 = 0.0260 \text{ lb-sec}^2/\text{in} \]

\[ m_2 = 0.0520 \text{ lb-sec}^2/\text{in} \]

\[ R_{11} = 1.920 \text{ lb/(lb-sec}^2/\text{in}) \]

\[ R_{12} = 0.385 \text{ lb/(lb-sec}^2/\text{in}) \]

\[ R_{21} = 0.960 \text{ lb/(lb-sec}^2/\text{in}) \]

\[ R_{22} = 0.000 \text{ lb/(lb-sec}^2/\text{in}) \]

\[ a_1 = 24.69 \text{ lb/in} \]

\[ a_2 = -93.33 \text{ lb/in} \]

\[ T_1 = 3.721 \times 10^{-3} \text{ sec} \]

\[ T_2 = 3.721 \times 10^{-3} \text{ sec} \]

\[ T_b = T_c = 0.000. \]

The case was designed to yield the following aeroelastic system frequencies and damping

\[ \omega_1' = 73.54 \text{ rad/sec} \]

\[ \omega_2' = 101.25 \text{ rad/sec} \]

\[ \zeta_1' = 0.00659 \]

\[ \zeta_2' = 0.0338. \]
Simulated responses are shown for this test case in Figure 7. The zero-crossing trigger method was used to obtain the set of Signatures in Figure 8. Convergence of the Signatures indicated again the feasibility of the Random Decrement method.*

6.2 FEASIBILITY OF CURVE-FIT

The feasibility of the curve-fit procedure as a method to identify system dynamic characteristics was next established. As pointed out earlier in Section 4, the selected study approach of this project is to apply a parameter identification technique which assumes that the Signature is the sum of a free response and a small-magnitude forced response of a two-degree-of-freedom system without aerodynamic forces. Therefore, checkout of the procedure can be logically divided into two steps. The first step is to verify that the procedure is accurate if the system to be identified is indeed a purely mechanical one. The second step is to determine whether force-fitting the Signature of a system with aerodynamic forces by free vibration solutions of a system without such terms would lead to useful answers for flutter prediction purposes.

Step 1 was accomplished by adding wideband random noises of various intensities to an ideal Signature to test the capability of the curve-fit procedure. The two components of the ideal Signature have equal initial amplitudes, and

\[
\omega_2 = 2 \omega_1 \\
\zeta_1 = 0.018 \\
\zeta_2 = 0.035
\]

*Detailed analyses of results will be found in Section 6.3.
The noise component has a Gaussian distribution, zero mean, and RMS magnitudes of up to 18% of the initial amplitude of the Signature. One hundred sampled points were used, representing approximately 8 cycles of the Signature at the average frequency of the two modes. Near-perfect (within 1%) identification of all properties was accomplished.

The number of iterations required to determine the least-squares curve-fit ranged from 7 to 20. The computer program was consequently modified to limit the number of iterations to prevent accidental high-cost computer runs. In its final form, the program will stop searching for the best fit if after 20 iterations, the convergence criterion of Equation (27) is still not satisfied.

It was also determined during this stage of checkout that as few as four sample points per cycle of the higher modal response frequency are sufficient for the curve-fit program to identify the correct system properties. This feature, together with its ability to determine individual modal damping values when the natural frequencies are very close* (and, consequently, with the total Signature displaying the characteristic "beating" of Figures 5-m through 5-r) are among the principal advantages of the procedure. In all subsequent investigations a sampling rate corresponding to approximately six points per cycle of the average frequency was used.

Figure 9 is a typical Simulated Randomdec Signature presented to the curve-fit routine. Figure 10 is the curve which fits the Signature in Figure 9 in the least-squares sense. Figure 11 shows the convergence paths of a typical parameter and the mean-squared error function.

*This ability was verified via test cases to be described later.
6.3 FEASIBILITY OF THE COMBINED PROCEDURE

Subsequently, the feasibility of combining Random Decrement and curve-fit procedures was demonstrated by curve fitting a Randomdec Signature of suitable length* obtained for the test case on page 39. Zero-velocity properties, i.e., those of the mechanical system, are

\[
\begin{align*}
\omega_1 &= 67.25 \text{ rad/sec} \\
\omega_2 &= 108.23 \text{ rad/sec} \\
\zeta_1 &= 0.03175 \\
\zeta_2 &= 0.00588 \\
m_1 &= 0.0260 \text{ lb-sec}^2/\text{in} \\
m_2 &= 0.0520 \text{ lb-sec}^2/\text{in}
\end{align*}
\]

A lag time constant of \(3.721 \times 10^{-3}\) sec, or exactly one fourth of the natural period of the first mode, was assigned. The quasi-static aerodynamic forces are

\[
\begin{align*}
a_1 &= 24.69 \text{ lbs/in} \\
a_2 &= -93.33 \text{ lbs/in}
\end{align*}
\]

corresponding to

\[
\begin{align*}
a_1/k_1 &= a_1/m_1\omega_1^2 = 0.2100 \\
a_2/k_2 &= a_2/m_2\omega_2^2 = 0.1422
\end{align*}
\]

The selected characteristics for the aerodynamic forces will simulate conditions for a velocity close to flutter**. The resulting values of \(b_1\) and \(b_2\) are 1.012 and 0.979, respectively. The factors \((T_1s + 1)/(T_1s + b_1)\) in Equation (18) will, consequently, not change the form of the impulse response function of the system. Based on Equations (15), (16) and (17), the calculated natural frequency for the low-frequency mode will increase

---

*The effect of Signature length on curve-fit accuracy will be investigated in Section 6.4

**So far as damping values are concerned. The natural frequencies were deliberately kept separated by a significant amount to minimize the cost of the computer run.
from a zero-velocity value of 63.25 rad/sec to 73.54 rad/sec, while that for the other mode will decrease from 108.23 rad/sec to 101.25 rad/sec. The corresponding changes in damping are:

\[
\begin{align*}
\zeta_1 & = 0.03175 \quad \Rightarrow \quad \zeta_1' = 0.00659 \\
\zeta_2 & = 0.00588 \quad \Rightarrow \quad \zeta_2' = 0.0338
\end{align*}
\]

The zero-crossing trigger method was used to obtain the Randomdec Signatures. A Signature length of 50 samples was used. The Signatures are shown in Figure 8. The following is a summary of numerical results from the test run:

<table>
<thead>
<tr>
<th>No. of Ensembles</th>
<th>Freq &amp; Error, rad/sec</th>
<th>Damping and Error</th>
</tr>
</thead>
<tbody>
<tr>
<td>Averaged</td>
<td>( \omega_1 ) Error</td>
<td>( \omega_2 ) Error</td>
</tr>
<tr>
<td>234</td>
<td>73.48 (+0.06)</td>
<td>103.91 (+2.66)</td>
</tr>
<tr>
<td>461</td>
<td>73.54 (+0.00)</td>
<td>102.17 (+0.92)</td>
</tr>
<tr>
<td>914</td>
<td>73.61 (+0.07)</td>
<td>101.42 (+0.17)</td>
</tr>
<tr>
<td>1806</td>
<td>73.53 (-0.01)</td>
<td>101.62 (+0.37)</td>

</tr>
</tbody>
</table>

The exceptionally good agreement between the exact and numerically obtained results indicate that the influence on the aerodynamic forces is, indeed, primarily on the frequencies and damping values and that the impulse response function of the aeroelastic system can be accurately approximated by the use of those for two second-order modes. The results also indicate that, when applied properly, the combined process is truly a useful tool for flutter prediction with subcritical test data.

6.4 SIGNATURE LENGTH AND AVERAGING TIME

Effects of Signature length on accuracy are demonstrated via results of two series of tests described below. Problems to be expected in selecting

*Obtained with a CDC6600 version of the developed computer programs.
a suitable Signature length for curve-fitting for a system whose dynamic properties are totally unknown will be discussed in Section 6.5.

In the first test series, parameters are set up to specify a system which may be described as having separated natural frequencies (by ± 15% of the average frequency) and moderate damping (0.04 of critical for each mode). Case parameters are

\[
\begin{align*}
\Delta f &= 0.020 \quad \text{Hz} \\
q_1(0) &= q_2(0) = \dot{q}_1(0) = \dot{q}_2(0) = 0 \\
\omega_1 &= 73.91 \quad \text{rad/sec} \\
\omega_2 &= 99.55 \quad \text{rad/sec} \\
\zeta_1 &= 0.040 \\
\zeta_2 &= 0.040 \\
m_1 &= 0.0260 \quad \text{lb-sec}^2/\text{in} \\
m_2 &= 0.0520 \quad \text{lb-sec}^2/\text{in} \\
R_{11} &= 1.920 \quad \text{lb/}(\text{lb-sec}^2/\text{in}) \\
R_{12} &= 0.385 \quad \text{lb/}(\text{lb-sec}^2/\text{in}) \\
R_{21} &= 0.962 \quad \text{lb/}(\text{lb-sec}^2/\text{in}) \\
R_{22} &= 0.000 \\
T_1 &= T_2 = T_b = T_c = 0
\end{align*}
\]

Signature lengths of 12, 25, 37, 50, 75 and 100 samples were curve-fitted.

For reference, the number of samples per cycle at the higher natural frequency is approximately 5, and the period of beating between two sine waves with frequencies equal to \(\omega_1\) and \(\omega_2\) would be approximately 40 sample periods.

Numerical results indicate that the natural frequencies are relatively easy to determine except when the Signature length was too short (the 12- or 25-point case where the curve-fit program did not have sufficient data to process), or when it was too long (the 100-point case, due to the excessive
weighting of the tail section of the Signature which contains mostly random forced response signals). In all other cases, natural frequencies were accurately determined (by within 2.5% of the exact value) after the number of ensembles used for averaging reaches 1,000.

Damping determination, on the other hand, requires considerably more data--approximately 2,000 ensembles were required to determine damping to within 0.007 (out of 0.040), for the 37-, 50-, and 75-point cases. The corresponding average time is approximately 145 seconds. Damping accuracies are summarized in Figure 11. Based on these test cases, it may be said that Signatures shorter than a beat period are usable for the two mode case. On the other hand, a Signature length greater than 200% of the beat period requires too much averaging time to be considered practical. An optimum Signature length appears to be the 50-point case which is 125% of the beat period.

In the second test series, natural frequencies are spaced much closer (within ±1.2% of the average frequency) and the damping values are 0.04 for one mode and 0.005 for the other. The case parameters are:

\[
\begin{align*}
\omega_1 &= 84.72 \text{ rad/sec} \\
\omega_2 &= 86.73 \text{ rad/sec} \\
\zeta_1 &= 0.040 \\
\zeta_2 &= 0.005
\end{align*}
\]

all other parameters are the same as the previous test case.

The beat period of two sine waves at frequencies equal to \(\omega_1\) and \(\omega_2\) is 512 sample periods. Signature lengths of 25, 50, 75, 100 and 512 were curve-fitted. Both the 25- and the 50-point Signatures failed to yield useful results after 16,836 averages. For the 75-point Signature, the natural frequency prediction did not yield useful results* until

*When the natural frequencies are close to each other, the accuracy criteria should be based on the measurement of the difference of the natural frequencies, rather than the natural frequencies themselves.
after 8,418 averages. For the 100-point case, 4,202 averages are required, for the 200- and 512-point case, 2,103 averages. The optimum Signature length for both natural frequency and damping predictions for this sample test series was found to be the 200-point Signature after 2,000 averages, or about 150 seconds at the 85 rad/sec average frequency. Damping measurement results are plotted against the number of averages for Signature lengths of 100, 200 and 512 in Figure 13.

6.5 APPLICATION NOTES

The practical usefulness of any on-line flutter prediction process greatly depends on the amount of data it has to use at near-critical velocities. The ideal situation is when the process requires so little data that the need to hold constant velocity at various subcritical stages is eliminated. With respect to the overall approach adapted in this investigation, this consideration leads to the requirement of developing a method to select the proper Signature length so that the Random Decrement averaging time can be minimized.

The following factors must be considered:

(a) Based on discussions in Section 3, the rms value of the residual forced response term (the noise term $\gamma_N(t')$) starts from zero for $t'=0$, and increases with $t'$ in accordance with Equation (8). The expected signal-to-noise ratio of the Randomdec Signature for a given number of averages is, therefore, maximum for small values of $t'$. Consequently, using a shorter length of the Signature would require less averaging and would yield answers with given expected accuracies in a shorter time.

(b) For a system known, a priori, to have only one degree of freedom, the Signature length and averaging time required to determine damping are derived in Reference (9).
(c) For systems with two degrees of freedom, the beating of the
two Modal Signatures makes it necessary to select a Signature length
which, in accordance with results described in Section 6.4, is some­
where between 50% to 125% of the beat period. Once the proper Signature
length has been selected, the curve-fit procedure can be used with
confidence.

This suggests the following approach in applying the techniques
put together during this investigation. It is assumed that (a) on-line
Random Decrement and curve-fitting programs (or hardware) have been
implemented, (b) real-time display of the developing Randomdec Signature
is available, and (c) it is possible to select the length and sample
density of the Signature to be presented to the curve-fit program. Starting
at a constant low velocity where the danger of explosive flutter is not
present, obtain an accurate reference Randomdec Signature by using a
large number of averages. A high sampling rate (about 16 points per
cycle of the response signal) should be used so that the beat period can
be determined from the visual display. Needless to say, the Signature
should be long enough to cover more than one beat period. Select from this
long and dense Signature the proper length (about one beat period) and
sample density (about 4-6 points per cycle) and present it to the curve­
fit program. With the properly selected Signature, we are assured of
fairly accurate frequency and damping results. The minimum number of
ensembles required to produce frequency and damping data to a given
accuracy with respect to the reference Signature is then determined
experimentally.
The velocity sweep can then begin. The real-time display of the current Randomdec Signature and results of the previous curve-fit analyses will be used to select the Signature length used for curve-fit, which will be actuated as soon as a sufficient number of ensemble averages have been reached.

It is, of course, possible to automate the above procedure and use preliminary curve-fit results to compute the proper Signature length for a second, more refined Signature analysis.
7.1 CONCLUSIONS

We have demonstrated analytically in Section 3 that applying the Random Decrement data reduction procedure to the random responses of a multi-mode system will produce a Randomdec Signature which is an approximation of the characteristic response function of the system. The error contained in the Randomdec Signature is in the nature of a residual forced response whose mean-squared value decreases as one over the number of ensemble averages.

Using computer programs developed in this project, sampled random responses of a two mode system were simulated. The feasibility of the Random Decrement procedure was established via a number of numerical experiments on different simulated two-degrees-of-freedom systems, including both a purely mechanical and an aeroelastic system.

A parameter identification procedure using least-squares curve-fitting of the Randomdec Signature was adapted. The method was found to be capable of determining frequency and damping values accurately from Randomdec Signatures of carefully selected lengths.

For optimum results, a Signature length between 50% to 125% of the beat period created by the two frequencies of the Modal Signatures should be selected. The number of ensembles required to produce accurate damping results by the combined process is found to be approximately 2,000.

The study was limited to one- and two-mode systems.
7.2 RECOMMENDATIONS

Simulation studies in this project were limited in scope on account of computer costs. Since the programs for response simulation, Random Decrement and curve-fit analysis can all be implemented on less powerful computers, exhaustive statistical studies are recommended using such computers for reasons of economy.

While flutter usually occurs on account of interaction between two modes of an aeroelastic system, the presence of other non-flutter modes at nearby frequencies cannot be denied in practical situations. The Randomdec Signature will contain characteristic responses in all modes. The Signature analysis (curve-fit) program should, therefore, be extended for such situations. On-line flutter prediction programs or hardware can then be implemented by suitable modification of the application approach suggested in Section 6.5.

PROGRAM RADCUP
USER DOCUMENTATION
SUMMARY

Program RADCUF synthesizes response data of an aeroelastic structure, generates Randomdec Signatures and determines the system dynamic characteristics (frequency and damping for each of the two modes of the system) via curve-fit procedures. The program is used to conduct parametric studies, and to verify the practicality of both Random Decrement and curve-fit procedures via numerical experiments.

The program is written in Fortran IV and is compatible with the UNIVAC 1108 Exec 8 version compiler. The overlay structure of this program as implemented in the UNIVAC computer is shown in Figure A-1.

Data-flow during execution can be summarized as follows: The main program, DRVR, resides in the primary link and directs the logical flow of four subprograms of the secondary link. The first subprogram called by DRVR is IDENT which provides the identification (name of the program, bin number, run ID, job number, date and time) of the job on output plots. The second subprogram called is FLTR which generates random responses of a simulated aeroelastic system and obtains Randomdec Signatures from the data. The third subprogram called is CURVFT which curve-fits the Signature generated by FLTR. The last subprogram called is ENDJOB which writes an END OF JOB on the last page of the output plots.
FIGURE A-1 OVERLAY STRUCTURE-PROGRAM RADCUF
2 DESCRIPTION OF PROGRAM

2-1 Primary Link

The primary link is named DRVR. The primary function of this program is procedural only, and it does not contain executable statements.

2-2 Secondary Link

Two major programs reside in the secondary link. They are FLTR and CURVFT. Their executions are mutually exclusive, and each of these programs can be executed independently from the other. Although program CURVFT normally requires input data generated by program FLTR, this data could be written on Tape Unit 15 by any other program, so long as the format is compatible.

2-2-1 FLTR

FLTR is a program that resides in the secondary link of the system. It creates an environment for the input of general control parameters, generates response data of a two-mode aeroelastic system and computes Randomdec Signatures. Basic functions of this program are:

(a) Accepts input data.
(b) Generates response data.
(c) Calls subroutine FPLT to plot intermediate or final results.
(d) Calls subroutine PKPLT to (1) determine and plot the peaks of Randomdec Signature, (2) determine initial estimates for subsequent curve-fitting and (3) establish initial conditions for subsequent response data.
(e) Calls subprogram RNDMCI to generate Randomdec Signatures.

(f) Writes final Randomdec Signatures, initial parameter estimates, and all system and Random Decrement parameters on Tape Unit 15.

CURVFT

CURVFT is a curve-fitting algorithm that operates on Randomdec Signatures created by FLTR. The following is the procedure:

(a) Reads Tape Unit 15 for Randomdec Signatures and all other data written by FLTR.

(b) Sets up an environment to curve-fit the Randomdec Signature with a four-parameter expression corresponding to a one-mode approximation of the Signature.

(c) Calls subroutine CF which accomplishes the actual curve-fitting procedure.

(d) Calls subroutine FPLT to plot the Randomdec Signature being curve-fitted, the analytical expression after convergence of the procedure and convergence paths of all parameters, and the error function. All problem oriented parameters are tabulated by FPLT also.

(e) Repeats steps (b), (c), and (d) above for an eight-parameter curve-fit.

(f) Calls subroutine CF to provide the final output of the program under simple English text headings.
Control parameters input to program RADCUF are made via cards utilizing Logical Unit 5 in the UNIVAC 1108 system. Four cards are used to define one typical case. The following logic is designed in the program for multi-case execution.

In the first execution, the program will read the first set of four data cards and execute until the generation of the Randomdec Signature for this case is completed. Then the flow of execution will be directed to read another card corresponding to Card Form 4 or to find an EOF (End of File). If a Card Form 4 is encountered, the program will execute utilizing the new parameters given by this card and previous input parameters given by Card Forms 1, 2 and 3. If an EOF is encountered, the program then will expect to find either another EOF or a completely new set of four data cards. If the second EOF is encountered, the program then proceeds to curve-fit the generated data.

The following is the card stream for typical multi-case type execution:

CARD FORM 1
CARD FORM 2
CARD FORM 3
CARD FORM 4
CARD FORM 4
CARD FORM 4
CARD FORM 4
EOF
CARD FORM 1
CARD FORM 2
CARD FORM 3
CARD FORM 4
EOF
EOF
It should be noted that Randomdec Signatures for all cases to be investigated are recorded on Tape Unit 15 before curve-fitting begins.

Input Card Form 1

Parameters: DF, MU(1), MU(2), QQ(1), QQ(2), P(1), P(2), A(1), A(2),
             LD(1), LW(1), LD(2), LW(2)

Format: 9F6.0, 4I6

Input Card Form 2

Parameters: KREF, NREF, NPRT, METHR, NRR, METHS, NRS, NUT, STN, RQ,
             AV(1), AV(2), SD(1), SD(2)

Format: F8.0, 2I4, 2(I2, I3), 5X, I1, 6F8.0

Input Card Form 3

Parameters: NA(1), NA(2), NB, NC, ISRS, IERS, ISC, IEC, ISS, IES,
             ISF, IEF, ISP, IEP, NSF, ISYM, NPF

Format: 4F7.1, 13I4

Input Card Form 4

Parameters: NU(1), NU(2), Z(1), Z(2), R(1,1), R(1,2), R(2,1), R(2,2)
             C(1), C(2), NP(1), NP(2), TH(1), TH(2)

Format: 2F4.0, 12F6.0

All input parameters are defined in Table A-1.

4-1 FLTR Procedure

The diagram below shows the order of execution in the response simulation program, FLTR. Contents in the lettered blocks in the diagram are described in the correspondingly lettered descriptive paragraphs following these flow charts.
B. Construct random components of forcing functions

C. Linearly combine forcing functions based on \( R(i,j) \)

D. Add cyclic and gate functions

Transform forcing functions to the frequency domain.

- If \( IERS > 1 \) and \( INRD = 2^n \) and \( \neq 2^n \), then FFLT

E. Multiply forcing functions by the system transfer function in the frequency domain

Extend product to fill 4096 points

Inverse transform to time domain

Plot of real and imaginary components of forcing functions in the freq. domain
DETERMINE TERMINAL MODAL VELOCITIES AND SAVE AS INITIAL VALUES FOR NEXT SEGMENT

CONSTRUCT SYSTEM RESPONSE SIGNAL BY ADDING SIMULATED RESPONSE TIME SERIES AND NOISE

CALC. YRMS AND SET REF=0, RG=0

CALL RNDMC1

PLOT DECIBEL TRANSFORM OF PEAKS OF CUMMULATIVE INDIVIDUAL SIGNATURES AND THE SUM SIGNATURE

WRITE CUMMULATIVE INDIVIDUAL AND SUM SIG RECORDS

Unit 15
INITIALIZE INRS

NORMALIZE THE SUM SIGNATURE BY THE TOTAL NO. OF TRIGGERS (NTK)

WRITE FINAL NORMALIZED SIG

WRITE FINAL SIG ON PRINTER

RETURN TO READ NEXT FORM-4 FROM THE INPUT STREAM
PROGRAM STOP 25 MAY OCCUR IF DECK IS NOT ARRANGED IN CORRECT ORDER

PROGRAM STOP 35 MAY OCCUR IF DECK IS NOT ARRANGED IN CORRECT ORDER

RETURN TO BEGINNING OF PROGRAM TO START AN ENTIRELY NEW CASE
Block A. JRQ is an internal variable, which contains the key for the generation of the next random integer by NRAND. It is initialized to the user specified input value, RQ, each time a new case is started with respect to reading a Card Form 4.

INRR is an integer program counter which indicates the number of segments of response data which have been processed for a given case. When it exceeds the required number of segments given by the user as NRR, "End-of-Case" procedures are initiated.

The variable NTM is 0-origin integer sample point counter in the time domain. The first point of the second response segment is considered point No. NTM = 4096 and etc.

NTK is an integer to be assigned as the total number of summation of input signature.

AK, BK and CK are constants to be assigned for the generation of complex function.

Fortran arrays SRF(L), SRG(L), S(L) for L=1, 4096, accumulate Signatures (triggered responses) of Mode 1, Mode 2 and the sum of Modes 1 and 2, respectively.

The variables P(1) and P(2) are the initial values of velocities of Modes 1 and 2, respectively for the first segment of response simulation.

The variables QQ(1) and QQ(2) are the initial displacements of Modes 1 and 2, respectively, used by the program in generating the first segment of the simulated response data.

The initial velocities and displacements of subsequent segments of simulation are obtained according to explanation for Block F below. Simulation will be started from initial
input values each time a new case is started after reading a Card Form 4.

**Block B.** The arrays (QR1(L) and QR2(L), L=1, 4096, are used for storage of pseudo-random number subsets used for the generation of forcing functions.

The Fortran function NRAND is used to generate the next pseudo-random integer from the previous one. This integer, converted to floating form and stored in the first location of the mode array, is used as a trigger to generate the pseudo-random number subset for each modal force. The means and standard deviations of these pseudo-random subsets are specified by the user as AV(1), and SD(1), and AV(2) and SD(2), respectively.

This logic assures that the same pseudo-random number subset will be used for each case with respect to Card Form 4 parameter variation.

**Block C.** After the construction of the random sequence component, functions are mixed. The equations of mixing are given by:

\[ F(L) = R(1,1) \times F(L) + R(1,2) \times G(L), \quad G(L) = R(2,1) \times F(L) + R(2,2) \times G(L), \]

where \( F \) is the forcing function for the 1st mode and \( G \) for the 2nd mode. Obviously, no mixing occurs if

\[ R(1,2) = R(2,1) = 0.0 \] in the control parameters.

The real and imaginary components of the resulting functions may be plotted against frequency for each segment number which is an integer power of 2. These plots are specified values of ISRS and IERS.
on control Card Form 3 upon the user's request. The subset of each segment from point No. ISRS to IERS will be plotted.

**Block D.** A cyclic component is added to the pseudo-random subset contained in $QR_1(L)$ and $QR_2(L)$ as follows:

$$QR_1(L) = QR_1(L) + C(1) \times \cos \left( \frac{2\pi}{4096} \times \text{NP}(1) \times \text{NTM} + \text{TH}(1) \right)$$

for $L=1, 2049$ and similarly for $QR_2(L)$. NP(1) and NP(2) are the frequencies in cycles/rad. TH(1) and TH(2) are the associated phase displacements. These parameters are specified by the user on Card Form 4.

In addition to adding cyclic components to the forcing functions, positive gate functions can also be added. The gate function generator, called DST in the program, is a function of NTM. The first 'rise' points of the functions are given by LD(1) for Mode 1, and LD(2) for Mode 2, on Card Form 1. These point No.s refer to the value of NTM, not the segment index. The number of 'rise' points is given by LW(1) and LW(2). The height of each gate is unity.

**Block E.** The forcing function and initial conditions are complex-multiplied by the modal frequency response functions.

The real parts are extended symmetrically about CF(2049) or CG(2049) respectively. The imaginary parts are also extended but anti-symmetrically. IM(CF(2049)) and IM(CF(2049)) are set to zero. The resulting complex functions, of length 4096 each, are inverse transformed into the time domain. The imaginary components of the resulting time series are zero-valued. The real valued time series are modal velocity data.
Block F. Initial conditions for the second and subsequent segments of simulation are determined by the procedure below.

The PKPLT subroutine is called to find the final peak in the modal velocity signals of each segment. These peak velocities are the respective initial velocities of the following segment.

The modal displacements are zero when the modal velocities peak. The initial displacements for the second and all subsequent segments are, therefore, zero.

Block G. STN is the value of signal to noise ratio which is an option to include the random noise to the total system response. The noise signals can be obtained by RANDN subroutine if STN is not equal to zero. The system response is, then, simply the summation of simulated response signals and the noise. The standard deviation of the noise component is equal to the absolute maximum value of the response divided by STN which is established by input.

The resulting data segments are input data for the RNDMCI algorithm (Randomdec). The Fortran array SIG(L), L=1, 4096 is the sum of the two modal response segments and is used by RNDMCI to establish trigger points, i.e., points which become origins of the ensemble summing operation which generates the Signature. The Fortran arrays RF(L), and RG(L), L=1, 4096 are used to hold the components of the Signature which arise within the current segment of Modes 1 and 2 respectively. On completion of RNDMCI algorithm, RF(L) is summed into SRF(L) and RG(L) is summed into SRG(L), the array S(L), L=1, 4096, is the cumulative sum of the two modal Signatures. YRMS is the RMS value of SIG(L), L=1, 4096.
The following diagrams show the logic of the RNDMCI algorithm and the application of its related control parameters, from Card Form 2.

CALL OF FOR MODE 4 FIT OF 4 PARAMETERS AFTER 1 SEGMENTS OF SIMULATED RESPONSE

Initial parameter estimates are given as follows:

\[
\begin{align*}
A1(1) &= 12.5364 \\
A1(2) &= 0.000006 \\
A1(3) &= 8.97696 \\
A1(4) &= 12.5364 \\
A1(5) &= 0.000066 \\
A1(6) &= 0.000060 \\
A1(7) &= 0.000060 \\
A1(8) &= 0.000060
\end{align*}
\]

No. of iterations on SIMPLANE = 938

(*) Entered
PRODUCT OF W*W(I) ON PASS 1 OUIJK : J = 4 , K = 4

\[
\begin{align*}
\text{PRODUCT OF W*W(I) ON PASS 1} & \quad \text{OUIJK} : J = 4, K = 4 \\
\hline
1 & \text{W(I)} & \text{W(I)} & \text{PRODUCT} & \text{W(I)} & \text{W(I)} & \text{PRODUCT} & \text{W(I)} & \text{W(I)} & \text{PRODUCT} & \text{W(I)} & \text{W(I)} & \text{PRODUCT} & \text{W(I)} & \text{W(I)} & \text{PRODUCT} & \text{W(I)} & \text{W(I)} & \text{PRODUCT} \\
